Excepting perinatal transmission and rare cases of person-to-person spread, *Listeria* infections are thought to be acquired by ingestion of contaminated food [4]. High profile outbreaks [4, 5] have highlighted the foodborne nature of this infection, but most sporadic cases have no identified food source. The incubation period for self-limited cases of febrile gastroenteritis is about 24 h, while the incubation period of invasive infection averages 35 days, with a range of 1–91 days [5, 6]. Invasive listeriosis occurs predominately in four risk groups: immunocompromised individuals, pregnant women, infants, and adults over 60 years of age. Three quarters of the 1651 of patients identified with listeriosis in the USA between 2009 and 2011 who did not have age or pregnancy as a risk factor were immunocompromised [7]. Recent surveillance data indicate that the incidence of both non-perinatal *Listeria* infection and *Listeria*-associated mortality are decreasing, trends that are likely due to improved control mechanisms in the food industry [8].

Experiments by Mackaness in the 1960s demonstrated the central role of cell-mediated immunity in protection against *Listeria* infection [9]. Multiple arms of the immune response are involved, but memory CD8 T cells seem to be most important to protection. *Listeria* infection has been reported after both solid organ transplantation (SOT) and hematopoietic cell transplantation (HCT). The risk for invasive listeriosis is highest early after transplantation or following augmentation of immune suppression [10, 11]. Some early posttransplant *Listeria* infections are postulated to arise by translocation from pretransplant gut carriage [12, 13]. *Listeria* infections also occur years after transplantation, when immunosuppression is generally less intensive [12]. Recent 7-year data from France showed an incidence of *Listeria* infection of 7.91 cases /100,000 persons/year in SOT recipients, which was 21 times higher than in the general population; the mortality rate in transplant patients was 6% [14].

In transplant recipients, listeriosis typically presents as a sepsis syndrome, often accompanied by central nervous system (CNS) involvement. The presentation can be acute or can follow a prodrome of milder symptoms. Almost all transplant recipients with listeriosis have bacteremia and between 40 and 60% have meningitis [11, 15]. Signs of CNS

P. Ljungman et al. (eds.), *Transplant Infections*, DOI 10.1007/978-3-319-28797-3_23

involvement may be subtle, and nuchal rigidity is present in only about one-half of patients [1]. Focal neurologic signs are less common than diffuse signs, such as personality changes or forgetfulness.

In the largest series of *Listeria* meningitis, the median cerebrospinal fluid (CSF) leukocyte count was 585 cells/mm^3 and nearly 70% of patients had <1000 leukocytes/mm^3 [16]. CSF smears typically showed a predominance of neutrophils. Elevated CSF protein and low CSF glucose levels were common, although these values were sometimes normal, particularly early in the illness. The organism is only occasionally visualized on Gram stains of CSF, but centrifugation of CSF may increase the yield. Cultures of CSF are relatively insensitive, identifying only 30–35% of cases [16, 17].

In addition to meningitis, *L. monocytogenes* can cause cerebritis, encephalitis, and brain abscess (see Figure 23-1). Rhombencephalitis is an unusual form of listerial encephalitis involving the brainstem. It presents with movement disorders, facial nerve palsies, cerebellar signs, and hemiparesis or hemisensory deficits. *Listeria* brain abscesses often involve subcortical areas, including the brain stem. Most patients with *Listeria* brain abscess are bacteremic, and 10–25% have meningitis [1, 11, 16, 17]. The mortality of isolated bacteremia with *L. monocytogenes* is only 3%, but is as high as 30% in patients with CNS involvement [11, 15–17]. Non-CNS *Listeria* also occasionally causes localized infection in transplant recipients, including peritonitis [18], hepatitis [19], arthritis [20], endophthalmitis [21], and endocarditis [22].

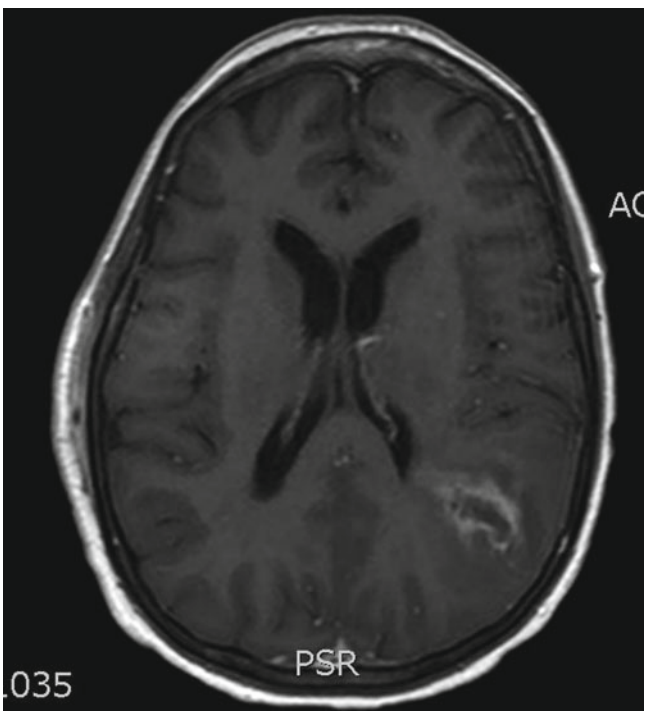

FIGURE 23-1. MRI demonstrating ill-defined enhancing focus with surrounding vasogenic-type edema in the juxtacortical left parietal lobe.

Lacking controlled studies, recommendations for treatment of listeriosis are based on in vitro testing, animal models, and clinical observation. The therapy of choice is high-dose ampicillin or penicillin [1, 17]. Laboratory evidence of synergy between ampicillin and aminoglycosides has led to the recommendation for combination therapy when infection is severe or occurs in immunocompromised hosts [23]. In transplant recipients, however, the potential benefit of aminoglycoside therapy must be weighed against the risk of nephrotoxicity. Trimethoprim-sulfamethoxazole (TMP-SMX) is the drug of choice in penicillin-allergic patients [1]. Imipenem and meropenem have been successfully used to treat *Listeria* infections, but they are generally less active than ampicillin and may lower the seizure threshold [24, 25]. Linezolid can be considered for patients with multiple drug allergies based on its excellent CNS penetration and effectiveness in a few clinical cases [26]. Vancomycin has good in vitro activity against *Listeria* but suffers from poor penetration into the CNS; clinical failure for both CNS and non-CNS listeriosis has been reported with vancomycin [27, 28]. Cephalosporins are inactive against *Listeria*. Due to the high risk of recurrence, transplant recipients should receive 3 weeks of therapy for bacteremia or meningitis, and longer courses for brain abscess.

Guidelines for preventing *Listeria* infection from the Centers for Disease Control and Prevention (CDC) include standard approaches to food safety, such as thorough cooking of meat, washing of fresh fruits and vegetables, and physical separation of uncooked meat from other foods [29]. Persons at high risk of listeriosis are encouraged to avoid foods that may harbor *Listeria*, including unpasteurized milk, soft cheeses, hot dogs, and luncheon meats. Standard sulfonamide prophylaxis for *Pneumocystis* infection is thought to prevent *Listeria* infection but the low incidence of infection has made this difficult to prove [1, 17].

23.2.2 Nocardia

Nocardia are aerobic gram-positive rods that have characteristic filamentous, branching chains (see Figure 23-2a). They are present in soil and decaying organic material, and most human infections result from the inhalation of airborne bacilli. A small number of patients are infected by accidental inoculation into the skin. *Nocardia* infection was first described in transplant recipients in the 1960s [30]. *Nocardia* infections occur in between 0.1 and 3.5% of SOT patients, with lung and heart recipients at highest risk [31, 32]. The reported frequency of nocardiosis after HCT is low. An incidence of 0.3% was reported in 6759 HCT recipients at three large transplant centers [33]; cases occurred exclusively in allogeneic recipients. In a separate single-center study, nocardial infection occurred in 1.7% of 302 allogeneic HCT recipients but only 0.2% of 542 autologous recipients [34];

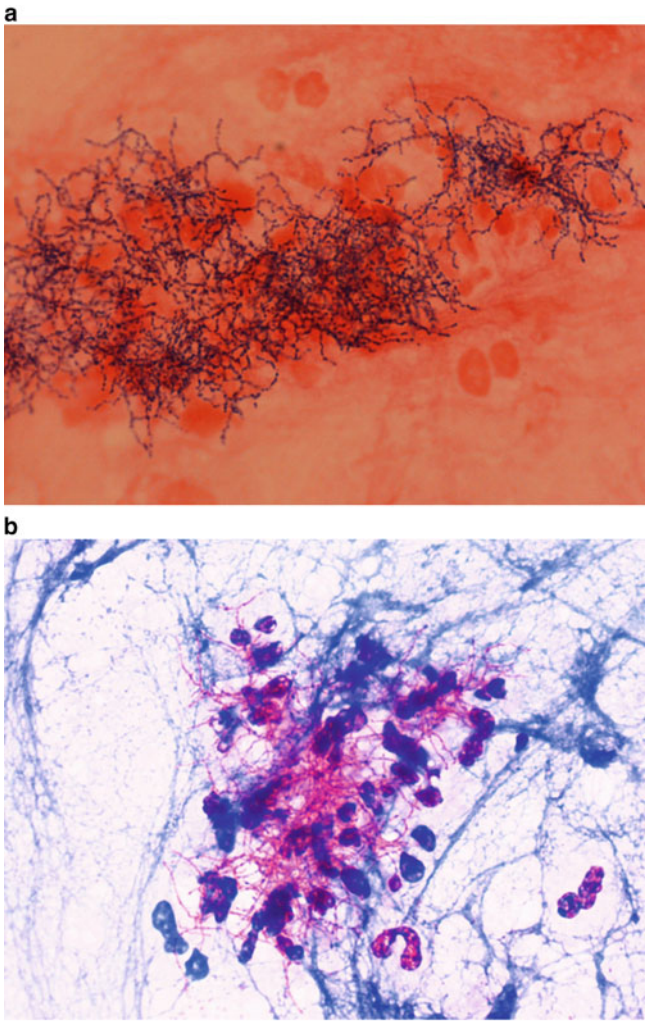

FIGURE 23-2. (**a**) Branching, beaded filamentous rods (hematoxylin and eosin stain). (**b**) Modified acid fast stain, demonstrating the weakly acid fast staining property of *Nocardia* species.

all patients with *Nocardia* infection had recently received immunosuppressive medications.

Nocardia infections are usually sporadic and acquired in the outpatient setting, but small nosocomial outbreaks have been reported [35]. Wilson and coauthors [30] noted few *Nocardia* infections in the first month after SOT; the frequency of cases peaked between 1 and 6 months after transplantation and then occurred sporadically at lower rates thereafter. Similarly, most cases of nocardiosis in HCT recipients occur after engraftment but within the first post-transplant year [33, 34]. Receipt of high-dose corticosteroids in the previous 6 months, high blood levels of calcineurin inhibitors and a history of cytomegalovirus disease have been shown to be independent risk factors for *Nocardia* infection in SOT recipients [32].

The clinical manifestations of nocardiosis are similar in SOT and HCT recipients [30–34]. Eighty percent to 90% of patients have a respiratory illness, ongoing for a week or more. Typical symptoms are fever, productive cough, pleuritic chest pain, dyspnea, weight loss, and hemoptysis. Lung nodules, which may be cavitary, are the classic radiographic finding, but alveolar consolidation and/or pleural effusion are also seen [36]. At presentation, up to one-half of patients have disseminated infection. Sites of dissemination include the CNS in roughly one-third of patients and the skin in up to 15%. Occasional patients have spread to the bone, joints or muscle [30–33]. Skin lesions of disseminated nocardiosis are palpable, mildly tender, deep abscesses that may or may not appear erythematous. Cerebral abscesses are the usual manifestation of CNS infection. They may manifest with focal neurologic defects, headache, and/or seizures [30]. Some brain abscesses are clinically silent. Given the relative frequency of CNS involvement, neuroimaging is advised in all patients with nocardiosis. Meningitis due to *Nocardia* also occurs but is considerably less common than brain abscess.

The gold standard for diagnosis of *Nocardia* infection is culture of the organism from a clinical specimen. Biopsy of lung, brain, or other involved tissue is often necessary. *Nocardia* colonies may appear on aerobic cultures as early as 3–5 days, but can take 2 weeks or longer to be detected. In a study of 11 lung transplant recipients with *Nocardia* infection, the mean time of culture diagnosis was 9 days [37]. The appearance of *Nocardia* on Gram stain (see Figure 23-2a) is distinctive enough to allow for a presumptive early diagnosis. Most strains of *Nocardia* are weakly acid fast (see Figure 23-2b), a feature that aids in identification and in differentiation from *Actinomyces* species.

Sulfonamides are the agents of choice for nocardiosis because of their reliable activity and the high drug concentrations achieved in affected tissues. Trimethoprim-sulfamethoxazole is the preferred sulfonamide, but excellent results also have been achieved with other sulfonamides [30, 34, 38, 39]. Adjustment of sulfonamide dosing for creatinine clearance is often necessary in transplant patients. Ideal serum levels are between 100 and 150 mcg/mL. Clinical failure of sulfonamide therapy is uncommon. A high rate of in vitro resistance of *Nocardia* isolates to sulfonamides was reported in one recent study [40]. However, a subsequent study from six reference laboratories showed resistance to TMP-SMX in only 2 of 552 *Nocardia* isolates [41]. Other antimicrobials that have good activity against most species are minocycline, amikacin, imipenem, meropenem, cefotaxime, and ceftriaxone [31]. A recent in vitro study demonstrated that tigecycline and moxifloxacin were active against the majority of 51 clinical isolates of *Nocardia* [42]. Selected strains are susceptible to ampicillin, ampicillin-clavulanate, ciprofloxacin, erythromycin, and other macrolides, but use of these antibiotics is only advised if supported by susceptibility testing. Ertapenem is 16-fold less active than imipenem and should not be viewed as a useful agent [42]. Linezolid has excellent in vitro activity against *Nocardia* species and has demonstrated therapeutic potential in case reports [43, 44]. Unfortunately, the long-term use of linezolid may

be limited by adverse effects such as myelosuppression and peripheral neuropathy.

Susceptibility testing of *Nocardia* species has not been rigorously correlated with clinical outcomes, but offers comparative data and may be helpful with more resistant strains, such as *N. farcinica* or *N. transvalensis*, or if therapy must be changed from a first-line agent because of toxicity or inadequate response [42, 45].

Animal models have demonstrated that certain antimicrobial combinations, such as imipenem with amikacin or moxifloxacin, may achieve more rapid reduction in bacterial colony counts than sulfonamides [46–48]. These regimens may be an excellent alternative to sulfonamides or serve as initial therapy until clinical stability is achieved and susceptibility data is available. Ultimately, most patients respond to initial therapy and can be transitioned to a simple oral regimen to complete treatment. The optimal duration of therapy is unknown, but treatment courses of 4–6 months are typical for pulmonary and soft tissue infections. Treatment is usually extended to 12 months or longer in patients who have disseminated or CNS disease.

Although TMP-SMX is generally an active agent for treatment of nocardiosis, low-dose TMP-SMX prophylaxis for *Pneumocystis* is not consistently protective against *Nocardia* infection [32–34, 37]. Interestingly, isolates from patients who develop nocardiosis while on low-dose TMP-SMX are usually susceptible to TMP-SMX [32].

23.2.3 Lactobacilli

Lactobacilli are strict or facultatively anaerobic, gram-positive rods that are ubiquitous inhabitants of the human oral cavity, vagina, and gastrointestinal tract. Previously, they have often been considered nonpathogenic. However, serious infections due to lactobacilli have been reported in both immunosuppressed and immunocompetent patient populations [49–55].

A review of 200 *Lactobacillus* infections found that 9% of the infections occurred in transplant recipients [54]. Patel et al. described *Lactobacillus* bloodstream infections in 8 patients within the first 6 months after liver transplantation [51]. All of the infections but one were polymicrobial, and in most cases the organisms were also isolated from abscess fluid or bile. The presence of a Roux-en-Y choledochojejunostomy was a strong risk factor for infection. Other reports of serious infection include endocarditis and mediastinitis in a heart recipient [49], splenic abscess in a kidney recipient with concomitant HIV infection [53] and relapsing bacteremia and meningitis in a cord blood transplant recipient [56]. A case of *Lactobacillus* pneumonia and empyema occurring early after lung transplantation was thought to be transmitted by the transplanted lung [52].

The current use of probiotics containing "non-pathogenic" microorganisms for various gastrointestinal conditions has raised concerns that this may be an unsafe practice in transplant patients. Indeed, serious *Lactobacillus* infections have been described in transplant recipients receiving probiotics that contained *Lactobacillus species* [57, 58]. In one case, an isolate from an empyema collection was found to be identical by molecular typing to the organism in the patient's probiotic preparation [58].

The standard treatment for *Lactobacillus* infection is high-dose penicillin or ampicillin, with or without an aminoglycoside for synergy [54, 55]. Other active antibiotics include erythromycin and other macrolides, carbapenems, linezolid, and quinupristin-dalfopristin [54, 55, 59]. Trimethoprim-sulfamethoxazole, metronidazole, and vancomycin have unreliable activity [51, 54, 55, 59]. Whenever possible, in vitro susceptibility tests should be obtained to direct therapy.

23.2.4 *Rhodococcus equi*

R. equi is a gram-positive coccobacillus of the order Actinomycetales. It is a veterinary pathogen that causes chronic suppurative pneumonia in foals and submaxillary lymphadenitis in swine [60]. Herbivores, such as horses and cattle, are colonized in the gut, and the organism inhabits soil contaminated by their manure. Approximately one-third of individuals with *Rhodococcus* infection report contact with farms or livestock [60]. *R. equi* infections occur primarily in patients who have defects in cell-mediated immunity. Approximately 10% of human *R. equi* infections occur in SOT and HCT recipients [61–64].

The lung is most common site of *Rhodococcus* infection. Patients present with a subacute course, characterized by fever, dyspnea, and nonproductive cough [60, 64, 65]. Other common symptoms include fatigue, weight loss, pleuritic chest pain and hemoptysis. Chest imaging demonstrates infiltrates or nodules, which frequently cavitate. Pleural effusions are common and often infected. Infection frequently disseminates to extrapulmonary sites such as the skin, bones, and brain. Disseminated infection is seen in roughly one-half of transplant recipients [61, 63].

The diagnosis of *Rhodococcus* requires laboratory isolation of the organism from a patient with a compatible clinical presentation. Early growth of *R. equi* may occur within 24–48 h, but the characteristic, mucoid, salmon-colored appearance of the colonies is not evident until a few days later [60]. The organism is easily missed in respiratory cultures and can be mistaken for "diptheroids" [66]; therefore, the laboratory should be alerted whenever *R. equi* infection is being considered. Blood cultures are positive in more than one-half of immunocompromised hosts [61, 65].

Many antibiotics are active against *Rhodococcus*. The most potent agents are vancomycin, imipenem, rifampin, quinolones, macrolides, and linezolid [61, 67, 68]. Clinical experience with linezolid is limited, but Munoz et al.

reported successful treatment of multidrug-resistant, relapsing *Rhodococcus* pulmonary infection in a heart transplant recipient [70]. Treatment with penicillins and cephalosporins has been unreliable and these antibiotics should be avoided. Treatment for immunocompromised hosts should consist of combination therapy with 2 or 3 active antibiotics. Intravenous therapy is commonly used initially, especially in patients with bacteremia or pulmonary abscesses. After the patient stabilizes and susceptibility results are available, therapy can be switched to an oral regimen. A treatment course of several months is typically required and it may be extended to 6 months or longer in disseminated infection [61]. Even with prolonged treatment, relapses may occur [71]. Adjunctive surgical therapy may be useful in selected patients [72].

23.2.5 *Clostridium difficile*

C. difficile is a spore-forming, gram-positive, anaerobic bacillus that elaborates toxins that cause colitis. Infection is usually associated with current or recent antibiotic use. *C. difficile* is part of the intestinal flora in approximately 3% of healthy adults, and as many as 30% of hospitalized patients [73]. Transmission in the health care setting is well documented.

The frequency of *C. difficile* infection is substantially higher in transplant populations than in other hospitalized patients. A meta-analysis, drawing on data from 21,683 SOT recipients, reported a pooled prevalence of *C. difficile* infection from transplantation to the first discharge of 7.4% [74]. The prevalence varied from 3.2% in pancreas transplant recipients to 10.8% in lung recipients. The *C. difficile* recurrence rate across the population was estimated to be 19.7%. In a large retrospective single center study spanning 6 years, the 1-year incidence of *C. difficile* infection among HCT recipients was 9.2%, with a breakdown of 6.5% among autologous and 12.5% among allogeneic recipients [75]. Relapsing *C. difficile* infection was observed in 21.7% of the patients at a median of 69 days after initial infection. Risk factor analysis showed the presence of gastrointestinal graft-versus-host disease (GVHD) to be highly associated with both overall and recurring *C. difficile* infection. *C. difficile* infection also correlated with the subsequent development of gastrointestinal GVHD. It was postulated that *C. difficile* infection triggered gastrointestinal GVHD by disruption of the mucosal barrier and release of proinflammatory cytokines. This association between *C. difficile* infection and gastrointestinal GVHD has been found in some but not all studies [76–78].

The symptoms of *C. difficile* infection in transplant recipients resemble those in other patients—watery diarrhea, lower abdominal pain and, at times, fever—and may be similar to symptoms of GVHD. The severity of *C. difficile* infection in transplant populations has been variably reported to be greater or less than in control populations [75–77, 79]. Authors who have found less severe disease in transplant recipients have speculated that immunosuppression attenuated the colonic inflammatory response and led to a less severe clinical course. It is also possible that less severe manifestations in transplant recipients were simply due to earlier diagnosis and treatment.

The cytotoxicity cell assay is the gold standard for diagnosis of *C. difficile* infection, but it is labor intensive and not widely used. Until recently the diagnosis was usually made by enzyme linked immunoassay (ELISA) for *C. difficile* toxin. Detection of *C. difficile* DNA by polymerase chain reaction (PCR) testing is more sensitive than ELISA and it is increasingly the primary test used for diagnosis. PCR testing has the drawback that it also detects asymptomatic carriage. Another accepted option for diagnosis is to employ a two-step algorithm, with an initial stool screen for a cell wall protein (glutamate dehydrogenase) common to both toxigenic and nontoxigenic strains, with subsequent testing by ELISA and/or PCR [80, 81].

The first consideration in treating *C. difficile* infection is cessation of the inciting antimicrobial agent(s) or transition to a narrower spectrum regimen, whenever possible. Management protocols for *C. difficile* infection generally recommend a stratified approach: oral metronidazole (500 mg every 8 h) is given for initial episodes of mild-to-moderate infection; oral vancomycin (125 mg every 6 h) is used for severe infection; and high-dose vancomycin (500 mg every 6 h) is administered orally or per rectum with or without intravenous metronidazole for severe, complicated infections [82]. Mild first recurrences can be retreated with oral metronidazole, but additional or severe recurrences should be managed with oral vancomycin using a tapered or pulse regimen. Fidaxomicin is an effective but costly alternative treatment which may be associated with a lower recurrence rate [83, 84]. For severely ill patients, especially those with toxic megacolon, colectomy may be a life-saving intervention.

No controlled studies are available to inform the treatment of *C. difficile* infection in transplant patients. Initial therapy is typically administered for 10–14 days, or longer if other antimicrobial therapy cannot be discontinued. If a prolonged duration of *C. difficile* treatment is planned, oral vancomycin is often the preferred agent to avoid the neurologic and hematologic toxicities associated with the extended use of metronidazole. Recently, fecal microbiota transplant (FMT) has emerged as an effective treatment for recurrent *C. difficile* infection [85]. Initial data on use of FMT in transplant recipients is limited but encouraging [86, 87]. There is a lack of conclusive data to support the use of probiotics to prevent *C. difficile* infection, particularly in transplant recipients where there is risk for bloodstream infection [57, 58, 82]. Prevention of *C. difficile* infection in populations at risk requires a multifaceted program, including aggressive infection control measures and an effective antibiotic stewardship program.

23.3 Gram-Negative Organisms

23.3.1 Legionella

Legionella are fastidious, aerobic, gram-negative rods that have been found in soil and freshwater lakes and streams. Over 50 species and 70 serogroups of *Legionella* have been described, and 20 species have been linked to human infection. The predominant species, *Legionella pneumophila* causes 95% or more of human illness in Europe and the USA [88]. Serogroup 1 makes up 80–90% of infectious isolates of *L. pneumophila*. Other *Legionella* species known to cause clinical infection in transplant patients include *Legionella micdadei, Legionella longbeachae*, and *Legionella dumoffii* [89–91].

Defects in cell-mediated immunity make transplant recipients particularly susceptible to legionellosis. Infection has been frequently reported in recipients of kidney [89, 90, 92], heart [93], liver [94], and hematopoietic cell [95, 96] transplants. *Legionella* infections can occur at any time after transplantation, but the frequency is greatest early after transplantation or following anti-rejection treatment.

Legionella infection is acquired by inhalation of infectious aerosols or by aspiration of infected water. Person-to-person transmission does not occur. Infections may be sporadic or part of health care-associated or community-associated outbreaks. Several outbreaks of *Legionella* infection in transplant recipients have been described [97–99]. *Legionellae* have a major, clinically relevant reservoir in institutional plumbing systems. They enter these systems via cold water intakes and subsequently colonize hot water heaters, from which they are dispersed to spigots and showerheads on patient wards [100, 101]. Outbreaks of *Legionella* pneumonia have been epidemiologically linked to several sources, including potable tap water, cooling towers, evaporative condensers, humidifiers, whirlpools, and decorative water fountains [88, 100, 102–107].

Pneumonia is the usual clinical presentation of *Legionella* infection. Some clinical features may suggest the diagnosis of legionellosis. Patients often experience a flu-like prodrome of high fever, chills, myalgias, and malaise, but antecedent upper respiratory symptoms are usually absent. Progressive infection results in dyspnea and a mildly productive cough, which is often associated with pleuritic chest pain. Approximately one-half of patients develop watery diarrhea. Mild CNS symptoms, such as headache and confusion, are often present. Some investigators have noted the presence of a pulse–temperature disassociation with a relative bradycardia [92]. The most common radiographic appearance of *Legionella* pneumonia is alveolar consolidation, which is frequently multilobar [108]. Pleural effusions, cavitation may be seen and focal nodular densities, mimicking invasive fungal infection, have been described [109] (see Figure 23-3).

Extrapulmonary *Legionella* infection is a rare occurrence, usually seen in immunocompromised hosts, with or without primary pneumonia. Some reported types of extrapulmonary involvement are cutaneous infection [110], aortitis [111], prosthetic valve endocarditis and sternal wound infection [112]. The morbidity of legionellosis in transplant recipients is substantial; the reported mortality ranges from 14 to 30% [96, 113], but can be as high as 80% for untreated health care-associated infection [92].

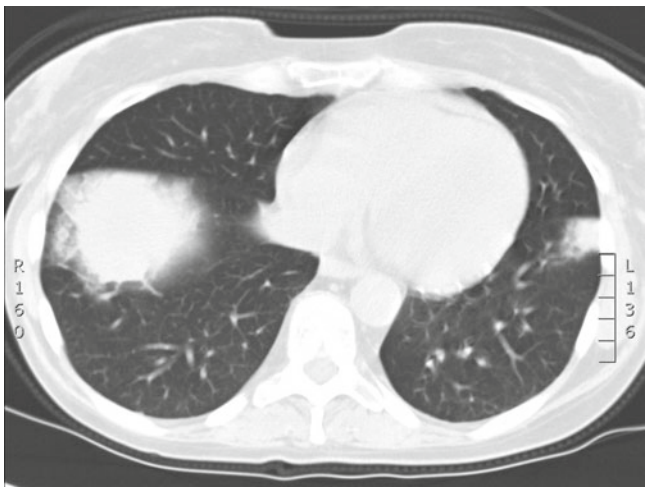

FIGURE 23-3. CT chest demonstrating multifocal nodular consolidations in a stem cell transplant recipient on high-dose immune suppression, demonstrated to have *Legionella* infection.

The laboratory diagnosis of legionellosis is often difficult and depends on the available level of expertise. Although *Legionella* are gram-negative bacilli, they are usually not visualized on Gram stain because of their small size and poor stain avidity. The definitive method of diagnosis is by culture. *Legionella* are fastidious and their isolation requires the use of enriched media (buffered charcoal yeast extract agar) in a CO2-rich environment (see Figure 23-4). Colonies appear after 3–5 days on agar plates but may be masked by overgrowth of other less fastidious organisms. Cultured organisms are more readily visualized by Gram stain than those in clinical specimens. It is notable that on tissue biopsy specimens *L. micdadei* can demonstrate weak acid-fast staining, highlighting the importance of *Legionella* culture when this diagnosis is suspected [114].

Several indirect methods for *Legionella* diagnosis are available. Direct fluorescent antibody (DFA) staining of sputum or tissue specimens is a rapid technique, but it has a low sensitivity (50%), and reagents are lacking for some species and serogroups [115]. *Legionella* serology has been useful for epidemiological studies but has limited value for diagnosis. The detection of urinary antigen is a well-established, rapid-turnaround assay with a sensitivity of greater than 85% for infections caused by *L. pneumophila* serogroup 1, but has little utility for the diagnosis of infection by other *Legionella* species. In the current era, most diagnoses of legionellosis are made by urinary antigen testing [88, 116]. Methods employing detection of *Legionella*

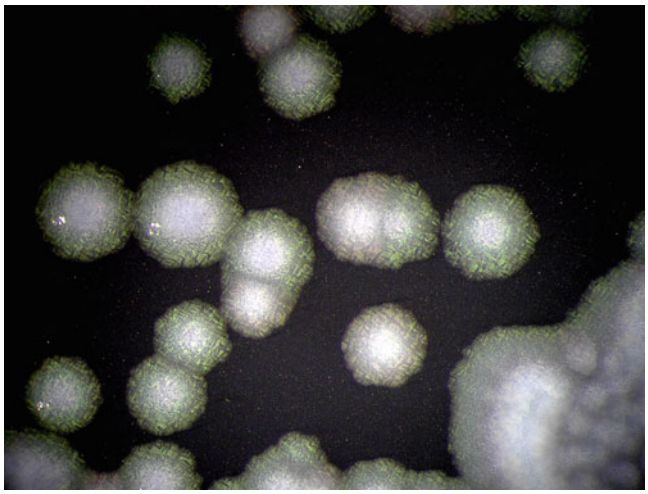

FIGURE 23-4. Colonies of *Legionella pneumophila* on buffered charcoal yeast extract (BCYE) agar. (Photo provided courtesy of A. William Pasculle Sc. D, Department of Pathology, University of Pittsburgh Medical Center, Pittsburgh, PA).

DNA by PCR have been developed and have potential for clinical application [88].

The most active antibiotics for *Legionella* treatment are the newer macrolides, such as azithromycin, and fluoroquinolones, especially levofloxacin and moxifloxacin. Erythromycin, rifampin, the tetracyclines, and TMP-SMX also have activity. All beta-lactam antibiotics, the aminoglycosides, vancomycin, and clindamycin are ineffective [92, 117–119]. Data regarding the benefit of combination therapy with rifampin are inconclusive [120], and drug-drug interactions pose a major drawback to the use of rifamycins in transplant populations.

Isolation for hospitalized patients with *Legionella* infection is unnecessary. If a hospital outbreak of legionellosis is detected, surveillance should include culturing of hospital water sources. Routine environmental sampling for *Legionella* in hospitals has been adopted in several states and by the US Veterans Affairs Healthcare System. It has also been recommended by the CDC for institutions with HCT programs. Community outbreaks of legionellosis have been linked to recreational or occupational exposure to aerosolized water, such as occurs in whirlpool spas or commercial water displays. It is therefore prudent to warn transplant recipients about the potential hazards of prolonged exposure to such aerosols.

23.3.2 Bartonella

Bartonella henselae is a fastidious, gram-negative bacillus that has a natural reservoir in domestic cats. Immunocompetent patients with *B. henselae* infection typically develop painful regional adenopathy and fever after a cat bite or scratch ("cat scratch disease"). Bacillary peliosis, bacillary angiomatosis, and persistent bacteremia with fever are typical manifestations of disseminated infection seen in patients with AIDS and other immunosuppressed hosts. Patients with bacillary peliosis have studding of the liver and spleen with numerous small inflammatory nodules that appear as hypodense lesions on computed tomography scanning. Bacillary angiomatosis is a vasculoproliferative form of disseminated *B. henselae* infection associated with lytic bone lesions and characteristic violaceous, friable skin nodules [121–123].

B. henselae infection has been reported in kidney, liver, heart, lung, and HCT recipients [121, 124]. Transplant recipients may present with localized cat scratch disease or with one or more of the syndromes associated with disseminated disease. Of 29 cases of *B. henselae* infection in SOT recipients reported by Psarros and coauthors, two-thirds were classified as disseminated [121]. An unusual form of bacillary angiomatosis with vegetating papillomatous lesions in the oral cavity has been described following HCT [124]. *Bartonella* endocarditis has been described in transplant recipients [121]. Unusual manifestations of *Bartonella* infection reported in kidney recipients include hemophagocytic syndrome [125] and vasculitis with allograft glomerulonephritis [126].

Donor-transmitted bartonellosis has been suspected in some cases, one of which had good documentation [121, 127]. In this case, a pediatric liver recipient was found to have a nodule of the liver and enlarged abdominal lymph nodes 2 months after transplantation [127]. Biopsies of the liver and lymph nodes showed granulomatous changes. *Bartonella* infection was confirmed by PCR of the liver. The recipient had no cat exposure and the donor was found to be seropositive for *B. henselae.*

Unlike *B. henselae*, humans are the only known reservoir of *Bartonella quintana. B. quintana* is transmitted by the human body louse, *Pediculus humanus*, and is the etiologic agent of trench fever. There is a single report of *B. quintana* infection after SOT presenting as bacillary angiomatosis in a kidney recipient from the Czech Republic [128].

Bartonella organisms are not routinely isolated from blood. Culture of tissue specimens on blood or chocolate agar may require an incubation period of 30 days and is not sensitive. For this reason, performing PCR on tissue specimens or blood is increasingly relied upon for diagnosis [129, 130]. Serology can be used as supportive evidence of infection in the appropriate clinical setting [121]. The diagnosis is strongly suggested when typical pathological changes are found in tissue sections, especially if Warthin–Starry stains of the tissue show organisms.

Cat scratch disease generally resolves without therapy in immunocompetent hosts. One small randomized trial showed a greater decrease in volume of affected lymph nodes in patients treated with azithromycin as compared with placebo [131]. No studies specifically address the treatment of bartonellosis in transplant recipients. Given the theoretical risk for dissemination, it seems prudent to recommend antimicrobial therapy for all transplant recipients with *Bartonella* infection.

Based on 2004 recommendations [132], a 5-day course of azithromycin is recommended as first-line treatment for cat scratch disease. Treatment for disseminated bartonellosis has not been studied, but observational data suggest that both macrolides and doxycycline should be effective agents; a treatment duration of 3–4 months is recommended [132]. Rifampin and gentamicin appear to be active agents and might be considered for adjunctive treatment of difficult or refractory cases [132]. Prevention of bartonellosis in transplant populations entails counseling individuals to avoid contact with cats, particularly younger cats, as they are associated with the highest risk for transmission [133].

23.3.3 *Bordetella bronchiseptica*

Bordetella bronchiseptica is a small, pleomorphic, aerobic, gram-negative coccobacillus. It is a cause of infection in household and farm animals and is known among pet owners as the etiologic agent of "kennel cough." Most human infections with *B. bronchiseptica* occur in immunocompromised hosts. There are numerous reports of *B. bronchiseptica* infection after SOT and HCT [134–140]. Most patients present with fever and cough. Findings on chest imaging are variable and include infiltrates, nodular densities, or cavities [136]. Some patients develop respiratory failure or bacteremia. The organism can be cultured from respiratory secretions or blood using standard laboratory techniques.

Infected patients frequently report contact with animals and sometimes there is a documented or suspected infection in a household pet [135, 137, 138]. In one instance, a kidney–pancreas transplant recipient with pneumonia appeared to have acquired the organism from a pet dog that had been immunized with live-attenuated, intranasal *B. bronchiseptica* vaccine [134]. In another report, two allogeneic HCT recipients at the same center developed severe *B. bronchiseptica* infection within 3 days of each other [139]. Pulsed-field gel electrophoresis analysis indicated that the two patients' isolates were identical. Neither patient reported contact with animals after transplantation, but both were being treated in the same transplant ward and clinic, suggesting the possibility that *B. bronchiseptica* was transmitted in the health care setting.

There are no definitive guidelines on treatment of *B. bronchiseptica* infection. The organism is often susceptible to erythromycin and azithromycin, antipseudomonal penicillins, third-generation cephalosporins, TMP-SMX, aminoglycosides, tetracyclines, and fluoroquinolones [135, 136, 139]; it is usually resistant to penicillin, ampicillin, and clindamycin [135–137]. Treatment is complicated by the fact that antibiotic susceptibilities do not always predict the clinical response. Patients may suffer microbiological or clinical relapses, possibly due to the capacity of *B. bronchiseptica* to invade and persist in respiratory epithelium and alveolar macrophages. Emergence of resistance after antibiotic treatment has also been documented [134, 137, 140]. Infection with *B. bronchiseptica* might be prevented by advising transplant recipients to avoid close contact with animals that are sick or have recently received live *B. bronchiseptica* vaccine.

23.3.4 *Helicobacter pylori*

H. pylori is a curved, gram-negative bacillus that infects 25–50% of adults in developed countries and causes chronic gastritis [141]. Infection with *H. pylori* has been definitively linked to the occurrence of peptic ulcer disease, and it is a major risk factor for the development of gastric cancer. Infected persons develop antibodies to *H. pylori*, and seropositivity is a reliable indicator of chronic infection in the stomach.

Several studies have investigated *H. pylori* infection in transplant recipients. An investigation found that 29% of 202 kidney transplant recipients were seropositive for *H. pylori* antibodies, a rate similar to patients on hemodialysis [142]. Seropositivity was associated with dyspeptic symptoms. In another study, 48% of 33 kidney recipients undergoing upper endoscopy between 2 and 4 months after transplantation had *H. pylori* identified by histology or urease testing [143]. The *Helicobacter*-infected patients were more likely to have gastritis, peptic ulcers, or dyspeptic symptoms. Somewhat disparate results were seen in a longitudinal study of 100 heart transplant recipients, 35% of whom were seropositive before transplantation [144]. Only 1 of the 65 seronegative patients seroconverted over a follow-up of 3.5 years. Seropositive patients did not have more episodes of ulcer disease, gastritis, or gastrointestinal bleeding than seronegative patients, but 40% of *Helicobacter*-seropositive patients became seronegative in follow-up. This finding correlated with a more intensive use of antibiotics, which appeared to have inadvertently cured the patients of their *Helicobacter* infections. Similar reversions to seronegative status have been reported from liver transplant recipients in Germany [145] and kidney transplant recipients in Finland [146].

Information on *Helicobacter* infection in patients undergoing HCT is limited. A study of 276 HCT recipients undergoing endoscopy, either before or after transplantation, disclosed only one case of *H. pylori* infection [147]. Castagnola et al. diagnosed *H. pylori* infection using a stool antigen assay in 13 (3%) of 478 children with hematologic malignancy, including 3 children who had undergone HCT [148]. Patients presented with dyspepsia or gastrointestinal bleeding and all improved with treatment of the *Helicobacter* infection; however, there was no direct evidence that *Helicobacter* infection had caused the patients' symptoms.

Despite limitations, these studies suggest that SOT and HCT recipients are not more likely, and they may be less likely, to be chronically infected with *H. pylori* than the general population. The available data does not answer the question whether transplant recipients with *Helicobacter* infection are more or less likely than immunocompetent hosts to develop ulcer disease.

An intriguing manifestation of *H. pylori* infection in transplant recipients is the occurrence of mucosa-associated lymphoid tissue (MALT) B-cell lymphomas. MALT lymphomas in the stomach are associated with *H. pylori* infection. They have been reported to respond to and even be cured by treatment of *Helicobacter* infection, thus obviating the need for cancer chemotherapy. Four cases of gastric MALT lymphoma were described in 1850 liver transplant recipients, a rate of 0.2%, which is 10–100 times more common than in the general population [149]. MALT lymphomas have also been described in heart and kidney recipients [150]. The mortality of MALT lymphomas appears low compared to other transplant tumors, as only two deaths from malignancy were seen among 16 cases in a transplant tumor registry [150].

The most commonly used regimen for *H. pylori* infection is 3-drug therapy, consisting of a proton pump inhibitor, clarithromycin, and amoxicillin [141]. Metronidazole is substituted for amoxicillin in penicillin-allergic patients. In areas where clarithromycin resistance is high, a 4-drug regimen is preferred. The most common 4-drug regimen employs a proton pump inhibitor, bismuth subsalicylate, metronidazole, and a tetracycline compound. Confirmation of cure is recommended when patients have persistent symptoms, underlying ulcer disease or a *Helicobacter*-associated cancer. Testing can be done with a urea breath test, a stool antigen assay, or repeat endoscopy and should be delayed until at least 4 weeks after the end of therapy [141].

23.4 Mycoplasma

23.4.1 *Mycoplasma* and *Ureaplasma*

The mycoplasmas and ureaplasmas differ from most bacteria in their small size (150–250 nm) and lack of a cell wall. The principal species causing transplant infections are *Mycoplasma pneumoniae*, which is a respiratory pathogen, and *M. hominis* and *Ureaplasma urealyticum*, which have a role in minor genitourinary infections, but occasionally cause severe extragenital disease [151, 152]. Because these organisms cannot be detected on Gram stain and their culture requires specialized techniques, only a minority of clinical infections receive an etiologic diagnosis.

M. pneumoniae is a common cause of bronchitis and pneumonia [151], but it is also is associated with a number of interesting extrapulmonary conditions, including cold agglutinin-positive hemolysis and Stevens–Johnson syndrome. Occasional patients with *M. pneumoniae* infection develop secondary carditis or CNS diseases such as aseptic meningitis or encephalitis [153, 154]. An unusual case of disseminated *M. pneumoniae* infection was diagnosed in a kidney recipient by PCR testing from multiple infected sites, including an axillo-femoral bypass graft, the knee joint, and a psoas abscess [155]. *M. pneumoniae* with Stevens–Johnson syndrome has been described in HCT and liver transplant recipients [156, 157]. Chronic *M. pneumoniae* pulmonary infection was reported in a pediatric kidney transplant recipient with hypogammaglobulinemia, The patient had fever and respiratory symptoms for 6 months and the diagnosis was finally established by PCR testing of BAL fluid [158].

M. hominis and *Ureaplasma species* have been isolated from the genitourinary flora of many sexually experienced men and women. They are often commensals, but seem to play a role in some common infections, such as nongonococcal urethritis (*U. urealyticum*) and bacterial vaginosis (*M. hominis*) [152]. *M. hominis* infections outside the genitourinary tract are well described, particularly in patients who are postpartum or have compromised immune systems [159]. Two-thirds of 17 patients in a case series of invasive extragenital *M. hominis* infections were immunosuppressed [159]. *M. hominis* infection has been reported in all types of SOT recipients [159–163]. Mixed infection with *M. hominis* and *U. urealyticum* has been reported in kidney, liver, and lung recipients [164–166].

Superficial or deep *M. hominis* sternal wound infections in heart and heart–lung recipients usually occur within a few weeks of transplantation. These patients have fever with sternal inflammation and drainage but Gram stains and cultures of the drainage are negative [167, 168]. Some reports of early posttransplant *M. hominis* pneumonia in lung recipients are suspicious for donor transmission, including a case of *M. hominis* and *U. urealyticum* coinfection [160, 166]. Cases of *M. hominis* deep wound infection reported following kidney transplantation seem likely to be due to spread of *Mycoplasma* colonizing either the donor or recipient urinary tract [169]. Other well-documented types of *M. hominis* infection are septic arthritis, peritonitis, meningitis and bacteremia [159]. *M. hominis* infection is rare after HCT. In the only reported case, *M. hominis* was cultured from BAL fluid, pharyngeal secretions and urine of a patient with diffuse alveolar hemorrhage [170]. It was unclear if the organism had any causal role in the clinical illness.

Diagnosis of *Mycoplasma* infection requires a high index of suspicion, as routine stains of purulent material are negative. Translucent colonies may be seen after 4–5 days of culture on blood agar plates but are often mistaken for water droplets. The organism grows best on *Mycoplasma*-specific media, producing colonies with a "fried egg" appearance. Because of these diagnostic challenges, clinicians should alert the microbiologist if *Mycoplasma* infection is suspected. Increasingly, diagnosis is made by PCR [155, 162].

Macrolides, tetracyclines and fluoroquinolones are active against *M. pneumoniae*, but resistance to macrolides has recently emerged in Asia and will undoubtedly spread to other countries [151, 171]. Most *M. hominis* isolates are sensitive to clindamycin, rifampin, fluoroquinolones, and tetracycline [159]. The organism is resistant to other macrolides, aminoglycosides, sulfonamides, and cell wall-active agents

including beta-lactam antibiotics. The treatment duration should be at least 2 weeks or longer when severe, deep-seated infection is present. There is a paucity of laboratory data to guide treatment of *Ureaplasma* infection, but resistance to macrolides and tetracycline appears to be increasing. Fluoroquinolones, particularly moxifloxacin, should be considered for management of complicated or refractory cases [172, 173].

23.5 Spirochetes

23.5.1 *Treponema pallidum*

T. pallidum, the causative organism of syphilis, is a non-cultivatable spirochete. The primary modes of acquisition are sexual contact, transplacental passage to the fetus or, rarely, accidental direct inoculation. Infection can also be transmitted by blood transfusion, but the risk is low because blood donors are screened and the organism cannot survive for longer than 24–48 h in stored blood units [174].

The potential for transmission of syphilis by donated organs is a concern and organ donors are routinely screened for syphilis. Transplantation of organs from donors with positive syphilis serology has been reported in kidney, liver, and lung transplantation [175, 176]. In these cases, the donors had no symptoms of active syphilis and were thought to have latent or convalesced infection. Transient seroconversion of both treponemal and non-treponemal serology occurred in some recipients, but without evidence of acute clinical disease or sequelae [175–177]. All recipients received penicillin therapy posttransplantation. Serological conversion may have represented an immune response to asymptomatic infection; however, it was also proposed that serological conversion in the recipients may have derived from antibodies elaborated by donor-derived B cells. This was likely the case in one Japanese patient who seroconverted their syphilis serology after allogeneic HCT [178]. The sibling donor had positive syphilis serology but had been appropriately treated with penicillin before harvest of stem cells. The available data are limited but suggest that screening of SOT and HCT donors should continue. Administering high-dose penicillin to recipients posttransplantation or to living donors pretransplantation should be adequate to prevent significant disease.

There are reports of active secondary syphilis in SOT recipients [179–181]. The clinical findings were typical and included fever, diffuse skin rash (see Figure 23-5), hepatitis and various neurological symptoms such as headache, dysesthesias and visual changes. Neurosyphilis was documented in over one-half of the patients. All patients responded well to antibiotic treatment.

The diagnosis of syphilis is based on serologic testing for non-treponemal antibodies (VDRL test or rapid plasma reagin) accompanied by a specific treponemal antibody test such as *T. pallidum* particle agglutination [TP-PA]. The diagnosis can also be suggested when typical pathological changes are found on tissue biopsy of affected organs [179, 181]. The treatment of choice is parenteral penicillin. Doxycycline or erythromycin are second-line agents for patients with penicillin allergy.

23.5.2 Borrelia

Lyme disease is an infection transmitted by *Ixodes* ticks and caused by various *Borrelia* species (*B. burgdorferi* and *B. pacificus* in the USA, and primarily *B. afzelii* and *B. garinii* in Europe and Asia). The animal reservoirs in the USA are small rodents, but large animals, such as deer and cattle, support the life cycle of the *Ixodes* ticks. Lyme disease has been reported in SOT recipients [182–184] and in a HCT recipient [185], with manifestations ranging from localized erythema migrans to disseminated disease with carditis or neurologic involvement. Given the paucity of data on Lyme disease in transplant recipients, it is not clear if the severity of disease is greater than in immunocompetent patients.

Because serologic diagnosis of infection has potential limitations in immunocompromised patients, a high index of suspicion is warranted in any transplant patient who has exposure in an endemic area and has signs or symptoms suggestive of Lyme disease [184, 185]. Treatment is universally indicated in patients with active Lyme disease. Oral doxycycline is commonly prescribed for most patients with erythema migrans, those with isolated facial nerve palsy or with arthritis without neurologic involvement. Parenteral therapy (e.g., ceftriaxone) is usually reserved for patients who have disseminated disease with neurologic or cardiac involvement [186].

23.6 Rickettsiosis

23.6.1 *Coxiella burnetii*

C. burnetii, the etiologic agent of Q fever, is a pleomorphic gram-negative coccobacillus. Infection usually arises from exposure to infected livestock or unpasteurized milk. The most common clinical manifestation is an acute febrile illness associated with pneumonia or hepatitis. Many patients who are untreated recover, but a small proportion may develop a chronic febrile illness, often accompanied by endocarditis.

C. burnetii infection has been reported in patients with a variety of immunocompromising conditions, [187], and there are a few reports of acute or chronic Q fever after SOT and HCT that have demonstrated response to doxycycline-containing regimens [188–191]. Although the literature on Q fever in the transplant population is sparse, treating a patient who has a positive serologic response seems prudent to prevent chronic infection, even when symptoms are mild or resolving.

23.6.2 Other Rickettsial Organisms

Rickettsia, *Ehrlichia*, and *Anaplasma* species are members of the order *Rickettsiales*. They are fastidious, obligate intracellular bacteria with gram-negative cell walls, but are poorly visualized by Gram stain. A number of these organisms are important human pathogens that are transmitted by arthropod vectors.

A single case report describes a heart transplant recipient with Rocky Mountain spotted fever, a tick-borne illness caused by *Rickettsia rickettsi* [192]. The patient had a mild febrile illness with rash and responded to 3 weeks of treatment with doxycycline. The diagnosis was initially made by immunofluorescence staining of a skin biopsy and later confirmed by seroconversion. There are two case reports of SOT recipients with Mediterranean spotted fever, a tick-borne illness caused by *Rickettsia conorii.* One kidney recipient presented with rash and spontaneous splenic rupture after recent travel to southern France; the patient improved on empiric doxycycline and the diagnosis was ultimately made by PCR amplification of spleen and skin tissue [193]. The second patient was a liver recipient in Spain who developed high fever, myalgias and rash; the diagnosis of *R. conorii* infection was made serologically and the patient responded promptly to doxycycline treatment [194]. Murine typhus is caused by *Rickettsia typhi* and transmitted by fleas. A single case of murine typhus was reported in a liver transplant recipient from Thailand who had fever, hepatitis, and interstitial pneumonia; the diagnosis was made by serology and treatment with doxycycline resulted in clinical cure [195]. Murine typhus may be encountered around the world and some recent cases have been described in Texas and Southern California [196].

Human ehrlichiosis and anaplasmosis have similar clinical manifestations but differ in their geographic distributions, the tick vector and the specific blood cells—either monocytes or granulocytes—that support infection. Human monocytic ehrlichiosis is caused by *Ehrlichia chaffeensis* and transmitted by the lone star tick (*Amblyomma americanum*). It was first reported in a liver transplant recipient from Kentucky in 1995 [197]. This patient developed fever, pancytopenia, elevated transaminases, and shortness of breath 2 weeks after a tick bite. He made a full recovery on empiric doxycycline therapy, with the diagnosis subsequently established by serology. Human granulocytic anaplasmosis is caused by *Anaplasma phagocytophilum* and transmitted by *Ixodes scapularis*. It was first reported in a kidney transplant recipient from Minnesota who developed fever, myalgia, diarrhea, and pancytopenia a week after tick exposure [198]. *Ehrlichia ewingii* is the agent of canine granulocytic ehrlichiosis, It was first reported to cause human infection in 1999 [199]. Infection with *E. ewingii* generally produces a milder illness than *E. chaffeensis*. Most reported cases have been in immunocompromised hosts, including transplant recipients [199, 200].

Cellular immunity is an important host defense against rickettsial infection and poor outcomes have been reported in HIV-seropositive individuals [201, 202]. It is not clear if transplant recipients have more severe disease or worse outcomes. Thomas et al. compared clinical characteristics of ehrlichiosis (both *E. chaffeensis* and *E. ewingii*) in 15 SOT patients and 43 immunocompetent patients [200]. Transplant recipients had less rash and less hepatic enzyme elevation but more leukopenia and renal dysfunction than the immunocompetent patients. All transplant patients responded rapidly to doxycycline therapy and their mean hospital stay was only 4 days. In a review of 23 immunocompromised patients with *Ehrlichia* infection, severe disease occurred in some of the 7 SOT recipients, but they all survived; the six deaths reported in the series occurred in patients with HIV or splenectomy [202].

A case of probable donor-derived *Ehrlichia* infection has been reported in two kidney recipients of a common donor [203]. Both recipients developed high grade fever in the early posttransplant period. The diagnosis was made by detection of *E. chaffeensis* DNA by PCR from serum in one recipient and by serology in the other; unfortunately, no serum or tissue was available from the donor for confirmatory testing.

Monocytic ehrlichiosis and anaplasmosis can sometimes be diagnosed by finding "morulae," or characteristic intracytoplasmic inclusions, in a buffy coat smear. Morulae are found in monocytes in monocytic ehrlichiosis but are uncommon (<10%); they are found in granulocytes in anaplasmosis and are relatively frequent (20–80%). Serology for *E. chaffeensis* and *A. phagocytophilum* is useful for retrospective diagnosis and epidemiologic studies, but not rapid enough for clinical purposes. Specific serology is not available for *E. ewingii*, although patients with *E. ewingii* infection

often develop cross-reactive antibodies to *E. chaffeensis* [199]. Culture is not commercially available. PCR testing is now the preferred way to make a rapid, species-specific diagnosis [199, 200, 204]. Empirical treatment should be initiated in patients with suspected ehrlichiosis or anaplasmosis, pending results of diagnostic testing. The agent of choice is doxycycline. In regions endemic for anaplasmosis doxycycline will treat for the possibility of coinfection with *B. burgdorferi*, which is also transmitted by *Ixodes* ticks.

Part V
Viral Infections

24
Cytomegalovirus Infection After Stem Cell Transplantation

Morgan Hakki and Per Ljungman

24.1 Virus Structure and Replication

Human cytomegalovirus (CMV) is a member of the beta (β) herpesvirus subfamily, along with human herpesvirus (HHV)-6 and HHV-7. The CMV virion shares structural similarities with other herpesviridae. Namely, the double-stranded DNA genome is encased within an icosahedral capsid, which in turn is surrounded by a proteinaceous tegument (or matrix). A lipid membrane containing surface viral glycoproteins that function in host cell binding and entry is the outermost component of the virion.

The CMV genome is approximately 230 kb, making CMV one of the largest among human viruses, and is organized into unique long (UL) and unique short (US) segments that are flanked by inverted genomic repeats. Most CMV genes are named according to their position within the genome based on the reference strain AD169 [1]. For example, UL97 is the 97th open reading frame (ORF) in the UL segment and US28 is the 28th ORF in the US segment. CMV genes may also have names that reflect historical usage, function, or homology to genes of other herpesviruses.

Like all herpesviruses, CMV establishes latency after primary infection, during which replication-competent virus remains present in the infected cell but evidence of viral replication is undetectable until triggered to reactivate. The viral and host factors that regulate latency and reactivation are poorly understood [2]. The site(s) of latency are not well defined but bone marrow stem cells of the myeloid lineage such as CD34+ and CD14+ cells have been shown to be one site of CMV latency [3, 4]. It has also been shown that the allogeneic effect can contribute to reactivation from peripheral blood mononuclear cells [5]. Since CMV can be transmitted from donor to recipient during solid organ transplant [6], parenchymal cells in these organs may also harbor latent virus.

24.2 CMV and the Host Immune System

24.2.1 Adaptive Immunity

Infection with CMV is associated with pronounced induction of $CD4^+$ and $CD8^+$ T cell responses. Immunodominant T cells responses are directed primarily against the gene products of UL123 (IE-1) and UL83 (pp65) [7–12]. However, CMV-specific T-cell immunity is now recognized as complex due to the large numbers of antigens, both lytic and latency-associated, that have been found to be targeted by T-cell responses [13–16]. Numerous studies have documented the importance of both CMV-specific $CD8^+$ and $CD4^+$ responses in determining the incidence and outcome CMV infection after allogeneic HCT [17–26]. Similar findings have been observed after newer HCT techniques such as haploidentical HCT [27] and umbilical cord blood transplant (CBT) [28–30].

The contribution of humoral immunity in controlling CMV replication is less clear. Antibodies to glycoprotein B (gB) and glycoprotein H (gH) predominate during infection [31–33], but while such antibodies may neutralize virus in tissue culture, their capacity to prevent primary infection is not well defined. While evidence suggests that antibody may serve to limit CMV dissemination and disease severity [34–36], lack of antibody does not alter the course of the primary MCMV infection in murine models [36]. Thus, the contribution of antibody to the control of CMV infection remains poorly understood.

24.2.2 Innate Immunity

Innate immunity plays a critical role in controlling herpesvirus infections through the production of inflammatory cytokines such as type I interferons (IFN α and β), interleukin 12

P. Ljungman et al. (eds.), *Transplant Infections*, DOI 10.1007/978-3-319-28797-3_24

(IL-12), and tumor necrosis factor (TNF) that exert a direct antiviral effect and induce adaptive immunity [37, 38]. The CMV glycoproteins gB and gH trigger the toll-like receptor 2 (TLR2) upon binding to the target cell [39–41]. In addition, viral DNA triggers TLR3 and TLR9 as well as the DNA sensor ZBP1 [42–47]. Attempts to correlate polymorphisms in donor and recipient TLRs and other innate immune sensors with CMV infection after HCT have yielded conflicting results that require further study [48–52].

Expansion of natural killer (NK) cells during CMV infection has been reported in both immunocompetent humans and after HCT [53–58]. While NK cells have been shown to limit MCMV replication in mice [59–63], their role in controlling CMV infection in humans is less clear although associative evidence strongly indicates an important contribution [22, 64, 65]. In addition, the genotype of the donor activating KIR (aKIR) has been demonstrated to influence the development of CMV infection after allogeneic HCT [66–68]. The mechanistic basis underlying these correlative findings is not well defined.

γδ T cells represent a minority (<6%) subset of circulating T cells in healthy individuals but are more prominent in peripheral sites such as mucosal surfaces [69]. Marked by the expression of receptors composed of γ and δ chains [38], as opposed to α and β chains associated with CD4+ and CD8+ responses, they respond to CMV infection with both in both innate- and adaptive- type immune function [70, 71]. CMV infection stimulates γδ T cell proliferation in both humans and mice, and deficient γδ T cell function has been associated with impaired regulation of CMV infection [70, 72–74].

24.2.3 Immune Evasion Mechanisms

As a successful human pathogen, CMV has necessarily evolved numerous mechanisms to evade and counteract virtually all aspects of the host immune response. Starting at the earliest stages of infection, CMV utilizes virion-associated and immediate-early proteins to effectively prevent host cell apoptosis, interferon-mediated pathways, and other innate immune responses such as shutoff of host cell protein synthesis in response to viral nucleic acid accumulation [75–79]. Multiple CMV proteins as well as the noncoding viral microRNAs miR-UL122 and miR-112 inhibit NK cell function [80–82].

A hallmark of CMV immune evasion is the blunting of CTL responses by inhibiting MHC-I restricted antigen presentation [83]. A number of CMV proteins contribute to this, including the tegument protein pp65 and genes of the US2-11 region [84–92]

Finally, CMV encodes several homologues of cellular proteins, including MHC class-I molecules, chemokine receptors, IL-10, TNF receptors, and CXC-1 homologues, that function to evade the host immune response [93–97].

24.3 Diagnostic Methods

The serologic determination of IgG and IgM has an important role in determining a patient's risk for CMV infection after HCT (see below, "Risk Factors") but is not useful in the diagnosis of active CMV infection or disease.

Histopathologic examination of tissue specimens remains the "gold standard" in the diagnosis of invasive CMV disease. In addition to observing nonspecific viral cytopathic effect in tissue, immunohistochemical techniques are used to identify CMV antigens (Figure 24-1a left and middle panels).

Growth of CMV in tissue culture takes several weeks, limiting its clinical usefulness as a diagnostic tool. Culture-proven viremia is highly predictive of CMV disease, but is of limited utility for screening since this finding frequently coincides with the onset of symptomatic disease [98–100].

The shell vial technique, in which monoclonal antibodies are used to detect CMV immediate-early proteins in cultured cells, can be performed within 18–24 h after inoculation. This assay is not sensitive enough to use for routine blood monitoring [99], but is highly useful on bronchoalveolar lavage (BAL) fluid in the diagnosis of CMV pneumonia due to its established specificity in this setting [101]. Many laboratories have abandoned culture-based techniques in favor of nucleic acid testing so that today these techniques have limited availability in many parts of the world.

The detection of the CMV pp65 tegument phosphoprotein in peripheral blood leukocytes offers a rapid, sensitive, and specific method of diagnosing and roughly quantitating CMV viremia. In the transplant setting, a positive or quantitatively increasing CMV pp65 assay has been shown to predict the development of invasive disease [102, 103] but is not always positive in the setting of proven end-organ disease, particularly gastrointestinal tract disease [104–107]. The predictive value of this assay has not been validated when performed on other body fluids such as BAL fluid. Since this assay relies on the detection of pp65 in circulating leukocytes, it may not be reliable in patients with profound leukopenia, such as in the pre-engraftment stage after HCT. At most centers, this assay has been replaced by nucleic acid testing primarily using quantitative polymerase chain reaction (qPCR).

qPCR relies on the amplification and quantitative measurement of CMV DNA. PCR is the most sensitive method for detecting CMV [108], while at the same time maintains high specificity. In addition, it is very rapid, with results usually available within 24 h, and does not rely on the presence of circulating leukocytes as does the pp65 antigenemia assay. qPCR provides a direct quantitative measurement of circulating CMV viral load, which is an accurate predictor of CMV disease after transplantation in most cases [109–113]. Like the pp65 antigenemia assay, serum or blood PCR may be negative in the setting of visceral disease [104, 106,

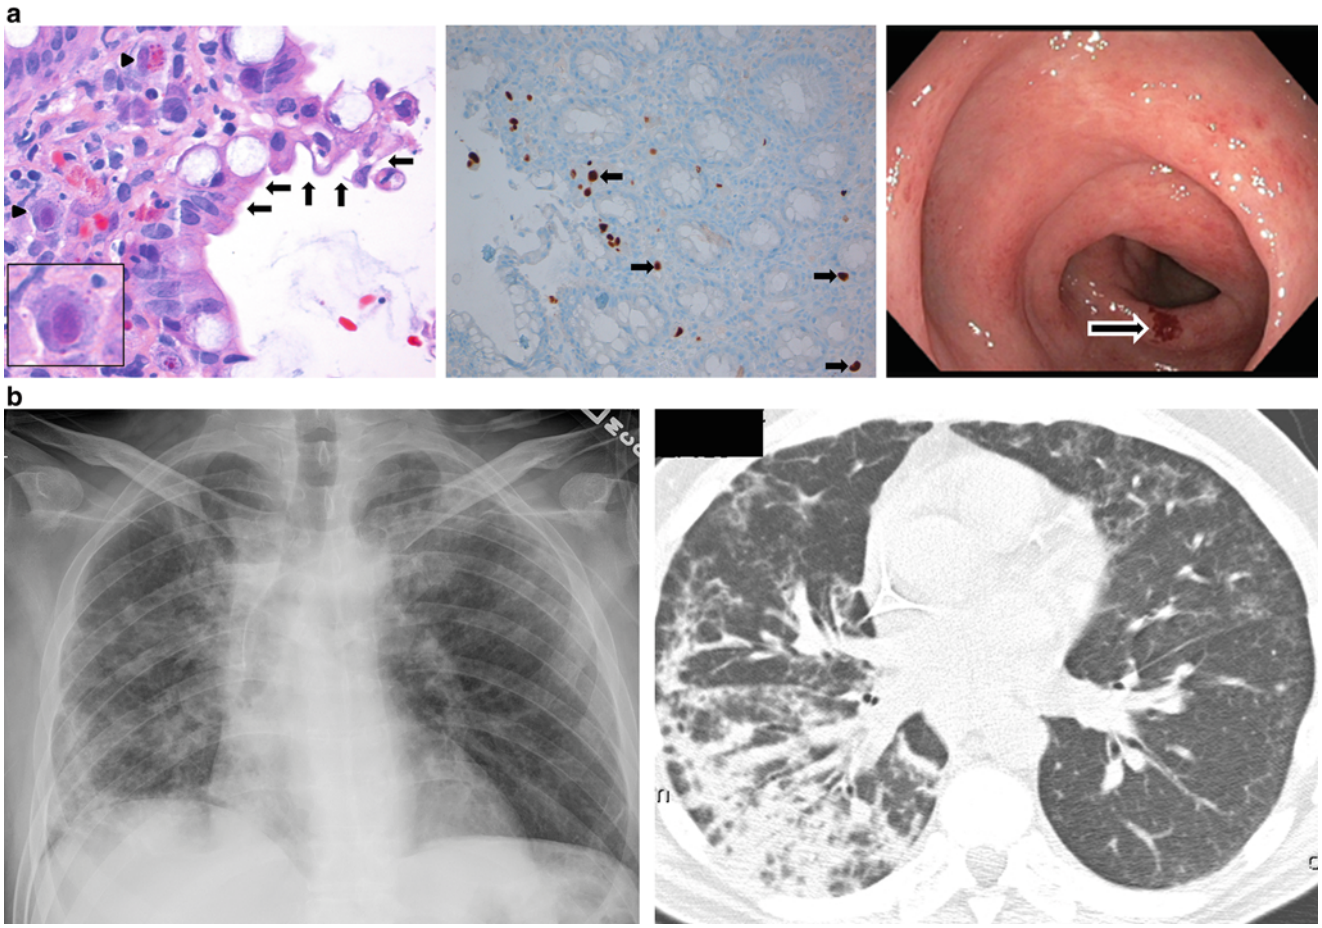

FIGURE 24-1. (**a**) CMV colitis in a CBT recipient. *Left panel*: histopathologic examination of ulcer biopsy specimen showing loss of superficial mucosal integrity (*arrows*) and viral inclusions (*arrowheads*). Inset shows higher magnification view of viral inclusion. *Middle panel*: immunohistochemistry demonstrating CMV-infected cells in biopsy specimen using an antibody recognizing the CMV gB protein. *Right panel*: endoscopic visualization of mucosal ulceration (*arrow*). 107]. qPCR values of circulating CMV in plasma versus whole blood in a given patient may vary [114]; therefore, it is important to use the same blood component for testing when following serial viral loads. Although PCR has been used on BAL fluid [115], viral-load cutoffs have not been defined, and while the sensitivity and negative predictive values are very high, the specificity and positive predictive values are not known. Similarly, the significance of detection of CMV DNA by PCR in tissue samples such as lung, colon, or liver biopsy specimens for the diagnosis of CMV end-organ disease is not well established and will require further development and evaluation. PCR testing of CSF is specific and strongly indicative of CMV replication in the CNS. PCR testing of vitreous fluid strengthens the diagnosis of CMV retinitis.

The detection of CMV mRNA by PCR amplification on blood samples is equivalent to utilizing DNA PCR or p65 antigenemia to guide preemptive therapy after HCT [116, 117]. However, this method has not been as widely adopted as DNA-based PCR assays.

24.4 Clinical Manifestations

Defining the fundamental concepts of CMV "infection" and "disease" has been tremendously useful in the care of the individual patient and also in patient-centered clinical research. First developed and published in 1993, CMV definitions were updated in 1995 and 2002 to reflect advances in diagnostics and recognition of the "indirect effects" of CMV infection [118]. CMV "infection" simply indicates the detection of CMV, typically by DNA or messenger ribonucleic acid (mRNA) PCR, or pp65 antigenemia, from plasma or whole blood. CMV "disease" was

historically limited to "proven," as defined by the presence of symptoms and signs compatible with CMV end-organ involvement along with the detection of CMV in tissue from the relevant organ by histopathology, immunohistochemistry, or DNA hybridization [118]. Only retinitis was defined based solely on symptoms and/or signs when assessed by an experienced ophthalmologist. These definitions are being revised and expanded to include "probable" disease categorization based on new diagnostic techniques, primarily PCR-based (Table 24-1). Since CMV infection and disease are generally managed differently (see below), distinguishing between the two is critical.

24.4.1 Direct Effects

Almost any organ can be affected by CMV in the HCT recipient. Since the introduction of effective antivirals such as ganciclovir and sensitive monitoring techniques such as PCR, the overall incidence of CMV disease in the first year after HCT has fallen from approximately 30–35 to 5–10% among seropositive recipients [119]. Gastrointestinal disease and pneumonia are the most common manifestations of CMV end-organ disease after HCT.

Pneumonia is the most important clinical manifestation of CMV disease due to its high associated mortality. Prior to the

Table 24-1. Definitions of CMV disease in HCT recipients

	Classification	
Disease manifestation	Proven[a]	Probable[a]
Pneumonia	Tissue CMV positive by: Immunohistochemistry or Histopathology or DNA hybridization *Or* BAL: culture/shell vial	BAL or lung tissue CMV positive by: qPCR value above established threshold
Gastrointestinal[b]	Macroscopic mucosal lesions *And* Tissue CMV positive by: Immunohistochemistry *or* Histopathology *or* DNA hybridization	Tissue CMV positive by: Immunohistochemistry *or* Histopathology *or* DNA hybridization
Hepatitis	Abnormal serum transaminases *And* Tissue CMV positive by: Immunohistochemistry *or* Histopathology *or* DNA hybridization *And* Absence of other cause of hepatitis	Not defined
Retinitis	Ophthalmological signs[c] Vitreal fluid CMV PCR positive[d]	Not defined
CNS[e]	Tissue CMV positive by: Immunohistochemistry *or* Histopathology *or* DNA hybridization *or* Culture *or* PCR	CSF CMV positive by PCR[f]

[a]Both require the presence of the appropriate symptoms and/or signs of CMV disease.
[b]Esophagitis, gastritis, small or large bowel disease.
[c]As determined by an experienced ophthalmologist.
[d]Use as supporting evidence if clinical presentation is atypical.
[e]Ventriculitis, encephalitis.
[f]Requires absence of significant (visible) bloody contamination in CSF sample obtained.

development of effective preemptive and prophylactic strategies, the incidence of CMV pneumonia ranged from 1 to 6% after autologous HCT and 10 to 30% after allogeneic HCT [120]. Currently, CMV pneumonia accounts for approximately one-third of the cases of CMV disease [121]. The vast majority of cases occur after allogeneic HCT and typically within the first 60 days, but up to 30% of cases occur after day +100 [109, 122]. CMV pneumonia often manifests with fever, nonproductive cough, and hypoxia. It is important to recognize that fever may be absent in patients receiving high-dose immune suppression. The onset of symptoms can occur over 1–2 weeks, often times with rapid progression to respiratory failure and the requirement for mechanical ventilation. Although there are no specific radiologic changes, the most common radiographic findings consist of bilateral, ground-glass interstitial infiltrates (Figure 24-1b); small centrilobular nodules and air-space consolidations may also be present [123, 124].

The diagnosis of CMV pneumonia is established ("proven") by detection of CMV by shell-vial, culture, or histology in BAL or lung biopsy specimens in the presence of compatible clinical signs and symptoms (Table 24-1). Pulmonary shedding of CMV is common, but CMV detection in BAL by shell vial assay from asymptomatic patients who underwent routine BAL screening at day 35 after HCT was predictive of subsequent CMV pneumonia in approximately two-thirds of cases [125]. In centers where these techniques are no longer available, quantification of CMV DNA by qPCR in BAL fluid at a level above the threshold established by the center is indicative of "probable" CMV pneumonia (Table 24-1). Due to the high negative predictive value afforded by its high sensitivity, a negative PCR result can be used to rule out the diagnosis of CMV pneumonia [115].

Prior to effective antiviral therapy, the mortality rate of CMV pneumonia after HCT approached 100% [126]. The introduction of agents with potent anti-CMV activity resulted in improved outcomes but mortality rates remain in the range of 30–50% [126–131]. In the current era of preemptive antiviral therapy, lymphopenia and requirement for mechanical ventilation predict both overall and infection-attributable mortality [131].

Gastrointestinal disease is now the most common end-organ manifestation of CMV infection after HCT [104]. As with pneumonia, most cases occur within the first 3 months after allogeneic HCT [132]; however, direct infection-attributable mortality with GI tract disease is uncommon.

Any part of the gastrointestinal tract can be affected, from the esophagus to the colon. Esophagitis typically results in odynophagia, while gastritis often presents with epigastric abdominal pain and nausea. Hematochezia, diarrhea, and diffuse abdominal pain may occur with colitis. As none of these symptoms are pathognomic for CMV infection, endoscopy with tissue biopsy of abnormal areas is required for diagnosis (Table 24-1). Ulcers are often seen on endoscopy (Figure 24-1a, right panel), and visual differentiation of these lesions from other processes that may affect the gastrointestinal tract in these populations, such as graft-versus-host disease (GVHD), is often difficult. Therefore, the diagnosis of gastrointestinal disease ultimately relies on detection of CMV in biopsy specimens by histology combined with immunohistochemistry or DNA hybridization techniques (Figure 24-1a, left and middle panels) or with viral culture (if available). Notably, gastrointestinal disease can occur in the absence of CMV detection in the blood [105, 106, 133]. It should also be noted that GVHD and CMV gastrointestinal disease frequently occur together and therefore each condition's relative contribution to the patient's symptoms might be difficult to assess.

CMV hepatitis is less common than GI tract disease. Based on presenting features alone, it is difficult to distinguish hepatitis caused by CMV from other causes of hepatitis encountered after HCT, including GVHD. Therefore, liver biopsy is required to establish the diagnosis.

Retinitis is relatively uncommon after HCT [134–137]. Patients will often present with decreased visual acuity or blurred vision, and approximately 60% will have involvement of both eyes [135]. Most cases present later than day 100 after transplantation and are associated with prior CMV reactivation, delayed lymphocyte engraftment, and GVHD [135]. The diagnosis of CMV retinitis can often be made by an experienced ophthalmologist based on signs and symptoms alone. Detection of CMV in vitreal fluid by PCR can give supportive evidence for the diagnosis (Table 24-1).

CMV infection of the central nervous system (CNS) is less common after HCT than in the setting of advanced human immunodeficiency virus (HIV) infection. As opposed to pneumonia and GI tract disease, the onset of CNS disease is often late (after day +100) after HCT [138]. The most common disease manifestations are typical of encephalitis, with cognitive dysfunction and confusion [138–140]. The diagnosis of CMV CNS disease is made by detecting CMV in cerebrospinal fluid (CSF) by PCR or culture, or in brain tissue by culture or histopathology, in the appropriate clinical setting (Table 24-1) [118].

CMV rarely causes end-organ disease including, but not limited to, nephritis, cystitis, pancreatitis, and myocarditis; these additional disease categories are defined by the presence of compatible symptoms and signs, and documentation of CMV by biopsy.

24.4.2 Indirect Effects

In addition to the direct end-organ effects of CMV infection, CMV appears to be associated with consequences indirectly related to active infection [141]. After HCT, CMV infection has been associated with an increased risk of invasive bacterial and fungal infections [142]. CMV infection has also been suggested to be a risk factor for subsequent both acute and chronic GVHD after HCT [143–145] similar to the associative finding with rejection after solid organ transplant [146–149]. These findings have been attributed largely to modulation of the host immune system during infection.

Recently, there has been great interest in the role of CMV on disease relapse after HCT. The first hint of an effect came with the observation that patients with CMV infection had less relapse of leukemia compared with patients who had no CMV infection after BMT [150]. This finding was confirmed in a pediatric population in which CMV donor (D) seronegative/recipient (R) seronegative HCT was associated with an increased risk of relapse compared to D+ or R+ HCT [151]. A subsequent study in adults undergoing allogeneic HCT for AML found that early CMV reactivation was associated with a significant reduction in risk of leukemic relapse at 10 years after HCT [152]. Evaluation of a larger cohort of adults found that CMV reactivation was associated with a decreased risk of relapse at day +100 among patients with AML, and was associated with a decreased risk of relapse at 1 year in all patients when analyzed together [153]. Finally, a protective effect of CMV reactivation on relapse was observed in a small cohort of patients who underwent transplant for CML [154]. A large CIBMTR study assessing CMV infection and relapse after HCT is now underway. The mechanisms underlying these findings are poorly understood. An interesting hypothesis is that CMV reactivation stimulates γδ T cells that cross-recognize leukemic cells [155]. Other proposed mechanisms are through stimulation of NK-cell mediated clearance of leukemic cells, or by direct induction of apoptosis in leukemic cells [156–159]. However, any potential benefit of CMV reactivation in terms of disease relapse is almost certainly outweighed by the negative effect of CMV serostatus and reactivation on non-relapse and overall mortality [104, 153, 160–162].

24.5 Risk Factors for CMV Infection and Disease

24.5.1 Allogeneic HCT Recipients

In the setting of allogeneic HCT, the most important risk factor is the serological status of the donor and recipient [161]; both should be routinely assessed prior to HCT. CMV D−/R− transplants have a very low risk of primary infection in the recipient. Primary infection can still occur if CMV is transmitted in transfused blood products or is acquired via contact with another individual with active CMV infection.

Approximately 20–30% of seronegative recipients who receive stem cells from a seropositive donor will develop primary CMV infection due most likely to transmission of latent CMV via the allograft [163, 164]. The risk of transmission is directly related to the allograft nucleated white blood cell count [163], consistent with hematopoietic myeloid lineage cells acting as a reservoir of latent CMV [2]. CMV D+/R− mismatching negatively impacts the overall survival and increases the transplant-related mortality, especially those caused by bacterial and fungal infections [142, 165]. More recent studies performed in the modern diagnostic and therapeutic era have confirmed the negative effect of CMV D+/R− mismatching [160]. Recently, a large study found a strong negative effect on overall survival, relapse-free survival, and transplant- related mortality in CMV D+/R− *unrelated* HCT but a much smaller negative effect for human leukocyte antigen (HLA)-identical sibling D+/R− HCT, and no effect in patients receiving mismatched related donor grafts [166]. Thus the impact of D+/R− sero-mismatching may be influenced by the type of HCT.

Without prophylaxis, approximately 60–70% of CMV-seropositive patients will experience CMV infection after allogeneic peripheral blood or bone marrow HCT. It is well-established that a CMV-seropositive recipient is at higher risk for mortality than a seronegative recipient after HCT [167–170].

Unlike the situation of D+/R− HCT, in which the negative impact of a seropositive donor is well-described, the impact of donor serostatus when the recipient in seropositive has been the subject of controversy. Some studies reported a beneficial effect of having seropositive donor with regard to a reduction in relapse- or nonrelapse-related mortality (NRM), whereas other studies found no such benefit [117, 151, 169, 171–179].

To reconcile these differences, a large retrospective analysis of over 29,000 patients from the European Society for Blood and Marrow Transplantation (EBMT) registry was performed [166]. Seropositive patients receiving grafts from seropositive unrelated donors had improved overall survival compared with seronegative donors if they had received myeloablative, but not reduced-intensity, conditioning, perhaps due to loss of CMV-specific T cell function after myeloablative conditioning. No effect was observed when they received allograft from HLA identical sibling donors. Thus, the negative effect of CMV D−/R+ mismatching may be limited to high-risk transplant settings.

In addition to the effects on non-relapse mortality and overall survival, the D−/R+ serological combination has been reported as a risk factor for delayed CMV specific immune reconstitution [180–183], CMV reactivation [181, 184], late CMV recurrence [185], and CMV disease [113, 181, 186].

Other risk factors for CMV infection after allogeneic HCT include the use of steroids at doses greater than 1 mg/kg body weight/day, T-cell depletion (either ex vivo or in vivo), acute and chronic GVHD, the use of total body irradiation $CD4^+$ lymphopenia, and the use of mismatched or unrelated donors [110, 113, 186–190]. Whether the source of stem cells (peripheral blood versus bone marrow) has a significant impact on the development of CMV infection and disease is not clear, as several studies have yielded conflicting results [186, 190–192]. Interestingly, the use of sirolimus for GVHD prophylaxis appears to protect against CMV infection, possibly due to the inhibition of cellular signaling pathways that are co-opted by CMV during infection for synthesis of viral proteins [186, 193, 194].

The use of HLA-matched, related nonmyeloablative conditioning regimens generally results in a less CMV infection and disease early after HCT compared to standard myeloablative regimens [195]. However, by 1 year after HCT, the risk of CMV infection and disease is equal among nonmyeloablative and myeloablative groups [194, 196].

Umbilical cord blood transplantation (CBT) is a technique that is now utilized when a suitable donor for bone marrow or peripheral blood stem cell transplantation is not available [197]. Since most infants are born without CMV infection, the transplanted allograft is almost always CMV-negative. CMV seropositive CBT recipients are at particularly high risk for infection compared to GSCF-mobilized peripheral blood stem cell transplant recipients due to delayed T cell immune reconstitution [198] and failure of functional CMV-specific T cells to achieve sufficient numbers to control CMV reactivation after CBT [29]. The reported rate of CMV reactivation after CBT varies widely, from 21 to 100%, while disease occurs in ~5–28% of recipients [190, 199–208]. The variability in reported infection rates likely reflects differences in conditioning regimens, inclusion of low-risk CMV seronegative recipients in certain data cohorts, and approaches to CMV prevention after CBT. One center reported a markedly high rate of CMV disease, particularly during the pre-engraftment period, and associated mortality after CBT [205], prompting a change in their preventative approach after CBT (discussed below).

An alternative stem cell source for patients who do not have matched donors is the HLA-haploidentical 2 or 3-loci mismatched family donor [209]. Such haploidentical transplantation has traditionally been associated with a high incidence of severe GVHD and graft rejection, prompting the implementation of T cell depletion strategies to reduce these adverse alloreactive events [209]. While T cell depletion does prevent GVHD, the consequent delayed immune reconstitution led to increased risk of infection [210–212]. High rates of CMV disease, antiviral drug resistance, and infection-attributable mortality have been reported in this population [213]. Performing T-cell-replete haploidentical HCT with posttransplant cyclophosphamide to induce immune tolerance [214] may reduce the incidence of CMV infection and disease compared to T-cell depletion [215, 216].

24.5.2 Autologous HCT

After autologous transplantation, approximately 40% of seropositive patients will have detectable CMV infection [217, 218]. While CMV disease is rare after autologous transplantation [191, 219–221], the outcome of CMV pneumonia is similar to that after allogeneic HCT [217, 222, 223]. Risk factors for CMV disease after autologous transplantation include CD34+ selection, high-dose corticosteroids, and the use of total-body irradiation or fludarabine as part of the conditioning regimen [191]. Therefore, while CMV is not typically considered a significant pathogen after autologous HCT, certain patients who are at high risk for CMV in this setting merit routine surveillance and preemptive therapy.

24.5.3 Late CMV Infection After Allogeneic HCT

Whereas CMV was typically seen by 100 days after allogeneic HCT [224], it has become recognized as a significant problem after day 100 as well [109, 185, 225]. Several factors predict the development of late CMV infection, including prolonged or repeated CMV infection and/or disease before day +100, use of antiviral prophylaxis during the early posttransplant period, slow response to antiviral therapy, qualitative or quantitative lymphopenia, cord blood transplants, patients with severe acute or chronic GVHD, and HLA-mismatched transplant [19, 20, 109, 113, 185, 186, 226]. Patients, who have experienced prolonged or repeated CMV episodes before day 100, cord blood transplant recipients, and patients with significant immunosuppression should have continued weekly surveillance to reduce the risk of late CMV disease.

24.6 Antiviral Agents

Agents licensed for the treatment or prevention of CMV infection include ganciclovir (GCV) and its oral prodrug valganciclovir (vGCV), foscarnet (FOS), and cidofovir (CDV) (Table 24-2). All exert their antiviral effect by inhibiting viral DNA synthesis through targeting of the viral DNA polymerase encoded by the UL54 gene. Acyclovir (ACV) and its oral prodrug valacyclovir (vACV) do not possess potent activity against CMV and therefore cannot be used for treatment of infection but have shown efficacy when used as prophylaxis (discussed below).

Table 24-2. Agents licensed for the treatment or prevention of CMV infection and disease

Agent	Target	Route of administration	Dose[a]		Toxicities[b]	Resistance mutations
			Induction	Maintenance		
Ganciclovir	UL54	IV	5 mg/kg bid	5 mg/kg/day	Neutropenia, anemia, thrombocytopenia, diarrhea, fever	UL97, UL54
Valganciclovir	UL54	oral	900 mg bid (≥40 kg)	900 mg/day (≥40 kg)	Same as ganciclovir	UL97, UL54
Foscarnet	UL54	IV	90 mg/kg bid	90 mg/kg/day	Nephrotoxicity, electrolyte, wasting, nausea, urethral ulceration, paresthesia, hallucination	UL54
Cidofovir	UL54	IV	5 mg/kg/week	5 mg/kg every other week	Nephrotoxicity, neutropenia, headache, nausea, uveitis/iritis, diarrhea, ocular hypotony	UL54

[a]All agents require dose adjustment in the setting of renal dysfunction.
[b]For full listing of toxicities, please refer to the summary of product characteristics (SPC) for each agent.

GCV is a nucleoside analogue of guanosine that acts as a competitive inhibitor of deoxyguanosine triphosphate incorporation into viral DNA by the viral DNA polymerase UL54. A CMV gene, UL97, encodes a kinase that phosphorylates GCV to GCV monophosphate, a necessary step in conversion of GCV to its active form. Cellular kinases then phosphorylate GCV monophosphate to the active triphosphate form. GCV is currently the first-line agent for CMV prophylaxis, preemptive treatment, and treatment of CMV disease, barring contraindications. Neutropenia occurs in up to 30% of HCT recipients during GCV therapy [227], thereby placing the patient at risk of invasive bacterial and fungal infections [227, 228]. vGCV achieves serum concentrations at least equivalent to intravenous GCV [229, 230] and the toxicity profile appears similar. However, drug levels can be unpredictable, especially in patients with gastrointestinal tract GVHD, and therapeutic drug monitoring can therefore be a useful tool in managing patients on vGCV therapy. Neutropenia often responds to dose reduction and support with granulocyte-colony stimulating factor, but occasionally discontinuation of GCV or vGCV is required, in which case FOS is typically the second-line agent of choice.

FOS is a pyrophosphate analogue that binds directly to and competitively inhibits the CMV DNA polymerase UL54. Although a randomized, controlled trial showed similar efficacy and rate of side effects for GCV and FOS when used as preemptive therapy [231], practical issues such as the need for intensive hydration along with the electrolyte wasting that accompany FOS have resulted in its use mostly as a second-line agent when GCV or vGCV are contraindicated or not tolerated, or there is suspicion of GCV resistance (see below).

CDV is a cytosine nucleotide analogue that, like FOS, does not require phosphorylation by the CMV UL97 kinase for antiviral activity. Instead, cellular enzymes convert CDV to CDV triphosphate, which then inhibits the CMV DNA polymerase. The long half-life of cidofovir allows a once-per-week dosing schedule. However, the major toxicity with CDV—renal tubular damage—limits its utility after HCT and it should therefore be considered third-line therapy after GCV and FOS.

24.6.1 Antiviral Resistance

Drug resistance is relatively uncommon after peripheral blood or bone marrow HCT [232] but the risk has been reported to be increased after T-cell-depleted haploidentical HCT [213]. Resistance typically occurs in the setting of ongoing, intermittent or recurrent viral replication in the presence of drug. This situation arises most often due to profound host immunosuppression and/or suboptimal drug levels. Therefore, reducing immune suppression and optimization of drug delivery are important aspects of management. CBT or T-cell-depleted transplant recipients and those on augmented immune suppression for GVHD should be considered at increased risk for resistance. Inadequate drug delivery may occur in a patient receiving vGCV during GI GVHD, or when dosages are improperly adjusted for renal dysfunction. When available, therapeutic drug level monitoring may be of benefit.

Drug resistance should be suspected in patients with some or all of the above risk factors who have a rising viral load after at least 2 weeks of antiviral therapy or who experience worsening or relapse of clinical disease or viremia while on prolonged therapy. In general, resistance requires accumulated drug exposure; in treatment-naïve patients, no decrease or even a moderate increase in the viral load will occur in many patients within the first 2 weeks of starting therapy that is likely due to the underlying immunosuppression, not true

drug resistance [103]. Thus, this situation does usually not warrant change of therapy. The duration of drug exposure required to select for resistance and the increase in viral load that should prompt testing for resistance after HCT are not well defined and likely depend on the above mentioned host factors, viral loads during therapy, and genetic barrier to resistance for the drug in question.

Since GCV/vGCV is typically used as a first-line agent for CMV infection and disease, resistance to this antiviral is the most commonly encountered problem. A general approach to the patient with suspected GCV resistance is presented in Figure 24-2. GCV resistance is usually due to mutations in the UL97 gene; mutations in UL54 may follow UL97 mutations with continued GCV exposure. UL97 and UL54 mutations that confer GCV resistance have been determined and genotypic assays are available for diagnostic analysis in reference laboratories [232]. Since different UL97 mutations confer varying degrees of GCV resistance, some cases of genotypically defined GCV -resistant CMV may still respond to high-dose GCV therapy (i.e., twice standard induction dose) if they confer low-level (two- to threefold) resistance [232]. However, if there is evidence of CMV disease or the viral load is increasing rapidly, a switch to FOS is recommended [232].

Since neither FOS nor CDV activity are dependent on phosphorylation by the UL97 gene product, CMV that has acquired GCV resistance due to UL97 mutations will still be susceptible to these agents. Due to its relatively favorable toxicity profile compared to CDV, FOS is most often used as the agent of choice in the setting of GCV resistance. Studies evaluating the utility of combination therapy of FOS and GCV for GCV-resistant CMV disease have been inconclusive, and therefore, this strategy is not routinely recommended [233].

Mutations in UL54 may confer resistance to GCV, FOS, CDV, or cross-resistance to combinations thereof. Cross-resistance between FOS and GCV due to UL54 mutations rarely occurs, while on the other hand most UL54 mutations that confer GCV resistance also result in CDV resistance [232]. Rarely, mutations in UL54 that confer resistance to all three agents—GCV, FOS, and CDV—are encountered [232]. Therapeutic options in such situations are limited and highlight the need for antiviral agents with targets other than UL54. The use of a sirolimus-based regimen for GVHD prophylaxis may provide some benefit for reasons discussed above but should be viewed as an adjunct to, not a substitute for, direct antiviral therapy.

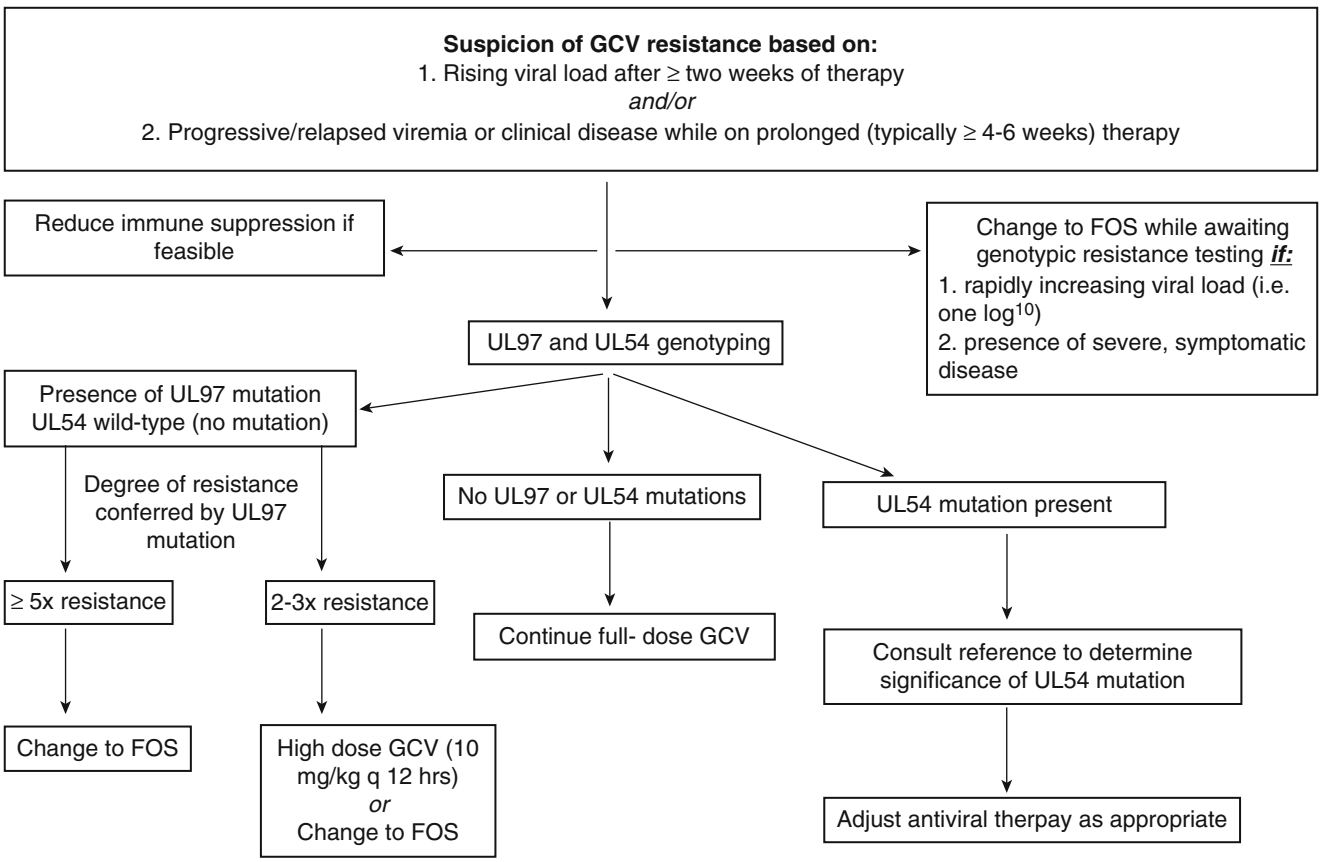

FIGURE 24-2. Approach to the patient with suspected GCV resistance.

24.6.2 Antiviral Agents in Development

Maribavir (MBV) (Table 24-3) is an oral agent that inhibits the CMV UL97 kinase and potently inhibits CMV replication in vitro [234]. Due to its mechanism of action, MBV is active against CMV strains resistant to GCV, FOS, and CDV [235] but antagonizes the antiviral activity of GCV [236]. After promising results phase I and II clinical trials, MBV failed to effectively prevent CMV infection compared to placebo after HCT when used as prophylaxis in a phase III trial [237–239]. The reason(s) underlying the failure of MBV in the phase III study are not clear but the use of too low a dose of MBV is often cited [240]. A phase II dose-ranging trial comparing higher doses of MBV to standard of care GCV (or vGCV) as preemptive therapy after allogeneic HCT (EudraCT: 2010-024247-32) has been completed. In addition, MBV has demonstrated efficacy in the treatment of refractory or resistant CMV infections after transplantation [241, 242] and a phase II study for this indication has been completed (ClinicalTrials.gov NCT01611974). Results from these two phase II trials are forthcoming. MBV resistance due to mutations in UL97 has occurred in patients treated with this agent [243, 244].

Letermovir (Table 24-3) inhibits the activity of the essential CMV UL56/UL89 DNA terminase complex [245]. Letermovir is active against wild-type and drug-resistant CMV in tissue culture [245]. Experience using letermovir for multidrug-resistant CMV disease in vivo is promising but very limited [246]. A phase II study of letermovir as prophylaxis in CMV-seropositive HCT recipients showed a dose-dependent reduction of prophylaxis failure (defined as discontinuation of letermovir or placebo because of CMV antigen or DNA detection, end-organ disease, or any other cause) compared to placebo [247]. A phase III randomized multicenter trial as prophylaxis in seropositive HCT recipients has completed patient enrollment (ClinicalTrials.gov NCT02137772). Letermovir appears to be very well tolerated, with few demonstrable side effects or toxicities [247]. Resistance mutations mapping to UL56 can be selected for in tissue culture [248]; whether similar mutations will be arise in patients treated with letermovir remains to be seen. Demonstration of an additive antiviral effect when combined with DNA polymerase inhibitors [249] raises the possibility of combination therapy similar to strategies currently employed for the treatment of hepatitis C and HIV.

Brincidofovir (CMX-001) (Table 24-3) is a lipid-conjugated nucleotide analogue of CDV that has a high oral bioavailability and long half-life. It has activity against most DNA viruses, including CMV [250]. In contrast to CDV, brincidofovir is not associated with significant nephrotoxicity. Brincidofovir at a dose of 100 mg twice daily was shown to be effective in preventing CMV infection after HCT when used as prophylaxis in a phase II placebo-controlled study [251]. However, diarrhea and acute gastrointestinal GVHD were reported more frequently in the group that received this dose compared to placebo or lower dose brincidofovir, and gastrointestinal side effects were dose-limiting at 200 mg twice weekly. A phase III randomized multicenter trial using a dose of 100 mg twice weekly as prophylaxis in seropositive HCT recipients (ClinicalTrials.gov NCT01769170) has been completed, and results are forthcoming. While resistance to brincidofovir has not been well characterized, it is expected that mutations in UL54 conferring CDV resistance will also result in brincidofovir resistance [252].

While reports of leflunomide and the antimalarial artesunate having anti-CMV activity exist [253–255], neither of these have conclusively demonstrated benefit and are not approved by European or American regulatory authorities for the treatment of CMV; therefore, their routine use cannot be recommended. The immunosuppressive drug sirolimus inhibits CMV replication in tissue culture by regulating key cellular signaling pathways and has been shown to reduce the risk of CMV reactivation after HCT and renal transplantation [186, 193, 256]. Thus, this agent may be a useful adjunct when ongoing immune suppressive therapy is required in the setting of refractory CMV infection.

TABLE 24-3. CMV antiviral agents in development

Agent	Target	Route of administration	Dose	Toxicities	Resistance mutations
Maribavir	UL97 kinase	Oral	400–1200 mg twice daily	Taste disturbance	UL97, UL27[a]
Letermovir (AIC-246)	UL56/UL89 terminase complex	Oral, IV	240 mg daily[b], 480 mg daily[c]	None apparent	UL56[a]
Brincidofovir (CMX-001)	UL54 DNA polymerase	Oral	100 mg twice weekly[b]	Gastrointestinal[d]	Not described

[a]Found only in tissue culture thus far.
[b]Dose chosen for phase III studies.
[c]In patients receiving cyclosporine for GVHD prophylaxis.
[d]Diarrhea, nausea, vomiting, abdominal pain, aGVHD, elevated ALT.

24.7 Prevention of Infection and Disease

24.7.1 Choice of Donor

Recipients who are CMV seronegative before allogeneic HCT should ideally receive a graft from a CMV seronegative donor to prevent primary infection via the allograft. No data exists indicating whether HLA-matching is more important compared to CMV serostatus in affecting a good outcome for the patient. Given the choice, an antigen-matched donor for HLA-A, B, or DR would most likely be preferred to a CMV-negative donor. For lesser degrees of mismatch, (allele-mismatches or mismatches on HLA-C, DQ, or DP), the CMV-serostatus of donor should be considered a factor even if the match was poorer. Compared to other donor factors such as donor age or blood group, a CMV-seronegative donor would have preference. If the patient is CMV seropositive, it has been shown that a CMV seropositive unrelated donor confers a survival advantage if the patient will receive myeloablative conditioning [166]. Similar to the situation with a CMV seronegative patient, an antigen-match on A, B, and DR is the major selection criterion but CMV-status should be weighed among other factors with lesser degrees of HLA-mismatch.

24.7.2 Transmission via Blood Products

Previously, the transfusion of blood products represents a significant source for CMV infection in seronegative transplant recipients. Today preventive measures such as using blood products from CMV seronegative donors or leukocyte-reduced, filtered blood products are widely used and greatly reduce this risk [257–259]. It is not clear which strategy is the most effective [260, 261] and no controlled study has investigated whether there is an extra benefit from the use of both methods.

24.7.3 Immune Therapy

Intravenous immune globulin (IVIG) is not reliably effective as prophylaxis against primary CMV infection. One study demonstrated a reduction in the rate of CMV infection but not disease, while another study was unable to confirm protection from infection [262, 263]. Similarly negative results were observed using a CMV-specific monoclonal antibody [264]. Likewise, the effect of immunoglobulin on reducing CMV infection in seropositive patients is modest, and no survival benefit among those receiving immunoglobulin has been reported in any study or meta-analysis [265–270]. Therefore, the prophylactic use of IVIG is not recommended.

24.7.4 Chemoprevention

The strategies of prophylactic or preemptive use of antiviral agents after HCT have markedly reduced the incidence of CMV disease and improved survival among at-risk populations. All centers performing allogeneic transplants should therefore have one of these strategies in place for all allogeneic HCT recipients at risk for CMV infection (seropositive recipients, or seronegative recipients of a seropositive donor graft) [271]. Studies in the eras of pp65 and qPCR monitoring have documented the equivalence of prophylaxis and preemptive therapy in terms of preventing CMV infection and disease after HCT [127, 272]. Most transplant centers have moved towards preemptive strategies as pp65 antigenemia and qPCR-based diagnostics techniques have become readily available [273]. DNA qPCR has become the standard for monitoring at many institutions as it is more sensitive than pp65 antigenemia [127] and technically easier to perform than mRNA detection. Additionally, it has been reported that qPCR-based initial viral load and viral load kinetics are important as risk factors for CMV disease [111].

Prophylaxis denotes the routine administration of antivirals to all at-risk patients regardless of the presence of active CMV infection, typically until day +100 after HCT. ACV and its vACV, while not approved for the treatment of CMV, are used at some centers for CMV prophylaxis after HCT [273]. High dose ACV and vACV have demonstrated efficacy in reducing the risk for CMV infection and disease after HCT [220, 274–276]. Routine monitoring for CMV infection is still required if vACV or ACV prophylaxis is used, and therapy with GCV or vGCV is indicated if CMV is detected. GCV prophylaxis, begun at engraftment and continued until day +100, has been demonstrated to reduce the risk of CMV infection and disease after HCT compared to placebo, although its use is limited by toxicity, primarily marrow suppression [127, 228, 277]. Data regarding vGCV prophylaxis is more limited. A recent randomized, double-blind study of vGCV prophylaxis compared to preemptive therapy for the prevention of late CMV infection after HCT demonstrated reduced CMV viremia in the prophylaxis group but no difference in CMV disease [272].

Preemptive therapy, on the other hand, withholds antiviral therapy until CMV infection is detected in whole blood or plasma samples. This strategy mandates sensitive, specific, and rapid turnaround laboratory tests to detect circulating CMV in order to enable initiation of antiviral therapy prior to the development of CMV end-organ disease. All patients who have undergone allogeneic HCT should be monitored at least once per week beginning either at the time of transplant or ~day +10 and extending to at least day +100 after HCT [271]. Surveillance should be extended past day +100 in those at risk for late infection and disease

(discussed above). The ideal duration and frequency of CMV monitoring in the later transplantation periods have not been defined [195, 278].

Although CMV infection is rare in D−/R− patients, such a monitoring strategy is effective in identifying CMV infection and preventing disease in a large cohort of such patients [279]. Routine monitoring of autologous HCT recipients is not recommended, with the exception being high-risk patients as described above.

In all patients in whom viremia is detected, a thorough evaluation of the patient in order to assess for signs and symptoms of CMV disease is necessary. Initiation of induction-dose preemptive antiviral therapy is generally recommended [271]. However, it has been clearly shown that most patients with low viral loads can be safely spared preemptive antiviral therapy unless there are special high risk features [104, 113, 280]. Currently, there are no validated universal viral load thresholds for starting preemptive therapy, and such thresholds are difficult to establish due to differences in assay performance and testing material (i.e., whole blood versus plasma) [281]; the development of an international standard for CMV qPCR calibration [282] may eventually allow for this. Additionally, thresholds for initiating preemptive therapy need to account for underlying patient characteristics which determine the risk for progression to CMV disease.

Currently, considerable variation in practice exists pertaining to the duration of induction dose preemptive treatment [273]. In general, this should be continued for a minimum of 1–2 weeks and a decrease in viral load has been documented by qPCR, followed by maintenance therapy until the CMV viral load is undetectable [271] or below a center's established cutoff. After discontinuation of preemptive therapy, routine weekly screening until day +100 or later if risk factors for late infection are present are still necessary to monitor for recurrence of viremia [271]. If less sensitive markers than qPCR, such as the pp65 antigenemia assay, are used, then preemptive therapy should be continued until 2 negative assays are obtained [231].

GCV is considered the first-line agent for preemptive therapy [271]. While FOS has demonstrated equivalence to GCV when used in a preemptive manner [231], practical aspects of its administration relegate its use to situations when GCV is contraindicated or not tolerated. The results of several uncontrolled studies suggest that vGCV is comparable to intravenous GCV in terms of efficacy and safety when used as preemptive therapy after allogeneic HCT [283–288]. A prospective, randomized trial comparing vGCV to intravenous GCV supported these observations [289]. Thus, in the HCT recipient who is able to tolerate oral therapy and in whom no barriers to efficient absorption of an oral agent exist, vGCV appears to be a reasonable alternative to intravenous GCV for preemptive therapy.

There has been great interest in utilizing methods to determine CMV-specific immune reconstitution after HCT as an additional means to stratify risk of CMV infection and disease ("immune monitoring") and further tailor surveillance and preemptive therapy strategies. The types of assays used, their strengths and limitations, and their predictive value in terms of CMV infection and disease after transplantation have been extensively reviewed elsewhere [69, 290]. While promising, the use of immune monitoring in this fashion requires validation in large, randomized trials before it can be recommended.

24.7.5 Vaccination

Given the costs and toxicities associated with antiviral therapy, a vaccine to prevent CMV infection would be of substantial benefit. Indeed, the Institute of Medicine has given the development of a CMV vaccine highest priority [291]. Historically, most vaccine candidates yielded mixed results [292]. Recently, the safety and efficacy of a DNA vaccine expressing the CMV immunogenic proteins gB and pp65 was evaluated in a phase II, placebo controlled trial in CMV seropositive allogeneic HCT recipients [293]. While no difference in initiation of preemptive anti-CMV therapy or duration of antiviral therapy was observed between the groups, the group receiving the vaccine had fewer episodes of viremia, lower viral loads, and was more likely to be viremia-free at 1 year after HCT. No differences in CMV disease were observed but the overall incidence of disease was low (7.5% in vaccine group vs. 8.8% in placebo group). A phase III study of this vaccine in a similar patient population is currently underway (ClinicalTrials.gov NCT01877655). CMV peptide vaccines designed to elicit pp65-specific CTL were found to be safe and immunogenic in healthy adults [294] and a phase II study in HCT recipients is under way (ClinicalTrials.gov NCT02396134).

24.7.6 Special Populations

Patients with CMV disease occurring prior to planned allogeneic HCT have a very high risk of death after transplantation [295]. After transplantation, a patient with documented pretransplant CMV disease should either be monitored for CMV very closely (i.e., twice weekly), or be given prophylaxis with GCV or FOS.

The CMV seropositive CBT recipient population may benefit from more intensive prevention strategies. The reactivation rate in CMV seropositive CBT recipients in the absence of high-dose ACV/vACV or anti-CMV prophylaxis has been reported at 70–100% [205, 207, 208, 296]. A combination approach of high-dose vACV prophylaxis coupled with continued monitoring and preemptive therapy was

associated with rates of CMV reactivation and disease similar to those seen after allogeneic BMT or PBSCT [190]. Other studies have described successful vGCV or GCV prophylaxis and preemptive treatment strategies after CBT using protocols similar to other allogeneic HCT recipients [208, 297]. More recently, an aggressive approach of pretransplant GCV along with posttransplant high dose ACV/vACV prophylaxis and biweekly monitoring was demonstrated to reduce the incidence of CMV infection and disease after CBT [205]; the relatively contributions of these interventions towards CMV prevention are unclear. Thus, the optimal approach to CMV after CBT has not been determined.

24.8 Management of CMV Disease

As mentioned earlier, the diagnosis of CMV disease requires documenting the presence of CMV in the appropriate diagnostic specimen, coupled with symptoms and signs consistent with CMV. GCV is considered first-line therapy for end-organ disease, with FOS reserved as an alternative if neutropenia or other factors precluding GCV use are present. As opposed to preemptive therapy, the treatment of end-organ disease requires longer courses of induction-dosing antiviral therapy. For gastrointestinal disease, standard therapy generally entails induction treatment with an intravenous antiviral, most often GCV, for 3–4 weeks followed by several weeks of maintenance. Shorter courses of induction therapy (2 weeks) are not as effective [298]. Recurrence of GI disease may occur in approximately 30% of patients in the setting of continued immunosuppression and such patients may benefit from secondary prophylaxis with maintenance antivirals until immunosuppression has been reduced. Similar to GI tract disease, the treatment of CMV pneumonia involves induction-dose GCV for 3–4 weeks, followed by a period of maintenance therapy.

The role of vGCV in the management of CMV disease after HCT is not well established. vGCV has been shown to be noninferior to IV GCV in the treatment of non-life threatening CMV disease after solid-organ transplant, primarily kidney transplant recipients [299]. However, similar studies have not been performed in HCT recipients. Therefore, IV anti-CMV therapy remains the standard of care, although oral vGCV may be considered for patients with mild or moderate, non-life threatening disease after an initial period of IV therapy to bring disease under control and suppress viremia. In general, vGCV should only be used if there are no factors that would impair the absorption of an orally administered medication, such as severe gastrointestinal GVHD.

The role of IVIG as an adjunct to antiviral therapy for CMV disease remains controversial due to the lack of prospective, randomized trials evaluating the additional benefit of this intervention over antiviral therapy alone [122]. There does not appear to be a specific advantage of CMV-specific immune globulin (CMV-Ig) compared to pooled immunoglobulin [300]. While there is no role for IVIG in the treatment of gastrointestinal disease [301], it has been considered as standard-of-care at many centers in the management of CMV pneumonia based on small studies showing improved survival rates with the addition of IVIG compared to historical controls using antiviral therapy alone [302–304]. On the other hand, a recent, large retrospective analysis was unable to demonstrate an improvement in overall or infection-attributable mortality with the addition of IVIG to antiviral therapy [131]. Thus, the role of IVIG in the management of CMV pneumonia remains unclear.

CMV retinitis is typically treated with systemic therapy, with or without intraocular GCV injections or implants [135, 305–307]. The optimal duration of therapy is not well established, but in general longer courses are needed in order to prevent recurrence.

Other manifestations of CMV disease, such as hepatitis and encephalitis, are uncommon and are typically managed with intravenous therapy. The duration of therapy for these manifestations has not been well established and should be tailored to the individual patient.

24.9 Adoptive Immunotherapy

Due to the importance of CMV-specific functional T cells in the control of CMV infection after HCT [23], there has been intense interest in promoting CMV immune reconstitution via the adoptive transfer of CMV-reactive T cells [308]. This topic is discussed in more detail elsewhere in this book.

25 Cytomegalovirus Infection After Solid Organ Transplantation

Raymund R. Razonable and Ajit P. Limaye

25.1 Epidemiology and Pathogenesis

Cytomegalovirus (CMV) is a β-herpes virus that commonly infects humans [1–5]. The seroprevalence rates of CMV vary from as low as 50% in the USA and the developed world to as high as >95% in developing countries [1–5]. The seroprevalence rate increases with age, and reaches over 90% of adults >80 years of age [5]. Primary CMV infection is acquired from contact with infected body fluids such as saliva, urine, or genital secretions [6]. In immunocompetent individuals, primary CMV infection is mostly asymptomatic, although it may occasionally manifest clinically as an infectious mononucleosis-like syndrome characterized by fever and lymphadenopathy [6].

The immune response to CMV infection is initiated upon the recognition of CMV antigens by pathogen-recognition receptors, such as Toll-like receptors, expressed on macrophages, dendritic cells, and other innate immune cells [7–11]. This pathogen–immune cell interaction results in the secretion of interferon-γ, tumor-necrosis factor (TNF)-α, various interleukins, and other cytokines, and the upregulation of co-stimulatory molecules that orchestrates the development of adaptive CMV-specific cell-mediated and humoral immunity [9–13]. Despite a robust innate and adaptive immune response, CMV infection leads to lifelong latency and persistence in the host, with intermittent periods of subclinical reactivation that is controlled by CMV-specific memory cells [14–16].

Cells that allow for CMV latency and persistence are widely distributed, including hematopoietic progenitor cells [17], peripheral blood mononuclear cells [6, 18], polymorphonuclear leukocytes [19], and macrophages [20]. CMV also infects fibroblasts, smooth muscle cells, and endothelial cells [21]. The wide distribution of CMV-infected cells in tissues and organs, such as blood, liver, kidney, lungs, and heart allows for its efficient transmission during organ transplantation [22–25].

25.2 Mechanisms of Acquiring CMV Infection After Solid Organ Transplantation

The three major patterns for acquiring CMV infection after solid organ transplantation are (1) primary infection, (2) reactivation, and (3) superinfection.

25.2.1 Primary Infection (CMV D+/R− and D−/ R−)

Primary CMV infection occurs when a CMV-seronegative person (CMV R-) receives an organ from a CMV-seropositive donor (CMV D+). Since latent CMV is widely distributed, it is likely harbored in the allograft of CMV-seropositive donors. About 15–25% of solid organ transplantation in adults is in CMV D+/R− mismatched patients, and is characterized by efficient transmission of latent CMV from donor to the recipient [26–29]. Multiple viral strains may be transmitted from a single donor [30, 31]. Without any specific prevention strategy, this often leads clinically to CMV disease, which can be severe in nature [32].

Much less commonly, primary infection may occur in a CMV D−/R− transplant recipient who acquires CMV from transfusion of blood products from CMV-seropositive donors (transfusion-transmitted CMV infection) or through natural transmission routes in the community (i.e., contact with CMV-infected body fluids and secretions such as saliva) [33, 34]; the latter two mechanisms account for primary CMV infection in CMV D−/R− solid organ transplant recipients. Use of CMV-seronegative or leuko-reduced blood products for transfusion among transplant recipients has reduced the incidence of transfusion-transmitted CMV infection [35].

P. Ljungman et al. (eds.), *Transplant Infections*, DOI 10.1007/978-3-319-28797-3_25

25.2.2 Reactivation (CMV D−/R+)

This mechanism occurs when endogenous latent CMV in a CMV-seropositive (CMV R+) transplant recipient reactivates during the periods of impaired immunity after solid organ transplantation. Because CMV R+ patients have preexisting CMV-specific cell-mediated and humoral immunity, the degree of CMV replication is lower compared to primary CMV infection in CMV D+/R− patients and hence a relatively lower risk of CMV disease [36, 37].

25.2.3 Superinfection (CMV D+/R+)

Superinfection (also termed reinfection) occurs when a CMV R+ transplant recipient is infected with an exogenous CMV strain from a CMV-seropositive donor (or other exogenous sources such as blood transfusion), and subsequently, either the donor allograft-transmitted exogenous CMV or recipient-derived endogenous CMV, or both, reactivate to cause clinical disease [38]. In the majority of cases, donor-derived CMV strain is the predominant virus that reactivates in CMV D+/R+ patients [38–40]. However, recent analysis of the CMV genomic variants indicates complex reactivation patterns after solid organ transplantation, and often, multiple viral strains reactivate concurrently, making it difficult to distinguish donor or recipient origin [30, 31].

25.3 Mechanisms of Cytomegalovirus Reactivation After Solid Organ Transplantation

Table 25-1 lists the major risk factors for CMV infection and disease after solid organ transplantation [27]. Central to these factors is a pro-inflammatory state characterized by secretion of cytokines [41–43], most notably TNF-α, which is a potent CMV transactivator [44]. Stimulation of the TNF-α1 receptor results in the activation of protein kinase C and nuclear factor-kappa B (NF-κB), which translocates into the nucleus and binds to the CMV-immediate early enhancer/promoter region [41, 45–48], triggering a cascade of events that lead to CMV reactivation [49]. Likewise, catecholamines that are released during periods of stress, whether physiologic or in response to critical illness, could stimulate CMV-immediate early enhancer/promoter activity through the cyclic adenosine monophosphate (cAMP) pathway [45, 46]. Collectively, inflammation, stress, and other factors that influence the cAMP and NF-κB signaling pathways could lead to CMV reactivation after solid organ transplantation. Indeed, conditions characterized by high TNF-α levels, such as bacterial sepsis and allograft rejection, have been associated with CMV infection in solid organ transplant and non-transplant settings [29, 50–52].

TABLE 25-1. Factors that influence the reactivation of CMV and the risk of clinical disease after solid organ transplantation

Factors that influence CMV reactivation	Factors that influence progression to CMV disease	
	Increase risk of CMV disease	Diminish risk of CMV disease
Allogeneic stimulation	Lack of CMV-specific immunity (i.e., D+/R−)	Preexisting CMV-specific immunity (R+)
Allograft rejection	CMV-seronegativity	CMV-seropositivity
Lymphocyte-depleting agents	Deficient CMV-specific T cells	CMV-specific CD4/CD8 T cells
ATG, ALG, OKT3	Pharmacologic immunosuppression	Antiviral prophylaxis
Stress	ATG, ALG, OKT3	Preemptive antiviral therapy
Critical illness	Alemtuzumab	Immunotherapy
Surgical procedure	Mycophenolate mofetil (>2 g/day)	Immunoglobulins
Bacterial sepsis	High-dose methylprednisolone	Adoptive T cell therapy[a]
Fungal sepsis	Viral burden (viral load)	CMV vaccine[a]
		Reduced immunosuppression
		mTOR inhibitors
		Sirolimus
		Everolimus

25.4 Risk Factors for CMV Infection

The incidence rates of CMV disease after solid organ transplantation vary, depending on several factors such as underlying immunity (or lack thereof), viral factors, and the type of transplant (Table 25-2) [53–55]. In general, these factors can be categorized into (a) those that favor disease progression (such as delayed immune recovery, immunosuppressive drugs, viral load, viral coinfections) and (b) those that control viral replication and prevent disease (such as CMV-specific immunity, antiviral therapy) (Table 25-1).

25.4.1 CMV D+/R− Serostatus

CMV D+/R− mismatch serostatus is the most common clinical predictor of CMV infection and disease after solid organ transplantation. Hence, it is standard practice to measure CMV-IgG (a measure of previous exposure and a surrogate marker for the presence of latent virus; see Laboratory Diagnosis of CMV Infection section below) on all transplant candidates and donors in order to stratify the risk of disease, and guide the type of CMV prevention strategy [56]. Historical data indicate that up to 70% of CMV D+/R− solid organ transplant recipients, who lack preexisting CMV-specific cellular and humoral immunity, will

TABLE 25-2. Estimated incidence rates of CMV disease after solid organ transplantation

±The estimated incidence after small bowel transplantation is 22% of all patients, including all donor and recipient CMV serostatus.
[a]Antiviral prophylaxis is given for a duration of 3 months unless otherwise indicated ([b] indicates 6–12 months of prophylaxis after lung transplantation).
[c]CMV disease in patients who received prophylaxis generally occurs after the completion of antiviral prophylaxis (delayed-onset CMV disease).

develop primary CMV infection and disease after transplantation, if they do not receive any CMV prevention strategy (Table 25-2) [27]. The lack of CMV-specific immunity in CMV D+/R− solid organ transplant recipients allows for a very rapid CMV replication dynamics, with an estimated CMV doubling rate of 1 day [57]; this translates to high rates of CMV disease [36, 37]. Mathematical estimates suggest that CMV doubling rate is slower among solid organ transplant patients with adequate lymphocyte function [58]. Indeed, preexisting immunity in CMV R+ solid organ transplant recipients is believed to dampen CMV replication dynamics [36, 37]. Hence, reactivation and reinfection are characterized by a slower CMV replication dynamics, lower viral load, and lower incidence and severity of CMV disease in CMV R+ solid organ transplant patients [36, 37, 59, 60].

25.4.2 Defects in CMV-Specific T-Cell Immunity

CMV-specific T lymphocytes are essential for the adequate control of infection [59–62]. Expectedly, CMV-specific CD4+ and CD8+ T lymphocytes are absent in CMV D+/R− mismatch patients, thereby predisposing to high levels of viral replication and greater severity of CMV disease [61, 63, 64]. In contrast, preexisting CMV-specific CD4+ and CD8+ T lymphocytes control CMV infection in CMV R+ solid organ transplant recipients, although the lymphocyte population and function can be severely impaired by immunosuppressive drugs [61, 62, 64, 65]. In this context, intense pharmacologic immunosuppression is a major risk factor for CMV disease in CMV D+/R− and R+ solid organ transplant recipients. Studies have attempted to estimate the optimal threshold of CMV-specific CD4+ and CD8+ T lymphocytes sufficient for protection from CMV disease, but these values have not been precisely defined (see Laboratory Diagnosis of CMV Infection section below) [61, 62, 64–66].

25.4.3 Hypogammaglobulinemia

Serum IgG level <700 mg/dl is common during the first year after solid organ transplantation [67]. Its incidence is highest among lung (69%) and heart (48%) recipients and lowest among liver recipients (16%) [67]. Severe hypogammaglobulinemia, defined as IgG level <400 mg/dl, has been associated with a higher risk of opportunistic infections, including CMV [67]. A small study reported that CMV-hyperimmunoglobulin replacement was associated with low incidence of CMV disease in heart recipients with hypogammaglobulinemia [68]. However, a recent study demonstrated that intravenous immunoglobulin and CMV-hyperimmunoglobulin supplementation did not improve overall patient and graft survival outcomes [69].

25.4.4 Defects in Innate Immunity

Deficiencies in innate immunity have been implicated as risk factors for CMV disease after solid organ transplantation [70–76]. In some studies, defects in cell signaling through Toll-like receptors, mannose-binding lectin, mannose-associated serine protease-2, and activating and inhibitory killer cell immunoglobulin-like receptors have been significantly associated with a higher incidence of CMV disease after solid organ transplantation [8, 71–78].

25.4.5 Pharmacologic Immunosuppression

Induction therapy and maintenance immunosuppressive drugs, which are administered for the prevention and treatment of allograft rejection, significantly impair adaptive immune responses to CMV. These drugs, especially lymphocyte-depleting agents, dampen CMV-specific cell-mediated and humoral immune responses, thereby allowing for CMV disease development [52, 79]. Among the drugs most commonly associated with CMV disease are high-dose mycophenolate mofetil, anti-lymphocyte globulins (ALG),

anti-thymocyte globulins (ATG), alemtuzumab, and high-dose steroids [80–90]. Administration of lymphocyte-depleting antibodies is often complicated by a cytokine release syndrome, characterized by high levels of TNF-α, fevers, and rigors [91], which could theoretically induce CMV reactivation [80]. In addition to the individual effects of specific immunosuppressive drugs, the net state of immunosuppression is a major factor predisposing to CMV disease after solid organ transplantation. In contrast, the mTOR inhibitors (everolimus and sirolimus) appear to be associated with a lower incidence of CMV disease after solid organ transplantation [92–94].

25.4.6 Allograft Rejection

Acute rejection is one of the major risk factors for CMV disease after solid organ transplantation [52, 79, 95–97]. Pro-inflammatory cytokines, such as TNF-α, released during acute rejection are a potent trans-activator of CMV. In one study, acute rejection increased the risk of CMV disease by sixfold in a cohort of CMV D+/R− liver and kidney recipients [52]. Conversely, CMV increases the risk of acute and chronic rejection, thereby establishing their bidirectional "synergistic" relationship after solid organ transplantation [79, 98]. Antiviral prophylaxis has been associated in some studies to reduce not only the incidence of CMV disease but also acute rejection [32, 99, 100].

25.4.7 Type of Organ Transplant

Lung, small intestinal, and pancreas recipients generally have the highest risk, while liver and heart recipients have intermediate risk, and kidney recipients have the lowest risk for CMV disease [27, 56, 101]. Composite tissue allograft transplant recipients are also at high risk of CMV disease [102, 103]. While this heightened risk for some types of transplant may be due to high intensity of drug-induced immunosuppression, it has also been suggested that the large amount of latent CMV harbored in the allograft (i.e., viral burden) may contribute to the increased predisposition of lung and small intestinal recipients to develop CMV disease [27, 101].

25.4.8 Viral Burden and Genotype

The degree of viremia, as measured by nucleic acid testing and antigenemia, is a predictor of CMV disease after solid organ transplantation [36, 37, 104–108]. Genetic variability of viral strains (i.e., the viral genotype) has also been suggested to influence the risk of CMV [109], potentially accounting for the higher rate of CMV disease among CMV D+/R+ compared to CMV D−/R+ patients [30, 31]. The majority of reactivated CMV strains in CMV D+/R+ solid organ transplant recipients appear to be of donor origin [38–40].

25.4.9 Bacterial, Fungal, and Other Viral Infections

Occurrence of bacterial and fungal infections has been associated with a subsequent higher incidence of CMV disease after solid organ transplantation [29, 110–112]. These pro-inflammatory conditions would favor CMV reactivation, and lead to clinical disease. Conversely, CMV increases the risk of other opportunistic infections, possibly through CMV-induced immunomodulation [112–114]. CMV disease is more common in liver and kidney recipients with human herpes virus (HHV)-6 and HHV-7 infections [96, 115–119]. The underlying mechanism for the association is not defined, although HHV-6 and HHV-7 have immunomodulating properties that could predispose to CMV disease [116, 117, 119, 120]. Alternatively, the heightened predisposition to develop other opportunistic infections in patients with CMV disease may merely indicate a severely impaired global immune function.

25.5 Clinical Manifestations of CMV Disease

CMV infection in solid organ transplant recipients exhibits a wide spectrum of clinical symptoms [121, 122]. Based on these clinical manifestations, CMV infection may be classified either as an asymptomatic infection (termed subclinical CMV infection) or symptomatic infection (termed CMV disease). CMV disease can be further classified based on the presence of organ involvement (termed tissue-invasive CMV disease) or lack thereof (termed CMV syndrome) (Table 25-3) [56, 123, 124].

Traditionally, the onset of CMV infection and disease occur most commonly during the first 3–4 months after solid organ transplantation [80, 125–128]. However, the onset has been delayed in some populations, especially among CMV D+/R− solid organ transplant recipients who are receiving anti-CMV prophylaxis; in these patients, CMV infection occurs most commonly during the first 3–6 months after completion of prophylaxis [28, 29, 32, 129–135].

25.5.1 Direct CMV Effects

CMV disease is characterized by the reactivation of the virus in latently infected cells (including the allograft), dissemination in the blood, and invasion and replication in target organs (such as the allograft and other organs, most commonly the gastrointestinal tract). Clinically, this produces a characteristic febrile illness, often accompanied by bone marrow suppression, and various end-organ invasive diseases such as pneumonitis, gastritis, enteritis, colitis, encephalitis, hepatitis, retinitis, among others (Table 25-3). The

TABLE 25-3. Impact of CMV on solid organ transplantation

Direct effects	Indirect effects	Other associated outcomes
CMV syndrome	Acute allograft rejection	Increased total cost
Tissue-invasive CMV disease	Chronic rejection and allograft failure	Increased resource utilization

diagnosis of CMV disease is confirmed by demonstrating the virus in the blood, other body fluids, or tissue specimens [121, 124]. Table 25-4 lists the various laboratory methods used for the diagnosis of CMV infection and disease after solid organ transplantation [136].

25.5.1.1 *CMV Syndrome*

CMV syndrome is the most common clinical presentation of CMV disease, and accounts for over 60–90% of all cases, after solid organ transplantation [28, 29, 124, 133, 137, 138]. CMV syndrome is the term for CMV disease without end-organ involvement, and it is most commonly manifested as fever (>38 °C for at least 2 days) and constitutional symptoms such as new or increasing malaise [121, 124, 139]. CMV syndrome is also characterized by bone marrow suppression, with patients presenting most commonly with new or increasing leukopenia and thrombocytopenia [121, 124, 139]. In some cases, atypical lymphocytosis and elevation in hepatic enzymes may be observed [121, 139]. In all cases of CMV syndrome, CMV should be demonstrated in the blood, either by nucleic acid testing or pp65 antigenemia [121, 124, 139]. For definite diagnosis of CMV syndrome, there should be no other etiology that could account for the clinical symptoms, such as bacterial and other viral infections [121, 139]. In some cases, however, coinfections with HHV-6 and HHV-7 may be demonstrated, although the role of these viruses in the clinical manifestations of CMV syndrome is debated [140–144].

25.5.1.2 *Tissue-Invasive CMV Disease*

CMV disease may manifest with signs and symptoms of organ dysfunction [27–29, 32, 121, 132, 133, 139, 145]. Patients with organ-specific symptoms should be suspected as having tissue-invasive CMV disease, and the diagnosis confirmed by the demonstration of CMV by histopathology (i.e., inclusion bodies and cytopathic changes), immunohistochemistry, or in situ DNA hybridization [121, 124, 139]. In most cases of tissue-invasive CMV disease, the virus is also demonstrated in the peripheral blood by nucleic acid testing or pp65 antigenemia. However, there is a proportion of localized or compartmentalized tissue-invasive CMV disease with no detectable virus in the blood [27]; in these cases, a tissue biopsy is needed to confirm the diagnosis of tissue-invasive disease [27, 121, 139].

The most common form of tissue-invasive disease is gastrointestinal CMV disease, which can involve any part of the gastrointestinal tract [27–29, 32, 132, 133, 145–147]. The most severe forms of tissue-invasive CMV disease are pneumonia and central nervous system disease (e.g., encephalitis) [129]. In some cases, multiple organs may be involved, such as concomitant CMV colitis and hepatitis. It is rare for solid organ transplant recipients to develop CMV retinitis, although this diagnosis should be considered and screened for in patients with compatible symptoms [101, 148]. Virtually any organ system can be affected by CMV, and some of the less common sites of tissue involvement are the gallbladder and biliary tree, epididymis, skin, and endometrium [149–154]. Congenital CMV has been reported in the offspring of female transplant recipients [155, 156].

CMV disease may involve the transplanted allograft, especially among CMV D+/R− patients. This is not unexpected since the virus is harbored in the allograft. CMV reactivates in the transplanted organ and cause graft dysfunction and allograft tissue-invasive CMV disease [157–161]. Hence, liver recipients may present with CMV hepatitis [162], pancreas recipients with CMV pancreatitis [157], kidney recipients with CMV nephritis [163], heart recipients with CMV myocarditis [161], and lung recipients with CMV pneumonitis [158–160]. Because the clinical manifestations of tissue-invasive CMV disease are difficult to differentiate from allograft rejection, tissue biopsy for definitive diagnosis is imperative to guide appropriate therapy [121, 139].

The clinical manifestations of tissue-invasive CMV disease depend on the organ and severity of involvement. CMV hepatitis typically manifests with fever and elevated serum levels of gamma-glutamyl transferase, alkaline phosphatase, and aminotransferases, with minimal elevations in serum bilirubin levels [162]. CMV pneumonitis manifests as fever, dyspnea, and cough, accompanied by hypoxemia and radiographic findings of bilateral interstitial, unilateral lobar, or nodular pulmonary infiltrates [164]. CMV can affect any segment of the gastrointestinal tract [165], and depending on

TABLE 25-4. Laboratory methods for the diagnosis of CMV infection and disease after solid organ transplantation

Method	Examples	Principle	Clinical use	Comments
Viral culture	Tube culture Shell vial assay	Virus isolation	Diagnosis of CMV infection and disease	High specificity but poor sensitivity Slow turnaround time Virus isolate may be used for phenotypic drug susceptibility
Serology	ELISA	Antibody detection (IgG, IgM)	Pretransplant assessment of CMV exposure (IgG only) Not used for real-time diagnosis of acute disease after transplantation	IgG preferred for screening IgM suggests acute infection, but caution for false positive results
Antigenemia	Slide method	pp65 antigen detection	Rapid diagnosis of CMV infection and disease Guide for preemptive therapy Guide for duration of antiviral therapy	More sensitive than shell vial assay Reduced sensitivity during leukopenia and neutropenia Labor intensive and lacks standardization Operator-dependent (subjective interpretation) Requires immediate processing (relies on life span of leukocytes ex vivo)
Nucleic acid tests	Commercial assays Laboratory-developed assays	Viral nucleic acid (DNA or RNA) detection	Rapid diagnosis of CMV infection and disease Assessment of risk of CMV disease Guide for initiation of preemptive therapy Guide for duration of antiviral therapy Marker for risk of relapse and drug resistance	Quantitation allows for assessing severity of infection; qualitative assay does not distinguish latency from active replication Standardization with the use of calibrators Thresholds for various clinical indications have not been fully determined to be applied widely

ELISA enzyme linked immunosorbent assay, *CMV* cytomegalovirus.

the segment involved, it may manifest with dysphagia and odynophagia (CMV esophagitis), nausea, vomiting, and abdominal pain (CMV gastritis), gastrointestinal hemorrhage (CMV gastritis, enteritis, or colitis), and diarrhea (CMV enteritis and colitis) [166–168]. The endoscopic findings of gastrointestinal CMV disease may be nonspecific such as erythema and diffuse, shallow erosions, but characteristic ulcers are typically observed [167]. Histopathologic examination to demonstrate cytomegalic cells with CMV inclusion bodies in tissue specimens, the use of in situ hybridization or CMV-specific immunochemical stains to demonstrate the presence of the virus in biopsy specimens are necessary to confirm tissue-invasive CMV disease [166]. CMV has been reported to cause vasculitis that resulted in ischemic colitis [169], or hepatic artery thrombosis [170, 171]. Rarely, CMV may cause retinitis, usually at a later stage beyond 6 months after solid organ transplantation [101]. Patients with CMV retinitis may be asymptomatic, or they may experience blurring of vision, scotomata, or decreased visual acuity [101]. Characteristic fundoscopic findings by an experienced ophthalmologist often reveal the diagnosis of CMV retinitis, although the demonstration of CMV in vitreous fluid by nucleic acid testing may be necessary in atypical cases [101]. Central nervous system involvement by CMV occurs very rarely, and it is manifested as change in mental function and confirmed by the demonstration of CMV by nucleic acid testing of the cerebrospinal fluid [153].

25.5.2 Indirect CMV Effects

CMV is associated with numerous indirect effects (Table 25-3), which occur as a result of its ability to modulate the immune system, either directly or through the upregulation of cytokines, chemokines, growth factors, and other immune molecules [172]. Some of the indirect effects may be delayed direct effects of persistent subclinical CMV infection in the transplanted allograft (e.g., chronic allograft failure) [173].

25.5.2.1 Opportunistic Infections

CMV causes immunomodulation that predisposes to opportunistic bacterial and fungal infections after solid organ transplantation [113, 174, 175]. Studies have shown that the incidence of bacterial and fungal infections was lower among solid organ transplant recipients who received antiviral prophylaxis [114, 176, 177]. The immunomodulatory property of CMV is postulated to increase the risk of Epstein–Barr virus-induced posttransplantation lymphoproliferative disorders (PTLD) in transplant patients [178].

25.5.2.2 Allograft Rejection

CMV has been associated with reduced allograft survival after liver, kidney, lung, pancreas, and heart transplantation [29, 179, 180]. Acute rejection was significantly higher

among CMV-infected transplant recipients [181]. Prolonged CMV replication has been associated with an increased risk of chronic rejection after liver transplantation [182]. Although the mechanisms underlying these associations have not been fully elucidated, persistent CMV replication may mediate persistent T-cell stimulation, either directly or indirectly, by increasing the immunogenicity of the allograft (i.e., γ-interferon-mediated up-regulation of major histocompatibility complex antigens) resulting in a chronic inflammatory process [183].

25.5.2.3 Chronic Allograft Failure

CMV has been significantly associated with bronchiolitis obliterans syndrome, a form of chronic lung allograft rejection characterized by bronchiolar inflammation and granulation [160]. Ganciclovir prophylaxis has been reported to reduce the incidence of bronchiolitis obliterans after lung transplantation [184]. Among heart recipients, CMV has been implicated in the pathogenesis of accelerated vasculopathy [184–186]. CMV disease has been implicated as a factor for the development of vanishing bile duct syndrome, characterized by ductopenia, severe jaundice, and pruritus after liver transplantation [187–189]. Among kidney recipients, CMV has been associated with tubulointerstitial fibrosis and glomerulopathy, characterized by enlargement and necrosis of endothelial cells and accumulation of mononuclear cell infiltration and fibrillary material deposition in glomerular capillaries [29, 154].

25.5.2.4 Vasculopathy and Procoagulation

A significant association between CMV and vasculopathy has been reported after heart transplantation [185, 186, 190–192]. This association is supported by experimental data showing the ability of CMV to infect endothelial cells, influence smooth muscle cell migration and growth in vitro, and induce neointimal proliferation in rat aortic allografts [193]. Experimental in vivo data demonstrate that rat CMV causes endothelial inflammation that results in intimal thickening in aortic and cardiac allografts, and this was diminished by ganciclovir [194, 195] or experimental CMV vaccination [196]. In addition, CMV-enhanced allograft vasculopathy may be mediated by a proliferative effect on the smooth muscle cells and/or inflammatory cells with enhanced production of growth factors [190, 194, 195, 197, 198]. CMV infection of endothelial cells may also lead to a procoagulant response that could account for the clinical association between CMV and vascular thrombosis [171, 199, 200]. Antiviral drugs together with CMV-hyperimmune globulins have reduced the risk of vasculopathy after heart transplantation [185, 186].

25.5.2.5 Viral Interactions

Reactivation of multiple latent viruses, including CMV, is common after solid organ transplantation, thereby creating an environment that would allow potential interactions [119, 141–143]. Such interaction may lead to altered clinical presentation of various viral infections [119, 120, 141–143, 179, 201, 202]. Examples are the proposed interactions among β-herpesviruses, which may be manifested as an increased incidence and severity of CMV disease [119, 120], the proposed association between CMV and EBV-associated PTLD [178], and the ability of CMV to accelerate the clinical course of recurrent hepatitis C, resulting in higher rates of inflammation, fibrosis, allograft failure and mortality after liver transplantation [201–203].

25.5.2.6 New-Onset Diabetes Mellitus After Transplantation

CMV has been associated with new-onset diabetes mellitus after transplantation. A meta-analysis of seven clinical trials reported that CMV was a risk factor for new onset diabetes mellitus [204]. However, the mechanism underlying this relationship is yet to be determined.

25.5.3 Mortality

Solid organ transplant recipients with CMV disease have a significantly higher mortality rate compared to those without CMV disease [29, 134, 205–208]. The causes of death are most commonly non-CMV related, although occasionally, CMV may directly cause death if not diagnosed and treated appropriately. The use of effective antiviral drugs for prevention and treatment has reduced all-cause mortality after solid organ transplantation [95, 111, 205, 209–212].

25.6 Laboratory Diagnosis of CMV Infection

The laboratory methods for the diagnosis of CMV infection detect (1) the virus in clinical samples, and (2) the immune response to the virus [104] (Table 25-4). The most common method to confirm clinical suspicion of CMV infection is a molecular test that quantifies viral nucleic acid in blood and other clinical samples [104]. Other methods that may be used for this purpose are pp65 antigenemia and viral culture, although their use has markedly declined during the last decade [104]. The diagnosis of tissue-invasive CMV disease is confirmed by histopathologic examination of biopsy samples. Serology to detect CMV IgG antibodies is the standard test to screen for prior exposure, and serve as a surrogate for

latent CMV, among donors and candidates [121]. A novel immunologic test undergoing clinical evaluation is the detection, quantification, and functional assessment of CMV-specific T lymphocytes [66].

25.6.1 Nucleic Acid Tests

Nucleic acid tests are the most common methods for the detection of CMV in blood and other clinical samples [104]. These tests are most commonly performed using polymerase chain reaction (PCR), which amplifies CMV nucleic acid in clinical samples of patients with active CMV infection [104]. There are numerous nucleic acid tests, including commercial and laboratory-developed (also known as "home-brew") tests. Until recently, the tests were not standardized, resulting in wide inter-assay variability in viral load reporting [213]. In a large multicenter study, which included 33 laboratories that were asked quantify the viral load of samples with known viral quantity, there was wide inter-laboratory variability in viral load values and limit of detection [213]. This variability in viral load values has limited direct comparison of practices among transplant centers. The calibration standard was identified as the most significant variable that accounted for the wide inter-assay variability [214, 215]. Hence, a WHO International Standard (National Institute for Biological Standards and Control, UK) and a certified reference material (National Institutes of Standards and Technology, USA) were developed [104]. Several commercial and laboratory-developed tests have now been optimized based on these calibration standards [104, 137, 216, 217].

Nucleic acid tests are used for several clinical indications, including (1) sensitive and rapid diagnosis of CMV infection, (2) assessment of the risk of CMV disease and its severity, (3) guiding initiation of preemptive therapy for preventing CMV disease, (4) assessment of the efficacy of antiviral therapy, (5) guiding the duration of antiviral treatment, and (6) assess the risk of relapse of infection and disease (Table 25-4) [104]. Three different viral load measures are often used for these clinical uses – absolute viral load, change in viral load over time, and viral load suppression. In one study, viral load of 3983 IU/ml was suggested and validated as the threshold for initiating preemptive therapy in CMV R+ solid organ transplant recipients [218]. In another study, a viral load threshold of 2275 IU/ml was suggested to discriminate self-resolving infection from those that need antiviral treatment in a cohort of CMV R+ solid organ transplant recipients [219]. A level of 2000 copies/ml was defined in another study as optimal threshold to initiate preemptive therapy in moderate risk CMV R+ kidney transplant recipients [220]. A lower viral load value may be more significant in CMV D+/R− solid organ transplant recipients, where clinical disease have been observed in as low as 1500 copies/ml, hence the need to treat high-risk patients even at much lower viral load values. In general, however, viral load values during the onset of CMV disease are significantly higher in CMV D+/R− compared to CMV R+ solid organ transplant recipients, and in tissue-invasive disease (mean value, 20,893 IU/ml) compared to CMV syndrome (9120 IU/ml) [137].

Nucleic acid tests have been compared, on multiple occasions, with antigenemia to compare their performance in diagnosis of CMV infection. While the results of numerous studies have been variable, there were more studies that indicated nucleic acid tests are more sensitive than pp65 antigenemia [104]. Indeed, more centers are currently relying on nucleic acid tests for diagnosis of CMV in solid organ transplant recipients.

25.6.2 Antigenemia

The pp65 antigenemia test is another common method for the diagnosis of CMV infection after solid organ transplantation, although its use is currently declining due to more widespread application of nucleic acid tests [219, 220]. The antigenemia test is based on the principle of detecting pp65 antigen that is expressed in polymorphonuclear cells during active CMV infection. Blood is collected and the polymorphonuclear cells are separated and stained with monoclonal antibody against the pp65 antigen. The number of pp65-staining polymorphonuclear cells are counted, and expressed per a predefined number of polymorphonuclear cells (for example, per 100,000 polymorphonuclear cells). Like nucleic acid tests, the pp65 antigenemia has been used for rapid diagnosis of CMV infection (more rapid than viral culture), assess severity of infection (higher number of cells suggest greater severity), guide preemptive therapy, and guide duration of antiviral therapy. Various cutoffs (e.g., number of positive cells) have been defined by different centers, and the variable thresholds identified are likely influenced by the underlying net state of immunity [219, 220].

25.6.3 Viral Culture

Detection of CMV using conventional culture methods and shell vial techniques have become less common due to their labor intensive nature, slow turnaround time, and low to modest sensitivity [104, 221–224]. While viral culture is highly specific for CMV disease, the sensitivity for viral detection is low. Moreover, the slow turnaround time limits real-time clinical applicability. Rapid and real-time tests such as nucleic acid tests have generally supplanted the use of viral culture in the clinical setting [104, 221].

25.6.4 Histopathology

The diagnosis of tissue-invasive CMV disease relies on tissue biopsy demonstrating histologic changes, including cytomegalic inclusion cells [121, 163]. In situ hybridization

and immunohistochemistry staining may be needed when the histologic findings are nonspecific. The most common organs biopsied are the gastrointestinal tract (the most common organ involved in tissue-invasive disease) and the transplanted allograft [163]. Allograft biopsy is often needed to distinguish CMV disease from allograft rejection [121]. One study suggested that detection of virus in the blood by nucleic acid testing may obviate the need for biopsy in patients presenting with symptoms of gastrointestinal CMV disease [147]. The overall sensitivity of this approach is 85%, which increases to 100% with primary gastrointestinal CMV disease but declines to 73% among CMV R+ solid organ transplant recipients [147]. The decline in sensitivity is accounted for by CMV R+ solid organ transplant recipients with compartmentalized or localized gastrointestinal CMV disease with low or absent viremia [147, 225]. Hence, biopsy should be considered when there is clinical concern for CMV disease even if the nucleic acid test in the blood is negative [121]. The virus is detected in the affected tissue for longer period compared blood [146]. In a study of primary gastrointestinal CMV disease, the virus was demonstrated in the tissue for at least 1 week beyond viral eradication in the blood [146]. However, it is not necessary to repeat endoscopy and intestinal biopsy to document clearance of infection before discontinuing antiviral treatment, except in cases of severe disease that involves multiple gastrointestinal segments [146].

25.6.5 Serology

CMV IgG serology is the standard test to screen transplant candidates and potential donors for previous exposure to CMV [121]; this serves as a surrogate marker of latent CMV. Based on the serologic testing of the donor and recipients, the risk of CMV infection and disease can be stratified as high risk (CMV D+/R−), moderate risk (CMV R+) and low risk (CMV D−/R−) [121]. Such risk profile assessment determines the type of CMV prevention strategy after solid organ transplantation [121]. One study further stratified the risk of CMV infection after liver transplantation among CMV R+ recipients based on the serologic titer; in this study, CMV R+ liver recipients with lower CMV-IgG titer has a higher risk of developing CMV disease [110]. However, serology should not be used to diagnose active CMV infection after transplantation, since patients have impaired ability to mount an effective immune response, resulting in delayed antibody production [121].

25.6.6 Cellular Immune Monitoring

Assessment of CMV-specific T cell number and function is an emerging tool to assess the risk of CMV after solid organ transplantation [66]. A variety of methods are available including cytokine flow cytometry, ELISpot, or assessment of cytokine secretion such as interferon-gamma (e.g., interferon-gamma release assays) [66]. Detection of functional CMV-specific T cells reflects the ability of a patient to mount an effective immune response, and a lower risk of CMV disease. Various thresholds for risk prediction have been suggested using different assays and patient populations, but their lack of standardization has limited their widespread clinical application. A positive QuantiFERON-CMV test, an investigational assay that measures interferon-gamma release after stimulation with CMV antigens ex vivo, was associated with lower risk of CMV disease in a large cohort of solid organ transplant recipients, including CMV D+/R− group [226, 227]. Several studies have examined the role of ELISpot, with variable positive thresholds as indicative of risk of CMV disease [228–230]. There are various studies using cytokine flow cytometry, with inconsistent results likely due to differences in techniques, reagents and antigens, patient populations and degree of immunosuppression [65, 66, 231, 232].

25.7 Prevention of Cytomegalovirus Infection and Disease

Because of the negative impact of CMV on outcomes, its prevention is a major focus of management after solid organ transplantation. The most common method is the use of antiviral drugs either as antiviral prophylaxis or preemptive therapy. In addition, a common practice is the use of CMV-seronegative, filtered, or leukocyte-reduced blood products when blood transfusion is necessary for patient care. CMV-seronegative donor and recipient matching, which would pair a CMV-seronegative donor and recipient, is logistically difficult and rarely performed. Waiting for a CMV-seronegative donor may result in an unnecessarily prolonged waiting time for a patient who needs a lifesaving transplant procedure. Currently, non-selected or CMV-hyperimmunoglobulin are less commonly used, partly because of its expense, modest efficacy, and the availability of effective antiviral drug strategies. There is no vaccine that is available clinically for active immunization against CMV in humans, although some are in early clinical development.

25.7.1 Antiviral Strategies

The two major antiviral strategies for preventing CMV disease after solid organ transplantation are (1) antiviral prophylaxis and (2) preemptive therapy [26, 56, 123, 233–237]. Antiviral prophylaxis entails the administration of an antiviral drug for a fixed duration of time (usually, a minimum of 3–6 months) to all patients or to “at-risk” patients after solid organ transplantation (Figure 25-1a) [56, 123, 233]. A variant of this approach is targeted prophylaxis, which administers antiviral drugs only during periods highly associated with CMV reactivation, such as those times when ATG,

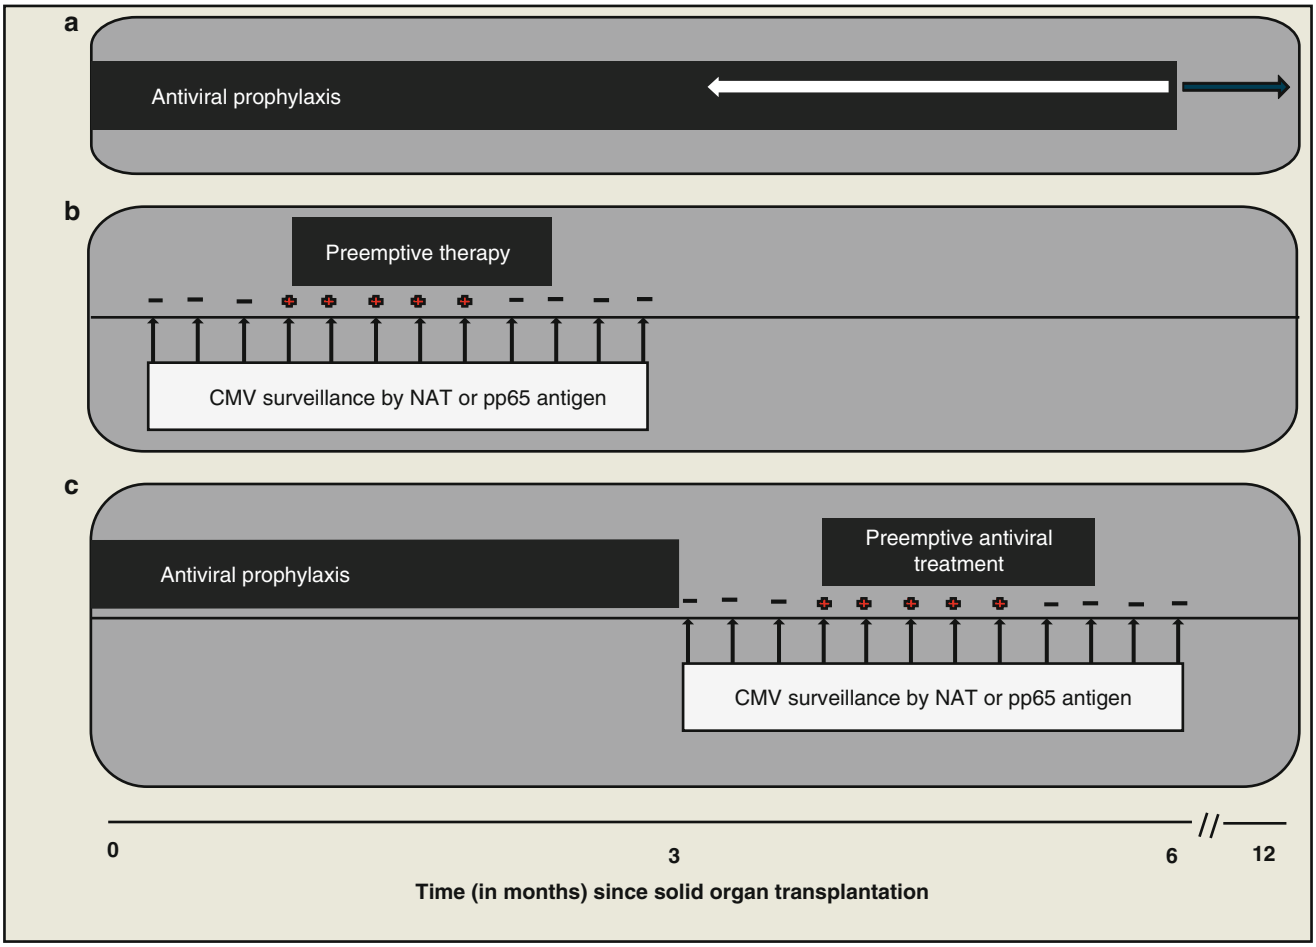

FIGURE 25-1. Schematic representation of antiviral prophylaxis (**a**), preemptive therapy (**b**) and a hybrid approach (**c**) after solid organ transplantation.

ALG, OKT3, and alemtuzumab are used for treatment of acute rejection [56, 123, 233]. In contrast, preemptive therapy involves the administration of antiviral drug only to transplant recipients with evidence of early asymptomatic CMV replication (Figure 25-1b) [56, 123, 233]. The goal of preemptive therapy is to treat early CMV reactivation prior to the onset of clinical disease [121].

There is an ongoing debate whether antiviral prophylaxis or preemptive therapy is the optimal strategy for preventing CMV disease after solid organ transplantation. It is generally believed however that both strategies are effective for CMV disease prevention [121, 238–240]. Several meta-analyses concluded that antiviral prophylaxis and preemptive therapy are both effective in preventing CMV disease (Table 25-5) [209–212]. A reduction in incidence of indirect effects was evident with antiviral prophylaxis [209–212], specifically, a reduction in all-cause mortality [27, 176, 241]. In head-to-head clinical trials that directly compared both strategies in cohorts of kidney recipients, both were similarly effective in preventing CMV disease (Table 25-6) [238–240]. The overall cost of both antiviral strategies appears to be similar, with cost of drug (for antiviral prophylaxis) being counterbalanced by the cost of laboratory monitoring (for preemptive therapy) [240]. Table 25-7 summarizes the potential benefits and disadvantages of the two antiviral strategies [27]. Which of these two strategies is more effective in a specific transplant setting or a specific transplant population is most likely influenced by a variety of factors, such as recipient and donor characteristics, underlying medical comorbidity, the logistics of frequent CMV surveillance, the availability of sensitive and rapid methods for CMV detection, and the availability and cost of antiviral drugs [242, 243]. Hence, the choice of which antiviral approach to use after solid organ transplantation is institution-, organ transplant-, and resource-dependent.

25.7.1.1 Antiviral Prophylaxis

The antiviral drugs for preventing CMV disease after solid organ transplantation are valganciclovir, oral and intravenous ganciclovir, and valacyclovir (Table 25-8) [32, 132, 135, 244–248]. Foscarnet and cidofovir are not routinely

TABLE 25-7. Benefits and risks of universal antiviral prophylaxis and preemptive therapy against CMV after solid organ transplantation

Strategy	Benefits	Risks and disadvantages
Universal prophylaxis	• Prevents reactivation of other herpes viruses (i.e., herpes simplex virus, HHV-6) • Does not rely on frequent laboratory monitoring for CMV detection • Reduces incidence of indirect CMV effects (acute rejection, chronic allograft failure, opportunistic bacterial and viral infections, posttransplant lymphoproliferative disease, mortality)	• Prolonged antiviral drug use may lead to the emergence of antiviral drug resistance • Prolonged antiviral drug use may lead to higher incidence of adverse drug effects • Associated with late-onset CMV disease
Preemptive therapy	• Reduced number of patients exposed to antiviral drugs • Reduced direct drug costs • Reduced duration of antiviral drug use • Reduced toxicity related to antiviral drugs • Lower risk of antiviral drug resistance (although resistance has been observed with prolonged preemptive therapy)	• Requires a predictive test for early identification of patients at risk of CMV disease • Requires patients to comply with stringent surveillance schedule • Requires personnel to actively implement the logistics of the CMV surveillance program • Increased cost of diagnostic surveillance testing • May not identify all patients at risk of CMV disease because of rapid viral replication in CMV D+/R− patients • CMV-selective nature does not prevent reactivation of other herpes viruses

[b]Amongst patients given, first listed vs. second listed regimen.

used for prevention of CMV disease after solid organ transplantation because of renal and other toxicities [27]. Numerous clinical trials have demonstrated the efficacy and safety of antiviral drugs for prevention of CMV disease after solid organ transplantation (Table 25-8) [32, 132, 135, 244–248]. As demonstrated in these clinical trials, the immediate benefits of antiviral prophylaxis are the reduction in the incidence and severity of CMV disease. In some trials, a

TABLE 25-9. Recommendations for the prevention of CMV disease after solid organ transplantation

Organ transplant type	CMV serostatus	General recommendations	Specific recommendations
Kidney, liver, pancreas and heart transplants	D+/R−	Universal prophylaxis is preferred over preemptive therapy Duration of antiviral prophylaxis is 6 months for kidney recipients, and 3–6 months for liver, pancreas and heart recipients Prophylaxis may be prolonged for patients who receive lymphocyte-depleting antibodies for treatment of acute rejection Preemptive therapy may be effective (if performed adequately) but the rapid replication dynamics of CMV in CMV D+/R− patients makes preemptive strategy logistically difficult in this population	Valganciclovir 900-mg QD (not FDA-approved in liver transplantation) is preferred Oral ganciclovir 1-g TID IV ganciclovir 5-mg/kg QD Valacyclovir 8-g/d (kidney transplant recipients only) Some centers add CMV-IG for high-risk patients (in heart transplant patients)
	R+	Either antiviral prophylaxis or preemptive therapy are acceptable options Duration of prophylaxis is 90–100 days Preemptive therapy is guided by PCR or antigenemia testing Other centers do not provide specific anti-CMV prevention strategy and opts to clinically observed low-risk patients (i.e., D−/R+)	*Antiviral prophylaxis*: Valganciclovir 900-mg QD (not FDA-approved in liver transplantation) is preferred Oral ganciclovir 1-g TID IV ganciclovir 5-mg/kg QD Valacyclovir 8-g/d (kidney transplant recipients only) *Preemptive therapy*: Valganciclovir 900-mg BID IV ganciclovir 5-mg/kg q12h
Lung and heart-lung transplants	D+/R−	Universal prophylaxis is preferred over preemptive therapy Duration of prophylaxis is 12 months, and others extend this longer periods	Valganciclovir 900-mg QD IV ganciclovir 5-mg/kg QD Some centers add CMV-IG to the antiviral regimen
	R+	Universal prophylaxis is preferred over preemptive therapy Duration of prophylaxis is 6–12 months	Valganciclovir 900-mg QD IV ganciclovir 5-mg/kg QD
Intestinal transplants	D+/R−	Universal prophylaxis is preferred over preemptive therapy Duration of prophylaxis is 3–6 months; some centers extend the duration beyond 6 months	IV ganciclovir 5-mg/kg QD Valganciclovir 900-mg PO QD Some centers add CMV-Ig to the antiviral regimen
	R+	Universal prophylaxis is preferred over preemptive therapy Duration of prophylaxis is 3–6 months after transplantation	IV ganciclovir 5-mg/kg QD Valganciclovir 900-mg PO QD

CMV cytomegalovirus, *IG* immunoglobulin, *D* donor, *R* recipient, *QD* once daily, *TID* thrice daily, *IV* intravenous.

reduction in the indirect effects of CMV was also demonstrated, such as its impact on other opportunistic infections [177], bacteremia [114], allograft rejection [184–186], and patient survival [184–186, 209]. Table 25-9 lists the current recommendations for the prevention of CMV disease after solid organ transplantation [56, 123, 233, 249].

Ganciclovir and Valganciclovir Prophylaxis

A synthetic analogue of 2′-deoxy-guanosine, ganciclovir exerts its anti-CMV effect through inhibition of CMV DNA polymerase [250, 251]. Ganciclovir requires three sequential phosphorylation steps in order to exert its antiviral activity. The initial step of this triphosphorylation process is carried out by CMV-encoded *UL97* kinase, and two additional phosphate molecules are later added by human cellular kinases [252]. Because of the need for CMV-encoded *UL97* kinase for its initial phosphorylation, ganciclovir becomes activated only in the presence of active CMV infection [252]. Upon its activation, ganciclovir triphosphate acts by competitively inhibiting the incorporation of deoxyguanosine-triphosphate by CMV DNA polymerase. The incorporation of ganciclovir triphosphate by CMV DNA polymerase alters the DNA conformation, which results in the termination of CMV DNA elongation.

The clinical efficacy of ganciclovir for preventing CMV disease after solid organ transplantation is demonstrated by multiple clinical trials that compared it with placebo, acyclovir, or different preparations of immunoglobulins [253–258]. Ganciclovir is available in intravenous and oral formulations [252]. However, oral ganciclovir is poorly absorbed in the gastrointestinal tract. Hence, it is no longer recommended as a first-line agent, and it has been replaced by the highly bioavailable oral valganciclovir [259]. A valyl-ester prodrug of ganciclovir, valganciclovir circumvents the pharmacokinetic limitations of oral ganciclovir and provides systemic ganciclovir levels that are comparable to intravenous ganciclovir [259]. Intraocular injection of ganciclovir is also used as adjunctive treatment of CMV retinitis [101].

Valganciclovir

Valganciclovir is currently the most common antiviral drug for prophylaxis against CMV in solid organ transplant recipients [135]. A prodrug of ganciclovir, valganciclovir is a highly recognized substrate of the intestinal peptide transporter PEPT1, which facilitates its rapid and efficient intestinal absorption [252]. Following absorption, valganciclovir undergoes rapid hydrolysis by intestinal and hepatic esterases into ganciclovir [252]. Because of enhanced absorption, valganciclovir provides serum ganciclovir levels that are comparable to intravenous ganciclovir [259]. The high levels achieved with valganciclovir may reduce the risk of antiviral resistance when compared to oral ganciclovir [260], although ganciclovir-resistance has been reported during prolonged use of valganciclovir.

For antiviral prophylaxis, valganciclovir is administered orally at a dose of 900-mg once daily in individuals with creatinine clearance >60 ml/min (Table 25-9) [135, 252]. In an international randomized controlled trial, valganciclovir (900-mg once daily for 100 days) was noninferior to oral ganciclovir (1-g three times daily for 100 days) for preventing CMV disease in a cohort of 364 CMV D+/R− kidney, pancreas, liver, and heart recipients [135]. The incidence of "endpoint committee-defined CMV disease" were 12.1 and 15.2% at 6 months and 17.2 and 18.4% at 12 months in the valganciclovir and oral ganciclovir groups, respectively [135]. The incidence of "investigator-treated CMV disease" were 30.5 and 28.0% in the valganciclovir and oral ganciclovir groups, respectively [135]. Notably, there was a higher incidence of tissue-invasive CMV disease among liver recipients who received valganciclovir compared to oral ganciclovir prophylaxis [135], and this observation resulted in its non-approval by the US FDA for the prevention of CMV disease after liver transplantation [135]. Despite this, valganciclovir remains as the most common drug used for the prevention of CMV disease after liver transplantation [261]. The incidence of neutropenia was significantly higher among patients who received valganciclovir compared to oral ganciclovir prophylaxis [135]; these findings were correlated with systemic drug levels [262]. Several single-center and retrospective analyses have mirrored these observations by demonstrating the efficacy of valganciclovir prophylaxis after heart, kidney, pancreas, and liver transplantation [28, 29, 133, 159, 263–265]. Clinical trials have also demonstrated the efficacy of valganciclovir for preventing CMV disease after lung transplantation (Table 25-8) [159, 265].

The optimal duration of valganciclovir prophylaxis for the prevention of CMV disease after solid organ transplantation remains debated, although 3 months is considered as the minimum duration for CMV D+/R− kidney, liver, heart, and pancreas recipients [56, 123, 233]. One study of a cohort of 372 CMV D+/R− kidney recipients demonstrated that the incidence of CMV disease is further reduced by doubling the duration from 3 months (100 days) to 6 months (200 days) of valganciclovir prophylaxis (36.8% vs. 16.1%) (Table 25-8) [266]. In another multicenter trial, valganciclovir prophylaxis for 12 months was significantly better than 3 months in reducing CMV disease in CMV D+/R− and CMV R+ lung transplant recipients (Table 25-8) [129, 158, 159]. Table 25-9 lists the recommendations for the prevention of CMV disease in CMV D+/R− and CMV R+ kidney, liver, pancreas, heart, lung, and intestinal recipients [56, 123].

Intravenous Ganciclovir

Clinical trials have demonstrated the efficacy of intravenous ganciclovir for the prevention of CMV disease after solid organ transplantation [255]. However, the need for vascular access and its associated complications of thrombosis, phlebitis, and catheter-related infections have limited the use of intravenous ganciclovir prophylaxis after solid organ transplantation [252]. Oral agents have generally replaced intravenous ganciclovir for prevention of CMV disease. Currently, intravenous ganciclovir remains used as short-course "bridge" prophylaxis during the early period after transplantation, when patients are still unable to take oral medications. The recommended dose for intravenous ganciclovir for prophylaxis is 5 mg per kg per day (dose adjusted based on renal function).

Oral Ganciclovir

Oral ganciclovir was developed to circumvent the limitation of intravenous ganciclovir [132]. For prophylaxis, oral ganciclovir is given at a dose of 1 g orally three times daily for 3 months after solid organ transplantation [56, 132]. The major drawback to oral ganciclovir use is its poor absorption [252, 259]. In a prospective, randomized, placebo-controlled trial involving 304 liver recipients, oral ganciclovir (3 g daily for 98 days) reduced the 6-month incidence of CMV infection from 51.5 to 24.5% and CMV disease from 18.9 to 4.8% [132]. Significant reduction in the incidence of CMV disease was demonstrated even in CMV D+/R− liver transplant recipients (from 44 to 14.8%) and those who received lymphocyte-depleting immunosuppressive drugs (from 32.9 to 4.6%) [132]. Prolonging oral ganciclovir prophylaxis to 6 months further decreased the incidence of CMV disease in kidney recipients [267]. In a single-center observational study, the incidence of CMV disease among patients who received 12 weeks was 31% compared to only 6.5% among patients who received 24 weeks of oral ganciclovir prophylaxis [267].

The prolonged suboptimal systemic levels attained during oral ganciclovir prophylaxis has been postulated as major contributor to the emergence of drug-resistant viral strains, particularly among CMV D+/R− solid organ transplant recipients [260, 268–272]. In an in vitro study, low ganciclovir levels predisposed to the selection of low-grade *UL97* mutations followed thereafter by accumulation of other

mutations [273]. In the clinical setting, persistent CMV replication has been demonstrated despite the use of oral ganciclovir [52]. Although an earlier study showed that ganciclovir prophylaxis in solid organ transplant recipients did not select for ganciclovir-resistant CMV isolates [251], subsequent studies have observed that prolonged use of ganciclovir may predispose to the selection of ganciclovir-resistant CMV [271, 272]. In a study of lung recipients on prolonged ganciclovir therapy, 9% developed ganciclovir resistance at a median of 4.4 months [271]. Currently, oral ganciclovir is no longer a first-line option, but it has been supplanted by valganciclovir for preventing CMV disease after transplantation [261].

25.7.1.2 Acyclovir and Valacyclovir

Acyclovir

Acyclovir was one of the earliest antiviral drugs for the prevention of CMV disease after solid organ transplantation, with modest success (Table 25-8) [244]. In its phosphorylated form, acyclovir acts as a competitive inhibitor of viral DNA polymerase. However, acyclovir possesses little in vitro activity against CMV at clinically achievable levels. In a prospective, randomized, placebo-controlled trial of kidney recipients, oral acyclovir (dose of 800–3200 mg four times daily for 12 weeks) reduced the incidence of CMV infection (36% vs. 61%) and disease (7.5% vs. 29%) compared to placebo [244]. However, other studies have not demonstrated these beneficial effects, particularly in liver and thoracic organ recipients [274, 275]. Thus, it is no longer recommended for the prevention of CMV disease after solid organ transplantation.

Valacyclovir

Valacyclovir, a valyl-ester prodrug of acyclovir, is characterized by improved oral bioavailability [32]. In a prospective, randomized, placebo-controlled trial, valacyclovir (2 g orally four times daily for 90 days) reduced the incidence of CMV disease from 45 to 16% in CMV D+/R− kidney recipients and from 6 to 1% in CMV-seropositive patients (Table 25-8) [32]. Reductions in the incidence of herpes simplex virus infections and allograft rejection were also observed, but hallucinations and mental confusion were prominent adverse effects of high-dose valacyclovir [32]. The clinical utility of valacyclovir prophylaxis has not been demonstrated in recipients of allografts other than kidney [276]. Currently, valacyclovir is indicated only for preventing CMV disease after kidney transplantation (Table 25-9).

25.7.1.3 Foscarnet and Cidofovir

There have been no randomized, placebo-controlled clinical studies of foscarnet and cidofovir prophylaxis for the prevention of CMV disease after solid organ transplantation. Both drugs exert a mechanism of action that is similar to ganciclovir, by inhibiting CMV *UL54 (pol)*-encoded DNA polymerase. Foscarnet is a pyrophosphate analogue that does not require intracellular activation, and terminates CMV replication by blocking the release of pyrophosphate by CMV DNA polymerase. Cidofovir requires a two-step phosphorylation process, catalyzed by human cellular kinases, in order to exert its antiviral effect. In contrast to ganciclovir, both foscarnet and cidofovir do not require phosphorylation by CMV *UL97* kinase. Hence, foscarnet and cidofovir have antiviral activity against ganciclovir-resistant CMV strains with *UL97* mutations [277]. While the long half-life of cidofovir may allow for less frequent and more convenient dosing (e.g., once every 2 weeks), the associated nephrotoxicity and need for parenteral administration are major factors that limited its use. Likewise, foscarnet is administered parenterally and the risk of nephrotoxicity has prevented its use as CMV prophylaxis after solid organ transplantation [277].

25.7.1.4 Delayed-Onset CMV Disease

Antiviral prophylaxis has not completely prevented CMV infection and disease, especially in a subgroup of high-risk CMV D+/R− transplant recipients. Instead, antiviral prophylaxis has merely delayed the onset of disease to a later period, hence the term delayed-onset (late-onset) CMV disease. The onset of delayed-onset CMV disease varies depending on the duration of antiviral prophylaxis. In general, delayed-onset CMV disease occurs mainly during the first 3–6 months after stopping antiviral prophylaxis [28, 29, 32, 56, 132, 133, 135]. The reported incidence of delayed-onset CMV disease varied in different studies, from as low as 8% to as high as 47% of CMV D+/R− solid organ transplant recipients [28, 29, 32, 56, 132, 133, 135, 264].

The clinical presentation of delayed-onset CMV disease appears similar to traditional-onset CMV disease, with the majority of cases presenting as CMV syndrome (estimated >60%) and less commonly as tissue-invasive CMV disease [28, 29, 32, 56, 132, 133, 135, 264]. The most common organ involved is the gastrointestinal tract [28, 29, 32, 56, 132–135, 208, 264]. The severity of illness appears to be comparatively lesser than early-onset CMV disease, possibly as a result of the lower degree of immunosuppression at later posttransplant period. In some cases, the clinical presentation may be atypical and the diagnosis may be missed, leading to death [278]. Delayed-onset CMV disease remains significantly associated with poor allograft and patient survival [29, 134, 208].

The major risk factor for delayed-onset CMV disease is a CMV D+/R− serologic status [28, 29, 32, 56, 132–135, 208, 264]. Viral load monitoring and CMV serology (at the end of antiviral prophylaxis) have not been particularly useful in predicting delayed-onset CMV disease [279, 280]. Routine surveillance using nucleic acid test to monitor early asymptomatic CMV reactivation that can be treated preemptively

before it progresses to clinical disease has been proposed to reduce the incidence of delayed-onset CMV disease, but only with modest efficacy (Figure 25-1c). In contrast, measurement of cell-mediated immunity, such as interferon-gamma release by T cells following CMV antigenic stimulation have been shown to stratify patients that remain at high risk of CMV disease after completion of antiviral prophylaxis [226]; these individuals may benefit from extended antiviral prophylaxis or a more aggressive CMV surveillance post-prophylaxis. The vast majority of delayed-onset CMV disease cases remain susceptible to ganciclovir, although some may be due to drug-resistant strains [281]. Ganciclovir-resistant CMV disease causes significant morbidity and results in poor allograft and patient survival [281–283].

25.7.2 Preemptive Therapy

Preemptive therapy involves the administration of antiviral drugs "selectively" only to patients with asymptomatic CMV reactivation with the main goal of preventing its progression to symptomatic CMV disease [56, 123, 233]. An algorithm for preemptive therapy is depicted in Figure 25-1b, c). Meta-analysis of clinical trials using preemptive therapy for the prevention of CMV disease is listed in Table 25-5. The results of comparative trials between preemptive therapy and antiviral prophylaxis for the prevention of CMV disease after solid organ transplantation are listed in Table 25-6.

For preemptive therapy to work optimally, a sensitive and highly predictive laboratory test should be readily available to identify patients at increased risk of developing CMV disease [56, 136, 257, 284]. Transplant recipients are monitored with this test, usually on a weekly basis, until a "viral threshold" is reached that triggers the initiation of antiviral treatment [136]. For more than a decade, there has been debate as to the optimal method and frequency for CMV surveillance. Among the various laboratory methods used for the diagnosis of CMV (Table 25-4) [136], those that have been shown to be effective for guiding preemptive therapy are pp65 antigenemia [257, 285–288] and nucleic acid tests [238, 284, 289–292]. Which of these laboratory methods is more effective in guiding preemptive therapy is dependent on a variety of factors. The low sensitivity and slow turnaround time of culture-based assays have limited their use for preemptive therapy, and are strongly discouraged for this purpose [293, 294]. The optimal frequency of CMV surveillance by CMV nucleic acid test or pp65 antigenemia has been suggested to be once weekly for the first 12 weeks after solid organ transplantation [56, 123, 233, 249].

The viral load threshold for initiating preemptive antiviral therapy has not been well defined. Differences in patient characteristics, lack of standardization among laboratory assays, and the varying analytical performance of diagnostic tests have made it difficult, if not impossible, to define a specific clinically significant level of viral replication [136, 213, 295]. Recent studies using standardized nucleic tests have suggested a viral load ranging between 2000 and 5000 IU/ml as threshold for initiating preemptive antiviral therapy for CMV R+ solid organ transplant recipients, while any viral load value may be significant for the CMV D+/R− solid organ transplant recipient [218]. These suggested values should be confirmed by others before it becomes widely adopted. Likewise, a clinically relevant cutoff value of pp65 antigenemia has not been widely defined nor adopted. A suggested threshold of >10 positive cells per 2×10^5 cells in solid organ transplant recipients has yet to be validated by prospective clinical trials [296]. Pending widespread confirmation of these suggested viral thresholds, it is imperative for individual transplant centers to develop clinically validated thresholds that will trigger the initiation of preemptive therapy. It is likely that the suggested threshold may differ between CMV D+/R− and R+ patients, between lung and non-lung transplant recipients, and between those who received or did not receive induction therapy with lymphocyte-depleting agents, among other factors.

Intravenous ganciclovir and oral valganciclovir are most commonly used antiviral drugs for preemptive antiviral therapy (Table 25-9) [297]. In a randomized trial, intravenous ganciclovir and oral valganciclovir were equally effective for the preemptive treatment of CMV infection [297]. High-dose oral acyclovir, intravenous acyclovir, valacyclovir, and immunoglobulin preparations should not be used for preemptive therapy since they are comparatively less effective than ganciclovir-based regimens in treating active CMV replication [56, 123, 233, 249]. Oral ganciclovir has been used successfully for preemptive therapy in some clinical studies [256, 284, 292, 298], but its poor absorption, the risk of emergence of ganciclovir-resistant CMV in the presence of low systemic ganciclovir levels, and the availability of more bioavailable valganciclovir has limited (and should discourage) the use of preemptive oral ganciclovir therapy. Because of associated severe toxicities, foscarnet and cidofovir are not used as first-line agents for preemptive treatment in solid organ transplant recipients [256, 258, 284].

The duration of antiviral administration with preemptive therapy is guided by CMV surveillance using nucleic acid test or antigenemia testing [56, 123, 233, 249]. It is generally recommended to continue preemptive antiviral treatment until CMV is no longer detectable in the blood for at least 2 weeks [56, 123, 233, 249]. CMV surveillance is recommended on a weekly basis for the duration of preemptive treatment and for the entire "high-risk" period (i.e., 12 weeks after transplantation) [56]. CMV testing would provide an indication of the efficacy of the antiviral treatment, with a decline in viral load as an indication of effective treatment, while non-decline or rising viral load is an indication of antiviral drug resistance or poor drug bioavailability [271, 272, 281, 299]. It is important to recognize, however, that viral load may occasionally transiently rise during the first 1–2

weeks of preemptive treatment, and this does not necessarily suggest antiviral drug resistance [300].

Table 25-9 lists the recommendation for using preemptive therapy for the prevention of CMV disease after solid organ transplantation. The rapid CMV replication in CMV D+/R− solid organ transplant patients has led many centers to question the implementation of preemptive therapy in this high-risk population [36, 37, 106]. In few studies [284, 292, 298], many CMV D+/R− solid organ transplant patients were not identified soon enough for the timely initiation of preemptive treatment. Hence, current guidelines have preferred antiviral prophylaxis over preemptive therapy in CMV D+/R− solid organ transplant recipients [56, 123, 233, 249]. Other centers however have reported good experience with preemptive therapy even in this high-risk CMV D+/R− population [256, 257, 301].

The benefits and disadvantages of preemptive therapy are listed in Table 25-7. Compared to antiviral prophylaxis, wherein antiviral drugs are administered to all at-risk patients, preemptive therapy will provide antiviral drugs only selectively to patients with asymptomatic CMV infection [302]. Accordingly, the duration of antiviral drug administration is relatively shorter and fewer patients will receive the antiviral drug; this has the potential advantage in reducing drug costs and adverse effects. Moreover, preemptive therapy may be associated with a lower risk for emergence of resistant strains, although ganciclovir-resistant CMV has been observed among transplant recipients who received prolonged preemptive therapy [271, 303].

25.7.3 Targeted Prophylaxis

Targeted prophylaxis involves the administration of antiviral drugs to selected patients with clinical and epidemiologic characteristics that heightened their risk of CMV disease [56, 80, 108, 304–307]. The principle of this prevention approach is that the intensity of antiviral strategy should parallel the intensity of the antirejection program. The most important risk is the use of lymphocyte-depleting anti-T-cell receptor antibodies, either as induction therapy or for treatment of allograft rejection [56, 80, 108, 307]. Intravenous ganciclovir therapy given during anti-lymphocyte antibody therapy has been shown to decrease the incidence of CMV disease from 33 to 14% in CMV R+ kidney transplant recipients [307, 308]. Currently, valganciclovir is the most commonly used drug for targeted prophylaxis. Intravenous and oral ganciclovir are alternative agents. In contrast, immunoglobulins, acyclovir, and valacyclovir are not generally recommended for targeted prophylaxis. The optimal duration of targeted prophylaxis is not well defined, although many centers provide antiviral therapy for 1–3 months following the use of anti-lymphocyte antibody therapy [56, 123, 233, 249].

25.7.4 Other CMV Prevention Approaches

25.7.4.1 Cytomegalovirus-Seronegative Blood Products and Protective Matching

The CMV serologic status of the donor and recipient prior to solid organ transplantation is an important predictor of the risk of CMV disease, with CMV D+/R− representing the highest risk [309–311]. The use of protective matching (i.e., transplantation of an allograft from a seronegative donor to a seronegative recipient; D−/R−) markedly reduces the risk of CMV disease in the seronegative recipient by avoiding the transmission of CMV during solid organ transplantation [309–311]. The overall rate of CMV disease during the first year after solid organ transplantation in CMV D−/R− is up to 1–2% [121]. However, this "selective" approach is impractical, and rarely used. Waiting for a CMV-seronegative donor is likely to be risky and detrimental since it may delay a life-saving transplant procedure. Moreover, the approach does not guarantee complete protection since natural transmission of CMV occurs in the community.

CMV-seronegative or leuko-reduced blood products are suggested for transplant recipients, especially CMV D−/R− transplant recipients, who require blood transfusions for any indication [121, 309–312]. Because majority of blood donors are CMV-seropositive, one limitation is the scarcity of CMV-seronegative blood products. In such a situation, filtered or leukocyte-poor products, which are associated with a low risk of CMV transmission, have been recommended [312]. In studies that compared CMV-negative vs. leuko-reduced blood products, there was no significant difference in the incidence of transfusion-transmitted CMV infection [310, 313–315].

25.7.4.2 Immunotherapy and Vaccination

In theory, one intervention to reduce the risk of CMV infection after solid organ transplantation is CMV vaccination [316–319]. In the 1980s, randomized, placebo-controlled, double-blind trials of the live-attenuated Towne vaccine in kidney recipients demonstrated safety and immunogenicity, but did not demonstrate significant prevention of CMV infection, although reduction in CMV disease severity by up to 85% was observed [320–322]. Moreover, among CMV D+/R− subgroup, the 1- and 5-year graft survival rates were higher in CMV-vaccinated patients (73 and 62%, respectively) compared to placebo (40 and 25%, respectively) [323]. Currently, there are major efforts to develop an effective CMV vaccine [324–327], including peptide-based, DNA-based, and subunit vaccines containing recombinant immunodominant glycoproteins [316–319, 328]. The glycoprotein B vaccine with MF adjuvant has reduced CMV infection in healthy women [329], while the ASP0113 vaccine is undergoing phase II–III clinical trials in transplant

recipients [330]. Currently, no vaccine is approved for clinical use.

The administration of unselected or CMV immunoglobulins have been used to boost humoral immune response in an attempt to prevent CMV disease after solid organ transplantation [159, 331–337]. Results from randomized, controlled trials in kidney recipients indicate that immunoglobulins prevented CMV disease in some, but not all trials [159, 331–337]. Two meta-analyses demonstrated that immunoglobulin prophylaxis was associated with reduction in CMV-related death [338, 339]. However, one study showed no significant reduction in CMV disease, CMV infection, and all-cause mortality when compared to placebo or no treatment [339]. This study further suggested that immunoglobulins did not have additional protective benefit to that provided by antiviral drugs alone [339]. A more recent analysis of a large database confirms the observation that while CMV-immunoglobulins with or without antivirals was associated with reduced risk of death or graft loss, this similar finding was observed with the use of antivirals alone [340]. Despite these data, some centers use unselected or CMV-immunoglobulins as "adjunctive" agent for the prevention of CMV disease in high-risk populations such as lung, heart, and intestinal transplants, in combination with antiviral drugs [56, 123, 233, 249]. The high cost of immunoglobulins and the risks associated with parenteral administration are the major disadvantages of immunoglobulins.

25.8 Treatment of Cytomegalovirus Disease

CMV disease in solid organ transplant recipients is a potentially fatal illness that should be treated aggressively as soon as possible. The antiviral drugs for treating CMV disease are intravenous ganciclovir, oral valganciclovir, intravenous foscarnet and intravenous cidofovir. All these drugs inhibit CMV by interference of the function of *UL54 (pol)*-encoded CMV DNA polymerase. Intravenous ganciclovir and valganciclovir are considered the first line agents and are similarly effective for the treatment of mild to moderate CMV disease in solid organ transplant recipients [138]. Because of significant toxicities, foscarnet and cidofovir are considered second line alternative drugs (Table 25-10) [56]. Foscarnet and cidofovir are reserved for the treatment of ganciclovir-resistant CMV disease. In addition to antiviral therapy, treatment of CMV disease should be complemented by a judicious reduction in pharmacologic immunosuppression.

25.8.1 Intravenous Ganciclovir and Valganciclovir

Clinical trials have demonstrated the efficacy and safety of intravenous ganciclovir for the treatment of CMV disease after solid organ transplantation [138, 233, 341–343]. The administration of intravenous ganciclovir resulted in a significant decline in the CMV DNA levels, which accompanied clinical resolution of symptoms [137, 138, 279, 295, 341, 344]. The half-life of CMV, which is a measure of the rate of CMV decline, during intravenous ganciclovir therapy ranges from 2.36 days in liver recipients [106] to as long as 5 days in a heterogenous group of solid organ transplant patients [279, 344]. The standard therapeutic dose of ganciclovir is 5 mg per kg every 12 h. Because ganciclovir is excreted by the renal system, patients with renal impairment require dose reductions [345].

The oral formulation of ganciclovir should not be used for treatment of CMV disease because its oral bioavailability is very low and the level achieved in the blood is not sufficient to treat active CMV replication [252, 259]. In contrast, oral valganciclovir is characterized by significantly improved bioavailability with serum ganciclovir concentrations that are ten times higher than oral ganciclovir and approximate those achieved with intravenous ganciclovir

Table 25-10. Antiviral drugs for the treatment of CMV disease after solid organ transplantation

Drug	Dose and duration[a]	Mechanism of action	Common adverse events	Comments
Ganciclovir	5 mg/kg IV every 12 h	Inhibits CMV DNA polymerase	Bone marrow suppression	First-line drug Oral ganciclovir is not readily absorbed and should not be used for treatment
Valganciclovir	900-mg PO twice daily	Inhibits CMV DNA polymerase	Bone marrow suppression	First-line drug for mild-to-moderate cases of CMV disease
Foscarnet	60 mg/kg IV every 8 h (or 90-mg/kg every 12 h)	Inhibits CMV DNA polymerase	Electrolyte abnormalities Nephrotoxicity Anemia Seizure	Second line antiviral drug; utilized in ganciclovir-resistant CMV cases
Cidofovir	5 mg/kg IV every week × 2 weeks then every 2 weeks thereafter	Inhibits CMV DNA polymerase	Nephrotoxicity Ocular hypotony Neutropenia	Rarely used as initial therapy; utilized in ganciclovir-resistant cases

CMV cytomegalovirus.

[a]All dosing should be adjusted based on renal function. The duration of therapy must be tailored as a function of the degree of viral replication, as assessed by CMV DNA PCR or pp65 antigenemia assay, and clinical response (i.e., resolution of symptoms).

[252, 259]. A prospective, randomized, multicenter trial showed that valganciclovir was as effective as intravenous ganciclovir for the treatment of non-severe cases of CMV disease in solid organ transplant recipients [138]. The rates of virological decline and clinical resolution by end of a predefined 21-day treatment course and by the end of maintenance valganciclovir treatment were similar between valganciclovir and intravenous ganciclovir [138]. The recommended dose of valganciclovir for treatment of CMV disease is 900-mg twice daily, with dose adjustments based on renal function. Valganciclovir is not indicated as first line therapy in severe cases of CMV disease, those with very high initial viral load, and in patients whose intestinal absorption is uncertain, such as those with vomiting and diarrhea [252]. In these cases, it is recommended to initiate therapy with intravenous ganciclovir followed by, when the clinical situation improves, step-down therapy with treatment doses of oral valganciclovir.

The duration of antiviral therapy should be individualized based on clinical and virologic response to treatment. The minimum duration of treatment is 2 weeks [56], but most patients require prolonged duration of therapy, especially those with severe disease, tissue-invasive disease, high viral load, and augmented immunosuppression. CMV nucleic acid test or pp65 antigenemia are generally performed once weekly during treatment to assess virologic response to antiviral therapy [56, 123, 233, 249]. CMV monitoring should be performed using the same assay, since viral load values can differ among various tests, especially if they have not been calibrated to the international standard [123]. Studies on CMV kinetics indicate that the degree of viral replication, as measured by the virus load in the blood at the start and end of antiviral therapy, and the degree of viral decay, influence the duration of therapy duration [104, 279, 341]. In a study of 267 solid organ transplant recipients, those patients with viral load higher than 18,200 IU/ml had significantly longer period to CMV disease resolution compared to those with lower viral load [137]. Clearance of viremia (i.e., undetectable viral load) is a useful guide for the discontinuation of antiviral therapy [137, 279, 341]. A study of liver recipients demonstrated that a detectable virus load at the end of antiviral therapy predicted the occurrence of CMV relapse [341]. In contrast, viral load decline to <137 IU/ml was significantly associated with clinical CMV disease resolution [137]. Clinical experience suggests that longer durations of treatment are required in patients with end-organ CMV disease, such as pneumonitis, retinitis, and gastrointestinal CMV disease [56]. Such prolongation of antiviral treatment with end-organ disease is due to the longer persistence of the virus in the tissues compared to the blood [146]. In a study of gastrointestinal disease, CMV remains detectable in tissue for at least 1 week after it has been cleared from the blood [146]. One important limitation of viral load as a clinically useful indicator of the duration of antiviral therapy is in cases of "compartmentalized" organ-invasive diseases, which are characterized by minimal or transient viremia (e.g., retinitis, some cases of hepatitis and gastrointestinal diseases) [27, 101]. Compartmentalized CMV disease is generally more common in CMV R+ solid organ transplant recipients with late onset gastrointestinal CMV disease [225].

The efficacy of maintenance antiviral therapy, wherein antiviral drugs are given at prophylactic doses following a full-dose induction treatment, is debated. Some authorities recommend their use in order to reduce the risk of CMV relapse. However, clinical data indicate that the rate of CMV disease relapse did not differ significantly between the group who received or did not receive secondary maintenance prophylaxis [146, 346]. Some experts have continued to recommend the use maintenance therapy in clinical situations where the degree of immunosuppression is high [121].

Recurrence of CMV infection and disease occurs in up to 25–35% of solid organ transplant recipients with CMV disease [341, 343]. CMV recurrence has been significantly correlated with incomplete clearance of virus from the blood at the end of treatment (i.e., the duration of treatment may have been insufficient). In addition, the immunologic condition of the host may influence the risk of relapse, and patients with persistent severe immunocompromise (i.e., CMV-specific T cell deficiency) are more likely to have recurrence of CMV infection and disease after cessation of antiviral therapy. Most cases of recurrent CMV disease respond to retreatment with intravenous ganciclovir [341, 343]; however, a few cases may be due to ganciclovir-resistant CMV.

The adverse effects of intravenous ganciclovir and valganciclovir include leukopenia, neutropenia, thrombocytopenia, anemia, eosinophilia, bone marrow hypoplasia, hemolysis, nausea, diarrhea, renal toxicity, seizures, mental status changes, fever, rash, and abnormal liver function tests [56, 135, 138, 252]. Thus, hematologic profile and liver and renal function should be monitored once weekly while the patient is receiving ganciclovir. Ganciclovir has teratogenic and carcinogenic potential, and gonadal toxicity has been shown in animal models [56, 135, 138, 252].

25.8.2 Foscarnet

Compared with intravenous ganciclovir and oral valganciclovir, there is limited clinical data on the use of foscarnet for the primary treatment of CMV disease in solid organ transplant recipients [233, 277, 347]. Because of the high risk of toxicity, foscarnet should be reserved for patients intolerant of ganciclovir (such as in cases of severe leukopenia not responsive to granulocyte colony stimulating factors) or for those who failed ganciclovir therapy as a result of drug-resistance. Because foscarnet does not require *UL97* phosphotransferase-mediated chemical modification for antiviral activity (see Antiviral Resistance below), it is the drug of choice for the treatment of *UL97*-mutant ganciclovir-resistant CMV disease [233, 277, 347]. Foscarnet is administered intravenously at a

dose of 60 mg per kg every 8 h (or 90 mg/kg twice daily); patients with renal insufficiency require dose adjustment. The major adverse effects of foscarnet are nephrotoxicity (e.g., acute tubular necrosis, interstitial nephritis, or the precipitation of crystals in the glomerular capillaries), hemorrhagic cystitis, urethral ulcerations, anemia, hyperphosphatemia, hypophosphatemia, hypercalcemia, hypocalcemia, hypomagnesemia, nausea, vomiting, and seizures [348]. The high incidence of electrolyte disturbances warrants aggressive monitoring and repletion, as needed.

25.8.3 Ganciclovir-Foscarnet Combinations

Small studies have investigated combined therapy with ganciclovir and foscarnet on the basis of in vitro data that suggest these agents have synergistic antiviral activity [349]. An small observational study on solid organ transplant recipients suggest that combined ganciclovir and foscarnet, with each administered at half doses, is effective in treating ganciclovir-resistant CMV infection [350]. However, a larger trial that evaluated a mixed group of bone marrow and solid organ transplant recipients demonstrated that the adverse events were more commonly observed among those patients receiving combination therapy, even at reduced doses, than among those receiving a single drug [351]. Moreover, when half doses are used, the risks associated with lower serum drug concentrations, such as fostering drug resistance, must be considered. Current guidelines do not recommend their use for the treatment of CMV disease [121].

25.8.4 Cidofovir

Cidofovir, a phosphonomethoxy analogue of cytosine, is used much less commonly than ganciclovir and foscarnet for the treatment of CMV disease in solid organ transplant recipients [121, 277]. Its long half-life offers the benefit of convenient once weekly dosing frequency. However, its nephrotoxicity has limited its clinical use. As with ganciclovir and foscarnet, it acts by inhibiting *UL54 (pol)*-encoded CMV DNA polymerase [277]. Like foscarnet, cidofovir does not require *UL97*-mediated phosphorylation for its activation and could potentially be used for the treatment of *UL97*-associated ganciclovir resistant CMV disease [277]. Mutations in DNA polymerase (*UL54*), however, would potentially confer cross-resistance among the three anti-CMV drugs [277].

25.8.5 Immunoglobulin Preparations

CMV hyperimmunoglobulin was used for the treatment of CMV infection before the availability of ganciclovir and other effective antiviral agents [332, 337, 339, 352]. However, data on its efficacy for the treatment of CMV disease, when effective antiviral drugs are standard of care, is conflicting. While some investigators found it ineffective in the treatment of CMV disease [353], others report potential efficacy as adjunct to antiviral therapy in patients with severe CMV disease [121, 334, 354]. One study reported that the combination of CMV immunoglobulin with intravenous ganciclovir was efficacious in the treatment of CMV disease [355]. However, the lack of large randomized, controlled studies addressing its efficacy, the expense of immunoglobulin, and the current availability of effective and less expensive antiviral drug alternatives have limited its widespread clinical use. Nonetheless, combinations of antiviral drugs and immunoglobulin therapy may be useful in certain subsets of patients, particularly in transplant recipients presenting with severe CMV diseases such as CMV pneumonitis [56, 123, 233, 249].

25.8.6 Adoptive CMV-Specific T-Cell Therapy

Because CMV-specific cell mediated immunity is required to control CMV disease, a strategy to boost CMV-specific immunity after solid organ transplantation may have a beneficial effect in decreasing CMV disease. Studies have correlated CMV disease with a lack or diminished CMV-specific T cells [321]. Thus, expanding the number and function of virus-specific cytotoxic T-lymphocytes could reduce the incidence of CMV disease, although this approach remains investigational. There is more clinical experience of this approach in allogeneic hematopoietic stem cell transplant recipients, but adoptive transfer of CMV-immune T cells have been used in a series of solid organ transplant recipients with multidrug-resistant CMV infection [356, 357].

25.8.7 Novel and Off-Label Therapeutics

Several novel drugs are currently being tested for their efficacy against CMV in solid organ transplant recipients. A lipid formulation of cidofovir, brincidofovir (CMX001), acts by inhibiting *UL54 (pol)*-encoded CMV DNA polymerase. In contrast to the nephrotoxic intravenous cidofovir, brincidofovir is given orally and does not exhibit renal toxicity [358]. It is currently undergoing clinical trials in transplant recipients with early phase studies in hematopoietic stem cell transplant recipients [358].

Letermovir is a novel drug that is currently in phase III clinical trials for the management of CMV disease in solid organ transplant recipients [359, 360]. It acts by inhibiting the viral terminase complex, which occurs at a step later than DNA synthesis, and prevents the incorporation of the CMV DNA molecules into viral capsids. Letermovir has been tested in a phase IIa clinical trial in a small cohort of kidney recipients, where it was found to be safe and with potential efficacy that is comparable to the standard preemptive treat-

ment of CMV infection [359]. Its main toxicities are nausea, vomiting, and diarrhea [359, 360].

Maribavir is a benzimidazole drug that inhibits *UL97* of CMV. Results of early clinical trials have been inconsistent. While the results of a phase II clinical trial in hematopoietic stem cell transplant recipients showed safety and potential efficacy [361], a phase III trial demonstrated it is less active than oral ganciclovir for preventing CMV disease in CMV D+/R− liver recipients [362]. However, maribavir has been used anecdotally, with some success, for the treatment of a series of multidrug-resistant CMV disease cases in solid organ transplant recipients [363, 364]. After a temporary halt in its clinical development as a result of the disappointing phase III trials, maribavir has resumed its clinical evaluation for the treatment of CMV disease in solid organ transplant recipients.

The antimalarial drug, artesunate, has been used off-label for the treatment of CMV disease in transplant recipients, but with inconsistent results [365, 366]. Leflunomide, a pyrimidine synthesis inhibitor, has also been used to treat a series of cases with multidrug-resistant CMV infection, but also with inconsistent results [367].

25.9 Antiviral Resistance

Drug resistance has emerged as an important clinical problem in solid organ transplant recipients with CMV disease. Drug resistance has been observed against all approved antiviral agents (ganciclovir, cidofovir and foscarnet) but the most common form involves resistance only to ganciclovir.

The major mechanisms underlying phenotypic resistance to ganciclovir are specific mutations in *UL97* kinase and less commonly, *UL54 (pol)* DNA polymerase [273, 368, 369]. Mutations in *UL97* kinase that confer ganciclovir resistance involve amino acid substitutions or deletions in specific regions of *UL97* (codons 460, 520, 590–607), and are associated with varying levels of phenotypic resistance [273]. The seven most commonly reported *UL97* mutations are M460I, M460V, H520Q, C592G, A594V, L595S, and C603W [370]. *UL97* encodes for a viral kinase that catalyzes the first step in the triphosphorylation of ganciclovir into the active ganciclovir triphosphate. The net effect of *UL97* mutations is an absent or low level of triphosphorylated (active) ganciclovir within CMV infected cells, and a resultant decreased inhibition of viral DNA polymerase. Depending on the type of *UL97* mutation, it may result in low-level or high-level resistance to ganciclovir [370]. Since *UL97* kinase is not involved in the pharmacodyamics of foscarnet and cidofovir, *UL97* mutations do not confer cross-resistance to cidofovir or foscarnet. Much less commonly, antiviral drug resistance may be conferred by mutations in *UL54 (pol),* which encode for CMV DNA polymerase. Isolated *UL54 (pol)* mutations are observed rarely, and they occur more commonly as second step mutations, after mutations in *UL97* have already occurred. Because *UL54 (pol)* encodes for the polymerase target of all three drugs, there is potential cross-resistance among ganciclovir, foscarnet and cidofovir in patients infected with *UL54*-mutant CMV strain [271, 272, 281, 283, 368, 370–374]. The degree of cross-resistance will vary depending on the *UL54* codon segment that is affected [370]. Cross-resistance is more often observed between ganciclovir and cidofovir, compared to ganciclovir and foscarnet [370]; hence, foscarnet is the first-line agent when ganciclovir resistance is suspected [121].

The single most important variable associated with drug-resistant CMV is a CMV D+/R− mismatch status. The vast majority of solid organ transplant recipients with ganciclovir-resistant CMV infection have been CMV seronegative prior to transplant [271, 272, 281, 373–375]. The estimate, among CMV D+/R− patients, of ganciclovir resistance in various studies has been 5–10%. Other factors associated with ganciclovir resistance are high viral load, augmented immunosuppression, and prolonged low-level antiviral drug exposure [374]. The incidence is also higher in lung and pancreas compared to other organ transplants, potentially reflecting the severity of drug-induced immune suppression [374].

There is an apparent fitness disadvantage of drug-resistant mutant CMV [105, 106], but these strains do not loss their replication ability and they remain fully pathogenic based on reports of progression to clinical disease despite full-dose ganciclovir therapy, demonstration of resistant strains directly in diseased tissue, and an association of resistant strains with the full spectrum of clinical CMV disease seen with wild-type susceptible strains [272, 376]. In addition, there is an association between drug-resistant CMV and higher morbidity [281, 375] and decreased survival [281, 282, 375, 377], when compared to wild-type susceptible CMV strains.

Antiviral resistance should be suspected in transplant recipients with risk factors (as discussed above) and an inadequate virologic and/or clinical response after 2 weeks of full-dose antiviral therapy. Historically, the diagnosis of antiviral resistance had been confirmed by demonstration of decreased susceptibility of clinical viral isolates by plaque reduction or other methodologies. However, these assays are cumbersome and have slow turnaround time, lack standardization, and thus have limited clinical availability. Currently, genotypic assays for *UL54* and *UL97* mutations directly from clinical specimens are the diagnostic tests of choice when drug-resistant virus is suspected in the clinical setting [121, 378, 379].

Treatment of drug-resistant CMV is based largely on expert opinion, and data to support the practice is supported mainly by anecdotal experiences. The choice of empiric antiviral therapy should account for theoretical considerations such as prior antiviral drug exposure, severity of disease, concurrent medical conditions (renal function), the organ transplanted, and degree of immunosuppression. In general, these patients should undergo reduction in pharmacologic

immunosuppression, if feasible. Depending on the disease severity and other risk factors, the initial empiric regimens have mostly included a switch to foscarnet therapy for those with severe symptoms [208, 281, 380]. Foscarnet is the preferred empiric choice for treatment of ganciclovir-resistant CMV strains, since *UL54 (pol)* mutation commonly confers cross-resistance between ganciclovir and cidofovir [370]. Mild clinical disease may be empirically treated with higher than standard regimens of intravenous ganciclovir (as high as 7.5–10 mg/kg every 12 h) [381]. Other treatment interventions have included adjunctive intravenous immunoglobulin or CMV-hyperimmunoglobulin [272, 281], leflunomide [380, 382–384], artesunate [367], and switch to sirolimus immunosuppression [385]. Alternative antiviral agents in various stages of clinical development that have shown in vitro activity against ganciclovir-resistant CMV strains are brincidofovir, letermovir, and maribavir. Definitive antiviral therapy can be chosen as directed by *UL97* and *UL54* genetic testing. As with the treatment of many transplant-related opportunistic infections, it is highly recommended that a reduction in pharmacologic immunosuppression be undertaken to complement the management of drug-resistant CMV disease.

Epstein–Barr Virus Infection and Lymphoproliferative Disorders After Transplantation

Jutta K. Preiksaitis, Sandra M. Cockfield, and Anthea C. Peters

Epstein–Barr virus (EBV) is among the most successful of human pathogens, infecting virtually the entire human population and persisting throughout the lifetime of its host. Having coevolved with man over millions of years, infection with EBV is most often benign despite the fact that EBV is one of the most potent transforming viruses in vitro and is the prototypical human tumor virus. EBV is strongly associated with the development of a wide variety of neoplasms, including lymphoid tumors such as Burkitt lymphoma, Hodgkin lymphoma, T and/or natural killer (NK) cell lymphoma, and immunosuppression-related lymphoproliferative disorders, epithelial malignancies such as undifferentiated nasopharyngeal carcinoma and a distinct subset of gastric carcinomas, and a smooth muscle tumor, leiomyosarcoma [1, 2].

EBV's ability to persist in the host, establish latency, and transmit infection arises from a finely balanced equilibrium between the virus and the host's immune response, particularly the EBV-specific cytotoxic T lymphocyte (CTL) response as reviewed by Taylor et al. [3]. In recipients of hematopoietic stem cell transplants (HSCTs) and solid organ transplants (SOTs), the use of increasingly potent and T cell-targeted immunosuppression disrupts this balance in favor of the virus. The proliferation of EBV-infected lymphoid cells that may result leads to a highly diverse spectrum of disease known as posttransplant lymphoproliferative disorders (PTLD) [4, 5]. PTLD has emerged as an increasingly important complication that affects both graft and patient survival.

In this chapter, the term PTLD is used to describe all clinical syndromes arising from lymphoproliferation, both driven by EBV and of unknown etiology, ranging from a benign self-limited form of polyclonal proliferation to true malignancies containing clonal chromosomal abnormalities, consistent with the World Health Organization (WHO) lymphoma classification system [6]. PTLD requires pathology for definitive diagnosis, but EBV can cause symptoms and signs in SOT and HSCT recipients in the absence of mass lesions. These syndromes are often designated as EBV "disease" when laboratory evidence for EBV infection exists and other causes have been eliminated. This chapter reviews the pathogenesis of EBV-associated disease and PTLD, the risk factors for PTLD development, and strategies that may permit early diagnosis, management, and prevention of this complication.

26.1 The Biology of Epstein–Barr Virus Infection

EBV, a herpesvirus of the γ (gamma)-1 or lymphocryptovirus genus, is an enveloped icosahedral virus with a 170–180 kb linear double-stranded DNA and a primate-restricted host range [1]. Transmission of EBV infection occurs primarily by saliva exchange. In the lower socioeconomic strata and developing nations, EBV infection is almost universally acquired in early childhood and is usually asymptomatic. Infants appear to be relatively protected from infection very early in life; passive maternal antibody may play a role [7]. In industrialized nations, particularly among the upper socioeconomic strata, subjects are often infected in adolescence and early adult life. A recent prospective study of EBV-naïve college students experiencing primary EBV found that only 11% were asymptomatic, with 77% experiencing the infectious mononucleosis syndrome [8]. Infectious mononucleosis is believed to be an immunopathological disease where symptoms are the result of an exaggerated T-cell response to a self-limited lymphoproliferative process. Although maturation of the immune system or heterologous immunity may contribute to the increased T-cell activation, other risk factors for symptomatic disease may include the initial viral inoculum, viral type (type 1 vs. type 2), and polymorphisms of HLA class 1 and immune response genes [3, 9, 10]. Even in Western industrialized societies, more than 90% of the population has immunity to EBV by the age of 40.

The naïve B cell is the primary target of EBV and the memory B cell is the site of EBV persistence. Host–pathogen détente is achieved with ongoing low-grade replication

P. Ljungman et al. (eds.), *Transplant Infections*, DOI 10.1007/978-3-319-28797-3_26

TABLE 26-1. Epstein–Barr virus transcription programs found in vivo

Latency	Genes expressed	Proposed function	Expression site normal host	Associated malignant conditions
Growth program (latency III)	*mRNA* EBNA-1,2,3s, LP LMP-1 LMP-2A, 2B *Noncoding RNA* EBERs BART miRNA BHRF1 miRNA	Activates a resting B cell to become a proliferating lymphoblast	Naïve B cell of tonsil	Immunodeficiency (congenital, HIV, PTLD[a])-related lymphoproliferative disorders
Default program (latency II)	*mRNA* EBNA-1 LMP-1 LMP-2A *Noncoding RNA* EBERs BART miRNA	Provides necessary survival signals for: 1. Infected lymphoblasts to differentiate into memory, and 2. Maintenance of persistently infected memory cells	Germinal center and memory cells of the tonsil	Hodgkin lymphoma, nasopharyngeal carcinoma, T-cell lymphoma, PEL
(Latency 1)	*mRNA* EBNA-1 *Noncoding RNA* EBERs BART miRNA	Ensures replication of viral genome during cell division	Dividing memory cells in peripheral blood	Burkitt lymphoma
Latency program (latency 0)	*Noncoding RNA* EBERs BART miRNA	Allows virus persistence in resting recirculating memory cells in nonpathogenic form, not detectable by the immune system	Memory cells in peripheral blood	
Lytic program	>80 Genes expressed	Viral replication Immune evasion by expression of proteins that modulate immune cell function, antigen presentation or apoptotic pathways	Plasma cells of the tonsil, oropharyngeal epithelial cells	Expressed within a minority of cells within most EBV-positive PTLD (diffuse large B cell lymphoma)

EBNA Epstein–Barr virus nuclear antigen, *EBER* EBV-encoded RNA, *BARTs* Bam H1 rightwards transcripts, *LMP* latent membrane proteins, *HIV* human immunodeficiency virus, *PTLD* posttransplant lymphoproliferative disorder, *PEL* primary effusion lymphoma.
[a]At an individual cell level in PTLD, latency patterns may be more variable with some cells expressing latency I, II, or a pattern that includes expression of EBNA-2 but not LMP-1 (designated as latency II-b).

in the oropharynx occurring simultaneously with a latent infection of B cells in the peripheral blood and lymphoid tissues despite the presence of strong humoral and cell-mediated immune responses to the virus. Both a "direct infection" model [1, 11] and a "germinal center" model have been used to explain persistent EBV infection [12, 13]. Controversial and unresolved issues in the theoretical models exist and have been discussed elsewhere [1, 11, 13]. In the germinal center model explained here, EBV usurps normal physiologic B-cell responses by expressing different gene "programs" depending on the location and differentiation state of the B cell (Table 26-1).

Infection of susceptible naïve B lymphocytes occurs primarily within the follicular mantle of the tonsil after the virus replicates in or is transcytosed across epithelial cells. B-cell infection requires binding of the major EBV outer envelope glycoprotein gp350/220 with the cellular complement receptor C3d (also known as CD21 or CR2) and gp42 with the major histocompatibility complex (MHC) class II molecule. Cell fusion is mediated by gH, gL, and gB (reviewed by Ref. [14]). The viral DNA is transduced into the cell in a naked, chromatin-free state and in the initial prelatent phase, an abortive lytic infection occurs that is believed to play a role in initial B-cell activation, cell cycle entry and immune evasion (reviewed in Ref. [15]). The viral DNA is circularized (episome) and methylated. This is followed by expression of a limited subset of latent viral genes as the "growth program" (latency III) as reviewed in Refs. [1, 12] (Table 26-1). This efficiently drives the B cells to become activated proliferating lymphoblasts by mimicking the signals of T-helper (TH) cells, antigen-presenting cells, and regulatory cytokines usually required for B-cell activation.

Proliferating blasts are not ordinarily a pathogenic threat because these cells migrate to the follicle, go through a germinal-center reaction, and then differentiate out of the cell cycle into a resting state by becoming a memory B cell [12, 13]. This requires a switch to the "default program" (latency II) (Table 26-1). Thus, the latently infected B cell

survives activation to enter the peripheral blood as a $CD27^+$ $sIgD^-$ memory B cell (mB_{Lat}), phenotypically resembling a cell that has undergone antigen selection. It contains one to two genome copies per nucleus and contains EBERs and BART miRNAs but expresses no EBV proteins (latency 0) and is invisible to the immune system. However, expression of EBNA-1 (latency 1) is required to tether the episome to the host chromosome to ensure its mitotic segregation during cell division.

Two latent EBV proteins, LMP-1 and LMP-2A have garnered significant interest, both for their role in moving EBV-infected cells to and allowing their survival throughout the germinal center process (reviewed in Ref. [13]) and their possible contribution to lymphomagenesis (reviewed in Refs. [16–18]). LMP-1 acts as a functional homolog of constitutively active CD40 and binds to several intracellular proteins activating the P13k/Akt, NF-kB, Jak/STAT, p38, and ERK MAPK pathways driving B-cell proliferation and survival. LMP-1 also modulates genes involved in cytokine expression (IL-6, IL-10, 1L-8), induces B-cell activation markers (CD23, CD30, and adhesion molecules) and inhibits apoptosis through induction of bcl-2, A20, and c-FLIP. LMP-2A prevents lytic reactivation of EBV in latently infected cells by blocking tyrosine kinase phosphorylation and mimics the nonproliferative tonic signal delivered by the B-cell receptor essential for the survival of all B cells.

Studies of EBV viral load (VL) in the peripheral blood of immunocompetent patients are limited making it difficult to define "normal" VLs during acute infection; adolescents and young adults with infectious mononucleosis have been studied most. In this setting, peak VLs are believed to antecede clinical symptoms, and as many as 10% (more commonly 0.1–1%) of circulating B cells are EBV-infected representing a staggering 50% or more of all memory cells [19]. These numbers decay rapidly (average half-life 7.5 days) through memory B-cell homeostatic mechanisms and/or culling by the CD8 T-cell response [20, 21]. EBV DNA is no longer detectable in plasma by day 15 after onset of symptoms [22]. Within a year there are only 1–60 per million EBV-infected B cells in the peripheral blood of healthy seropositive subjects [20]. This "set point" level remains stable over many years. Whether ongoing seeding of the memory compartment by recurring cycles of infection is required to maintain this equilibrium is uncertain [23]. Using assays that do not detect these low set point levels, Balfour found EBV DNA had cleared from the blood of almost all seroconverting college students by 200 days (median 95 days) [8]. VL data from immunocompetent preadolescent children are sparse [21] and data in infants are limited to studies of African children where infection at a very young age (<6 months) was associated with higher and more persistent VLs [7, 24].

The major site of infectious virus production is the oropharynx. Lytic gene expression is triggered when mB_{Lat}s differentiate into $CD38^{hi}$, $CD10^-$, $CD19^+$, $CD20^{lo}$ plasma cells [25], migrate to mucosal epithelium, and secrete infectious virus into saliva. During the lytic cycle, the EBV genome is linear, and more than 80 viral genes are sequentially expressed under the control of two potent transactivators BZLF1 and BRLF1. These genes play a key role in the switch from latency to the lytic cycle; the epigenetic state of EBV DNA controls this switch (reviewed in Ref. [26]. Lytic genes include two immediate early (IE) proteins that transactivate early gene expression, >30 early (E) proteins that include components of the viral DNA replication complex, and >30 late proteins that include virion structural proteins [1]. The triggers that initiate differentiation and viral replication in mB_{Lat}s in vivo are incompletely understood [26]; whether cognate antigen is required is unknown.

Despite the fact that epithelial cells lack CR2 and constitutively expressed MCH class II, they are an important site for replication and amplification of EBV as a result of either direct infection or infection by contact with lytically infected B cells. Epithelial cell entry does not involve gp42 or HLA II but rather involves the interaction of gH/gL with cell surface integrins [14]. EBV shedding in the saliva of seropositive individuals is continuous and rapid [27]. Quantitative levels in saliva do not directly correlate with numbers of mB_{Lat}s in peripheral blood [8, 27]. EBV-infected cells secrete exosomes, small vesicles important in intercellular communication that may modify the cellular microenvironment, by inhibiting immune cell function or stimulating angiogenesis (reviewed in Ref. [28]). They are found in high levels in human saliva.

Forty-four miRNAs encoded by two regions within the EBV genome, BART and BHRF1, have been described (reviewed in Refs. [29, 30]). Expression is influenced by tissue and latency type. Although viral genes targeted by EBV miRNAs include EBNA-2, LMP-1 and BHRF-1, the majority of viral miRNA target human transcripts including those involved in apoptosis and immune modulation/evasion pathways. Viral miRNAs work in networks with human miRNAs to co-target the same transcripts. The role of viral miRNAs in EBV biology and the pathogenesis of malignancy is the subject of ongoing study.

EBV isolates comprise two major groups, EBV-1 and EBV-2 (also named types A and B), based on the allelic polymorphism of genes encoding EBNA-2, EBNA-3A, EBNA-3B, EBNA-3C, and EBNA-LP. EBV-1 predominates throughout the world whereas EBV-2 is equally prevalent in Africa and New Guinea. Further subclassification systems based on polymorphisms in LMP-1, EBNA-2, EBNA-3s, and BZLF1 have been used to examine the impact of strain variability on virus tropism, immune response, and oncogenesis. However, it has been difficult to clearly link EBV genotype variants to specific clinical disease states as reviewed by Hatton [16]. Transmission of EBV is complex with simultaneous transmission of multiple strains, reinfection events and strain evolution. In individual patients, different strains may exist within distinct biologic compartments such as the oral cavity, peripheral blood lymphocytes (PBL), and plasma [31–34].

26.1.1 The Normal Immune Response to Epstein–Barr Virus Infection

The immune response to EBV infection is the result of a complex interaction between humoral and cell-mediated responses, in the face of a significant number of viral immune evasion strategies (as reviewed in Refs. [3, 16, 35]).

There is emerging evidence that natural killer (NK) cells play a significant role in controlling EBV infection (reviewed in Ref. [36]). Phenotypically and functionally distinct NK subsets are found in lymphoid tissue such as the tonsil in comparison to peripheral blood. In the tonsil, less mature $CD56^{bright}$ CD16– cells produce high levels of γ (gamma)-interferon; these cells are believed to reduce or prevent B-cell transformation by EBV. NK cells with intermediate differentiation ($CD56^{dim}$ CD16–) expand in peripheral blood during acute EBV infection and preferentially target cells expressing lytic antigens [37].

Both neutralizing and non-neutralizing antibodies directed against a variety of virally encoded products, many of which persist throughout the lifetime of the host, are generated in response to infection. Neutralizing antibodies may function by limiting the spread of cell-free virus, preventing superinfection with other virus strains, and rendering lytically infected cells susceptible to antibody-dependent cell-mediated cytotoxicity [3]. However, despite the presence of such antibodies, viral replication continues in the oropharynx.

EBV-specific $CD4^+$ and $CD8^+$ CTLs play a particularly crucial role in controlling the infection level during both acute and persistent infection. Even in the peripheral blood of healthy EBV-seropositive subjects, 0.2–2% of the $CD8^+$ population is directed against EBV lytic epitopes with up to 0.5% directed against latent epitopes. During acute infection, there is a highly amplified $CD8^+$ CTL response against lytic antigens that peaks and decays, while the latent antigen-specific response is slower, smaller, and less heavily culled. $CD4^+$ responses are much smaller. Marked hierarchies of immunodominance exist for both lytic and latent antigens with lytic CTL responses focused on IE and E antigens. Lytic and latent antigen $CD8^+$ cells vary in the recovery of migration markers after acute infection. This results in different rates of migration into the tonsil and temporal differences in controlling lytic and latent infections [3], explaining the high levels of virus detected in the oropharynx for >6 months after acute infection.

EBV has also evolved diverse strategies to evade the immune system that include modulation of immune cell function, antigen presentation and apoptotic pathways (reviewed in Refs. [16, 35]). During the lytic cycle, EBV encodes a number of proteins with functional homology to human proteins. BCRF-1 is a homolog of human IL-10, that appears to have retained the immunosuppressive but not immunostimulatory functions of its human counterpart, promoting viral persistence by inhibiting interferon (IFN)-γ (gamma). BARF-1, homologous to colony-stimulating factor 1, acts as a decoy receptor to block the action of this cytokine inhibiting the expression of IFN-α (alpha). EBNA-1 is poorly recognized by CTL because of a long glycine–alanine repeat that inhibits proteasomal processing and MHC class 1 presentation. In addition, a number of proteins expressed during the lytic cycle (BNLF2a, BGLF5, BILF1) inhibit discrete stages of the MHC class I and class II antigen presentation pathways. Latent proteins LMP-1 and LMP-2A perturb apoptotic pathways allowing survival of cells that would normally die in the germinal center process. The lytic antigen, BHFR-1 encodes a homolog of Bcl-2 capable of inhibiting apoptosis induced by multiple stimuli. EBV exosomes and miRNA may also contribute to immune evasion.

Regulatory T cells (T regs) developed during the course of the immune responses provide a counterbalance to immune T-cell activation, protecting the body from pathogen-induced immunopathology. Preliminary evidence exists that T regs are induced during the course of acute EBV infection in both immunocompetent hosts [38] and SOT recipients [39]. They may also play an important role in some EBV-associated malignancies including Hodgkin lymphoma and nasopharyngeal carcinoma [40].

26.1.2 Epstein–Barr Virus Infection After Solid Organ and Hematopoietic Stem Cell Transplantation

Primary EBV infection is very common in the EBV-seronegative patient who receives a transplant from a seropositive individual [41] or HSCT [42], making the donor the most important source of infection in this setting. How the biology of EBV is altered when virus is transmitted though latently infected B cells in the donor organ or hematopoietic stem cells rather than saliva is uncertain. Although a case of transfusion-acquired EBV infection has been described in a liver transplant recipient [43], the risk of transfusion-acquired EBV after transplantation is uncertain but likely low, particularly when blood products are universally leukoreduced. Community-acquired EBV infection is common in young children, adolescents, and young adults [8, 44] and will continue to occur in the transplant setting [45].

Studies of the prevalence/incidence of EBV DNAemia in transplant recipients are difficult to compare because of differences in the characteristics of the populations studied, assays and sample type. In EBV-mismatched (donor positive/recipient negative) SOT patients, EBV DNAemia detection in whole blood ranged from 33% [46, 47] to 100% [41]. In seropositive adults, EBV VL detection in whole blood is highly prevalent and may increase with time after transplant. Reported rates of detection in adult SOT recipients vary from 13 to 72% [48–52]. In a recent study of allogeneic HSCT recipients, the 3-year cumulative incidence of EBV DNAemia measured in plasma was 31.1%; use of antithymocyte globulin (ATG) and intensified conditioning were

identified as risk factors for its occurrence [53]. Umbilical cord blood (UCB) stem cells should not be EBV-infected or transmit EBV. However, EBV DNAemia has been observed in this setting particularly when reduced intensity conditioning (RIC) is used. This likely reflects reactivation of recipient virus. Since PTLD cases in this setting are donor-derived, recipient virus must infect donor cells. The absence of EBV-specific T cell responses in naïve UCB donors combined with T cell depletion can result in rapid uncontrolled proliferation of EBV-infected cells in this setting [54–56].

EBV DNA in the peripheral blood of transplant recipients is strongly cell associated, particularly in the SOT setting, and is usually found exclusively in memory B cells [57, 58] including $IgD^{+}CD27^{+}$ memory B cells that appear to have non-germinal center origins [58]. In some HSCT patients with high VL, EBV DNA has been found in cells lacking B, T, NK, plasma cells, and monocyte markers [59]. In contrast to the latency 0 EBV gene expression observed in the memory B cells of immunocompetent EBV seropositive patients, several investigators found both "growth/latency III" and lytic gene expression surprisingly frequently in the peripheral blood of non-PTLD SOT patients although this expression was transient; these patterns appear to predominate early after transplant [60].

Over 20 years ago several investigators studying SOT and HSCT recipients observed that peak EBV VL measured in PBL or oropharyngeal excretions was higher in primary infection than in reactivation infection and in patients who went on to develop PTLD vs. those who did not; these high levels antedated clinical symptoms. Assays measuring EBV DNA, most commonly using quantitative real-time PCR technology, have been implemented internationally to prevent, diagnose and monitor PTLD treatment, for safety monitoring in clinical trials of new immunosuppressive agents, and for tailoring immunosuppression in individual patients. However, the evidence to support the clinical utility of these assays in many settings is suboptimal (reviewed in Refs. [61–63]).

With more extensive use of VL monitoring a number of investigators observed that many SOT recipients with asymptomatic primary EBV infection or recovering from EBV disease or PTLD have altered EBV "set points" with sustained and elevated EBV VLs in peripheral blood for >6 months, often lasting many years. These patients have been described as having a chronic viral load phenotype (CVLP). Although a study in pediatric thoracic SOT suggests that 45% of CVLP patients developed late onset EBV-positive PTLD at a median follow-up of 7 years [64], the risk appears, in part, to be organ-specific. Intermediate risks have been observed after intestinal SOT [65] with lower risks reported in liver [66] and kidney transplant recipients [41, 67]. However, even among specific allograft types, reported long-term risks vary among centers [66, 68]. Both the prognosis of the CVLP state and its pathogenesis remains uncertain. Recipient HLA [67] and cytokine gene polymorphisms [69] have been suggested as possible risk factors for CVLP. Even in patients with CVLP, EBV DNA is most often B cell-associated [70, 71] although virus was also observed within T cells and monocytes in some patients [71]. In pediatric SOT patients with high VL, Schauer et al. [72] found that up to 30% of EBV-infected cells were aberrant "crippled" or "forbidden" Ig-null cells containing 30–60 genomes/nuclei. Although the results EBV gene expression profiling in CVLP patients [67, 70, 71, 73] are variable, most studies confirm that these patients express a latency 0 pattern with some expressing LMP-2; LMP-1 expression is rare [67, 70, 71]. The number of EBV-specific CD8 cells in these subjects is high [47, 70, 74, 75] but Macedo et al. [74] observed signs of cellular exhaustion (programmed cell death (PD1)+/CD 127− and a decline in γ (gamma)-interferon release) in these cells. In contrast, Moran et al. [75] recently reported a similar frequency of PD1 expression on EBV-specific T cells in CVLP patients vs. those who resolved infection.

Although high levels of antibody to EBV lytic cycle (anti-viral capsid antigen [VCA] IgG and anti-early antigen [EA]) are often seen in SOT and HSCT recipients, serologic responses seriously underestimate infection. SOT patients with the poorest responses or antibody loss (anti-EBNA-1) may be at increased risk of developing PTLD [76, 77]. Passive antibodies from blood products further complicate the interpretation of humoral immune responses in these settings.

26.2 Pathogenesis of Lymphoproliferative Lesions in the Immunosuppressed Host

Although almost all transplant recipients are either infected with EBV pre-transplant or experience primary EBV infection in the early posttransplant period, lymphoproliferative disorders remain a relatively uncommon event. A wide spectrum of PTLD disease states is seen, particularly in the SOT setting. The frequency of specific types of PTLD varies with time after transplant and EBV's role in their pathogenesis may differ [11]. Immunodeficiency, particularly in EBV-specific innate and adaptive responses, is an important contributor to early PTLD but other factors likely participate.

A conceptual framework caller "cancer immunoediting" has been developed to integrate the immune's system's dual role in cancer. It not only suppresses cancer by destroying or inhibiting cancer cells, but also promotes cancer by selecting for cells that escape immune surveillance or creating a tumor microenvironment that facilitates tumor outgrowth [78]. Three phases of cancer immunoediting have been described—elimination, equilibrium, and escape. Early EBV-positive PTLD is an example of failure of the elimination phase; late PTLD may reflect the latter two phases of this process.

Models for EBV-associated lymphomagenesis have been proposed and are summarized in Figure 26-1 [11, 13, 79].

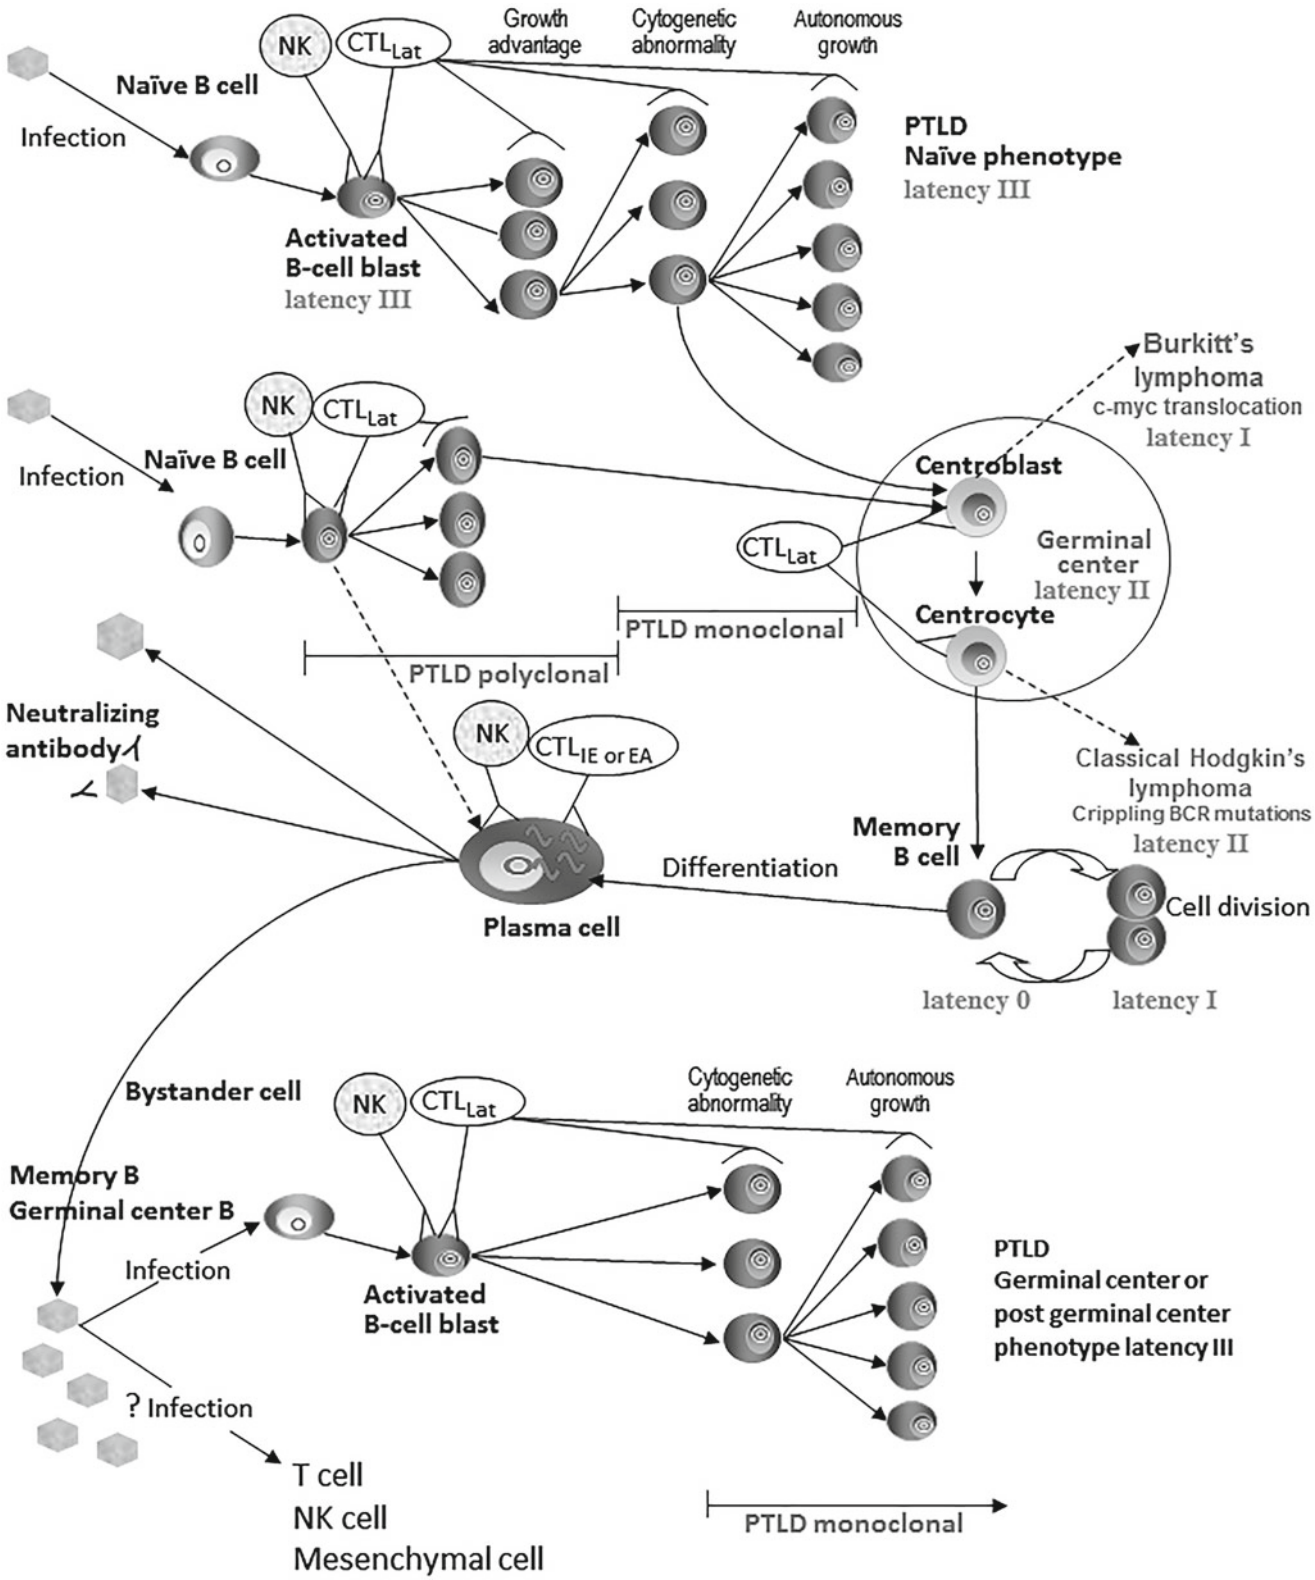

FIGURE 26-1. A model for how Epstein–Barr (EBV) might give rise to posttransplantation lymphoproliferative disorders (PTLDs). Naïve EBV-infected B cells express a repertoire of latent EBV proteins known as "the growth program/latency III," resulting in polyclonal cellular proliferation. Specific clones may have a growth advantage resulting in oligoclonal or monoclonal proliferation. These cells would be cleared by a combination of differentiation into memory cells and killing by EBV-specific cytotoxic T lymphocytes (CTLs). The differentiation to memory cells involves downregulation of latent EBV gene expression from the growth program through a "default program/

When naïve B cells are infected by EBV, they express "the growth program/latency III" resulting in polyclonal cellular proliferation. The local microenvironment may give growth advantage to specific clones resulting in oligoclonal or monoclonal proliferation. The microenvironment encompasses not only immune cells such as T cells, B cells, macrophages; soluble factors such as cytokines and chemokines; but also other cells including endothelial cells, stromal cells, fibroblasts and other viruses (reviewed in Ref. [80]). Variations in the expression of viral genes, host genes transactivated by EBV latent proteins, and virus-induced cytokines such as IL-6 and IL-10 may also drive proliferation. Normally B cells expressing latency III gene products would be cleared by a combination of differentiation into memory cells and destruction by EBV-specific CTLs. In the presence of an impaired immune response, rates of proliferation may exceed rates of clearance and differentiation, leading to clinical presentations with morphology such as plasmacytic hyperplasia and polymorphic PTLD. Genetic or epigenetic abnormalities may also occur, resulting in a more "malignant" form of PTLD. In the transplant setting, particularly with primary infection, delays in the development of the CTL response could result in amplification cycles of new cell infection that continues unabated for significant periods of time and results in the production of enormous virion loads. Chronic B-cell stimulation within the allograft may also increase cycling of cells through the germinal center and possibly lytic reactivation in EBV-infected memory B cells.

Studies of V-gene sequences in PTLD cases suggest that most PTLD is not derived from naïve B cells but have their origin from germinal center and post-germinal center B cells. This dramatically changes theories of pathogenesis. The model has been adjusted by suggesting that de novo EBV infection of these non-naïve "bystander" B cells is an accidental event [12, 79]. When EBV-infected, these cells will express "the growth program," be unable to differentiate out of the cell cycle, and be dependent on the CTL response for destruction. Alternative explanations include the possibility that EBV may be able to impose a memory phenotype without the requirement for a germinal center reaction, or that latently infected germinal center and memory cells fortuitously received signals that caused them to inappropriately turn on the growth program. Failure of a vigorous CTL response to destroy these expanding clones sets the stage for secondary transforming events in the form of genetic and epigenetic alterations in cellular DNA. EBV-positive germinal center B cells may be particularly vulnerable to additional mutation events as this is the site at which somatic hypermutation and class switching occur. Moreover, EBV infection affects both the stability of host genome and DNA damage response pathways [81]. Mutations in viral genes may also alter either critical function or the antigenicity of their protein products, promoting clonal outgrowth.

EBV-1 appears to be more virulent than EBV-2 in promoting lymphoproliferation in vitro and in vivo and PTLD development in vivo. Although epidemiologic and mouse studies suggest that specific strains may be more oncogenic, particularly those with deletion mutations of the carboxy-terminus of LMP-1, or mutations in EBNA3B, a gene that normally might be functioning as a tumor suppressor. However, these data are not conclusive [16, 69]. The post-transplant environment is an ideal setting for the development and selection of these variants because of the opportunity for reinfection events by donor isolates and the high VLs facilitating mutation and recombination events.

How EBV gets into T cells and B cells to cause T and NK cell PTLD is uncertain. It has been suggested that this occurs rarely and only when mature T and B cells are in contact with foci of high EBV replication; ongoing survival of these clones may be dependent on an inflammatory microenvironment [2]. The presence of extremely high levels of infectious virus, particularly during a primary infection, may significantly increase the probability of "accidental" infection of memory and germinal center B cells, T cells, NK cells, and mesenchymal cells that would only very rarely be infected in the immunocompetent host.

FIGURE 26-1. (continued) Latency II" to a transcriptionally silent state in the memory cell (Latency 0). In the presence of an impaired immune response, rates of proliferation may exceed rates of clearance and differentiation, leading to clinical PTLD presentations. Differentiation of EBV-infected B cells into plasma cells results in lytic viral replication, thereby continuing to recruit newly infected cells into the process. NK cells both restrict initial B cell transformation and target lytically infected cells. Mutations may occur during the lymphoproliferation process. If this occurs during the activated B cell blast stage, it results in PTLD with a naïve B phenotype (less common). EBV may provide an anti-apoptotic function to cells lacking functional B cell receptors including those with "crippling mutations" in the germinal-center centrocyte stage, resulting in Hodgkin disease (constitutive expression of the default program), or cells which perhaps because of chronic immune stimulation acquire a c-myc translocation in the germinal-center centroblast stage (Burkitt lymphoma); however, these cells express a virus latency profile similar to dividing memory cells (Latency 1). In the presence of high levels of infectious virus, "bystander" cells, such as germinal-center and memory B cells, that are not normally infected with EBV may become infected. These cells will express the growth program, be unable to differentiate out of the cell cycle, be dependent on the T cell response for destruction, and be vulnerable to mutation events resulting in clinical PTLD (germinal center or post germinal center phenotype, more common). Similarly, accidental infection of T,NK or mesenchymal cells may occur. (Adapted from Thorley-Lawson DA, Gross A. Persistence of the Epstein-Barr virus and the origins of associated lymphomas. N Engl J Med. 2004;350:1328–1337 and Vockerodt M, Ypa LF, Shannon-Lowe C et al. The Epstein-Barr virus and the pathogenesis of lymphoma J Pathol 2015;235:312–322).

Studies of lymphoproliferative disorders in HIV populations suggest that specific types of lymphoma occur at different levels of immunodeficiency, with latency III type lymphoproliferations occurring in the setting of profound immunodeficiency (CD4 T cells <50 cells/ml), Hodgkin lymphoma at intermediate levels (CD4 T cells 50–250 cells/ml) and Burkitt lymphoma in settings with less immunodeficiency (CD4 T cells 250–500 cells/ml) [2]. Whether the same immunodeficiency patterns apply for these types of PTLD is uncertain. EBV's role in Burkitt lymphoma and Hodgkin lymphoma may be to rescue and clonally expand post-germinal center B cells with c-myc mutations (Burkitt lymphoma) or crippling mutations that result in lack of a functional B cell receptor (Hodgkin lymphoma), conditions that would normally have resulted in apoptotic cell death [11]. Increased rates of Hodgkin disease and other HIV-associated lymphoma have been observed in HIV patients with significant initial immunodeficiency within 6 months of receipt of highly active antiretroviral therapy; the presence of immune reconstitution inflammatory syndrome is believed to play a role in lymphoma pathogenesis in this setting [82, 83]. This has not been clearly described in PTLD but might occur in HSCT and SOT settings where there are profound and rapid changes in immunosuppression in the presence of high VLs.

A significant and increasing proportion of PTLD cases late after transplant in the SOT setting do not contain EBV [84]. Suggestions with respect to pathogenesis of these lesions include infection with oncoviruses other than EBV, "hit and run" EBV infection, or coincidental lymphomas identical to those seen in immunocompetent patients [17]. Recently, the importance of chronic inflammation and immune stimulation in lymphomagenesis has been highlighted (reviewed in Refs. [2, 11, 17, 80, 85]). Transplant recipients are particularly vulnerable to this cofactor as a result of chronic graft vs. host disease (GVHD) after HSCT and antibody-mediated rejection as a cause of chronic allograft dysfunction after SOT.

26.3 Epidemiology and Risk Factors for the Development of Posttransplant Lymphoproliferative Disorders

26.3.1 Epidemiology

Immunosuppression in SOT recipients increases the risk of many types of cancer, including those associated with infectious agents, such as Hodgkin and non-Hodgkin lymphomas (NHL) [86–88]. In a large US study, NHLs were among the most common malignancies in transplant recipients, occurring at an incidence of 194 cases per 100,000 person-years (PY) compared to 26 per 100,000 PY in the general population (standardized incidence ratio (SIR) 7.5)) [88]. The overall incidence rate of PTLD after SOT is 1–5% [17], whereas it is lower after HSCT, ranging from 1 to 4% [42, 55, 56, 89]. The incidence of PTLD has likely been underestimated due to limited study follow-up, lack of standardized diagnostic criteria, and the absence of non-monomorphic PTLD in cancer registries.

In kidney and kidney-pancreas transplant recipients, PTLD incidence occurs in a bimodal pattern: an initial peak occurs in the 1st year and a second peak in the 8th to 10th posttransplant years [90–94]. The late peak was not confirmed in non-renal transplants [88]. In sharp contrast, the incidence of PTLD after HSCT peaks at 3 months posttransplant and declines drastically after 6 months [95, 96].

The epidemiology of PTLD has undergone a shift over the past decade. A decrease in the incidence of PTLD has been documented in recipients of renal and non-renal transplants after 2000 even after adjusting for immunosuppressive drugs [90, 97, 98]. The median latency time from transplant to PTLD has increased from 1 to 3 years [99, 100] and EBV-negative PTLD has become more prevalent than EBV-positive PTLD [84]. A decrease in early PTLD (ie. within 1-2 years posttransplant) may account for the overall decline in PTLD incidence; this trend has been attributed to evolving immunosuppressive regimens and EBV VL monitoring with preemptive treatment in seronegative patients [84, 98].

26.4 Risk Factors for the Development of PTLD in Solid Organ Transplantation

Accurate risk stratification for PTLD facilitates the targeting of those at particularly high risk for monitoring and possible preemptive therapy. Although risk factors have been defined, the magnitude of risk attributable to a specific parameter is less clear. Risk factors are often interrelated, requiring rigorous multivariate analysis in large datasets to establish independent effects. Unfortunately, data concerning donor and recipient EBV serostatus, other viral infections, and exposure to immunosuppressive agents is often lacking in registry data. Single center data may provide greater granularity regarding the presence or absence of potential risk factors but lacks statistical power.

26.4.1 Infection with Epstein–Barr Virus and Other Viruses

EBV plays a major pathophysiologic role in the development of almost all early and many late PTLD. Recent analyses have confirmed an observation first made by Ho et al. [101]; patients at risk for primary EBV infection experience a 5- to 18-fold greater incidence of early PTLD compared to seropositive recipients [45, 90, 102–107]. In seropositive individuals, the relative contribution of EBV reactivation vs.

reinfection is unknown. The role of primary EBV infection in late PTLD has been less well studied. However, a case–control study reported a 7.1-fold increased risk of late PTLD in EBV-seronegative adult renal transplant recipients [108] and recent registry analyses suggest increased risk beyond the first posttransplant year [90, 104].

The contribution of other viruses to the risk of PTLD is less clear. Conflicting single-center data exists regarding the impact of CMV mismatching or CMV disease [108–110]. Registry analyses have also reported conflicting results with some reporting no effect [97, 105, 111], a 2.5-fold increase in risk [98] or a modest increase in risk of EBV-negative PTLD only [90]. Missing data is a significant problem, raising concerns that conclusions drawn from registry data may be unreliable. In addition, widespread use of antiviral prophylaxis may have reduced the potential impact of CMV on PTLD risk. Infection with other members of the herpesvirus family may also facilitate the development of PTLD. Human herpesvirus 8 has been linked to serous cavity-based primary effusion lymphoma in recipients of SOT [112].

Hepatitis C virus (HCV) infection may increase the risk of NHL in the general population in certain geographic regions. Liver and cardiac transplant recipients infected with HCV appear to have a 4- to 9.5-fold increased risk of EBV-related PTLD in some [113, 114], but not all studies [110]. Data are lacking regarding the impact of HCV infection in other types of SOT or following HSCT.

26.4.2 The Type of Organ Allografted

The incidence of NHL is highest in intestinal and multivisceral transplant recipients (>10%), followed by lung and heart transplant recipients (3–9%) and lowest for liver and renal recipients (1–3%) (Figure 26-2) [87, 88, 90, 98, 103, 110, 115–117]. In an analysis of the American registry, the SIR of NHL was 6.05 [95% CI 5.59–6.71] for kidney transplant recipients, 7.77 [95% CI 6.99–8.61] for liver recipients, 7.79 [95% CI 6.89–8.79] for heart recipients and 18.73 [95% CI 15.59–22.32] for lung transplant recipients [88]. Registry analyses fail to include intestinal and multivisceral transplant recipients but in a single center analysis of 394 such recipients, the incidence of PTLD was 8% at 6 months, 11% at 1 year, 16% at 5 years, and 27% at 10 years [103]; the majority of cases (71%) occurred during the first posttransplant year with a median time to diagnosis of 5.5 months. The disproportionate number of young pediatric recipients susceptible to primary EBV infection and the relative intensity of immunosuppression may explain the high rates of PTLD in recipients of lung, bowel, and multivisceral transplants. However, it is possible that the amount of lymphoid tissue contained within the allograft and the liberal use of biopsies that detect allograft involvement may contribute.

26.4.3 Recipient Demographics

Most studies have not revealed a gender or racial bias in the risk of PTLD [87, 88, 90, 98, 115, 118]. Recipient age is an important determinant of the risk of PTLD with a U-shaped distribution [87, 88, 98, 115]. In the Collaborative Transplant Study (CTS) registry, those <10 or >60 years of age were at greatest risk [115]. In the American registry, transplant patients aged ≥50 years had the highest incidence of NHL but the SIR was highest in those transplanted under 35 (SIR 46) [88]. A Swedish registry reported a SIR for NHL of 127 for pediatric (age <18) SOT recipients [119]. Similarly, the Australian and New Zealand registry of non-renal transplant recipients reported a SIR for lymphoma of 88.5 in pediatric patients (0–15 years of age) vs. 7.82 in those >15 years of age [87]. High rates of EBV-seronegativity and prolonged immunosuppression confer a high risk to pediatric patients

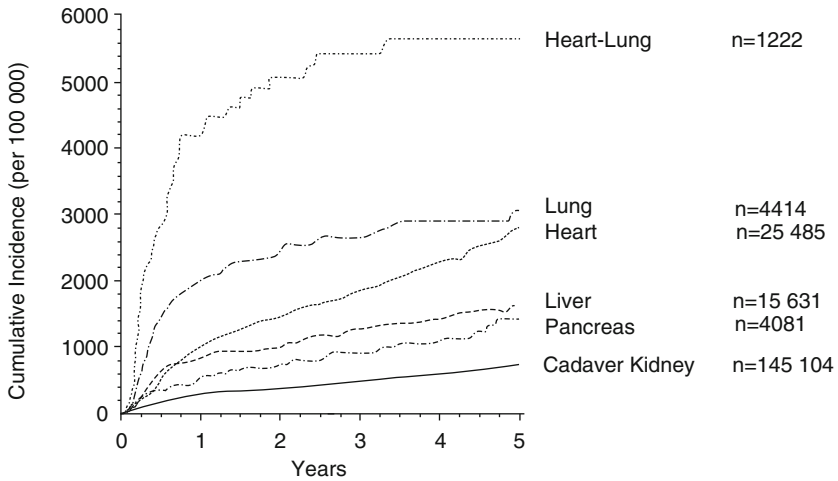

FIGURE 26-2. Five-year incidence of non-Hodgkin lymphomas (NHLs) in organ transplant recipients. Relative risk (RR): heart–lung 239.5, lung 58.6, heart 27.6, liver 29.9, pancreas 34.9, cadaver kidney 12.6 when compared to an age-matched non-transplant population. (From Opelz G, Dohler B. Lymphomas after solid organ transplantation: a Collaborative Transplant Study report. Am J Transplant. 2004;4:222–230, with permission).

[4, 120, 121]. Multi-institutional data in pediatric heart transplantation provides insight as to the complex interaction between recipient age and EBV status [97]. Nearly 25% of EBV-seronegative recipients of EBV-positive donor hearts at age 4–7 years developed some form of PTLD by 5 years posttransplant, although the incidence has declined in the most recent era (2001–2009).

In contrast, older recipient age is a significant risk factor for late PTLD, perhaps due to senescence in immune surveillance exacerbated by immunosuppression [90, 92, 111]. Whether modifications to immunosuppressive protocols in the elderly could ameliorate this risk is unknown. Interestingly, Japanese investigators have described an age-related (senile) EBV-positive lymphoproliferative disorder in immunocompetent individuals that closely resembles PTLD [122].

26.4.4 The Role of Antigenic Stimulation, Cytokine Gene Polymorphisms and HLA

Chronic inflammation may play an important role in the pathogenesis of certain lymphomas as reviewed by Rickinson [2]. The degree of HLA mismatching has not been consistently shown to influence the risk of PTLD, when adjusted for differences in exposure to immunosuppressive medications [90, 91]. However, the alloimmune response may explain the predisposition for PTLD to involve the transplanted organ [103, 115], perhaps facilitating homing, proliferation, and inhibition of apoptosis of EBV-infected recipient B cells. The role of specific HLA antigens on the risk of developing PTLD remains uncertain. Results of studies evaluating the association between HLA alleles and the risk of PTLD have yielded inconsistent findings [84, 106, 123–125], perhaps due to variability in the ethnic makeup of study participants, or the proportion of late or EBV-negative PTLD cases included.

Genetic polymorphisms may determine inter-individual variation in the expression of cytokines, their receptors, or other molecules regulating the response to EBV infection [126]. Results have been inconsistent with respect to the role of low vs. high producer phenotypes for IFN-λ (gamma), TBF-β (beta), or IL-10 on the risk of PTLD [127–129]. Larger studies are required to determine whether cytokine gene polymorphisms or specific HLA alleles determine susceptibility to or the outcome of PTLD.

26.4.5 The Presence and Intensity of the Immunosuppressed State

PTLD was first described as a complication of SOT in the pre-cyclosporine (CsA) era where it presented late and resembled NHL in the immunocompetent population. As immunosuppressive protocols became more potent, complex, and T cell-targeted in nature, a new form of PTLD appeared that is highly associated with EBV infection, occurring earlier after transplant with a tendency to involve the allograft, lymph nodes and gastrointestinal tract. These early lesions are more likely to be polymorphic and respond to reduced immunosuppression. Whether this evolution in the clinical spectrum of disease is the result of widespread use of calcineurin inhibitors (CNI) or reflects the cumulative effects of multidrug protocols is unclear. Fortunately developments in EBV monitoring and preemptive intervention over the last decade have reduced the incidence of this early form of PTLD in SOT.

The lack of randomized controlled trials with sufficient power and long-term follow-up constrains the ability to draw firm conclusions regarding the relative risk of any one agent or regimen. However, anti-lymphocyte antibodies employed for induction or the treatment of acute rejection are associated with a 1.5 to 4-fold increased incidence of early NHL [88, 90, 110, 115]. The subgroup undergoing primary EBV infection is particularly vulnerable [109, 130]. Surprisingly, alemtuzumab, a humanized anti-CD52 monoclonal antibody capable of marked lymphocyte depletion, was not associated with an increased risk of early PTLD in a registry analysis [131]. Whether this is the result of relative sparing of EBV-specific memory T cells or control of the EBV reservoir through concomitant B-cell depletion is unknown.

While the initial experience with CNI suggested an increased incidence of PTLD, lower exposure and improved therapeutic drug monitoring have diminished this risk. There remains controversy as to whether there is still a significant difference in risk between CsA and tacrolimus (TAC) [90, 98, 115]. Amongst the antiproliferative agents, a consistent effect on risk has not been demonstrated for azathioprine vs. mycophenolate [45, 90]. The potential impact of mammalian target of rapamycin (mTOR) inhibitors (sirolimus and everolimus) is of particular interest as these agents have both immunosuppressive and antitumor effects [132, 133]. mTOR inhibitors arrest the cell cycle of EBV-transformed lymphoblastoid cells lines in vitro and fail to protect them from apoptosis. In the SCID mouse model, everolimus reduced the outgrowth of EBV-associated lymphoid tumors. The mTOR pathway is constitutively active in the entire spectrum of PTLD lesions independent of EBV status [134]. In addition, these agents may exert direct effects on EBV replication [135]. Although favorable responses with conversion to an mTOR inhibitor in the setting of PTLD have been described, this may be a reflection of reduced immunosuppressive potency rather than a specific antitumor mechanism. Moreover, some data suggest an increased risk of PTLD in patients receiving mTOR inhibitors [90, 131, 136].

Recent experience with novel immunosuppressive agents highlights the importance of the immune response in controlling EBV infection and its complications. In the initial phase II and phase III trials of belatacept, a fusion protein that selectively blocks costimulation, use of this agent was associated with an increased risk of PTLD (reviewed in Ref. [137]).

In the extended 3-year follow-up of both phase III trials in de novo renal transplant recipients, 1.62% of belatacept-treated patients developed PTLD vs. 0.49% of CsA-treated patients. Pretransplant EBV-seronegativity was a significant risk factor with a ninefold increased risk in those receiving the currently recommended dosing regimen. Of great concern is the observation that 44% of PTLD cases in the belatacept-treated patients involved the central nervous system (CNS). Similarly the early experience with tofacitinib, an oral Janus kinase (JAK) inhibitor identified an increased risk of PTLD in de novo renal transplant recipients receiving the experimental agent (2.35% of 213 patients) vs. none in the CsA control arm [138]. Four of the five cases occurred in EBV-seropositive individuals and in those receiving more intensive dosing.

While it is the cumulative intensity of immunosuppression that impacts the risk of early PTLD, is it less clear whether specific immunosuppressive agents have altered the risk of developing PTLD beyond the first posttransplant year. Rather, the duration of immunosuppression appears to be important. Altering the long-term risk of PTLD may be impossible as long as the success of transplantation hinges on chronic pharmacologic manipulation of the immune response.

26.5 Risk Factors for the Development of PTLD after Hematopoietic Stem Cell Transplantation

PTLD arising in the setting of HSCT is uniquely different from that occurring in SOT recipients (reviewed in Refs. [139, 140]). It is largely an infectious complication in which donor-derived EBV-infected B cells proliferate in the setting of severe and sometimes prolonged T cell dysfunction caused by depletion of EBV-specific CTL in the recipient. The highest risk period is during the first 6 months posttransplant corresponding to the period of most profound immunodeficiency [42, 95]. Lesions are usually of donor origin; recipient-origin disease occurs only in the setting of mixed chimerism or failed engraftment. Although nearly all cases are EBV-associated, EBV serostatus has not been identified as a reproducible risk factor, perhaps due to the lack of documentation of donor and recipient EBV serostatus in many series. However, multivariate analyses from two large centers have reported a 13.6- and 4.6-fold increase in risk of PTLD in EBV-mismatched (donor positive, recipient negative) recipients [42, 141]. The apparent reduction in risk seen in the more recent cohort may reflect the implementation of routine EBV VL monitoring with preemptive rituximab therapy if the EBV VL rose above a certain threshold.

PTLD has been reported to occur in <1% of recipients of allogeneic unmanipulated HSCT from HLA-identical siblings and is extremely rare in the setting of autologous HSCT despite periods of profound immunodeficiency. Patient characteristics such as older age, baseline presence of immunodeficiency, prior splenectomy and repeat HSCT may contribute to the risk [42, 95, 140]. But the use of alternative sources of stem cells from HLA-mismatched related or unrelated donors, reduced intensity conditioning (RIC) protocols with in vivo or ex vivo T-cell depleting regimens, and the more intense prophylaxis and treatment of GVHD has resulted in an evolving epidemiology. The cumulative incidence of PTLD in recipients of HSCT was approximately 4% in recent series, independent of the stem cell source [42, 55, 56]. In a large multi-institutional cohort of 26,901 patients receiving allogeneic HSCT [95] between 1964 and 1994, the use of ex vivo T cell depletion was associated with a RR 3.1 to 9.4 of PTLD depending upon depletion method while the use of in vivo depletion with ATG led to a RR of 3.8. Indeed much of the apparent increase in risk of PTLD in HLA-mismatched (≥2 mismatches) HCST was attributed to the use of these strategies. Methods of ex vivo depletion that specifically targeted T cells or T/NK cells were more strongly associated with early PTLD than those removing both T cells and B cells with a RR of 9.4 vs. 3.1, respectively, when compared to no depletion. Concomitant depletion of donor B cells may reduce the size of the EBV reservoir or number of latently infected donor B cells capable of proliferation in the absence of CTL activity. The more recent use of RIC protocols has proved to be an additional potent risk factor. In a large single center study of 1021 recipients of HSCT between 1996 and 2011 [42], RIC was associated with a 3.25 RR of EBV-PTLD. Of note, all patients developing PTLD in this study had also received ATG. Others have suggested that RIC in combination with either in vivo or ex vivo T cell depletion greatly increases the risk of EBV-reactivation and PTLD [55, 56, 141–143]. While these protocols are less cytotoxic, they are highly immunosuppressive, delaying reconstitution of cellular immunity.

The availability of larger datasets has allowed for robust multivariate analyses capable of addressing the impact of multiple simultaneous risk factors on the incidence of PTLD. A multi-institutional report [95] found that rates of PTLD among patients <50 years of age rose from 0.13% without any additional risk factors, to 1.0% (RR 9.3 on multivariate analysis) with a single risk factor, and 3.9% (RR 45) with two or more risk factors. Patients >50 years old with two or more risk factors had an RR of PTLD that was 237-fold greater than that of younger individuals without risk factors. Similarly the study by Uhlin et al. [42] identified 6 risk factors for the development of EBV-PTLD: HLA-mismatch (RR 5.89), EBV-mismatch (RR 4.97), splenectomy (RR 4.81), use of RIC (RR 3.25), mesenchymal stromal cell treatment (RR 3.05), and acute GVHD grades II–IV (RR 2.65). ATG was not included amongst the variables studied as all patients with PTLD had received this agent. The cumulative risk of EBV-PTLD rose from 0.4% in individuals with one risk factor (ATG included) to 3.0% with two risk factors, to 10.4, 26.5, and 40% with three, four, and five risk factors,

respectively. This approach assists in the identification of specific high-risk groups for targeted surveillance and preemptive intervention.

Less is known about the risk factors for the much less frequent occurrence of late PTLD in HSCT recipients. As in SOT, late PTLD is less likely to be EBER-positive. In the multi-institutional analysis of patients receiving HSCT between 1964 and 1994, chronic GVHD (RR 3.0) and selective T-cell depletion (RR 4.2) were the only significant variables identified [95]. Whether this risk arises from ongoing deficiencies in the CTL response, chronic antigenic stimulation, or the proliferative effects of cytokines produced in the setting of GVHD remains speculative. Treatment of chronic GVHD with immunosuppressive therapy with CsA alone (RR 3.18) or in combination with azathioprine (RR 7.0) further increased risk when compared to the use of steroid and azathioprine, suggesting a similar impact of intensity and duration of pharmacologic immunosuppression as described in SOT.

26.6 Clinical Presentation

The spectrum of the clinical presentation of PTLD ranges from localized lesions to widely disseminated disease, and the histology ranges from an indolent self-limited form of lymphoproliferation to fulminant malignancy. PTLD occurring during the first posttransplant year in recipients of SOT is more likely to involve the allografted organ. In contrast, late PTLD (i.e., beyond the first posttransplant year) is more likely to present with multi-site disease [4]. PTLD may present with a variety of symptoms, making a high index of suspicion valuable. Similar to non-transplant lymphoma, symptoms and signs of PTLD may include B symptoms (i.e., fever, weight loss, and night sweats), painless enlargement of peripheral lymph nodes, and organ dysfunction secondary to infiltration or compression by a mass lesion. Extranodal involvement by PTLD is common, occurring in up to 85% of cases; the best characterized sites are the allografted organ (particularly in kidney and lung recipients), the gastrointestinal (GI) tract and the CNS [90, 99, 100, 144]. In a large cohort of French renal transplant patients, renal allograft PTLD occurred within 2 years, CNS PTLD occurred between 2 and 7 years, and gastrointestinal (GI) tract PTLD predominated after year 7 [90]. Involvement of the thorax, mainly the lung parenchyma or thoracic lymphadenopathy, has been described in recipients of all organ types [145]. Cutaneous involvement occurs in 5–10% of cases [146].

GI tract PTLD occurs in 19–56% of patients [90, 100, 147]; it is particularly common late posttransplant [90] and is most often EBV-negative monomorphic B cell subtype. GI disease can present as ulceration and occult bleeding, bowel obstruction by a mass lesion, or bowel perforation. Significant early mortality can occur both at diagnosis and upon excellent response to therapy, especially with extensive multifocal GI involvement [148]. Posttransplant GI symptoms and unexplained anemia or iron deficiency should be investigated as possible signs of GI PTLD.

PTLD limited to the allograft occurs more commonly early posttransplant and the vast majority involves EBV [99, 115, 149]. Primary involvement in the allograft occurs in 10–30% of cases in renal or liver transplant recipients and more than 50% of cases in lung or intestinal allografts [150, 151]. In contrast, the cardiac allograft appears to be spared from clinically relevant disease. Because of the tendency for early allograft involvement with PTLD, a high index of suspicion must exist for patients presenting with allograft dysfunction, particularly in the presence of known risk factors for PTLD. The detection of EBV with EBER probes by in situ hybridization is useful in differentiating between PTLD and rejection [152]. Disease limited to the allograft was predictive of improved prognosis in some series [115, 144, 153, 154].

Isolated CNS disease (i.e., primary CNS lymphoma) occurs in 5–15% of patients with PTLD on current immunosuppressive protocols; renal allograft recipients appear to have the highest risk of localized CNS disease [90, 115, 155, 156]. CNS involvement may also occur in the setting of disseminated disease where involvement may be isolated to the leptomeninges or cerebrospinal fluid (CSF), without overt lesions in the brain or spinal cord parenchyma. CSF analysis is diagnostic in approximately 50% of such cases. Patients with CNS involvement typically present with an altered mental status or focal neurologic findings. In the largest reported series of primary CNS lymphoma, over 80% of cases occurred late posttransplant and imaging with computed tomography (CT) or magnetic resonance imaging (MRI) revealed a single lesion in 63% [155]. Stereotactic biopsy revealed polymorphic histology in 18% and monomorphic histology in 81%, the vast majority of which were diffuse large B-cell lymphoma (DLBCL); overall 88% were EBV-positive [116]. The prognosis of patients with CNS involvement is poor, with a 3-year overall survival (OS) of 43%, although some patients survive more than 10 years after diagnosis [155].

Recipients of HSCT are at particular risk of developing disseminated PTLD [141, 157]. Such patients usually present within the first few months after transplant with widespread lymphoproliferation and multiorgan failure complicated by the presence of concomitant viral infections or systemic sepsis. The CNS is frequently involved. Prognoses for polyclonal and monoclonal diseases in this setting are similarly poor. Presumably, this aggressive form of PTLD is a reflection of the greater global immunodeficiency that arises from profoundly impaired EBV-specific CTL activity in this setting. If engraftment is delayed and the disease is disseminated, approximately 90% of such patients succumb despite aggressive management. Even if the disease is localized, mortality approaches 30%.

26.7 Other Epstein–Barr Virus Clinical Syndromes

As a result of more widespread use of EBV DNA assays, there has been increasing recognition of clinical syndromes, other than PTLD, that have been attributed to EBV infection after both SOT and HSCT. Infectious mononucleosis syndromes, hepatitis, pneumonitis, gastrointestinal symptoms, and meningoencephalitis have been described [4, 158–160]. EBV infection-associated hematologic signs include leukopenia and thrombocytopenia [4]; a case report of EBV-associated fatal aplastic anemia after bone marrow transplantation has been published [161]. EBV-associated hemophagocytic lymphohistiocytosis, characterized by exaggerated macrophage activation and phagocytosis is seen rarely after SOT or HSCT. Usually observed in the context of primary EBV infection, proliferation of virally driven T cells is important in its pathogenesis [1, 162].

Oral hairy leukoplakia, a nonmalignant lesion of the lateral borders of the tongue, is uncommon after SOT, but spontaneously reversible EBV-positive hairy leukoplakia has been reported in patients early after bone marrow transplantation [163]. This lesion is associated predominately with lytic EBV infection and is usually responsive to antiviral therapy. Sharply circumscribed EBV-positive mucocutaneous ulcers involving the oropharyngeal mucosa, skin, or gastrointestinal tract, previously described in non-transplant patients with immunosenescence or receiving iatrogenic immunosuppression for autoimmune diseases and in a single HSCT recipient [164], have recently been described in the SOT setting [165]. Often misdiagnosed as polymorphic or monomorphic PTLD after SOT, these isolated lesions occur in the absence of a tumor mass; patients have no involvement at other sites and no detectable EBV DNAemia. Pathology is characterized by polymorphous infiltrate and atypical large B cell blasts co-expressing B-cell antigens and CD30, often with Hodgkin/Reed–Sternberg (HRS) cell-like morphology. SOT patients with these ulcers responded to minimal therapeutic intervention including reduction in immunosuppression or rituximab monotherapy [165].

EBV also appears to play a pathophysiologic role in the development of rare EBV-positive smooth muscle tumors after SOT reported most commonly in pediatric recipients. The tumors occur late after transplant at a median of 48 months in a recent literature review [166] and 9.4 years in a single center review of adult kidney transplant recipients in Singapore [167]. These non-hematopoietic proliferations of mesenchymal/stromal origin appear to be multifocal, rather than metastatic when multiple sites are involved and have extranodal presentations similar to PTLD. The liver is a common site of involvement [166]. Tumor cells may be of either donor or recipient origin and have features of type III latency, although LMP-1 expression is rarely observed [166, 168]. Optimal treatment strategies for this type of tumor are unknown. The clinical course may be indolent and complete remission has been described in some cases with immunosuppression reduction alone [166]. Surgical resection (when possible) and reduced immunosuppression appear to result in comparable outcomes; multiorgan involvement, particularly intracranial involvement, is associated with a poorer overall survival [166]. Because these tumors are characterized by Akt/mTOR cell cycle activation, a switch in immunosuppression to mTOR inhibitors has been suggested with some positive responses reported [167–169]. Poor responses have been reported with the use of cytotoxic chemotherapy [168, 169].

26.8 Diagnosis

When PTLD is suspected clinically, a tissue biopsy is required to confirm the diagnosis and to characterize the lesion histologically. Imaging with ultrasound, CT, MRI, or positron emission tomography (PET) scans is used to localize a biopsy target and to establish the stage of disease, but is not considered diagnostic. An excisional biopsy is superior, but a needle biopsy may be acceptable when there is no accessible lymph node or mass. Cytologic analysis of bronchoalveolar washings or CSF can support the diagnosis of PTLD, but is inadequate to subclassify PTLD [61].

26.8.1 Histopathology

Tissue biopsies in suspected cases of PTLD should be reviewed by experienced pathologists and lesions should be classified according to the WHO Classification System updated in 2008 [6]. Table 26-2 summarizes the features of this classification system, which is based largely on cellular lineage and morphology. Ancillary pathological techniques should include routine morphology, immunohistochemistry, and EBER in situ hybridization (Table 26-3); molecular genetic studies of antigen receptor genes may be useful in determining clonality but are not essential for diagnosis [6, 61]. Institutional protocols should be implemented to ensure that the tissue is handled appropriately for ancillary tests.

Most PTLD lesions in SOT recipients are recipient-derived, as confirmed by a recent population-based analysis and review of previous case series [170]. Donor-derived PTLD is more common in recipients of renal and liver transplants, where it tends to occur early after transplantation, to involve the allograft, and to have polymorphic histology [170]. Although intestinal transplant recipients experience a high rate of PTLD involving the allograft, donor derived disease is uncommon [120]. PTLD in HSCT recipients is primarily donor-derived [6]. Molecular profiling has suggested that recipient-derived disease has a phenotype of a B cell in the germinal-center stage of differentiation while

Table 26-2. Categories of posttransplant lymphoproliferative disease (PTLD)

Early lesions[a]
Plasmacytic hyperplasia
Infectious mononucleosis-like lesions
Polymorphic PTLD
Monomorphic PTLD (classify according to lymphoma they resemble)
B cell neoplasms
Diffuse large B cell lymphoma
Burkitt lymphoma
Plasma cell myeloma
Plasmacytoma-like lesion
Other[b]
T cell neoplasms
Peripheral T cell lymphoma, NOS
Hepatosplenic T cell lymphoma
Other[b]
Classical Hodgkin lymphoma-type PTLD

[a]Some mass-like lesions in the posttransplant setting may have the morphologic appearance of florid follicular hyperplasia or other marked but non-IM-like lymphoid hyperplasias.

[b]Indolent small B cell lymphomas arising in transplant recipients are not included among the PTLD.

Table 26-3. Ancillary pathological studies useful for the categorization of PTLD

Immunophenotype[a]
Presence of EBV (EBER in situ hybridization)[a,b]
Clonality (immunoglobulin genes, T cell receptor, EBV)
Genetic/cytogenetic studies (chromosome or oncogene abnormalities)
Donor-vs.-recipient origin
Therapy-dependent markers (expression of CD20, cytotoxic T cell epitopes)

[a]Studies essential for classification.

[b]Immunohistochemical analysis for EBV LMP-1 is specific but less useful.

donor-derived PTLD are more consistent with a mature post-germinal center phenotype [171]; this suggests antigen stimulation may be involved in the pathogenesis of donor-derived disease when antigen-selected cells acquire genetic lesions as they expand in the recipient environment.

26.8.1.1 Early Lesions

Early PTLD lesions are composed of mixed populations of small lymphocytes, plasma cells, and immunoblasts with no cytologic atypia and preserved tissue architecture. This category includes lesions with features of plasmacytic hyperplasia and infectious mononucleosis. Most occur within a short time after transplant and are related to EBV infection [116].

26.8.1.2 Polymorphic PTLD

When lesions demonstrate the full spectrum of B cell maturation, efface the architecture of lymph nodes, or form destructive extranodal masses that do not fulfill criteria for recognized lymphoma types in the immunocompetent host, the lesions are classified as polymorphic PTLD. They are composed of a heterogeneous population of cells with variable atypia, such as atypical immunoblasts and Reed–Sternberg-like cells, and variable plasmacytic differentiation. The majority are monoclonal and some harbor genetic changes. Most of the cases that occur early posttransplant are positive for EBV [17, 116].

26.8.1.3 Monomorphic PTLD

Monomorphic PTLDs are neoplastic lymphoproliferations with sufficient architectural and cytologic atypia to constitute lymphomas, and they are histologically indistinguishable from corresponding pathologic entities in immunocompetent patients [6]. Most monomorphic PTLDs are of B-cell origin, and over 80% of these are DLBCLs; other subtypes include plasmablastic lymphoma, plasma cell neoplasms, and Burkitt lymphoma. The remaining monomorphic PTLDs originate from T or NK cells. Despite the morphologic similarities between monomorphic PTLD and their non-transplant counterparts, recent studies have identified distinct molecular features (reviewed in Ref. [17]).

PTLD of T- or NK-cell origin comprises 5–15% of monomorphic PTLD. The most common subtypes are peripheral T-cell lymphoma (PTCL) NOS and hepatosplenic T-cell lymphoma (HSTCL). Several case series characterize these lesions as occurring late posttransplant (median over 5 years), and primarily involving extranodal sites [172, 173]. Monomorphic T-cell PTLD carries a poor prognosis [154], and HSTCL has particularly poor outcomes with median OS of 4 months [173]. Other predictors of poor survival include bone marrow, CNS or graft involvement [173]. EBV is only detectable in about a third of cases, including all extranodal NK/T cell lymphomas, about half of PTCL, and almost no HSTCLs, but its presence predicts a more favorable prognosis [172]. The pathogenesis of EBV-associated T-cell PTLD is uncertain; EBV episomal monoclonality suggests that it is not simply due to bystander infection. In Japan, T-cell PTLD is also frequently associated with HTLV-1 [174]; its role in other geographic regions is unknown. Disease is often aggressive and refractory to reduction in immunosuppression and therapy, with a median survival of 6 months [172, 174].

Plasma cell neoplasms, including multiple myeloma and extramedullary plasmacytomas, were 1.8 times more likely to occur in SOT recipients than the general population in a recent study [175], but they comprise only 10% of PTLD [176]. Patients with plasmacytoma-like PTLD involving

solitary extranodal masses have a particularly good prognosis [177]. The literature also includes several cases of mucosa-associated lymphoid tissue (MALT) lymphomas involving the stomach or parotid gland in SOT recipients [178], but the most recent WHO classification system does not include these indolent lesions among PTLD subtypes [6].

26.8.2 Hodgkin Lymphoma Type PTLD

Classical Hodgkin lymphoma type PTLD is the least common subtype of PTLD. Incidence of Hodgkin lymphoma after SOT does not exceed the population rate in the first 2 years, but rises steadily thereafter, reaching 13.8 cases per 100,000 at 8–10 years posttransplant (i.e., SIR 4.1) [179]. Males and patients younger than 20 at transplant appear to carry two and four times the risk, respectively, but a predilection for renal recipients was not confirmed, contrary to early reports [180]. It is important to distinguish classical Hodgkin type PTLD from Hodgkin lymphoma-like PTLD histologically. Reed–Sternberg cells in Hodgkin lymphoma-like PTLD are EBV-positive, CD15-negative, CD45-positive, and CD20-positive, and can be accompanied by small or intermediate-size EBV-positive lymphoid cells [6]. It is best categorized as polymorphic or monomorphic PTLD. In contrast, classical Hodgkin type PTLD meets the criteria used for this diagnosis in immunocompetent patients. It appears to respond best to conventional management for Hodgkin lymphoma, namely chemotherapy [148, 181]. Despite morphologic similarities, outcomes for Hodgkin lymphoma type PTLD are inferior to those in non-transplant patients [182]. Interestingly, there are several reports of patients developing classic Hodgkin disease several years after more typical PTLD [183]. Epidemiologic population-based studies in Scandinavia and England have clearly identified symptomatic infectious mononucleosis as a risk factor for EBV-positive Hodgkin lymphoma in immunocompetent patients [184, 185]. Whether EBV disease or early PTLD after primary EBV infection increases the risk for future Hodgkin disease in the transplant setting in a similar way requires further study.

26.8.3 Staging

Staging is important to provide a standardized reference system for the relationship of tumor burden to outcome. At the very minimum, staging should document the precise anatomic location and size of lesions. While the Ann Arbor staging system is typically used for adults [186], other staging approaches such as the Murphy system have been used in children [187]. Although clinical assessment, including inquiry for symptoms and performance status as well as physical examination, remains important, the sensitivity for identifying areas of disease involvement is poor. Therefore, imaging of the chest, abdomen, and pelvis is recommended at baseline [61, 188].

There are no high quality studies to establish the ideal imaging technique for patients with PTLD. Recently published guidelines recommend PET-CT scans as the modality of choice for fluorodeoxyglucose (FDG)-avid lymphomas, specifically Hodgkin lymphoma and aggressive subtypes of NHL, for initial staging and response evaluation in the non-transplant setting [188]. PET-CT scans improve accuracy of staging when compared to CT scans and results lead to a stage change in 10–30%, although no impact on overall outcomes has been demonstrated [189].

Several small case series have confirmed that PTLD lesions are FDG-avid and that PET-CT is an effective imaging modality in staging PTLD patients, with a higher sensitivity than CT for detecting extranodal disease [190–194]. A retrospective review of 150 SOT or HSCT recipients who had PET scans either for biopsy-proven or suspected PTLD found an overall sensitivity and specificity of 89%, and a positive and negative predictive value of 91 and 87%, respectively, demonstrating an excellent ability to differentiate PTLD from non-malignant disease [195]. However, some subtypes of PTLD, such as monomorphic T-cell lymphomas, may not be FDG-avid, necessitating CT as an alternate staging modality. In addition to staging, PET-CT is more accurate than CT in assessing treatment response in non-transplant lymphomas as it can better distinguish residual viable tumor from necrosis or fibrosis [188]. Whether this is also true in the setting of PTLD requires further study, but preliminary data are encouraging [190]. Availability of PET-CT may be limited in some regions, and CT should be the default modality in these cases.

Bone marrow biopsy has traditionally been recommended for routine staging in non-transplant lymphomas, but no data is available on its utility in PTLD. Bone marrow involvement by PTLD represents a negative prognostic factor in some series [100, 173, 196]. Recent guidelines for non-transplant lymphomas cite bone marrow signal on PET-CT as a valid surrogate for bone marrow biopsy [188].

Assessment for CNS involvement is not routinely performed at diagnosis in non-transplant lymphoma [188], and no data is available on this practice in PTLD [61]. In the presence of neurologic symptoms, MRI brain is an excellent imaging modality for detecting CNS PTLD [197].

26.8.4 Epstein–Barr Virus Viral Load

Although EBV VL testing is used extensively to support EBV disease and PTLD diagnosis, the interpretation of results in this setting is problematic. A major problem is the lack of assay standardization. Studies have documented large variability in assay sensitivity and quantitative results reported when the same sample is tested [198, 199]. This variability is exacerbated by relatively few available

commercial assays and the large number of laboratory-developed assays used. In 2011, the WHO approved an international reference standard (IS) for EBV DNA to be used as a common assay calibrator [200]. Although it is hoped that this will improve harmonization of assay results, other factors such as extraction methods, gene targets, and instrument platforms also influence results [201]. Until the impact of the WHO IS on reported result variability has been evaluated, inter-institutional comparisons require formal cross-referencing of assay results. This also means that, currently, it is not possible to recommend specific qualitative or quantitative EBV DNA measurements to serve as globally applied triggers for preemptive intervention, PTLD diagnosis, or treatment end-points.

The optimal matrix for EBV VL measurement (i.e., whole blood vs. plasma) also remains uncertain. Measurement of EBV DNA in whole blood and lymphocytes appears to be more sensitive than measurement in plasma for the early detection of EBV reactivation, suggesting that whole blood may be a better matrix for use in preemptive monitoring strategies [71, 202]. Recent studies in whole blood showed a close correlation between copies/ml and copies/μg DNA with similar dynamic trending in patients using both reporting formats; normalization to cell number or genomic DNA in cellular specimens may be unnecessary [202, 203]. Although EBV generally becomes detectable in plasma as VL rises in matched whole blood samples, the quantitative results reported in plasma have suboptimal correlation with those reported in whole blood or lymphocytes, particularly in HSCT [71, 202].

Studies evaluating EBV VL as a diagnostic test for PTLD in patients with symptoms or signs but with no previous VL monitoring are limited. In lower risk adult SOT patients with unknown pre-transplant serology, qualitative detection of EBV DNA in plasma was highly specific for EBV-positive PTLD but lacked sensitivity, missing some cases of localized EBV-positive PTLD and all EBV-negative PTLD, the predominant form of late PTLD in adults [52]. Whether these data can be extrapolated to high-risk patients or to the broader transplant population is uncertain. Some investigators have suggested that plasma has better specificity for "high load" and may be the preferred specimen when used for the diagnosis and monitoring of therapeutic response of PTLD but studies to date have been small and require further validation [52, 159, 204, 205].

PTLD may be compartmentalized in only CNS or the allograft. EBV DNA detection in CSF in the absence of detection in peripheral blood has been reported in HSCT patients with CNS PTLD [206, 207] and in bronchoalveolar lavage (BAL) fluid in pediatric thoracic transplant recipients with lung PTLD [208]. However, EBV DNA, sometimes at high levels, can be frequently detected in BAL fluid of adult transplant recipients without PTLD as well as in immunocompetent patients [209, 210]. There has only been limited evaluation of EBV DNA measurement in CSF for the diagnosis of CNS lymphoma and CNS disease in transplant recipients [160, 211]. The gold standard of biopsy-proven disease is lacking in many patients in these studies, making interpretation difficult. Additional validation of EBV DNA measurement in CSF and BAL fluid, including assessment of quantitative levels that might improve specificity and positive predictive values for EBV disease or PTLD, is required.

26.9 Strategies for the Prevention of Posttransplant Lymphoproliferative Disorder

Given the absence of reliably effective therapy for all stages or forms of PTLD after SOT and HSCT, strategies for prevention in high-risk recipients have emerged as a major focus for PTLD management. It is important to identify these patients prior to transplantation. EBV serostatus should be determined in all donors and recipients. Wherever appropriate, particularly in EBV-mismatched recipients, immunosuppression should be minimized and the risk vs. benefit of using immunosuppressive agents that selectively deplete T cells relative to B cells as induction or rejection therapy should be carefully evaluated.

Two major approaches have been used for PTLD prevention. The first strategy, "universal prophylaxis," involves the administration of antiviral drugs, immunoglobulin or adoptive immunotherapy to all patients considered to be at increased risk for PTLD, usually beginning shortly after transplant. The second, termed a "preemptive" strategy, combines serial monitoring of peripheral blood EBV DNA levels with interventions that might lower the risk of PTLD. Such interventions would be triggered by EBV DNA levels that are predictive of PTLD risk, but occur before the onset of clinical disease.

26.9.1 Universal Prophylaxis Using Antiviral Drugs or Immunoglobulin

Antiviral drugs such as acyclovir, ganciclovir, foscarnet, and cidofovir [212] as well as the newer agents, brincidofovir [213] and maribavir [214], under development for CMV disease, have in vitro activity against lytic EBV replication but have no activity against EBV infection in its latent form. Acyclovir and valacyclovir treatment in immunocompetent patients with infectious mononucleosis significantly reduces or eliminates oropharyngeal EBV shedding [215, 216]. In seropositive immunocompetent patients remote from acute infection, although 1 month of acyclovir therapy had no effect on EBV VL in peripheral blood [217], a 1-year course of low dose acyclovir did result in a modest reduction.

The use of antiviral drugs for universal prophylaxis has not been evaluated in randomized controlled trials; their role

in PTLD prevention remains controversial. Cases of PTLD have occurred in patients receiving both acyclovir and ganciclovir prophylaxis. When compared to historical controls some studies evaluating antiviral prophylaxis demonstrated a reduction in PTLD incidence; others observed no effect as reviewed by Funch [218]. A multicenter case-control study found that the risk of PTLD was reduced in kidney transplant patients receiving acyclovir or ganciclovir for prophylaxis or treatment, with protective effects most marked in the first transplant year, increasing with duration of therapy, and greater for ganciclovir than acyclovir [218]. In contrast, the use of acyclovir or ganciclovir CMV prophylaxis did not impact PTLD incidence in a registry study of recipients of deceased donor kidney transplants [219].

Since primary, often donor-transmitted EBV is a major PTLD risk factor after SOT, reduction in early infections may extrapolate to reduced PTLD risk. A reduction in primary EBV infection was observed in a recent analysis of ganciclovir/valganciclovir prophylaxis vs. no prophylaxis in a small non-randomized study of mismatched pediatric kidney SOT recipients [41]. Intriguingly, a pilot study in a similar population suggested that 2 weeks of valganciclovir treatment of organ donors may reduce recipient PTLD risk [220]. These preliminary observations require further evaluation, ideally in randomized controlled trials.

The utility of passive administration of EBV neutralizing antibodies (via IVIG) as a prophylactic strategy also remains unclear. Two prospective randomized placebo-controlled trials, one using CMV-IVIG prophylaxis in EBV-seronegative pediatric liver recipients [221], and the second examining the benefit of IVIG when added to ganciclovir in EBV-mismatched adult and pediatric SOT recipients [222] failed to observe a reduction in PTLD rates in patients receiving the immunoglobulin products. The latter study also did not observe an impact of IVIG on EBV VLs in peripheral blood. In contrast, results of an epidemiologic study by the CTS registry added to the uncertainty by reporting that the use of CMV-IVIG reduced the incidence of NHL in kidney transplant recipients but only in the first posttransplant year [219].

26.9.2 Prophylactic Adoptive Immunotherapy

Adoptive transfer of T-cell immunity is an attractive strategy to facilitate the restoration of EBV-specific CTL responses. This is particularly true in HSCT where most lesions are of donor origin and express the most immunostimulatory EBV latent cycle antigens. The infusion of unfractionated lymphocytes from their EBV-seropositive donors (i.e., donor lymphocyte infusion (DLI)) has been shown to be effective in HSCT recipients but is associated with a significant risk of developing GVHD. A refinement of this approach is the infusion of polyclonal, EBV-specific, predominately $CD8^+$ CTL cell lines prepared from donor leukocytes (reviewed in Refs. [5, 223] in the setting of HSCT or recipient leukocytes in the setting of SOT. In HSCT recipients, this approach is safe and effective, with functional EBV-specific CTL responses persisting for up to 9 years [224]. Moreover, this strategy provides cellular immunity targeted at EBV-disease while avoiding the unwanted responses of GVHD. However, in SOT patients who are EBV-seropositive prior to transplant, the low incidence of PTLD renders the routine production of autologous cloned, EBV-specific CTL impractical and costly. The patients at highest risk for PTLD, EBV-seronegative recipients, do not have autologous CTLs from which to develop cell lines. To generate a CTL response from naïve T cells ex vivo has proved challenging. Moreover infused CTL have limited persistence in the SOT setting, perhaps due to ongoing pharmacologic immunosuppression. The production of EBV-specific CTL is time-consuming (usually 2–3 months) and expensive, limiting widespread clinical applicability. Several groups have focused on developing rapid manufacturing strategies to overcome these obstacles (reviewed in Ref. [5]; these include rapid capture techniques to identify polyclonal EBV-CTL, the use of genetically modified dendritic cells as stimulator cells, or the use of overlapping EBV peptide pools as a source of antigen. There is also great interest in the development of banks of cloned, third-party EBV-specific CTL [225]. This would allow for an immediately accessible source of EBV-CTL, particularly for patients with rapidly progressive disease or those recipients of transplants from EBV-seronegative donors. Other notable developments that might improve the in vivo efficacy of adoptive therapy include genetic manipulation to create CNI-resistant CTL [226] and the availability of banked third-party virus-specific T cells with simultaneous activity against other viruses (CMV and adenovirus) that can also cause serious disease in both SOT and HSCT recipients [227].

Adoptive immunotherapy for prevention of PTLD has been given either to all high-risk patients, or preemptively in response to EBV DNAemia (reviewed in Refs. [223, 225]. These approaches have been most extensively evaluated in patients receiving HSCT from matched unrelated donors or mismatched family members in the context of T-cell depletion protocols, in those with a previous history of EBV-PTLD, or who had an underlying immunodeficiency where the incidence of EBV-PTLD may be as high as 11% [224]. Only one case of PTLD was observed in 108 HSCT and 21 SOT high-risk patients who received EBV-CTL prophylactically; that patient had received a CTL line that lacked strong EBV-specificity [223, 225]. None of the HSCT recipients developed de novo GVHD following CTL infusion.

26.9.3 Preemptive Management

The preemptive approach has evolved as the preferred PTLD prevention strategy and is recommended in international guidelines in EBV-mismatched (donor seropositive/recipient seronegative) SOT recipients and in high-risk HSCT recipients [4, 61, 62, 228]. European guidelines for SOT also

recommend use of a preemptive strategy for all lung and intestinal allograft recipients and all patients receiving treatment for acute rejection [62]. However, the evidence to support this strategy in adult EBV-seropositive recipients in these cohorts is weaker. These strategies are not recommended for lower risk populations where the risk vs. benefit is uncertain.

26.9.3.1 Monitoring Algorithms and Trigger Points for Intervention

In addition to issues related to EBV assay standardization and choice of specimen type, optimal monitoring algorithms have not yet been defined. Monitoring algorithms are most cost-effective when used during the posttransplant period of highest risk, defined as 3–6 months in HSCT and at least 1 year in SOT. Measurement of CD4+ cells as a marker of immune reconstitution in HSCT [229, 230] and SOT recipients [231] may better tailor the monitoring period in individual patients; patients with GVHD may require longer monitoring [229, 230]. VL can rise very quickly, particularly in severely immunosuppressed HSCT patients. In a recent HSCT study, the median time to EBV disease from onset of EBV DNAemia was 7 days (range 0–17 days) [53]. EBV DNA kinetics may be as important as absolute quantitative values for triggering interventions [4, 53, 61, 62]. Monitoring more frequently than the currently recommended once weekly may be indicated in the highest risk HSCT subgroups [53]. Less frequent monitoring at intervals varying from weekly to monthly has been recommended in SOT recipients [4, 61, 62].

There are very few natural history studies relating EBV DNAemia levels to PTLD events where clinicians were blinded to results. Interpretation from non-blinded studies is complicated by both the heterogeneity of the populations studied, as well as the non-standardized assays and sample types used (reviewed in Ref. [63]). As a result of these factors, defining optimal trigger points for preemptive intervention is difficult [232, 233]. A recent multicenter analysis of HSCT PTLD cases highlights this problem. EBV DNA levels at the time of PTLD diagnosis were below two commonly used trigger points for preemptive intervention in 45 and 23% of cases, respectively [157]. Although EBV DNA detection has an excellent negative predictive value for early EBV+ PTLD after both SOT and HSCT, preemptive trigger points, often center-specific, have a positive predictive value of only 28–65% in SOT [63] and 25–50% in HSCT [229, 234].

To improve the specificity of high VL for PTLD prediction, combining VL with testing of additional biomarkers has been explored. The most promising is the quantitation of EBV-specific CTLs using tetramers, ELISPOT or flow cytometry-based intracellular cytokine staining [235–238]. However, there are few commercially available CTL assays and current assays are costly, complex, not very rapid, and not standardized [239]. Additional biomarkers proposed for risk stratification that require additional evaluation include assessment of global immunosuppression using commercial ATP-release assays [74], and measurement of IL-6 and 1L-10 [240, 241], soluble CD30 [242], CXCL13 [243], or serum free light chain levels [244, 245].

26.9.3.2 Preemptive Interventions in SOT

Effective preemptive strategies require that the intervention lowers PTLD risk without significant adverse events including graft rejection [5, 246, 247]. Although preemptive interventions are recommended for high risk, predominantly EBV-mismatched SOT patients early after transplant during the course of acute EBV infection, there is no data to support their use in patients with established CVLP later after transplant. Whether any intervention strategy described has any long-term effect on either VL kinetics or PTLD risk in CVLP patients remains uncertain.

Reduction in immunosuppression (RIS) remains the mainstay of preemptive treatment in SOT [248]. However, the process for best achieving this is uncertain; suggestions are outlined in international guidelines [62, 249]. Some advocate a change in immunosuppression to mTOR inhibitors [248]. Although antiviral drugs (ganciclovir/valganciclovir) or intravenous immunoglobulin (IVIG) are sometimes given, often simultaneously with RIS [250, 251], the added benefit of these agents is uncertain [252]. Rituximab, a chimeric antibody directed against the CD20 antigen expressed on B cells, has been used less frequently as a preemptive intervention in SOT than in HSCT [248]. The risks vs. benefits of using rituximab when compared to RIS alone in SOT are unknown. Benefits may be greater in the setting of thoracic transplantation where the consequences of acute rejection following RIS may be higher. Experiences with rituximab have been reported in heart transplant recipients failing RIS [253] and EBV-mismatched kidney transplant patients given rituximab simultaneously with RIS [137]. Preliminary data from intestinal SOT [254] suggest that incorporating rituximab into routine induction regimens in high-risk patients might also be considered as an alternate strategy to reduce risk.

26.9.3.3 Preemptive Interventions in HSCT

RIS is recommended as an initial preemptive intervention in HSCT when possible [228]. However, RIS often fails to alter VL kinetics in the short term particularly very early after HSCT when viral load is rising quickly, the patient is profoundly immunosuppressed and immune reconstitution will take some time [140]. In addition, the risk vs. benefits of reduced immunosuppression, particularly in patients with preexisting GVHD, should be considered. The routine use of sirolimus for GVHD prophylaxis in HSCT has been suggested but the impact of this strategy in reducing the incidence of PTLD has not been evaluated [246]. The utility of using anti-viral drugs alone for preemption is uncertain. Liu

found that only 2 of 16 HSCT patients who received antiviral drugs as the only preemptive intervention responded vs. a complete response (CR) rate of 45.8% when combined with reduced immunosuppression [53].

Because RIS and antiviral therapy have high failure rates as interventions, rituximab therapy has become a common initial preemptive intervention in HSCT [5, 246]. Although a standard weekly dose of 375 mg/m^2 is recommended, optimal dosing and number of doses required remains uncertain [233]. Incorporating rituximab into HSCT conditioning regimens in high-risk patients has also been employed as an alternate strategy to reduce PTLD risk [255]. Safety concerns associated with preemptive rituximab include possible excess bacterial infection due to delayed immune reconstitution, higher non-relapse mortality in HSCT recipients [256] and CD20 escape mutants causing PTLD [257]. Significant side effects of rituximab observed in other settings include infusion reactions, B cell lymphopenia sometimes associated with hypogammaglobulinemia, CMV and hepatitis B reactivation, and progressive multifocal leukoencephalopathy [4]. Ongoing safety monitoring and improved targeting of rituximab therapy to the highest risk patients is warranted. Although adoptive immunotherapy for preemptive intervention is attractive as an alternative to rituximab or in cases of rituximab failure in HSCT, widespread accessibility to this therapy remains problematic [223, 225].

26.9.3.4 *Efficacy of Preemptive Therapy*

There are neither randomized controlled trials comparing preemptive strategies vs. placebo nor specific interventions to each other. However, there is an increasing body of evidence (primarily single center reports) that suggests that preemptive strategies have reduced the incidence of early PTLD in high-risk patients when compared to historical cohorts after both SOT and HSCT (reviewed in Refs. [4, 5, 62, 249]).

26.10 Treatment of Posttransplant Lymphoproliferative Disorders

The approach to treating established PTLD in both SOT and HSCT involves restoring the immune response to EBV and eradicating the proliferating lymphocytes while maintaining graft function. Patients are vulnerable to toxicity in both arms of this approach, and therefore must be monitored closely with involvement of multiple disciplines, including the transplant physician, infectious diseases specialist, and hematologist/oncologist [249]. The mainstays of therapy for PTLD in SOT include reduction of immune suppression, rituximab, and chemotherapy. Adequately powered randomized controlled trials of therapeutic interventions for established PTLD have not been performed primarily due to its rarity. Therefore, recommendations for the management of PTLD in SOT have been solely based on small phase II clinical trials, retrospective case series, and expert opinion [148, 249]. Recently, however, results from the largest international multicenter phase II clinical trial ever conducted in PTLD were published, laying the groundwork for high-quality clinical evidence for treatment of PTLD in SOT (discussed in Sect. 26.10.6) [258] (Table 26-4).

Table 26-4. Options for the treatment of posttransplant lymphoproliferative disorder

Increase the cytotoxic T cell (CTL) response
Reduction or withdrawal of immunosuppression
Adoptive immunotherapy with autologous EBV-specific CTL
Adoptive immunotherapy with partially HLA-matched allogeneic CTL
Antiviral strategies
Ganciclovir/valganciclovir, acyclovir/valganciclovir
Foscarnet, cidofovir
Histone deacetylase inhibitor combined with ganciclovir
Intravenous immunoglobulin (IVIG)
Cytokine therapy
Interferon-α
Anti-IL-6 monoclonal antibodies
Tumor debulking
Anti-B cell monoclonal antibody therapy (rituximab)
Cytotoxic chemotherapy
Surgical resection
Local irradiation

IL interleukin.

Therapeutic options are limited in HSCT patients with established PTLD. Reducing immune suppression is not always feasible or effective, whereas adoptive immunotherapy is highly effective but unavailable at most centers. Rituximab monotherapy is relied upon, but approximately 30% fail [157]. Published outcomes of therapy in this setting are limited to case series and retrospective reviews (reviewed in Refs. [5, 259]).

26.10.1 Reduction of Immunosuppression (RIS)

Reduction or discontinuation of immunosuppression is the most important initial step in the management of PTLD after SOT [4] but may have less utility in early PTLD after HSCT where regeneration of cellular immunity is delayed and the risk of developing GVHD is significant [246]. In SOT recipients, response rates to this strategy have ranged from 0 to 73%. A retrospective study reported that 45% of 67 patients responded to RIS, an effect not limited to those with polyclonal or EBV-associated disease [260]. A favorable response was less likely in older recipients, those with bulky disease, or advanced stage; there was a 17% rate of relapse in complete responders and a 32% rate of acute rejection. In contrast, others have reported CR rates of <10% to RIS alone [261, 262]. RIS are unlikely to have a significant impact on the course of some forms of PTLD such as late NHL, multiple myeloma, and most T-cell lymphomas.

There is no consensus on which agent should preferentially be reduced or the duration of the reduction. A recommended strategy is to discontinue any antiproliferative agents and

reduce the dose of CNI by 25–50% while maintaining the dose of steroid [62, 249]. Recent studies suggest that maintaining a low dose of CNI rather than discontinuing it completely is associated with better long-term graft survival without impairing the response to other PTLD treatments [262, 263]. Responses are typically seen in 2–4 weeks; waiting up to 6 weeks in stable patients without progressive disease may be warranted given that the median time to failure in non-responders was 45 days [260]. The utility of conversion to an mTOR inhibitor after PTLD is diagnosed is uncertain but warrants further investigation.

26.10.2 Adoptive Immunotherapy

In some settings, reduction of immunosuppression is not possible. Papadopoulos et al. [264] initially described dramatic responses to infusions of unfractionated donor leukocytes (DLI) in HSCT patients with PTLD. A more recent study reported complete or partial remissions in 73%, although GVHD complicated longer-term outcomes in 17% [265]. The use of polyclonal, EBV-specific CTLs prepared from donor leukocytes (reviewed in Refs. [5, 223] yielded response rates (CR and partial remissions (PR)) of 68 and 84% in two recent HSCT series [224, 265]; no patient developed GVHD. Responders experienced exponential increase in the EBV-specific CTL population within 7–14 days with subsequent clearance of EBV viremia [265]. While more extensive disease was associated with treatment failure, four of six patients with CNS involvement achieved CR. Both DLI and EBV-CTL were able to rescue patients failing rituximab therapy, although the response rate was not as high as when adoptive immunotherapy was used initially. Limited data are available concerning the efficacy of adoptive transfer of autologous EBV-specific CTLs in SOT, although preliminary data suggest that regression of disease may occur (reviewed in Refs. [223, 225, 228]. The utility of cloned third-party EBV-specific CTLs was demonstrated in a phase II clinical trial involving 33 patients (2 HSCT, 31 SOT) who had failed conventional therapy with immunosuppression reduction ($N=33$), rituximab ($N=12$), chemotherapy, and/or radiotherapy ($N=8$) [266]. Administration of third-party EBV-specific CTL selected by best available HLA match was associated with a 52% response rate at 6 months with 14 patients achieving a CR; responses were superior with better HLA-matching between the recipient and the CTL donor. In a study of HSCT recipients with PTLD resistant to conventional therapy, responses were achieved in 4 (3 CR, 1 PR) of 11 patients [267]. Recent technologic advances that have lowered cost and decreased the complexity and time for EBV-CTL production should make adoptive immunotherapy more clinically accessible. At present, it has not been recommended in SOT outside of a clinical trial [249]. If adoptive immunotherapy is to be considered in the setting of SOT, it would be critical to determine whether the PTLD lesions are of donor or recipient origin.

26.10.3 Antiviral Drugs and Immunoglobulin

Although EBV lytic transcripts are expressed in some cells in most EBV-positive PTLD [268, 269], the role of antiviral drugs or immunoglobulin as a therapeutic agent in patients with established PTLD is uncertain. At best, these agents may reduce the recruitment of new B cells into the lymphoproliferative process or may influence the expression of lytic viral proteins that modulate the immune response. Alternatively, they may have an indirect benefit on PTLD development by eliminating other viral infections that act as cofactors in PTLD development. It is likely that that these agents exert greater benefit when they are used either as prophylaxis or preemptively rather than as therapy for established disease.

26.10.4 Interferon-α (Alpha) and Blockade of Interleukin-6

IFN-α (alpha) administration and IL-6 blockade by monoclonal antibodies have been used historically, but both of these therapeutic modalities have limited evidence supporting their efficacy in the treatment of PTLD [261, 270] and generally are not used in current practice.

26.10.5 B-Cell Antibodies

The introduction of rituximab has improved response rates in virtually all B-cell CD20-positive lymphoproliferative disorders when combined with chemotherapy [271, 272]. Several retrospective reviews and phase II clinical trials have confirmed the efficacy of rituximab monotherapy in CD20-positive PTLD post-SOT in patients that fail to respond to reduced immunosuppression. Phase II trials show overall response rates (ORR) of 44–71% and CR rates of 26–53% after 4 weekly doses [273–276]. In the setting of HSCT, no prospective trials have been published, but retrospective series report ORRs of 70–84% [96, 157]. Rituximab is well tolerated with no mortality events directly related to treatment toxicity reported in these trials.

Unfortunately, remissions achieved using rituximab monotherapy are durable in only a subset of patients. In a combined analysis of two prospective phase II trials, 58% of responders progressed within 1 year, and 50% of enrolled patients required further treatment within 6 months of rituximab monotherapy. Patients with one or more risk factors, including age ≥60, ECOG performance status ≥2, or elevated LDH, were more likely to relapse and required further treatment [277]. Repeating a course of 4 weekly rituximab doses in patients that initially achieved PR did improve response rates, but did not eliminate subsequent progression [275]. Patients that progress after rituximab remain salvageable with chemotherapy [278].

In summary, while PTLD responds to single-agent rituximab in most patients with very few adverse effects, responses tend to be durable in a minority of patients, necessitating further definitive treatment.

26.10.6 Cytotoxic Chemotherapy

SOT patients with CD20-positive PTLD that fail reduced immunosuppression and rituximab may benefit from chemotherapy. The standard of care in non-transplant aggressive B-cell NHL, and therefore the default regimen in PTLD, is currently rituximab combined with CHOP (cyclophosphamide, doxorubicin, vincristine, prednisone) [148, 271, 272]. Historically, chemotherapy has been associated with high treatment-related mortality (TRM) in SOT patients, largely from infectious complications. The improvement in TRM seen in recent studies may be due to improved supportive care measures. However, cytotoxic chemotherapy is often not feasible in HSCT patients due to bone marrow toxicity, and (limited) published response rates are unfavorable [259].

Accurate assessment of remission rates of PTLD in SOT treated with chemotherapy and identification of a superior chemotherapy regimen are elusive, due to the almost entirely retrospective nature of the publications. Results of retrospective studies of other anthracycline-based chemotherapy, mainly CHOP with or without rituximab, show ORRs of 65–73%, 5-year OS of 25–78%, and TRM of 0–31% [279–283]. In one of the few prospective studies, investigators treated 16 adult patients with EBV-related PTLD using a sequential protocol starting with reduced immunosuppression, followed by interferon-α (alpha) and then ProMACE-CytoBOM for those not achieving CR at any step. ORR to reduced immunosuppression, IFN-α (alpha), and chemotherapy were 12.5, 7, and 67%, respectively, and the median OS was only 19 months [261]. A low-dose chemotherapy protocol (cyclophosphamide and prednisone) has been studied prospectively in children post-SOT with EBV-positive PTLD that failed reduced immunosuppression; CR rate was 84%, 2-year OS and event-free survival (EFS) were 73 and 67%, respectively, and TRM was 6% [284]. A subsequent study in a larger cohort added 3 weekly doses of rituximab in the first 2 cycles but saw a lower CR rate (69%) and similar 2-year OS (83%), EFS (71%), and TRM (5%) [285]. The heterogeneity of transplant and histologic subtypes between the studies precludes comparisons to determine the added benefit of rituximab.

The PTLD-1 trial, the largest phase II international multicenter trial in adult PTLD post-SOT, utilized a sequential treatment approach in an attempt to improve the suboptimal relapse rate with rituximab and diminish the toxicity of chemotherapy [258]. Seventy patients with CD20-positive PTLD (mainly late-onset and monomorphic) that failed reduced immunosuppression but had a good performance status were given 4 weekly doses of rituximab followed by four cycles of CHOP every 21 days. Support with granulocyte-colony stimulating factor was required and prophylactic antibiotics were recommended. They reported an ORR of 60% after initial rituximab monotherapy, increasing to 90%, the highest ever reported in any PTLD trial, after sequential chemotherapy. EBV-positive and -negative PTLDs responded equally. Seventy-four percent (74 %) of responders remained in remission 5 years later. There were no TRM events related to rituximab, and TRM related to CHOP was 11%; serious infections related to chemotherapy were more frequent in rituximab non-responders (58 vs. 30%, $p=0.025$). Sequential therapy produced a longer median OS (6.6 years) than rituximab monotherapy trials (1.2–3.5 years) [273–275].

An important question not yet addressed by a prospective trial is whether patients with an excellent response to rituximab alone could be managed without additional chemotherapy. Trappe et al. analyzed prognostic factors in PTLD-1 patients and predicted that patients in CR after four doses rituximab and those in PR with a low-risk international prognostic index (IPI) score were unlikely to have derived benefit from chemotherapy [286]. A prospective phase II multicenter clinical trial to examine risk-stratified sequential therapy (RSST) is currently underway; those who achieve CR with rituximab do not proceed to RCHOP [287]. Preliminary data are promising for 91 patients treated with RSST: 3 year OS was higher with RSST (70%) than with sequential therapy in PTLD-1 (61%). Twenty-seven percent achieved CR with rituximab alone, and only three of these patients have relapsed. The publication of the experience of the PTLD Study Group with RSST is highly anticipated, because it may inform preselection of those likely to avoid chemotherapy without sacrificing disease control.

In summary, in the absence of prospective clinical trials comparing rituximab monotherapy, sequential rituximab followed by CHOP (±R), and RCHOP for the treatment of CD20-positive PTLD in SOT, the standard of care remains elusive. Prior to the PTLD-1 trial publication, British experts had recommended rituximab alone for clinically low-risk PTLD, defined as having no risk factors (age >60, elevated LDH, and poor performance status), whereas they had recommended RCHOP for patients with any of the aforementioned risk factors or for patients who fail rituximab monotherapy [249]. Sequential therapy may offer the highest response and survival rates published to date for CD20-positive PTLDs that fail reduced immunosuppression. While the avoidance of chemotherapy in low risk patients is desirable, patient selection remains unclear [287].

Rare subtypes of PTLD that resemble non-transplant lymphomas, such as Burkitt lymphoma, T cell lymphomas, and plasmablastic PTLD, require specific chemotherapeutic treatment extrapolated from the lymphoma literature (reviewed in Refs. [148, 249]). Treatment for primary CNS PTLD is discussed in a separate section.

26.10.7 Surgical Resection or Radiation

Patients with localized PTLD, such as isolated skin, GI, or renal allograft lesions, can achieve prolonged remissions with surgery or localized radiation [146, 260]. Surgical

resection can be used for tumor debulking, as in allograft PTLD, or management of local complications, such as gastrointestinal hemorrhage, obstruction or perforation in cases of GI PTLD. In cases of PTLD with GI involvement, excess early mortality often results from excellent systemic treatment response causing GI perforation, and some experts consider surgical resection prior to initiating systemic therapy if GI disease is localized [148].

Radiation may be used for patients with life-threatening obstructive or compressive symptoms, and may also be useful for palliation in those with obstructive symptoms that fail to respond to systemic therapy [249]. However, radiation is not considered curative in most cases, and patients with monomorphic PTLD should be treated primarily with systemic therapy [249]. Radiation is potentially curative for plasmacytoma-like PTLD [177].

Radioimmunotherapy using ^{90}Y-Ibritumomab Tiuxetan, or Zevalin, a CD20-directed radiotherapeutic antibody, has produced prolonged remissions in 8 PTLD patients who had failed reduced immunosuppression and rituximab with or without chemotherapy [293]. ORR was 62.5%, and at a median follow-up of 37 months, four patients remained in CR. Toxicity was primarily hematological, and no TRM or graft rejection occurred. Therefore, Zevalin may be an effective salvage treatment for relapsed or refractory PTLD; however, cost and accessibility outside clinical trials may limit its use.

26.10.8 Treatment of PTLD Affecting the Central Nervous System

CNS involvement by PTLD portends a poor prognosis [100, 154, 196]. Management of lymphoma in the CNS involves a different approach than systemic PTLD due to the poor CNS penetration of standard agents, including rituximab. Favored regimens in non-transplant primary CNS lymphoma include high-dose methotrexate (HD-MTX) (3.5–8 g/m^2) alone or combined with cytarabine followed by consolidation of remission using autologous HSCT or whole brain radiation (WBRT) [197]. However, the toxicity of these regimens precludes many patients with SOT and HSCT, as MTX is renally excreted and should be avoided in those with renal or hepatic impairment. Several case series have reported success with HD-MTX in highly selected patients with primary CNS PTLD with reasonable tolerability [288, 289]. In the largest reported retrospective series of primary CNS PTLD ($n=84$), patients treated with rituximab and/or cytarabine (most often given after MTX) tended to have better outcomes, although the optimal treatment regimen was not discernible due to the significant variation in approaches [155]. Overall, lack of response to initial therapy was the strongest predictor of adverse survival (HR 8.7). The retrospective nature of these studies precludes definitive conclusions, but it appears that young patients with primary CNS PTLD should be offered MTX and rituximab if performance status and organ function allow [148, 249]. There are several reported cases of CNS PTLD, particularly early posttransplant, responding to reduced immunosuppression and rituximab monotherapy [155, 290, 291]; which patients would be suitable for this conservative approach is unclear.

Radiotherapy may be useful in the setting of CNS disease, particularly in patients ineligible for chemotherapy due to renal impairment and/or poor performance status and in those that progress or have residual disease following chemotherapy [148, 197]. Although CNS lymphoma is radiosensitive, CRs are rare and the vast majority relapse [197]. WBRT may provide improved disease control in patients with partial remission after chemotherapy [292]. Unfortunately, brain radiation is known to cause significant CNS side effects, such as memory loss [197].

26.10.9 Prognosis with Treatment

Despite advances in prevention, diagnosis, and therapy, mortality from PTLD remains excessive. Lymphomas were the most common cause of cancer-related mortality in SOT patients in a recent study of Australian thoracic and liver transplant recipients, and the risk of death from NHL was 17-fold higher than the general population [294]. In another study, however, a comparison of mortality from lymphoma subtypes in SOT to outcomes of non-transplant lymphomas in a registry yielded no significant difference [147], suggesting that the excess mortality from NHL in SOT patients reflects the increased incidence [294]. Patients with PTLD have a five-fold higher rate of graft failure [295]. Retrospective series of PTLD post-SOT report OS of 30–68% at 5 years, with excess mortality in the first year post-diagnosis [100, 110, 115, 154, 196]. Treatment with rituximab did improve survival in a recent retrospective series [100]. A large UK series of PTLD after HSCT reported 1- and 2-year OS of 46 and 40%, respectively [157].

Several groups have published retrospective studies that identify clinical prognostic factors, but their applicability is limited by small patient numbers, heterogeneous histologic subtypes, and treatment modalities. Previously identified adverse prognostic factors include monomorphic histology, T-cell histology, lack of allograft involvement, bone marrow involvement, CNS involvement, advanced stage, poor performance status, elevated LDH, and hypoalbuminemia [99, 100, 116, 147, 196, 274]. The IPI, a clinical score validated in aggressive NHL [296], was predictive of outcome in some PTLD series [99, 147, 286]. A prognostic score was developed from 500 PTLD cases in renal transplant patients incorporating elevated LDH, disseminated disease, monomorphic disease, serum creatinine >133 μmol/L, and age >55 years; predicted 10-year OS was 85% for low-, 80% for moderate-, 56% for high- and 0% for very high-risk scores [154]. Independent predictors of adverse OS in patients treated in

the PTLD-1 prospective trial were advanced age (>60 years), thoracic transplant, and poor response to rituximab monotherapy [286]. In contrast to earlier studies [153, 297], neither late PTLD nor EBV-negativity was predictive of outcome in several more recent series [84, 100, 154, 277, 286, 298].

Adverse prognostic factors for OS of recipients of T-cell depleted HSCT with PTLD treated with rituximab were age >60, advanced stage, over 1 extranodal site, poor performance status, and absence of peripheral lymphadenopathy. Furthermore, rituximab failure resulted in extremely poor prognoses [157]. Other adverse prognostic factors reported for PTLD in HSCT treated with rituximab include age ≥30, acute GVHD, and no reduction in immunosuppression at PTLD diagnosis [96].

26.10.10 Retransplantation After Posttransplant Lymphoproliferative Disorder

Successful retransplantation in kidney, liver, and cardiac allograft recipients who have recovered from PTLD has been reported. In an analysis of the UNOS database, 69 patients (27 kidney, 22 liver, 9 lung, 6 heart, 4 intestine, 1 pancreas) were identified who underwent repeat transplantation after an episode of PTLD [299]. One third of patients had developed PTLD within the first posttransplant year with only 1.4% diagnosed beyond the first decade. The interval between PTLD and retransplantation was greater than 1 year in 75%. The majority were children at the time of first transplant, suggesting that many may have developed PTLD in the setting of a primary EBV infection. No recurrent PTLD was identified in this cohort, suggesting that retransplantation is appropriate as long as patients have remained disease-free for a significant interval and an immune response to the initial EBV infection has occurred. The optimal time from PTLD remission to retransplantation is unknown, and in the setting of liver, heart, and lung transplantation, timing is largely dictated by clinical need. At present, no data suggest that any one immunosuppressive protocol is superior to another when retransplantation is performed in patients with prior PTLD. In general, there is a trend to avoid induction with anti-thymocyte preparations.

26.10.11 Viral Load Testing to Monitor Treatment Response and Predict Relapse

In some SOT and HSCT recipients with EBV-positive PTLD and high VL at diagnosis, treatment is associated with a fall and clearance of VL coincident with clinical and histologic regression [204, 300, 301]. In a multicenter study of HSCT recipients with PTLD treated with rituximab, Styczynski et al. [96] observed that an increase in EBV DNAemia 1–2 weeks after treatment was a predictor of poor response and was associated with an increased risk of death. However, virologic and clinical responses are not always concordant in SOT PTLD patients receiving rituximab [302, 303] or adoptive immunotherapy with EBV-specific CTL [223]. In SOT pediatric patients, particularly those experiencing primary infection after transplant, asymptomatic intermittent or persistent VL rebound occurs frequently with no short-term consequences [300, 301]. These data, which involved VL monitoring in cellular blood compartments, suggest VL monitoring to measure PTLD therapy response or predict relapse in the SOT setting cannot be recommended. However, as noted earlier (see Sect. 26.8) plasma may be the preferred sample type in this setting [52, 204].

26.11 Potential Future Options for Treatment and Prevention of PTLD

The presence of the EBV genome in all EBV-PTLD cells represents an opportunity for highly "tumor-specific" targeting of therapy. Several investigators have explored the concept that inducing lytic infection in these latently infected cells could cause cytotoxicity and this effect could be further accentuated by the addition of anti-herpesvirus drugs such as acyclovir or ganciclovir [304]. Studies in EBV-positive lymphoid cell lines and animal models suggest that a number of agents used for treatment of hematologic malignancies including doxorubicin, gemcitabine, rituximab/dexamethasone, bortezomib, cyclophosphamide, and γ (gamma)-irradiation induce lytic phase EBV gene expression and the concomitant use of antiviral drugs like ganciclovir increases cytotoxicity [305, 306]. The use of short hairpin RNA to inhibit TERT, a key component of the telomerase complex necessary for EBV-cellular transformation, combined with ganciclovir has demonstrated similar effects as reviewed in Ref. [307].

A number of histone deacetylase inhibitors including butyrate and valproic acid are potent inducers of EBV lytic phase gene expression [304]. In a pilot study, the combination of arginine butyrate and ganciclovir induced complete clinical remissions in four of six patients with PTLD refractory to conventional chemotherapy and/or radiation [308]. In a phase I/II trial using a similar protocol and inclusion criteria, 10 of 15 patients with EBV-associated lymphoid malignancies experienced regression of tumor with four CR and six PR; one third of enrolled patients had PTLD [309]. Two newer histone deacetylase inhibitors suberoylanilide hydroxamic acid and romidepsin have been approved for the treatment of T-cell lymphomas [310]. Determining the impact of this class of drug or chemotherapeutic agents with EBV lytic induction activity when combined with antiviral

drugs on EBV-positive lymphoproliferative disorders requires further clinical trials in both the general population and transplant recipients.

Other EBV-targeted therapies being explored in preclinical studies include the elimination of episomal EBV genomes by low dose hydroxyurea treatment, use of anti-sense RNA against the LMP-1 oncoprotein, expression of detrimental cellular proteins using an EBV-specific promoter dependent expression vector, and the use of small molecules that block signaling pathways constitutively activated by EBV [304, 311]. Manipulation of virally encoded miRNA and virally induced cellular miRNAs is a strategy of significant interest for the development of novel therapeutics [29, 312]. However, targeted delivery of some of these potential therapeutic agents to tumor cells is an unresolved challenge.

A number of new therapeutic approaches are currently being investigated for NHL in the immunocompetent host [313]. Most of these are novel molecularly targeted therapies in various stages of development such as proteasome inhibitors (e.g., bortezomib), immunomodulatory drugs (e.g., lenalidomide), B-cell receptor signaling inhibitors (e.g., ibrutinib), apoptosis effectors (e.g., venetoclax), and novel monoclonal antibodies (e.g., obinutuzumab). Gene expression profiling and next-generation sequencing studies have identified that DLBCL can be further categorized by cell-of-origin (activated B cell (ABC) or germinal center B cell (GCB)), and that these subtypes may be dependent on unique molecular pathways. Monomorphic B cell PTLDs are more often ABC subtype [116]. The targeted novel therapies showing more promise in ABC subtype include ibrutinib and lenalidomide. Whether these agents will be used alone or in combination with chemotherapy has yet to be determined.

Bexarotene, a synthetic retinoid analogue approved for use in cutaneous T-cell lymphoma, may have activity against other forms of T cell-derived PTLD. Bexarotene has been used with good effect in a single case of refractory EBV-associated peripheral T-cell PTLD where it appeared to induce remission [314]. Other novel agents holding promise in the treatment of non-transplant T-cell lymphomas include romidepsin and belinostat (histone deacetylase inhibitors), and brentuximab vedotin (an anti-CD30 monoclonal antibody) [315].

Interest has recently turned to the potential use of pamidronate, a widely available bisphosphonate that reduces bone turnover, in the treatment of PTLD (reviewed in Ref. [316]). It activates and expands a class of λδ (gamma delta) T cells that have NK cell characteristics and participate in the innate immune system. In vitro, these cells led to lysis of EBV-transformed autologous human lymphoblastoid B-cell line. In a murine model of human B-cell lymphoproliferative disease, adoptive transfer of these pamidronate-expanded λδ (gamma delta) T cells both prevented the development of disease when given preemptively and led to remissions and prolonged survival in mice with established disease [317]. Similar results were seen when tested in a murine model where immunodeficient mice had been reconstituted with a functional human immune system. Whether these preliminary results will translate into clinical efficacy has yet to be determined.

Research in vaccine development has focused on strategies that would affect EBV-associated disorders, such as PTLD, Burkitt lymphoma, and nasopharyngeal carcinoma (reviewed in Ref. [318]). A recombinant gp350 vaccine reduced the rate of symptomatic infectious mononucleosis from 10 to 2%, although it failed to reduce the rate of asymptomatic primary infection [319]. Because the theory of PTLD pathogenesis suggests that very high VLs may be important, vaccines that lower VL in infected patients, even if not preventing infection, may reduce PTLD risk. The EBV-seronegative patient awaiting SOT may be a particularly important subgroup in whom to further evaluate this vaccine. A phase I clinical trial of the gp350 vaccine in EBV-seronegative children with chronic kidney disease ($N=16$) failed to prevent either wild-type EBV infection pretransplant or reduction in EBV VLs when compared to non-vaccinated patients undergoing primary EBV infection posttransplant [320]. Neutralizing antibody developed in the minority and titers declined rapidly. Moreover one of the vaccinated children developed PTLD. Whether better adjuvants or a modified vaccination schedule would produce greater vaccine efficacy requires further testing. Immunosuppression due to the presence of uremia may also have had an impact.

An alternative vaccine strategy is aimed at the generation of a CTL response to latently infected cells by using formulations of synthetic peptides that mimic immunodominant epitopes recognized by EBV-induced $CD8^+$ CTLs in vivo. Recently, a phase I trial of such a vaccine has revealed that it is well tolerated and induced EBV-specific CTL in healthy volunteers [321]. The development of this type of vaccine faces the immense obstacle of including sufficient peptides in the formulation to address the large number of HLA polymorphisms in the population.

26.12 Summary

Significant progress has been made both in the understanding of the biology of EBV infection and in the pathogenesis of PTLD. This has resulted in major advances in the prevention and treatment of EBV-associated PTLD occurring early after transplantation. Nonetheless, morbidity and mortality associated with PTLD persists. As transplant recipients survive longer, the risk of late EBV-negative PTLD has become more significant. A standardized approach to pathology is critical for both understanding pathogenesis and designing therapy. New techniques for monitoring EBV VL hold promise, but they suffer from a lack of standardization. Prospective, multicenter, controlled trials evaluating prophylactic,

preemptive, and therapeutic strategies are needed to reduce the incidence, morbidity, and mortality associated with this complication of transplantation.

Herpes Simplex and Varicella-Zoster Virus Infection after Hematopoietic Stem Cell or Solid Organ Transplantation

Joshua T. Schiffer and John W. Gnann Jr.

27.1 Introduction

Because of the impaired cell-mediated immunity that accompanies antirejection therapy, clinical manifestations of herpesvirus diseases in organ transplant recipients are more frequent, severe, and prolonged than those in immunocompetent individuals [1]. A key characteristic of herpesviruses is establishment of latent infections of specific tissues that persist for life. The viral genome is present within latently infected cells, but does not undergo full replication cycles to produce infectious progeny. Nevertheless, immune-mediated eradication of the infection does not occur. Periodically, latent HSV and VZV will replicate and temporarily overwhelm the immune response, resulting in herpes labialis or herpes zoster.

Infections with herpes simplex virus (HSV) and varicella-zoster virus (VZV) are common (>50 % seroprevalence in most populations). Most primary infections occur during childhood and diagnosis of latent infections is established by serological testing. Diseases in adult transplant patients are usually due to reactivation. When primary infection occurs in transplant patients, manifestations are frequently severe.

While CMV causes more than half of viral infections in transplant patients, HSV and VZV are the next most common viral infections [1–5]. The intensity of immunologic suppression is associated with frequency and severity of disease. For example, the VZV attack rate is five times higher after allogeneic hematopoietic stem cell transplantation (HCT) than renal transplantation. Reduction in immunosuppressive therapy may be necessary to achieve control of life-threatening infections. While prophylactic antiviral therapy reduces the risk of herpesvirus disease, the ultimate goal is to develop selective immunosuppression that prevents graft rejection without suppressing antiviral cellular immune responses.

27.2 Description of the Pathogens

Herpes simplex viruses type 1 and type 2 (HSV-1, HSV-2) and VZV are alpha herpesviruses, characterized by similar structures, rapid replication cycles, destruction of host cells, lifelong latency in sensory nerve ganglia, and a robust cell-mediated immunologic response in tissue. Each virion is 100–200 nm in diameter. The nucleocapsid is composed of 162 capsomeres arranged in icosahedral symmetry. An amorphous tegument layer surrounds the capsid. The virion is enclosed in a lipid-containing laminated envelope with external glycoproteins that mediate entry into cells and serve as antigens. The herpesvirus genome consists of a linear, double-stranded DNA molecule (120–230 kb) with unique regions flanked by terminal repeating sequences. Herpesviruses specify a variety of enzymes to catalyze steps in the replication cycle, including nucleic acid metabolism, DNA synthesis, and protein processing. Synthesis of viral DNA and capsid assembly occurs in the nucleus; the envelope is acquired as the capsid passes through the nuclear membrane. Productive infection with release of progeny virus results in cell death.

27.3 Herpes Simplex Virus

27.3.1 Epidemiology

HSV-1 is transmitted most commonly during childhood by oral secretions. Since HSV-2 is sexually transmitted, seroprevalence remains low until puberty. In the USA, HSV-1 and HSV-2 seroprevalence is 62 % and 16 %, respectively, with significant variation by age and socioeconomic groups [6, 7]. A recent trend in developed countries is that HSV-1 is a more common cause of incident genital herpes than HSV-2, though the long-term recurrence rates of genital HSV-1 may be attenuated relative to genital HSV-2 [8]. In the modern treatment era, the incidence of HSV disease in HCT patients is determined by the duration of antiviral prophylaxis: the 2-year incidence of HSV disease in patients receiving 30 days of prophylaxis was 32 % versus 0.2 % in patients receiving a full year of prophylaxis [9].

Clinical manifestations of HSV occur with increased frequency in patients with reduced cell-mediated immune responses due to disease or immunosuppressive therapy.

P. Ljungman et al. (eds.), *Transplant Infections*, DOI 10.1007/978-3-319-28797-3_27

Prior to routine antiviral prophylaxis, HSV disease was noted in 70–80 % of HCT and 40–50 % of solid organ transplant (SOT) recipients [10–16]. Cumulative incidence in the era of antiviral prophylaxis is considerably lower.

27.3.2 Pathogenesis

In a newly infected individual, viral replication and spread occurs within keratinocytes on the mucocutaneous surface, followed by viral transport via cutaneous neurons to nerve cell bodies in ganglia where latency is established. When latent HSV reactivates, virus travels via sensory nerves back to the skin, where replication occurs in epidermal layers, sometimes producing clusters of painful vesicles. For HSV-1 and HSV-2, most shedding is asymptomatic, which is critical for transmission [17].

The immune mechanisms that control HSV reactivation are not fully elucidated. $CD8^+$ T lymphocytes surround latently infected neurons, and persistent $CD8^+$ cytotoxic T-lymphocyte (CTL) activity has been demonstrated in infected patients [18, 19]. HSV-2 specific T-cell aggregates persist at mucosal lesion sites for months. The spatial heterogeneity of these cells may contribute to the episodic nature of -2 shedding over time [20, 21]. Both adaptive and innate responses can be suppressed by antirejection immunosuppressive therapy. Donor anti-HSV immunity is transferred during HCT and provides protection against recurrent disease, dissemination, and development of antiviral drug resistance [22].

Most HSV infections that occur following HCT or SOT result from reactivation of endogenous virus, rather than primary infection. Primary infections account for ~2 % of HSV disease in HCT recipients [23]. Determination of HSV-1 and HSV-2 serologic status prior to transplantation aids subsequent prophylactic strategies. Asymptomatic oropharyngeal shedding is common in seropositive transplant patients not receiving antiviral prophylaxis [24, 25]. A subset of these patients will develop orofacial lesions. Patients occasionally transmit virus to remote anatomic sites via autoinoculation, resulting in syndromes such as herpes keratitis or whitlow.

Herpesviruses can be transmitted via a solid organ graft from a seropositive donor [26–28], though this has not been observed following HCT. If the recipient is seronegative, primary infection occasionally results in viremia, which can lead to lethal, visceral organ involvement. Two patients who received kidneys from the same donor developed fulminant, fatal HSV-2 hepatitis. Isolates from both recipients had identical restriction endonuclease patterns, proving transmission via the transplanted organs [27]. No such cases have been observed in the era of antiviral prophylaxis.

In the absence of prophylaxis, most HSV infections occur within 30 days after SOT or HCT [13, 14, 28–33]. HSV reactivates rapidly after initiation of immunosuppressive therapy, which coincides with suppression of lymphocyte responsiveness to HSV antigens [34, 35]. Intensity of immunosuppression predicts risk of posttransplant HSV disease, with higher rates in SOT patients who received OKT3 or antithymocyte globulin [13, 36], and after haploidentical transplant [37]. No correlation between HSV antibody titers and disease has been established. Donor immunity does not prevent reactivation in the graft recipient, but does limit recurrence and drug resistance. Following SOT, lymphocyte responsiveness to HSV antigens normalize within about 6 months, and recurrence frequency declines [34]. In HCT recipients, reestablishment of specific lymphocyte reactivity is dependent on reexposure to HSV antigens [35]. Patients who develop a lymphocyte response to HSV after first posttransplantation recurrence maintain a lower frequency of subsequent recurrences [35]. In HCT populations, acute graft-versus-host disease (GVHD) [38] or a matched-unrelated/mismatched donor [39] are associated with increased HSV disease risk. No detrimental effect of HSV infection on graft survival has been demonstrated.

27.3.3 Clinical Presentation and Natural History

Seventy to eighty percent of seropositive HCT patients will develop HSV disease [13, 14, 24, 35, 40, 41]. Certain chemotherapies, including lenalidomide for multiple myeloma, are associated with high incidence of HSV disease. These high attack rates provide rationale for antiviral prophylaxis to prevent HSV during the weeks after transplantation.

The initial presentation of mucocutaneous disease in transplant patients often does not differ from infection in immunocompetent hosts. However, a subset of lesions in immunocompromised patients heal more slowly, and a smaller percent undergo fatal dissemination [14, 40, 42].

Herpetic lesions begin as painful erythematous papules that progress to clusters of vesicles. If vesicles remain intact, they evolve into pustules with the influx of inflammatory cells. Vesicles are fragile and rupture results in erosions on an erythematous base that crusts. Healing occurs over 5–10 days in normal hosts, but may take 4–6 weeks in immunocompromised hosts off therapy [40, 42]. In some patients, large, atypical, mucocutaneous ulcerations develop that require biopsy or viral culture for accurate diagnosis.

Orolabial lesions account for most HSV disease in after transplant [23]. Lesions involve the lips, gingiva, tongue, posterior pharynx, and perioral skin. In HCT patients, intraoral HSV disease during the granulocytopenic period is difficult to distinguish from chemotherapy induced mucositis [43]. If typical lesions are present, the diagnosis of HSV gingivostomatitis is suggested but should be confirmed with a viral culture or assay for viral DNA, particularly if there is concern for drug resistance. Herpetic gingivostomatitis can cause severe pain resulting in diminished nutritional intake and possible bacterial superinfection.

Anogenital herpes usually results from HSV-2 reactivation in sacral ganglia [44], and ranges from self-limited lesions to extensive chronic ulcerations that persist for weeks [45, 46]. Cases of atypical HSV that mimic HPV disease, hemorrhoids, or malignancy have been noted in transplant patients [44–47]. Anogenital HSV-2 may be complicated by lymphocytic meningitis, which is usually self-limited and does not progress to encephalitis.

Mucocutaneous HSV infections can cause serious morbidity, but are usually self-limited. HSV dissemination can result in visceral organ infections that are difficult to diagnose and frequently lethal. HSV can spread by direct extension from the oropharynx to the gastrointestinal or respiratory tracts, causing esophagitis or pneumonia. The presence of a nasogastric tube may increase risk of esophagitis in a transplant patient with oral HSV. HSV may mimic skin GVHD with histologic features resembling HSV associated erythema multiforme [48]. HSV encephalitis does not occur with increased frequency in transplant patients. Viremic dissemination to multiple organs, while rare, is associated with high mortality.

Patients with HSV esophagitis present with dysphagia and odynophagia that may be indistinguishable from syndromes caused by *Candida* or CMV [49, 50]. Because clinical and radiographic findings cannot distinguish among the etiologies of esophagitis, endoscopy for biopsy and cultures is required. Endoscopic examination reveals herpetic superficial erosions and ulcerations that become confluent [49, 50]. Colitis in transplant patients is much more commonly caused by CMV than by HSV in the era of antiviral prophylaxis [51, 52].

HSV pneumonia is more common in HCT, lung, and heart–lung transplant recipients, than other SOT patients [12, 53–55]. Pulmonary HSV involvement with HSV most commonly results from aspiration or local extension from the upper airway, rather than viremia [56]. HSV-1 pneumonia resulting from contiguous spread is characterized by focal or multifocal infiltrates on chest radiograph. Endotracheal intubation increases the risk of direct extension to the tracheobronchial tree. HSV pneumonia resulting from viremia may be due to either HSV-1 or HSV-2, presents with diffuse infiltrates, and is usually accompanied by disease affecting other organs [57]. HSV pneumonia presents with fever, cough, dyspnea, hypoxemia, and chest radiograph abnormalities that may be indistinguishable from bacterial pneumonia [54]. Chest computed tomography may demonstrate focal consolidation with small centrilobar nodules and areas of ground-glass attenuation [56]. Bronchoscopy reveals tracheobronchitis. Since HSV is frequently present in oral secretions, positive cultures from expectorated sputum are misleading. A definitive diagnosis of HSV pneumonia is based on positive viral culture or polymerase chain reaction (PCR) of deep lung specimens, coupled with histopathologic evidence of infection on biopsy.

Viremic HSV-1 or HSV-2 dissemination can result in infection of the liver, lungs, adrenal glands, gastrointestinal tract, and skin during the first 30 days after transplant. This syndrome has been described most frequently in renal and liver transplant patients, but also in HCT recipients [26, 27, 58–62]. Systemic HSV usually occurs within 1 month of transplantation. Primary HSV infection with dissemination has occurred when an organ is transplanted from a seropositive donor to a seronegative recipient [26, 27, 63], though reactivation in seropositive patients is the more common etiology [64]. Computed tomography may demonstrate innumerable tiny low-density hepatic foci that may be mistaken for *Candida* micro-abscesses [28, 65]. Clinical findings included abdominal pain and tenderness, fever, and elevated hepatocellular enzymes. Not all patients have HSV skin lesions. Liver biopsy (for HSV cultures, PCR, and histopathology) [28, 66], or PCR of blood are diagnostic studies of choice, the diagnosis is often made postmortem.

The mortality rate for transplant patients with untreated HSV hepatitis is 60–80 % and approaches 100 % if disseminated intravascular coagulopathy develops [28]. Rapid diagnosis and early antiviral therapy are essential for survival [67], although a few cases of less fulminant hepatitis (>60 days after transplantation) have been reported [68]. Empiric therapy with intravenous acyclovir should be initiated as soon as the diagnosis is considered. Liver transplantation has been attempted in a few patients with liver failure due to fulminant HSV [62, 69–71].

CMV hepatitis is also rare, but presents differently. HSV hepatitis tends to occur within 5–25 days of transplantation is rapidly progressive, and is associated with leukopenia with an increased percentage of band forms [62]. CMV hepatitis usually occurs 20–50 days after SOT, has a subacute course, and is associated with leukopenia and atypical lymphocytes. A liver biopsy is essential to provide an accurate diagnosis, especially in liver transplant recipients in whom the differential diagnosis also includes hepatitis B, hepatitis C, or graft rejection.

Another scenario in which implantation of allogeneic tissue can transmit HSV is ocular surgery, especially keratoplasty or corneal transplantation [72, 73]. HSV transmitted by a donor cornea can result in graft failure and ulcerative keratitis after transplantation [74].

27.3.4 Diagnosis

Typical mucocutaneous herpetic lesions can be accurately identified by experienced clinicians. Atypical lesions or visceral organ involvement requires laboratory confirmation. Intraoral HSV lesions can be difficult to distinguish from mucositis. When performed early during infection, viral culture of lesions is a sensitive technique: vesicle or ulcer exudate is collected on a swab and placed in appropriate transport media. Biopsy specimens can be minced and extracted for culture and should be inoculated onto cells as soon as possible. Specimens can be stored at 4 °C for up to 48 h, although

some reduction in yield may result. HSV grows readily on many mammalian cell lines. Characteristic cytopathic changes can be observed within 24–48 h, though growth occasionally takes a week. Viral typing can be performed by staining cells from the culture monolayer with fluorescein-labeled HSV-1 and 2-specific monoclonal antibodies.

A variety of rapid diagnostic assays to detect HSV antigens or nucleic acids have replaced virus culture at many centers. PCR is the method of choice for diagnosing central nervous system infections, is sensitive for detecting HSV DNA in tissues and blood, and should be employed for culture negative lesions and suspected visceral disease [47, 75–78].

A sensitive direct immunofluorescence assay (DFA) is available for diagnosis of mucocutaneous lesions in under an hour [79]: cells scraped from a vesicle or ulcer base are stained with fluorescein-labeled monoclonal antibodies specific for HSV-1, HSV-2, or VZV.

Because most HSV infections are due to reactivation in patients with preexisting antibody, serology is helpful to define susceptibility, but not to diagnose active disease. A negative assay for anti-HSV antibodies excludes recurrent, but not primary HSV. In the past, most laboratories used a whole-virus enzyme-linked immunosorbent assay (ELISA) that did not reliably distinguish between antibodies against HSV-1 or HSV-2. Current highly specific serologic tests usually allow identification of patients who are infected with HSV-1, HSV-2, or both [80, 81]. In cases of borderline serologic results, or results discordant with clinical history, HSV Western Blot is the gold standard for diagnosis.

27.3.5 Therapy

The release of acyclovir in the early 1980s revolutionized the treatment and prophylaxis of HSV. Small trials of intravenous acyclovir for mucocutaneous HSV infections in immunocompromised patients demonstrated efficacy and safety [82]. Subsequent large, randomized, placebo-controlled trials in BMT and SOT populations with intravenous acyclovir (5 mg/kg or 250 mg/m^2 IV every 8 h) demonstrated reduced duration of shedding (median 2.8 vs. 16.8 days), pain (median 8.9 vs. 13.1 days), and lesions (median 13.7 vs. 20.1 days), compared with placebo [83].

While intravenous acyclovir is preferred for severe, life-threatening infections, oral acyclovir is more convenient for less serious HSV infections, and is safe and well tolerated. In 21 BMT recipients, oral acyclovir reduced the duration of mucocutaneous shedding (median 2 vs. 9 days), pain (median 6 vs. 16 days), and lesions (median 8 vs. 21 days), compared with placebo (Figure 27-1) [84]. Valacyclovir (an acyclovir prodrug) and famciclovir (a penciclovir prodrug) have in vitro antiviral activity similar to acyclovir, but produce higher serum concentrations, which allows simpler dosing schedules. Clinical trials in immunocompetent hosts with valacyclovir and famciclovir demonstrate high effectiveness, though controlled studies with these drugs are limited.

A topical preparation of acyclovir is beneficial for treatment of mucocutaneous HSV in immunocompromised patients [82], but is not as effective as systemically administered drug. There is no role for topical acyclovir or penciclovir in transplant patients given the safety of oral preparations.

No prospective, controlled studies have been performed to evaluate acyclovir in transplant patients with disseminated or visceral HSV infections. However, clinical experience clearly supports the value of high-dose intravenous acyclovir (10 mg/kg IV every 8 h) in this setting [14, 66, 85].

Antiviral therapy of mucocutaneous disease should be continued until lesions are healed, which will usually be at least 10 days. Premature discontinuation can result in relapse and emergence of acyclovir-resistant HSV. Ganciclovir, foscarnet, and cidofovir are primarily used to treat CMV but also have excellent activity against HSV. Acyclovir has

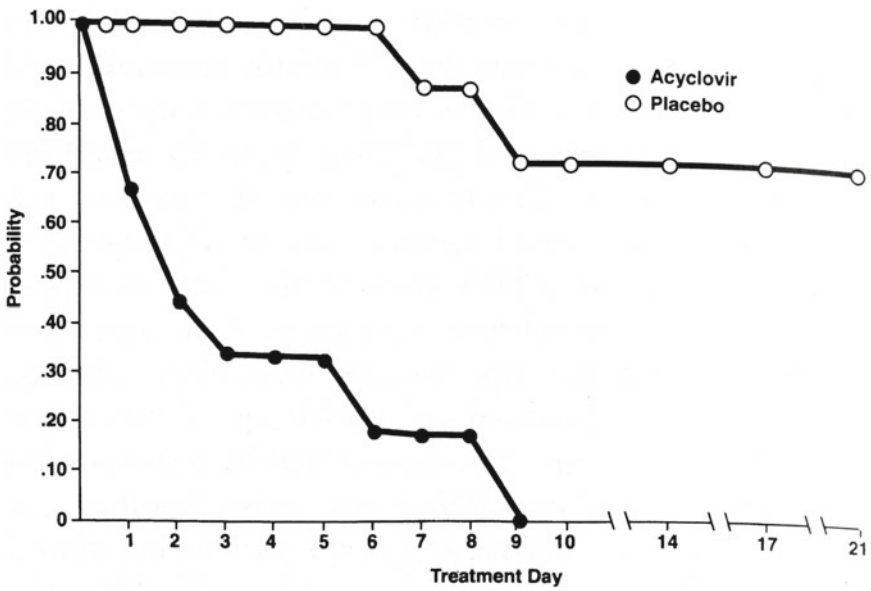

FIGURE 27-1. Time-to-event curves showing probability of remaining culture-positive for HSV, from a study of BMT patients with mucocutaneous HSV disease treated with oral acyclovir (*closed circles*) or placebo (*open circles*) for 10 days ($P = 0.0008$). (Modified from Shepp DH, Newton BA, Dardliker PS, et al. Oral acyclovir therapy for mucocutaneous herpes simplex virus infections in immunocompromised marrow transplant recipients. Ann Intern Med. 1985;102:783–785).

limited therapeutic activity against CMV, though high dose valacyclovir dosed at 2 g every 6 h is effective in preventing CMV reactivation [86]. In transplant patients with concurrent CMV and HSV infections, high-dose ganciclovir, foscarnet, or cidofovir provide effective treatment for both pathogens.

About 2–5 % of HSV isolates recovered from HCT patients are acyclovir resistant; the frequency in SOT patients is lower [87–91]. While HSV incidence following HCT remains low, the percentage of resistant isolates continues to increase with the advent of longer and deeper immunosuppression [92]. The most common manifestation of acyclovir-resistant HSV is extensive, chronic mucocutaneous disease [91]. Serious visceral infections have been reported [88, 93, 94]. Immunocompromised patients with cutaneous lesions or mucositis that fail to heal despite acyclovir therapy should be recultured and submitted for antiviral susceptibility testing [94, 95].

Acyclovir prophylaxis suppresses viral replication and reduces the probability of resistance mutations [95, 96]. In HCT patients, resistance develops more frequently in patients receiving short-term prophylaxis or repeated treatment for recurrent disease than in patients on long-term high-dose (acyclovir 800 mg twice daily or valacyclovir 500 mg twice daily) prophylaxis [9, 24, 91, 96].

The initial phosphorylation step in acyclovir activation is catalyzed by virally encoded thymidine kinase. HSV with mutations that alter thymidine kinase will be resistant to acyclovir [86, 94, 97–99]. Famciclovir and ganciclovir are also dependent on thymidine kinase for activation, and are against most acyclovir-resistant HSV strains. Foscarnet, which is not dependent on thymidine kinase, can be used to treat acyclovir-resistant HSV [88, 100–102]. Foscarnet is more toxic than acyclovir and can lead to renal insufficiency in 25 % of patients as well as electrolyte wasting and aphthous genital ulcers [103]. Infections caused by rare strains resistant to acyclovir and foscarnet may respond to cidofovir [89, 104–106]. Cidofovir is associated with dose-dependent renal insufficiency and a Fanconi like syndrome with proteinuria, glucosuria, and bicarbonate wasting [107]. Cidofovir is co-dosed with probenecid, which is associated with nausea and potentially dehydration. Patients on foscarnet and cidofovir should have their renal function tested frequently and receive vigorous hydration. Brincidofovir (CMX001), an investigational oral prodrug of cidofovir, has greater potency, less toxicity and broad activity against CMV, HSV, adenovirus, smallpox and Ebola virus [108, 109].

27.3.6 Prophylaxis

The widespread adoption of antiviral prophylaxis has dramatically altered the natural history of HSV infections in HCT [106, 110–112]. Prophylaxis minimizes HSV-associated morbidity and mortality in the posttransplant period and reduces emergence of acyclovir-resistant strains [9, 95, 110]. Clinical trials using intravenous acyclovir prophylaxis in BMT patients documented reduction in HSV incidence from 70 % to <5 % [111–113]. Prophylaxis using oral acyclovir was nearly as effective as (Figure 27-2), although some patients in the immediate posttransplant period had difficulty taking pills due to stomatitis or nausea [113–116]. Due to an increased frequency of HSV disease shortly after acyclovir prophylaxis was discontinued, a current highly effective strategy is intravenous acyclovir during the immediate posttransplant period followed by long-term

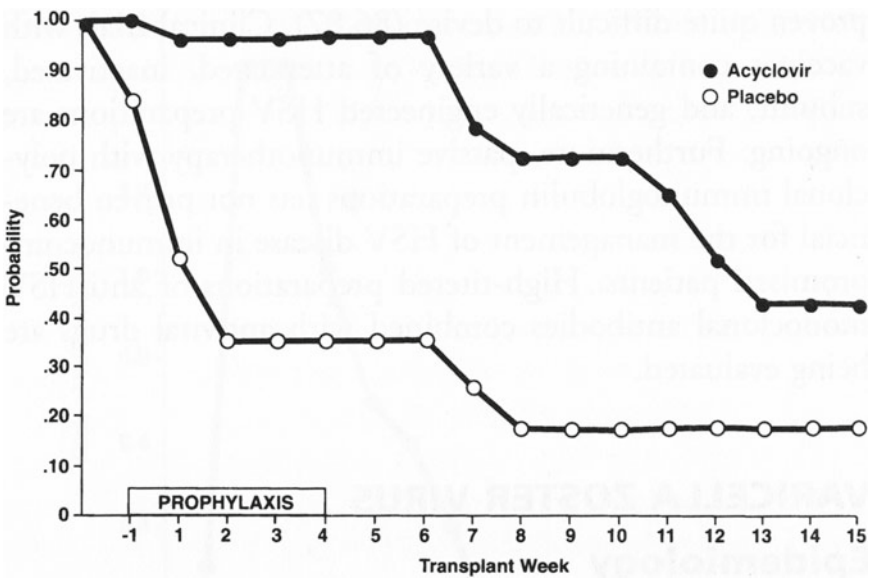

FIGURE 27-2. Time-to-event curves showing probability of remaining culture-negative for HSV, from a study of BMT patients receiving prophylaxis with acyclovir (*closed circles*) or placebo (*open circles*) for 5 weeks ($P=0.0002$). (Modified from Wade JC, Newton B, Flournoy N, et al. Oral acyclovir for prevention of herpes simplex virus reactivation after marrow transplantation. Ann Intern Med. 1984;100:823–828).

oral prophylaxis [112, 115, 117]. An oral acyclovir regimen of 800 mg twice daily has >90 % virologic efficacy and is not associated with development of resistance. This dose is well-tolerated, associated with high patient compliance, and affordable [118–120], and does not delay marrow engraftment [112, 114, 115, 119]. Many centers use acyclovir 400 mg twice daily [121], though this dose has not been tested as extensively for its ability to prevent resistance. Oral valacyclovir is well tolerated in HCT patients, offers a simplified prophylactic dosing regimen [113, 122–124], and is more cost-effective than intravenous acyclovir [113, 123].

acyclovir prophylaxis is also safe and effective in SOT [118, 124, 125], including renal [30, 126], liver [127], and cardiac transplant patients [128, 129]. Ganciclovir or valganciclovir administered for CMV prophylaxis provide effective prevention of HSV disease [106]. Physicians who use a preemptive therapy approach to CMV should use HSV prophylaxis with acyclovir or valacyclovir in the early posttransplant period.

27.3.7 Immunoprophylaxis of HSV Infections

Vaccinating HSV-seronegative transplant candidates is theoretically attractive, but an effective vaccine is not licensed [130]. Clinical trials are ongoing with a variety of attenuated, inactivated, subunit, and genetically engineered HSV preparations. Passive immunotherapy with polyclonal immunoglobulins has not proven beneficial for management of HSV disease in immunocompromised patients.

27.4 Varicella-Zoster Virus

27.4.1 Epidemiology

Humans are the only known reservoir for VZV. In temperate regions, varicella (chickenpox) epidemics occur annually in the late winter and early spring. Prior to introduction of the varicella vaccine in 1995, about 3.8 million annual varicella cases occurred in the USA. About 60 % occurred in children aged 5–9, and 90 % occurred in patients under 15 years of age [131]. Greater than 90 % of the population had varicella before age 20. With widespread vaccination, the chickenpox incidence has dramatically declined [132]. Due to either past infection or vaccination, fewer than 5 % of adult organ transplant recipients in the USA are VZV-seronegative [133].

Herpes zoster (shingles) results from reactivation of latent VZV. The incidence of zoster in the USA is about four cases per 1000 population per year [134–136]. Incidence is age-related, exceeding ten cases per 1000 patient-years in individuals more than 80 years of age [134, 135]. Impaired cell-mediated immunity due to lymphoproliferative malignancies, AIDS, or organ transplantation increases risk for development of zoster [137, 138].

27.4.2 Pathogenesis

Primary infection occurs when a susceptible individual is exposed to airborne VZV. Patients with chickenpox are infectious for 48 h prior to and 4–5 days after rash onset. Varicella is most often acquired from exposure to another individual with chickenpox, but can occur from exposure to a patient with zoster. Rare cases of VZV transmission via the donor organ have been reported when the donor had recent chickenpox [139]. Varicella is highly infectious, with attack rates exceeding 70 % following household exposure.

As VZV replicates in the skin during acute varicella, some virions are transported via sensory nerves to the corresponding dorsal root ganglia, where latency is established. The specific immune responses that limit VZV reactivation from ganglia are incompletely understood, but the most important factor predisposing to the development of zoster is declining VZV-specific cellular immunity, resulting from aging or immunosuppressive illness or therapy [140]. Impairment of VZV-specific effector memory T-cells occurs in SOT patients [141]. Although zoster is usually a disease of adults, VZV-seropositive children who undergo organ transplantation are at high risk for zoster [142]. Following VZV reactivation and replication in ganglion, virus travels along the sensory nerve to the skin, where it replicates in epithelial cells, producing the characteristic painful dermatomal vesicular eruption of herpes zoster (Figure 27-3).

27.4.3 Incidence and Risk Factors

The frequency of zoster in transplant populations correlates with intensity of immune suppression [138]. For HCT, the cumulative risk of zoster at 5 years posttransplant is 15–25 % for autologous and 20–45 % for allogeneic recipients, with most infections occurring within the first year [143–151]. Among SOT recipients, herpes zoster incidence is about

FIGURE 27-3. Herpes zoster in a heart transplant patient involving the right S2 dermatome. Photograph courtesy of John Gnann, MD.

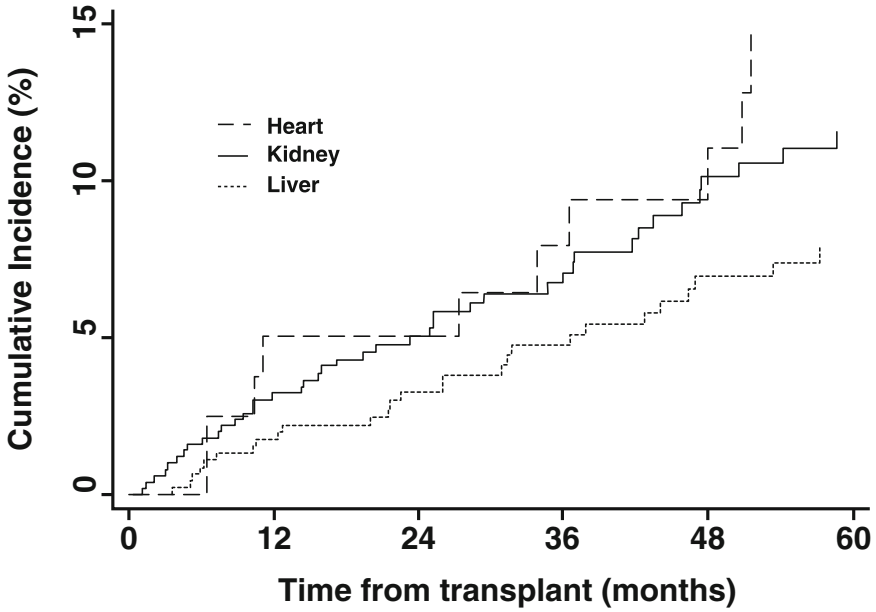

FIGURE 27-4. Cumulative incidence of herpes zoster posttransplant in cohort of VA SOT recipients from 1996 to 2007, by organ type. A log-rank test between curves shows a significant difference between the three groups ($P = 0.007$). (Modified from Pergam SA, Forsberg CW, Boeckh MJ, et al. Herpes zoster incidence in a multicenter cohort of solid organ transplant recipients. Transplant infectious disease: An official journal of the Transplantation Society 2011;13:15–23).

20 cases per 1000 patient-years, although risk varies significantly by organ type. The cumulative 5-year risk for herpes zoster is higher in lung or heart (20–25 %) than in kidney or liver recipients (15–20 %) [133, 152–159] (Figure 27-4). In addition to morbidity and mortality, this high incidence in transplant patients results in substantial resource utilization and cost burden [160].

Several factors predispose transplant recipients to zoster. Among SOT recipients, African-American race and older age are associated with increased relative hazard [156]. Among BMT patients, underlying disease, lymphopenia and GVHD are associated with higher risk. The risk is 46 % among patients transplanted for Hodgkin disease or lymphoma, 23 % for leukemia, and 9 % for solid tumors [151, 161]. Patients with a $CD4^+$ lymphocyte <200 cells/μL and $CD8^+$ lymphocytes <800 cells/μL on posttransplant day 30 had an actuarial risk of 48 % at 1 year [146]. In studies of VZV-seropositive children, the risk of herpes zoster was higher after cord blood than after BMT [158] and higher for allogeneic than autologous transplant [142]. Among allogeneic HCT patients, GVHD probably increases the incidence of herpes zoster and dissemination once zoster occurs [145, 147, 157].

No correlation exists between anti-VZV IgG titers and subsequent risk of herpes zoster [162]. Instead, risk correlates with the level of VZV-specific cell-mediated immunity, which is suppressed after transplant. Higher zoster rates may occur in patients receiving more intensive immunosuppressive therapy, including mycophenolate mofetil or high doses of corticosteroids [155, 159, 163–166]. Bortezomib therapy prior to autologous HCT for multiple myeloma has been associated with increased risk of herpes zoster [167–171].

Following allogeneic HCT, VZV-specific immune responses may be lost, even if the donor and the recipient were seropositive. As with HSV, T-cell recognition of VZV proteins may not be fully reconstituted until the patient experiences reexposure to VZV via clinical disease or possibly subclinical reactivation [172]. However, most patients develop durable immunity, and few experience more than one episode of zoster.

27.4.4 Clinical Presentation and Natural History

27.4.4.1 Varicella

Because most adults are latently infected with VZV, true primary infection occurs mostly in unvaccinated children [173]. Varicella is only occasionally diagnosed in adult transplant patients [166, 174–176]. Rare cases of primary varicella occur in VZV-seropositive HCT patients, indicating reinfection [177]. Determination of VZV serologic status prior to transplantation aids clinical decision-making and prevention strategies. Chickenpox in patients undergoing HCT or SOT has been associated with high rates of morbidity and mortality [166, 176, 178]. Skin lesions may be unusually numerous and severe, with ongoing new lesion formation for up to a week. Cutaneous complications in immunocompromised children include bullous or hemorrhagic lesions, necrotizing fasciitis, purpura fulminans, and bacterial superinfection. Prior to antiviral therapy, visceral involvement (especially

pneumonitis and hepatitis) was reported in nearly half of immunocompromised children with chickenpox, resulting in 10–20 % mortality [179]. VZV pneumonia occurred in 25–30 % of these children, presenting with fever, cough, and dyspnea within 3–5 days after onset of skin lesions. VZV meningitis has also been described in pediatric HCT patients [180]. Potent antirejection therapy and absolute lymphopenia (<500/mm^3) are risk factors for dissemination and death [181]. The availability of effective antiviral therapy has reduced mortality rate to <5 % in transplant patients with chickenpox [182–185].

27.4.4.2 Herpes Zoster

Unlike HSV infections that occur in the immediate post-transplant period, VZV reactivation usually occurs later in transplant patients (Figure 27-5). In the pre-antiviral era, median time to zoster following HCT was 5 months, with >75 % of cases occurring in the first year [161, 186–188]. Widespread adoption of prophylactic antiviral regimens has resulted in a delay in zoster until a median of 7 months post-transplant, when prophylaxis has been discontinued [145]. Only 12 % of the episodes occurred within the first 100 days. Among patients who survived 24 months after transplantation, 59 % developed zoster. In a cohort of 239 lung transplant patients, zoster incidence was 12.1 % and mean time to first episode was 486 (±265) days. The cumulative incidence of zoster was 5.8 %, 18.1 %, and 20.2 % at 1, 3, and 5 years after lung transplantation, respectively [155].

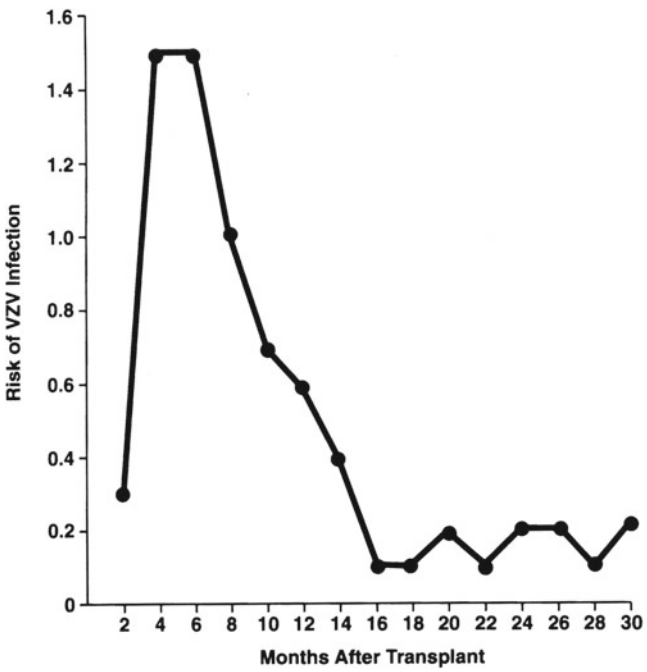

FIGURE 27-5. Risk of herpes zoster by month after BMT expressed as incidence per patient-day (%). (Modified from Locksley RM, Flournoy N, Sullivan KM, et al. Infection with varicella-zoster virus after marrow transplantation. J Infect Dis. 1985;152:1172–1181, by permission of Oxford University Press).

Clinical herpes zoster in transplant patients can present in one of three patterns. In most instances, the patient will develop a typical dermatomal skin eruption similar to that seen in immunocompetent patients, although the risk of dissemination is higher. Malaise and neuralgic pain in the involved dermatome precede onset of the rash by hours to a few days. A small number of patients present with a prodrome of fever, abdominal pain, nausea, and vomiting [187, 189, 190]. In 195 BMT patients with zoster, the rash involved the following dermatomes: cranial, 16 %; cervical, 17 %; thoracic, 47 %; lumbar, 21 %; and sacral, 12 % [187]. Multiple or noncontiguous dermatomes are involved more frequently in transplant recipients than immunocompetent hosts. In untreated immunocompetent patients, cessation of new vesicle formation occurs in about 3–5 days and lesion healing requires 2–3 weeks; in immunocompromised patients, these intervals are 8 days and 3–4 weeks, respectively. Prior to antiviral therapy, transplant patients sometimes developed indolent lesions that persisted for weeks or months and resolved only when immunosuppression therapy was reduced. Complications related to dermatomal herpes zoster may include postherpetic neuralgia (20–35 %), cutaneous scarring (19 %), ocular complications following trigeminal zoster, and bacterial superinfection (17 %) [133, 145, 150, 154, 155, 187, 191, 192]. Second zoster episodes of occur in 5–15 % of transplant patients [155].

Cutaneous VZV dissemination occurs in 15 % to 30 % of HCT patients who initially present with dermatomal herpes zoster, with higher rates among allogeneic HCT patients [145, 151, 187]. Cutaneous dissemination does not increase mortality rate, but predicts possible visceral disease, including encephalitis [193–197], myelitis, cranial neuropathies [198–201], pneumonitis, hepatitis [202], and necrotizing retinitis [203, 204]. Approximately one third of HCT patients with dermatomal zoster and cutaneous dissemination subsequently develop visceral complications.

In HCT patients, 15–20 % of VZV reactivations consist of disseminated varicella-like skin lesions with no obvious primary dermatomal eruption, a syndrome termed *atypical generalized zoster*. This probably represents reactivation of endogenous latent VZV in a patient with no effective immune responses, although a second primary infection following reexposure to exogenous VZV may occur. This syndrome resembles varicella, with a 40–50 % risk of visceral involvement [151, 187]. Mortality due to VZV visceral dissemination was at >50 % in the pre-antiviral era, but is <15 % with effective treatment [205].

Visceral VZV disease with no cutaneous involvement, an uncommon presentation, is difficult to diagnose and carries a high mortality rate. HCT (and rarely SOT) patients present with fever, severe abdominal pain, nausea and vomiting, and gastrointestinal bleeding [190, 206–210]. Rapidly rising transaminases suggest acute necrotizing hepatitis, warranting

empiric intravenous acyclovir therapy. Inappropriate antidiuretic hormone secretion has been observed with this syndrome [206, 211]. In a series of ten HCT patients with visceral VZV, mean time from transplantation to onset was 153 days (range 60–280 days) [212]. At laparotomy or autopsy, these patients have ulcerations in the gastrointestinal tract; hemorrhagic necrosis in the liver, pancreas, and kidneys; and positive VZV cultures and PCR from blood and involved organs [211, 213].

Lastly, patients may develop subclinical reactivation of latent VZV (due to boosted humoral and cellular immune responses). In some HCT patients, subclinical VZV reactivation has been documented by PCR detection of VZV DNA in circulating mononuclear cells, accompanied by restoration of lymphocyte proliferation responses to VZV antigens [172]. Patients with subclinical reactivation are at low risk for subsequent zoster. A related group of patients has been described who developed neuralgic pain typical of zoster, but no cutaneous lesions (termed *zoster sine herpete*), followed by a boost in VZV-specific humoral and cellular immune responses [214].

Prior to availability of effective antiviral therapy, the mortality rate for zoster in transplant populations was about 10 %, with deaths due to visceral dissemination, especially pneumonitis [215]. In a review of 195 BMT patients, mortality associated with dermatomal zoster and varicella-like syndrome was 6.7 % and 28 %, respectively [187]. In a more recent study of 43 acyclovir treated episodes in autologous BMT patients, all patients survived, including ten patients with varicella-like syndrome [151]. In a study of 25 liver transplant patients with zoster (1993–2004), only eight (29 %) were hospitalized, 16 (55 %) were treated with oral antivirals alone, and none developed visceral involvement [183].

27.4.5 Diagnosis

The appearances of classical varicella and herpes zoster are distinctive. In most cases, a clinical diagnosis is accurate and reliable. However, in transplant patients, presentations can be atypical and distinguishing between VZV and HSV disease can sometimes be difficult. When there is diagnostic uncertainty or visceral disease is suspected, laboratory confirmation is required.

Unlike HSV or CMV, VZV is not shed asymptomatically. Therefore, identification of VZV virions, antigens, or nucleic acids from cutaneous lesions or tissue biopsies is diagnostic of active infection. VZV can be cultured by inoculation of vesicular fluid or tissue extracts into monolayers of human fetal diploid kidney or lung cells. VZV is labile and efforts should be made to minimize specimen transport and storage time. Characteristic cytopathic effects are seen in tissue culture within 3–7 days. VZV identification can be confirmed by direct immunofluorescent staining of infected cells using VZV-specific monoclonal antibodies. A more rapid diagnosis can be made by using direct fluorescent antibodies (DFA) to detect VZV glycoprotein antigens in cellular scrapings obtained from the base of a fresh vesicle when the clinical presentation is atypical [216, 217].

PCR is useful for detecting VZV DNA in skin lesions, tissues or fluids (e.g., cerebrospinal fluid) and is much more sensitive than culture [218]. PCR of blood is the diagnostic method of choice for patients with visceral disease, including patients without cutaneous involvement [219–221].

Serologic assays help determine patient susceptibility to VZV but are not useful for diagnosing acute infections. Most laboratories use an ELISA method that can detect either IgG or IgM. Antibodies appear several days after onset of varicella and peak at 2–3 weeks. Patients with zoster are typically VZV-seropositive at the time of disease onset, but most show a significant rise in titer during the convalescent phase. Serologic boosting only provides retrospective confirmation of the diagnosis.

27.4.6 Therapy

The availability of safe and effective antiviral drugs has greatly reduced the high mortality rate previously associated with VZV disease in transplant patients. Controlled trials of intravenous acyclovir in immunocompromised patients with varicella demonstrated a dramatic reduction in complications, especially pneumonitis. Therapy should be initiated immediately with intravenous acyclovir at 10 mg/kg every 8 h, though some experts recommend higher doses of 12–15 mg/kg every 8 h (adjusted for renal function, as necessary). A switch to oral acyclovir, valacyclovir, or famciclovir, can be considered when the patient is afebrile and new lesion formation has ceased, to complete 10–14 days of therapy. In a retrospective review of 14 pediatric heart transplant patients with varicella, half were treated with intravenous acyclovir and half received oral valacyclovir; all patients recovered without serious complications [222]. Among 61 pediatric liver transplant patients with chickenpox, 95 % were treated with oral antiviral therapy with no evidence of visceral dissemination [223]. When feasible, immunosuppressive treatment should be temporarily reduced in transplant patients with varicella. If the patient is hospitalized, isolation procedures are essential to prevent nosocomial transmission.

Intravenous acyclovir (dosed as above) remains the therapy of choice for zoster in severely immunocompromised patients, including allogeneic HCT patients within 4 months of transplantation, HCT patients with moderate-to-severe acute or chronic GVHD, any patient requiring potent antirejection therapy, or any patient with suspected visceral dissemination. Studies in BMT patients with zoster proved that acyclovir was highly effective at preventing visceral dissemination [224, 225]. Since most VZV-related fatalities result from disseminated infection, treatment with acyclovir has

markedly reduced the herpes zoster mortality rate in transplant patients. Intravenous acyclovir is also the drug of choice for treating disseminated disease. When disease is well-controlled, the patient can be switched from intravenous to oral antiviral medication to complete therapy. For less severely immunosuppressed patients, including most SOT and autologous HCT patients with zoster, oral therapy with acyclovir (800 mg five times daily), valacyclovir (1000 mg t.i.d.), or famciclovir (500 mg t.i.d.), coupled with close clinical observation, is reasonable [226]. Patients should be treated until healing is complete (or a minimum of 10–14 days) to reduce risk of relapsing disease. Herpes zoster involving the first division of the trigeminal nerve (herpes zoster ophthalmicus; HZO) carries a substantial risk of ocular complications. Patients who present with HZO should initially be treated with intravenous acyclovir and evaluated promptly by an ophthalmologist [227, 228].

Since zoster tends to occur late after transplantation, most patients have been discharged from the hospital when the disease develops. Treating shingles in transplant patients on an outpatient basis with oral antiviral drugs is an attractive approach, although data from controlled studies are limited. In one study, 27 allogeneic BMT patients with zoster were randomized to receive oral or intravenous acyclovir [229]. No VZV dissemination occurred in either group, and no differences in healing or clinical outcome were apparent. Published data from clinical trials with famciclovir and valacyclovir for herpes zoster in immunocompromised patients remain limited, but a large body of clinical experience suggests these drugs are safe and effective and can replace oral acyclovir [230, 231].

Resistance to acyclovir occurs less frequently with VZV than with HSV and occurs more frequently in patients with AIDS than in transplant recipients [232, 233]. The possibility of acyclovir-resistant virus should be considered in immunocompromised patients who have progressive VZV disease despite appropriate antiviral therapy Based on anecdotal experience, foscarnet is recommended for management of disease caused by acyclovir-resistant VZV [234].

27.4.7 Prophylaxis

Antiviral prophylaxis in the posttransplant period has the dual advantage of effectively preventing both HSV and VZV disease. Results from two trials of 6 months of acyclovir prophylaxis in BMT patients showed zoster in 11 of 62 placebo recipients (18 %) and in none of 62 acyclovir-treated patients [112, 235]. In subsequent studies, oral acyclovir was extended to 12 months and the risk of zoster was reduced throughout the prophylaxis period [118, 143, 236]. These studies revealed no negative impact of acyclovir therapy on marrow engraftment, organ rejection or VZV-specific immune reconstitution. Zoster incidence increased after prophylaxis was discontinued. For populations receiving prophylaxis for 6 months, the cumulative number of zoster cases at 12 months was identical between acyclovir and placebo groups [112, 126, 235, 237, 238]. In HCT patients receiving 12 months of prophylaxis, the highly significant difference in zoster risk seen at 12 months was not present at 24 months after randomization [143]. Risk factors for zoster after prophylaxis termination included continued immunosuppression and HLA-mismatch donor status. However, in larger, more contemporary studies, “rebound” herpes zoster following 12 months of acyclovir prophylaxis was not observed [239, 240]. Importantly, acyclovir prophylaxis (e.g., 400–800 mg p.o. bid) effectively prevents herpes zoster during the early posttransplant period when patients are most severely immunosuppressed and are at highest risk for VZV-related complications. Because of its superior pharmacokinetic properties, many experts recommend valacyclovir (e.g., 500 mg p.o. daily or bid) as an alternative [241, 242]. Famciclovir would likely also be efficacious for prophylaxis, but supporting data are lacking.

Prophylactic antiviral drug regimens (e.g., valganciclovir) intended to prevent CMV disease in transplant patients effectively prevent herpes zoster [106, 144, 147, 149, 159, 243, 244]. However, some studies have shown that SOT patients receiving only preemptive therapy for CMV have a higher incidence and shorter time to onset of herpes zoster when compared with patients receiving daily prophylaxis [245]; other studies do not support this observation [246]. Daily acyclovir or valacyclovir should be considered in the early posttransplant period for patients whose CMV risk is managed with preemptive rather than prophylactic therapy.

Recommendations for duration of HSV/VZV-specific prophylaxis following HCT have evolved [239, 244, 247]. In 2009, a CDC panel published guidelines recommending acyclovir prophylaxis for 1 year following HCT, due to proven efficacy and safety [248]. Continuing prophylaxis beyond 1 year does result in continued reduction of herpes zoster risk in HCT patients and can be considered for those patients with continued need for systemic immunosuppression or with chronic GVHD [239, 248]. In all transplant patients, resumption of prophylaxis should be considered during intensification of immunosuppressive therapy, a period of enhanced risk [249].

A recent investigation was undertaken to determine if allogeneic HCT recipients managed with reduced-intensity conditioning (RIC) could safely forego routine antiviral prophylaxis [250]. The cumulative 2-year incidence of zoster was 20.7 % and did not differ between patients receiving myeloablative conditioning or RIC; 29 % of the zoster patients developed complications [250]. Therefore, antiviral prophylaxis is still warranted even in the setting of non-myeloablative conditioning regimens [149].

27.4.8 Prevention

27.4.8.1 Post-Exposure Prophylaxis

Serological screening prior to transplantation to determine susceptibility to VZV is essential to guide decision-making regarding immunoprophylaxis. Transplant patients (especially VZV-seronegative patients) should avoid exposure to persons with active VZV infection. Susceptible transplant patients with a close exposure to VZV (either chickenpox or zoster) should receive varicella-zoster immune globulin to provide passive immunity. VariZIG™ (Cangene Corporation, Winnipeg, Canada), the varicella-zoster globulin product available in the USA since 2006, can be ordered on a patient-specific basis from FFF Enterprises, Temecula, CA (24-h hotline: 1-800-8437477). In most cases, varicella-zoster immune globulin administration will not prevent infection in the susceptible host, but will significantly reduce illness severity [185]. Placebo-controlled trials in high-risk immunocompromised children demonstrated that varicella-zoster immune globulin ameliorated severity of chickenpox. A single treatment will reduce the risk of disseminated infection by about 75 % and provide 4 weeks of passive immunity. Controlled studies of post-exposure immunoprophylaxis have not been conducted in transplant populations and current recommendations are extrapolated from the pediatric data [251]. For maximal efficacy, varicella-zoster immune globulin must be administered as soon as possible after exposure (optimally within 96 h, but as late as 10 days may still provide benefits) [252]. Standard intravenous immunoglobulin (IVIG) contains substantial amounts of VZV-specific IgG and can be used if varicella-zoster immune globulin is not available. In situations where immune globulin is not available, post-exposure chemoprophylaxis with acyclovir or valacyclovir should be considered in seronegative or high-risk transplant patients who have been exposed to VZV [177, 248, 253, 254]. Some experts recommend combination prophylaxis with varicella-zoster immune globulin plus antiviral therapy for all VZV-seronegative HCT patients exposed to VZV [177]. Varicella-zoster immune globulin is not useful for treatment of established varicella or herpes zoster. Post-exposure vaccination, the intervention of choice in immunocompetent persons, is not recommended in transplant patients.

27.4.9 Vaccination

27.4.9.1 Varicella Vaccine

A more attractive option for prevention of VZV infection and disease is vaccination [255–259]. The VZV_{Oka} live-attenuated virus varicella vaccine (Varivax®) has been routinely administered to immunocompetent children in many countries for 20 years [260]. Concerns about use of live-attenuated virus vaccines in immunocompromised patients have focused on the potential for the vaccine virus to cause disease and that immunocompromised patients may fail to mount a protective immune response [261–263]. Preliminary data suggest that varicella vaccine is safe and effective when given prior to SOT [223, 264–269]. In a study conducted in France, all VZV-seronegative renal transplant candidates were given a single dose of the varicella vaccine; patients who failed to seroconvert received a second dose [264]. Following transplantation, varicella incidence was 12 % among vaccinees and 45 % among unvaccinated patients with no history of chickenpox. Varicella was less severe in the vaccinated population (no deaths) than in the seronegative unvaccinated population (three deaths). Zoster developed in 13 % of the patients with a history of varicella, in 7 % of the vaccine recipients, and in 38 % of the seronegative unvaccinated patients who developed primary varicella after transplantation [264]. When feasible, two doses of vaccine should be administered with a minimum interval of 4 weeks, and completed at least 2 weeks (preferably 4 weeks) prior to transplantation. VZV-seronegative household members should be vaccinated to minimize exposure of the transplant recipient to wild-type virus [248, 270].

An alternative approach is to administer primary or booster varicella vaccination after organ transplantation [142]. Pediatric SOT patients who received varicella vaccine demonstrated good humoral and cellular immune responses with few adverse effects [251, 271–274]. In similar studies involving pediatric HCT patients, administration of live-attenuated varicella vaccine after transplantation resulted in seroconversion and reduced rates of varicella [275, 276]. Posttransplant varicella vaccination of adults has not been studied [258]. Although further research is necessary, vaccination will likely play an increasingly important role in protecting transplant patients from varicella. Compared with varicella-zoster immune globulin or treatment of varicella, immunization would be highly cost-effective [277].

27.4.9.2 Herpes Zoster Vaccine

Over 90 % of adult transplant patients are latently infected with VZV and at risk for zoster [257, 268]. A VZV_{Oka}-containing vaccine (Zostavax®) reduces the incidence and severity of herpes zoster in immunocompetent adults, but has not been fully evaluated in immunocompromised populations [278, 279]. Small studies of live, attenuated VZV_{Oka} vaccine administration (usually >1 year after transplantation) for prevention of zoster in adult autologous HCT recipients have been reported [280, 281]. The vaccine was well tolerated and immunogenic in selected immunologically stable patients, but much larger studies are required to assess safety and efficacy [282]. Pretransplant administration of herpes zoster vaccine to SOT candidates should theoretically be safe and is being evaluated in ongoing trials.

Due to concerns regarding use of live-virus vaccines after HCT, a novel approach to preventing herpes zoster is the use

of a non-replicating VZV vaccine to boost cellular immune responses and prevent reactivation. Randomized studies have been performed that compared heat-inactivated VZV vaccine or placebo administered after HCT transplantation. Compared with the placebo group, vaccine recipients had a lower rate of zoster [283] and significantly reduced disease severity [284]. The level of protection correlated with the level of reconstitution of $CD4^+$ T-cell immunity against VZV. Recently, an adjuvanted subunit herpes zoster vaccine containing VZV glycoprotein E has shown to be highly effective for preventing shingles in immunocompetent adults [285]. While studies in transplant populations have not yet been reported, this vaccine avoids the risk associated with replicating vaccine virus and has great promise for use in immunocompromised patients.

Human Herpesvirus-6, -7, and -8 After Solid Organ Transplantation

Nina Singh

Since 1986, three novel herpes viruses, human herpesvirus (HHV)-6, -7, and -8, have been discovered. Kaposi sarcoma herpesvirus is causally associated with all forms of Kaposi sarcoma, including the type seen after transplantation. The role of HHV-6 and HHV-7 as pathogens in transplant recipients is less well understood. Although the complete spectrum of clinical sequelae and ultimately the effective prophylaxis and management of these viruses has yet to be fully elucidated, existing data suggest that these viruses are potentially pathogenic and clinically relevant in transplant recipients.

28.1 Human Herpesvirus-6

28.1.1 Biologic Features

HHV-6 belongs to the subfamily Beta herpesviridae in the genus Roseolovirus. HHV-6 is an enveloped virion with an icosahedral nucleocapsid of 162 capsomeres that contains a large, double-stranded DNA [1, 2]. Phylogenetically, HHV-6 is most closely related to HHV-7 and cytomegalovirus (CMV); nucleotide sequencing shows 66% DNA sequence homology between CMV and HHV-6 [3].

The primary target cell for HHV-6 is $CD4^+$ T lymphocytes, a characteristic that HHV-6 shares with human immunodeficiency virus (HIV) [4, 5]. The propensity to infect $CD4^+$ T cells preferentially differentiates HHV-6 from other DNA viruses. The virus utilizes CD46 as a cellular receptor; however, role of a cofactor has been suggested given that some human T-cell lines are not permissive of the virus despite high expression of CD46. The cellular host range of HHV-6 is broad and includes not only $CD4^+$ T cells but also $CD8^+$ T lymphocytes, NK cells, macrophages, megakaryocytes, glial cells, and epithelial cells [6]. HHV-6 has immunomodulatory characteristics; virus-infected peripheral blood mononuclear cells have been shown to demonstrate reduced cellular proliferation [7]. HHV-6 also modulates host immune response by altering cytokine and chemokine responses and by promoting a shift of T-helper responses from Th1 to Th2 phenotype [7–9].

Based on genomic DNA sequences, cell tropism, and protein expression, research studies have described two distinct variants of HHV-6 that have been designated as the A (HHV-6A) and B variants (HHV-6B) [10, 11]. The two variants exhibit 88% identity at the nucleotide level but differ in a number of their biologic properties. Most infections in transplant recipients are due to HHV-6B; the isolation of HHV-6A from blood samples is distinctly rare in transplant recipients. Lack of detection of HHV-6A may imply either that HHV-6A reactivation occurs infrequently or that it may be limited to sites other than the blood [12].

28.1.2 Transmission

Seroepidemiologic studies have shown that primary infection due to HHV-6 is usually acquired during the first year of life, with saliva the most likely mode of transmission. As with other herpesviruses, HHV-6 persists in the host in a latent form; seroprevalence in healthy adults exceeds 90% [13, 14]. Evidence of prior HHV-6 infection has been documented in 87–91% of the solid organ and 78–100% of the hematopoietic stem cell transplantation (HSCT) recipients [15]. Although the precise site of latency in the body is not known, the epithelial cells of the bronchial epithelia, salivary glands, and possibly monocytes/macrophages represent the most likely sites [16]. Neurons and glial cells may also be the sites where HHV-6 may be latent. A novel and an increasingly recognized form of HHV-6 persistence is integration of HHV-6 DNA sequences in the chromosomes of host peripheral blood mononuclear and other cells [17–20]. Chromosomal integration of HHV-6 DNA is a genetically inherited phenomenon and is considered to be responsible for vertical transmission of HHV-6 [21] and for the transmission of HHV-6 through stem cell transplantation [17]. This condition is present in ~1% of people and has been anecdotally implicated in HHV-6 central nervous system disease [22].

P. Ljungman et al. (eds.), *Transplant Infections*, DOI 10.1007/978-3-319-28797-3_28

Most infections in transplant patients are considered to result from reactivation of the latent virus. Donor transmission of HHV-6 with the transplanted allograft has also been documented. Mononuclear cells latently infected with HHV-6 in the donor allograft are believed to be the likely source of transmission. Following liver transplantation, primary HHV-6 infection has been reported in 61–100% of the patients who were seronegative for HHV-6 prior to transplantation [23, 24]. HHV-6 has been shown to develop latency in the kidney in vivo [25]. Indeed, two renal transplant recipients who received the allografts from the same cadaveric donor were documented to have identical genomic pattern of their HHV-6 isolates [26]. Transplanted allograft was the likely source of fatal infection due to HHV-6 variant A in a renal transplant recipient who was seronegative for HHV-6 prior to transplantation [27].

28.1.3 Epidemiology

Overall, 38–55% of the renal, 22–54% of the liver, 36% of the heart, and up to 57% of the lung or heart–lung transplant recipients develop HHV-6 infection [27–35]. Following living-related liver transplantation, HHV-6 infection has been documented in 48% of the patients [36]; these included all seronegative and 42% of the recipients seropositive for HHV-6 prior to living-related transplantation [36].

HHV-6 infections typically occur between 2 and 4 weeks after transplantation; this characteristic timing of onset distinguishes HHV-6 from other beta herpesvirus infections that usually occur posttransplantation [37]. In a study in liver transplant recipients where HHV-6 and HHV-7 DNA detection was sought in the plasma, HHV-6 infection occurred in 38% (15/40) patients; 67% of the infections occurred at 2 weeks posttransplantation after which the frequency of viral genome in the plasma sharply declined [36]. In contrast, only 31% of the HHV-7 infections were detected at 2 weeks with no distinct peak in time to detection. Further, HHV-7 DNA remained detectable in 10–20% of the patients until 8 weeks posttransplant [36]. Temporal sequence of infections with the three beta herpesviruses in organ transplant recipients showed that HHV-6 reactivation occurred at a median of 20 days, followed by HHV-7 (median 26 days) and CMV (median 36 days) [38].

Risk factors for HHV-6 infection in organ transplant recipients have not been fully defined. Receipt of OKT3 monoclonal antibodies or antithymocyte globulin has been associated with HHV-6 reactivation in solid organ transplant (SOT) recipients [27, 39]. HHV-6 seroconversion in one study was noted more frequently in patients who received immunosuppressive regimens containing sirolimus and IL-12 receptor antibodies as induction therapy [40]. There is conflicting data on the association of HHV-6 with rejection. HHV-6 infection has been shown to increase the expression of adhesion molecules and the number of human leukocyte antigen class II–positive T cells [41]. HHV-6 infection has been associated with acute allograft rejection in some, but not in all reports [30, 34, 38]. HHV-6 infection and peak HHV-6 viral load in liver transplant recipients were associated with only those rejection episodes that occurred after day 30 post-transplantation [42]. In renal transplant recipients, HHV-7, but not CMV or HHV-6, correlated with biopsy-proven cellular rejection [43]. An association between chronic allograft nephropathy and HHV-6 infection has been reported [44]. Histopathologic findings of chronic allograft nephropathy were observed in late biopsies in renal transplant recipients who had received antithymocyte globulin/ALG as induction therapy and had HHV-6 reactivation [45].

Liver transplant recipients with hepatocellular carcinoma in one report were more likely to develop HHV-6 viremia than patients without it [34]. The association between HHV-6 and hepatocellular carcinoma was considered to be mediated through hepatotropic viruses, for example, hepatitis B and C viruses [34]. It was proposed that hepatotropic viruses may facilitate the emergence of HHV-6 from latency by transactivating its immediate early proteins.

HHV-6 infections develop in 35–42% of allogeneic stem cell transplant recipients. Higher rates (87–92%) in cord blood transplant recipients are considered to be due to paucity of primed HHV-6 specific memory T cells and low ability of cord blood cells to produce protective cytokines [46, 47]. Risk factors for HHV-6 infection in HSCT recipients include younger age, transplantation for hematologic malignancy, HLA mismatch, and corticosteroid administration [46, 47].

28.1.4 Clinical Manifestations

The clinical sequelae of HHV-6 may result from symptoms directly attributable to the virus or from its immunomodulatory effects. Symptomatic infection due to HHV-6 occurs more frequently in HSCT recipients than it does in SOT recipients (Table 28-1). The most frequently observed

Table 28-1. Clinical sequelae of human herpesvirus-6

Supportive evidence from cohort studies
Encephalitis
Bone marrow suppression
Association with fungal infections
Association with cytomegalovirus infection
More aggressive recurrence of hepatitis C virus after liver transplantation
Evidence from case reports or case series
Pneumonitis
Exanthem
Hepatitis
Gastroduodenitis
Leukocytoclastic vasculitis
Proposed association with conflicting supportive evidence
Association with allograft rejection
Association with graft-versus-host disease
Mortality

clinical features of HHV-6 are skin rash and bone marrow suppression. Organ-specific involvement (e.g., interstitial pneumonitis, encephalitis, and hepatitis) is less common.

28.1.5 Direct Effects

A nonspecific febrile syndrome with or without a skin rash is attributed to HHV-6 in both HSCT and SOT recipients. The febrile mononucleosis syndrome attributable to CMV in transplant recipients may be related to concurrent infection with HHV-6 and HHV-7 rather than just CMV alone. HHV-6 is associated with acute and, less frequently, chronic myelosuppression [48]. In vitro studies have shown that colony-forming units of granulocyte–macrophage precursor decrease by 43% with HHV-6 infection; the growth of the multipotential precursor of granulocytes, erythrocytes, monocytes, and megakaryocytes was inhibited by 71%, and that of erythroid burst-forming units was reduced by 73% [9]. The most common hematologic sequelae of HHV-6 infection are delayed platelet engraftment and leukopenia. Cytokine-produced or virus-produced soluble factors may mediate the marrow suppressive effect of HHV-6 [9]. However, research findings have documented the direct effect of HHV-6 on the hematopoietic progenitor cells in vitro [49].

HHV-6 is a neurotropic virus. A number of well-documented case reports of HHV-6 encephalitis, as well as at least three studies that included concurrent controls, have documented an association between HHV-6 and central nervous system (CNS) complications of unidentifiable etiology [50–52]. In a report in liver transplant recipients, 15% (12 of 80) of the patients had mental status changes of unknown etiology after transplantation [34]. Patients with HHV-6 viremia had a significantly higher incidence of mental status changes of unidentifiable etiology (29%; 9 of 31), compared with those without HHV-6 viremia (6%; 3 of 49; $P=0.008$). Among 338 bone marrow transplant (BMT) recipients, CNS symptoms developed in 24 (7.1%). Researchers detected HHV-6 DNA in the cerebrospinal fluid (CSF) in 23% (5 of 22) of the patients with CNS symptoms [51]. None of the five cases in whom HHV-6 DNA was detected in the CSF samples had an identified cause of their CNS symptoms, and none of the 11 cases with a known etiology of CNS symptoms had HHV-6 DNA in the CSF ($P=0.03$). Allogeneic BMT recipients who received CD3-specific monoclonal antibody (anti-CD3) were more likely to develop encephalitis than were those patients who did not receive anti-CD3 ($P=0.008$) [53]. After adjusting for anti-CD3 therapy, HHV-6 was significantly associated with encephalitis ($P=0.009$) [53].

Mental status changes ranging from confusion to coma, seizure, and headache are the predominant clinical manifestation of HHV-6. Focal neurologic findings are rare. CSF pleocytosis ranging from 6 to 53 cells/mL was present in 50% of the patients with HHV-6 encephalitis in one review [52]. In the same review, neuroimaging abnormalities were present in two out of eight patients on magnetic resonance imaging [52]. These abnormalities included multiple, nonenhancing, low-attenuation lesions in the gray matter. More recently, HHV-6 has been identified as an etiologic agent for posttransplant acute limbic encephalitis, a distinct syndrome characterized by seizures, dense anterograde amnesia, and neuroimaging abnormalities showing low-attenuation lesions typically involving bilateral medial temporal lobes [54, 55].

Some but not all studies in HSCT recipients have suggested a causal association between HHV-6 and graft-versus host disease) (GVHD [56–58]. HHV-6 may present as an exanthem that may be indistinguishable clinically from GVHD; skin biopsy with demonstration of HHV-6 by immunohistochemistry and polymerase chain reaction (PCR) may be diagnostically useful in differentiating the two conditions or showing their coexistence [56, 58].

Case reports in stem cell transplant recipients have documented an association between obliterative bronchitis and HHV-6 [59, 60]. Although HHV-6 has been detected in 9.4–14.6% of the bronchoalveolar lavage fluid samples in lung transplant recipients [33, 61], its relevance as a pathogen in this setting is controversial. HHV-7, on the other hand, was proposed to have a role in the pathogenesis of bronchiolitis obliterans with organizing pneumonia (BOOP) given that HHV-7-DNA was detected in all (7/7) transbronchial biopsies that showed BOOP while coinfection with other beta herpesviruses was rare [61]. Rare cases of gastrointestinal disease, hepatitis, and hemophagocytic syndrome due to HHV-6 have also been documented in transplant recipients [30, 62–64].

28.1.6 Indirect Sequelae

HHV-6 has been described as an immunomodulatory and immunosuppressive virus that may facilitate superinfections with other opportunistic infections in transplant recipients, particularly CMV [7, 23, 37, 48]. A study identified primary HHV-6 infection as a significant risk factor for the development of symptomatic CMV infection, including tissue invasive CMV disease in liver transplant recipients [23]. In renal transplant recipients at risk for primary CMV infection, HHV-6 infection is significantly associated with the development of CMV viral syndrome and CMV hepatitis [48]. HHV-6 infection is an independently significant predictor of invasive fungal infections in liver transplant recipients. When the risk of opportunistic infections is controlled for the level of immunosuppression, HHV-6 infection increases by 3.68-fold in liver transplant recipients [42]. Another study reported that liver transplant recipients with HHV-6 had a significantly higher mortality; the independent association between HHV-6 and late mortality approached statistical significance in that study [34].

HHV-6 infection has been shown to have a role in the pathogenesis of hepatitis C [42, 65]. Although HHV-6 viremia did not affect the overall rate of recurrence of hepatitis C, it was associated with a more severe form of recurrence [42]. Patients with HHV-6 viremia tended to have an earlier recurrence and higher fibrosis scores on recurrence than did those with HHV-6 viremia [65]. Of note, patients who received ganciclovir as preemptive therapy for CMV infection had lower total Knodell scores and a trend toward lower fibrosis scores than those of patients who did not receive ganciclovir [65]. A protective effect of ganciclovir on the severity of HCV recurrence was proposed to be mediated via its mitigating effect on HHV-6 infection [65].

Although the pathophysiologic basis of the association between HHV-6 and severity of HCV, particularly the progression of fibrosis remains to be determined, a number of biologic plausibilities exist. HHV-6 is a potent inducer of cytokines, e.g. TNF-α, that play a role in the development of hepatic fibrosis. It is proposed that TNF-α leads to activation of Kupffer cells in the liver, a key component in the cascade of hepatic fibrogenesis [66]. Production of TNF-α can also lead to the induction of transforming growth factor (TGF-β1), a fibrogenic cytokine that is a potent stimulus for hepatic stellate cells to increase the production of extracellular matrix protein that ultimately results in hepatic fibrosis [67].

Clinical relevance of chromosomally integrated HHV-6 has not been fully defined in transplant recipients. Chromosomally integrated HHV-6 was documented in ~1% of the organ transplant recipients and correlated with an insignificantly higher risk of allograft rejection compared with patients who had low grade or no HHV-6 viremia [68].

28.1.7 Diagnosis

Although viral inclusion–bearing cells may appear in histopathologic samples [48], HHV-6 characteristically elicits little inflammatory response. Multinucleated giant cells, which are similar to the cytopathogenic effect caused by HHV-6 in human T lymphocytes in vitro, and enveloped virions with a prominent tegument that can by visualized by electron microscopy in the tissue have been proposed as morphologic criteria when assessing the possibility of tissue-invasive HHV-6 disease [69].

Serologic, virologic, and in situ immunohistochemistry assays have been used for the diagnosis of HHV-6. For the serologic diagnosis of HHV-6, enzyme immunoassays are more sensitive than are the fluorescence assays [70]. As with all herpesviruses that establish latency, serologic tests may not be reliable indicators of active infection, although they are useful for the determination of seroprevalence. Antigenic cross-reactivity or concomitant infection with other herpesviruses may confound the specificity of the serologic assays or the interpretation of changes in HHV-6 antibody titers. Immunoglobulin M (IgM) per se is also not a reliable marker for HHV-6 infection because most cases confirmed by culture or seroconversion have no detectable IgM [70]. Furthermore, up to 5% of healthy adults demonstrate IgM positivity at any time [70].

HHV-6 induces a characteristic cytopathic effect in primary lymphocyte culture with “large ballooning” refractile cells and the loss of normal lymphocyte clumping. The detection of HHV-6 in cell culture, however, must be confirmed by HHV-6–specific reagents and not merely by the cytopathic effect. HHV-6 isolation in cell culture is labor-intensive and time-consuming, requiring from 5 to 21 days for detection. A rapid shell vial (early antigen) assay can detect HHV-6 within 72 h [48]. This assay is analogous to the shell vial assay for the diagnosis of CMV. Compared with conventional cell culture, the assay has a sensitivity of 86% and a specificity of 100% in BMT and liver transplant recipients [71].

The ability of qualitative PCR to detect latent virus limits its use for the diagnosis of HHV-6. Latently infected peripheral blood mononuclear cells, however, contain fewer than ten HHV-6 genomes per 106 cells. Nevertheless, PCR has other advantages. PCR positivity in cell-free specimens can be diagnostically useful. Furthermore, HHV-6 variant discrimination is readily accomplished by PCR. The blood compartment used for the detection may influence the yield of the virus. Whereas HHV-6B DNA is detectable in both peripheral blood leukocytes and plasma, HHV-6A DNA is detected primarily in the plasma according to one report [72].

A potential caveat is that patients with chromosomally integrated HHV-6 may have detectable virus in the CSF or serum even in the absence of active infection [17]. Antigenemia or viral isolation may have diagnostic utility in such cases [17]. A decline in viral load in temporal association with treatment also suggests a causal role of HHV-6 in patients with a clinical illness compatible with HHV-6 [17–19].

Immunohistochemical stains for detecting HHV-6 in formalin-fixed, paraffin-embedded tissue are also available. Immunohistochemical staining of tissues with murine monoclonal antibody that is reactive against both the structural protein p101 of variant B and the structural protein glycoprotein 82 (gp82) of variant A detects cells that are productively, and not latently infected with HHV-6.

28.1.8 Management

28.1.8.1 Prevention

Of currently available antiviral agents, acyclovir has consistently shown poor activity against HHV-6 in vitro [73]. Ganciclovir, on the other hand, has anti-HHV-6 activity with EC_{50} ranging from 0.56 to >25 in various studies. HHV-6 UL69 is the functional homolog of human CMV

UL97-encoded kinase that converts ganciclovir to its monophosphate metabolite in the infected cell [73]. In vitro studies have shown that the capacity of HHV-6 UL69 phosphorylates ganciclovir is 10-fold lower as compared to that of human CMV UL97 [74]. Furthermore, the affinity of ganciclovir triphosphate for HHV-6 DNA polymerase is 6-fold less than that for CMV and 800-fold less compared to acyclovir triphosphate for herpes simplex virus (HSV) DNA polymerase [75].

Antiviral prophylaxis with ganciclovir has been shown to be protective against HHV-6 infection in some but not all studies. In HSCT recipients, HHV-6 infection was documented in 39% (11/28) of the patients who did not receive ganciclovir compared to 0/13 in those who did [74]. In renal transplant recipients receiving ganciclovir HHV-6, viremia appeared later after transplantation (42 vs. 21 days) and was shorter in duration (29 vs. 62 days); however, there was no difference in the incidence of viremia (71% vs. 61%) [76]. Low-grade viremia was documented in ~14% of the organ transplant recipients receiving valganciclovir for 100 days posttransplant; however, no clinical manifestations could be attributed to it [77]. In contrast, suppression of CMV was complete. Thus, antiviral prophylaxis is not consistently effective in the prevention of HHV-6. The role of targeted prophylaxis based on periodic monitoring for HHV6 viremia has also not been defined. Given lack of standardized quantitative PCR cutoffs that can reliably predict disease, and erratic efficacy of currently available antiviral agents against HHV-6, a preemptive therapeutic approach cannot be recommended at this time.

28.1.8.2 Treatment

Overall mortality in patients with HHV-6 meningoencephalitis has ranged from 45% to 58% [50, 51]. Both ganciclovir and foscarnet have been successfully used for the treatment of meningoencephalitis, although outcomes have not been uniformly good. Of 13 HSCT recipients with HHV-6 encephalitis, 46% (6) died, that included four treated with ganciclovir and two who received ganciclovir and foscarnet [78]. In a review of HHV-6 encephalitis in transplant recipients, cure was documented in 7/8 patients who received ganciclovir or foscarnet for at least 7 days as compared to 0/4 who did not receive these drugs or received them for less than 7 days ($P=0.01$) [52].

There is evidence that antiviral activity against HHV-6 is different in serum and CSF. Amongst 11 HSCT recipients, median log decrease in the serum from 2.0 to 0 copies/mL and in the CSF from 4.4 to 2.0 copies/mL was documented with antiviral therapy [50]. Furthermore, decreases in CSF levels lagged behind that in the serum; earliest negativity in the CSF was observed at week 3 of antiviral therapy. Overall 5/11 patients died, including 4/5 who received foscarnet and ganciclovir [50]. In a recent report, ganciclovir and foscarnet were effective in inhibiting HHV-6 in peripheral blood mononuclear cells, but only foscarnet and cidofovir inhibited the virus in glial cells [79]. Rarely, ganciclovir-resistant HHV-6 disease has been documented in the setting of prolonged ganciclovir exposure [80]. It should be noted that while chromosomally integrated HHV-6 is not treatable with antiviral agents [17, 19], a case of severe encephalomyelitis due to chromosomally integrated HHV-6 successfully treated with foscarnet and ganciclovir has been reported [18].

Maribavir has been shown to be inactive against HHV-6 [73]. However, a recent study that evaluated the activity of maribavir against HHV-6 in a cell culture to slow the growth of lymphocytes documented that maribavir inhibits the replication of HHV-6 and the activity of UL69 protein kinase [81]. Other agents with diverse targets and enhanced activity are in various stages of development [82]. Hexadecyloxypropyl cidofovir or CMX001, is a lipid conjugate of cidofovir with in vitro activity against numerous double stranded DNA viruses. In vitro studies in propagated cell lines showed a 100-fold increase of cidofovir-diphosphate concentration in cells exposed to hexadecyloxypropyl cidofovir compared to cidofovir although clinical data are pending [83].

28.2 Human Herpesvirus-7

28.2.1 Overview

Infection due to HHV-7, like HHV-6, is ubiquitous. HHV-7, however, is more cell-associated, less lytic, and slower growing than HHV-6 [84]. HHV-7 not only exhibits selective tropism for $CD4^+$ T lymphocytes, but it also uses the CD4 molecule as its receptor. Primary infection due to HHV-7 also occurs during childhood, albeit at a slightly later age than does HHV-6. The salivary glands are believed to be the sites of persistence and replication of this virus.

HHV-7 may be a causative agent of roseola (exanthema subitum), particularly of the second attack. HHV-7 causes up to 10% of the cases of exanthema subitum. An association between HHV-7 infection and neurologic manifestations (e.g., acute hemiplegia in childhood and febrile convulsions) has been reported in nontransplant settings [85].

Viremia due to HHV-7 has been demonstrated by the detection of HHV-7 DNA via PCR of the peripheral blood mononuclear cells in 57% of the bone marrow and 39% of the renal transplant recipients [86, 87]. HHV-7 may be a cofactor in the pathogenesis of CMV in transplant recipients. Patients with CMV disease are more likely to have HHV-7 DNA detection than are those with asymptomatic CMV infection [57]. In a study of renal transplant recipients, patients coinfected with CMV and HHV-7 were more likely to have CMV disease, as compared to those with CMV infection only [43]. The febrile syndrome associated with CMV in liver transplant recipients may be due to concurrent infection with HHV-6 and/or HHV-7 [88]. A possible association between HHV-7 with bronchiolitis obliterans and organizing

pneumonia was reported in a lung transplant recipient [61]. One report of fatal encephalitis in association with HHV-7 in a peripheral blood stem cell transplant recipient has been published [89].

28.2.2 Management

Conflicting reports exist regarding the in vitro susceptibility of HHV-7 to ganciclovir. Researchers have evaluated the inhibitory activity of four classes of antiviral agents against HHV-7 [90]. These included foscarnet; the β-guanine analogues, acyclovir, ganciclovir, and penciclovir; the acyclic nucleoside phosphonates e.g., cidofovir and its cyclic derivatives, cyclic HPMPC [(S)-1-(3-hydroxy-2-phosphonylmethoxypropyadenine)]; and a series of benzimidazole ribonucleosides [90]. In this study, HHV-7 was most sensitive to cidofovir and its related compounds and least sensitive to the β-guanine analogues, including ganciclovir [90]. In another study, however, ganciclovir was shown to be highly active against HHV-7 [91].

Data regarding the clinical efficacy of antiviral agents for HHV-7 are sparse. One study reported clearance of HHV-7 DNA in the blood, as detected by PCR, in one of two BMT recipients who received ganciclovir and in two of those who received foscarnet [86]. A study of renal transplant recipients, however, showed that neither oral nor intravenous ganciclovir had an effect on the prevalence of HHV-7 viremia, as detected by PCR [92].

28.3 Human Herpesvirus-8 or Kaposi Sarcoma Herpesvirus

28.3.1 Biologic Features

Kaposi sarcoma herpes virus (KSHV) is a member of the subfamily Gammaherpesviridae that belongs to the genus Rhadinovirus. These herpesviruses are transforming viruses that are capable of causing tumors in their natural hosts. KSHV is most closely related to herpesvirus saimiri with which it bears 51% DNA sequence homology [93].

KSHV is unique among herpesviruses in that it contains an unprecedented number of genes that are transduced from the host cellular genomes during its evolution, a phenomenon known as molecular piracy [94]. While they are less important for viral replication, these genes do encode for cellular homologs that induce angiogenesis, regulate antiviral immunity, and alter cellular growth [94]. Spindle cells are the histopathologic hallmark of Kaposi sarcoma (KS). Most of these cells stain positive for endothelial cell markers; however, some cells express proteins that are characteristic of smooth muscle cells, macrophages, or dendritic cells. These data suggest that KS spindle cells are derived from a pluripotent mesenchymal progenitor cell [94].

Whether KS is a true malignancy or a cytokine-driven hyperplasia is unknown. KSHV is a potent inducer of angiogenic cytokines, such as IL-6, basic fibroblast growth factor, and IFN-γ [94]. KS spindle cells produce IL-6, and the addition of exogenous IL-6 to culture can enhance the proliferation of KS cells in culture, which has led many to believe that KS is a cytokine-driven lesion.

28.3.2 Epidemiology and Clinical Manifestations

The incidence of KS in transplant recipients largely parallels the geographic seroprevalence of KSHV in that region (Table 28-2). Consequently, wide geographic variations in KS rates are observed. In areas of low seroprevalence of KSHV (e.g., United States), KS affects less than 1% of the transplant recipients, and it accounts for 3–10% of all malignancies in transplant recipients. On the other hand, in South Africa and Saudi Arabia, KS affects up to 5% of the transplant recipients, and it accounts for between 59% and 87% of the posttransplantation malignancies [95, 100–102]. The striking male predominance of KS lesions in the nontransplant setting is less pronounced in transplant recipients, who have a male-to-female ratio of 3:1.

Although most KS lesions in transplant recipients result from the reactivation of latent virus, transmission via the transplanted allograft can occur. In a liver transplant recipient with KS, the anatomic distribution of KS in an autopsy study and the HLA haplotyping suggested that KS arose in the stromal endothelial cells of the donor liver [103]. After transplantation, the seroconversion rates range from 2% to

TABLE 28-2. Geographic variations in the incidence of Kaposi sarcoma in solid organ transplant recipients

Country	Incidence of Kaposi sarcoma (%)	Proportion of all malignancies in transplant recipients that are due to Kaposi sarcoma (%)
United States	0.5	3–10
France	0.6	8.3
Italy	1.6	–
Israel	2.4	–
South Africa	4	59
Saudi Arabia	5.3	87

Transplantation. 1998;66:214–8 [95]; Penn I. Incidence and treatment of neoplasia after transplantation. J Heart Lung Transplant. 1993;12:S328–36 [96]; Harwood AR, Osoba D, Hofstader SL, et al. Kaposi's sarcoma in recipients of renal transplants. Am J Med. 1979;67:759–65 [97]; Hiesse C, Kriaa F, Rieu P, et al. Incidence and type of malignancies occurring after renal transplantation in conventionally and cyclosporine-treated recipients: analysis of a 20-year period in 1600 patients. Transplant Proc. 1995;27:972–4 [98]; and Montagnino G, Bencini PL, Tarantino A, et al. Clinical features and course of Kaposi's sarcoma in kidney transplant recipients: report of 13 cases. Am J Nephrol. 1994; 14:121–6 [99].

12% [104, 105]. Higher rates of seroconversion are observed in liver transplant recipients than in renal transplant recipients [105]. Another study indicated that seroconversion occurred at a mean of 5 months after transplantation and that it preceded KS by 11.5 months [100]. KS is one of the earliest posttransplantation malignancies to occur in transplant recipients. The median time to onset is 22 months for KS, 32 months for lymphomas, and 69 months for epithelial malignancies [96]. The frequency of KS is higher in liver transplant recipients than it is in other organ transplant recipients [96]. Notably, rare reports of KS in BMT recipients are encountered. KSHV viremia as quantified by a real-time PCR correlates with the progression of KS in transplant recipients [106].

Although the skin is the most commonly involved site of KS, up to 40% of transplant recipients may develop visceral lesions, including gastrointestinal, pulmonary, bladder, and laryngeal KS. Gastrointestinal involvement may often be occult, or it may be associated with nonspecific gastrointestinal symptoms and bleeding. Occasionally, perforation, obstruction, and protein-losing enteropathy caused by lymphatic obstruction may occur. In addition, some authors report nonneoplastic manifestations (e.g., a syndrome characterized by fever, splenomegaly, and marrow failure with plasmacytosis) after transplantation [107].

28.3.3 Management

Reduction or withdrawal of immunosuppression remains the mainstay of the management of KS in transplant recipients. Although the regression of KS with the reduction or cessation of immunosuppression occurs in all forms of KS, remission rates are higher for visceral lesions than for those that are nonvisceral. However, up to 50% of the patients treated with the cessation of immunosuppression may lose their grafts [101, 108]. In patients with disseminated or visceral KS that fails to respond to modifications in immunosuppression, combination chemotherapy has been employed in some reports [109]. Of five transplant recipients treated with combination therapy with doxorubicin, bleomycin, and vincristine, two experienced a complete remission and two had a partial response [109]. In this setting, retransplantation in renal allograft recipients leads to the recurrence of KS lesions almost universally [108]. However, some case studies have reported a successful outcome after retransplantation [110].

The existence of lytically infected cells in KS lesions has implications for the treatment of KS with antiviral agents. Nucleoside analogues (e.g., acyclovir and penciclovir) have minimal in vitro activity against KSHV. Although the virus is susceptible to ganciclovir and foscarnet, the acyclic nucleosides phosphonate analogues, cidofovir and HPMPA, are potent inhibitors of HHV-8 DNA synthesis [111]. Reportedly, adefovir blocks HHV-8 DNA replication at a fourfold lower concentration than does foscarnet [111].

In the setting of HIV, a significant reduction in the risk of KS in patients who receive ganciclovir has been reported; however, experience with antiviral therapy in the transplant setting is limited. In four thoracic organ transplant recipients who received cidofovir for KS recurrence or for intolerance of cytotoxic chemotherapy, researchers documented the clearance of KSHV from the blood in two out of two and from skin lesions in two out of four patients [112]. Clinical improvement of one patient's gastric KS lesions was observed [112]. However, results regarding a role for antiviral therapy in the management of posttransplantation KS are inconclusive.

B cells in the lymph nodes of patients with KSHV-related, multicentric Castleman disease stain positively for CD20 surface antigen; one study used anti-CD20 antibody therapy in a patient with HIV infection [113]. The role of other experimental therapies (e.g., inhibitors of angiogenesis and retinoids) is unproven [114].

The immunosuppressive agent rapamycin has been shown to inhibit the growth of primary effusion lymphoma (PEL) cell lives, and to prevent and delay the development of PEL tumors in animal models of severe combined immunodeficiency [115]. Anecdotal reports have documented regression of KS lesions in transplant recipients upon conversion to rapamycin-based immunosuppression [116, 117]. Others have reported no such beneficial effect [118].

28.4 Summary

Existing literature supports the role of HHV-6 as a potential cause of encephalitis and bone marrow suppression in transplant recipients. An association of HHV-6 with fungal infections and CMV infection has been documented. HHV-7 also appears to be an immunomodulatory agent that may facilitate the pathogenicity of CMV. One possibility is that the beneficial effect of antiviral prophylaxis for CMV in transplant recipients could have been mediated in part through its effect on these newer beta herpesviruses. Trials for CMV chemoprophylaxis may consider assessing the effect of antiviral agents on HHV-6 and HHV-7 since these data have implications for the further elucidation of the pathogenicity of these viruses.

Human Herpesvirus 6A, 6B, 7, and 8 Infections After Hematopoietic Stem Cell Transplantation

Joshua A. Hill and Danielle M. Zerr

29.1 Introduction

Herpesviruses have plagued persons undergoing hematopoietic stem cell transplantation (HCT) since the introduction of this life-saving therapy in the 1950s. With the early recognition of severe disease due to local or disseminated herpes simplex virus (HSV), it was clear that preventative measures were necessary, and acyclovir prophylaxis studies were initiated in the early 1980s [1]. Similarly, human cytomegalovirus (CMV) reactivation was found to occur in the majority of patients, many of whom developed severe pulmonary and gastrointestinal disease unimpeded by acyclovir. This prompted the development of prophylactic and preemptive treatment strategies using ganciclovir and foscarnet [2]. Human herpesvirus (HHV) 6A, HHV-6B, HHV-7, and HHV-8 (also known as Kaposi's sarcoma associated herpesvirus, or KSHV) were unknown in the early era of HCT, only to be discovered in an 8-year period between 1986 and 1994 [3–5].

HHV-6A, HHV-6B, and HHV-7 are T lymphotropic viruses closely related to CMV, placing them in the betaherpesvirus family. Given their etiologic link to roseola infantum, these viruses are designated Roseoloviruses. Population based studies demonstrate that upwards of 95% of the human population is infected in the first few years of life. KSHV is a member of the gammaherpesvirus family in the rhadinovirus genus. Infection with KSHV is less frequent, and seroprevalence ranges widely from <10% to >40% depending on geographic region and risk factors [6–8].

The preponderance of evidence suggests an important role for HHV-6B in complications after allogeneic HCT, whereas there is less support for a significant role for HHV-6A, HHV-7, and KSHV. The utility of screening and preventive approaches for these viruses remains unclear given a still limited understanding of the full spectrum of their clinical impact after HCT, coupled with costly diagnostics and limited low-risk therapeutic options.

This chapter will focus on recent advances in our understanding of the post-HCT epidemiology, clinical impact, diagnosis, and treatment of HHV-6B in particular, in addition to HHV-6A, HHV-7, and KSHV.

29.2 Epidemiology

29.2.1 HHV-6A and B

HHV-6A and HHV-6B were classified as separate species in 2012 due to epidemiological, biological, and immunological distinctions [9]. HHV-6B infects most children within the first few years of life and is likely transmitted by saliva [10, 11]. The epidemiology of HHV-6A is not as well described. Primary infection with HHV-6A appears to occur later in life and with less frequency [12], although early infection may be more common in Sub-Saharan Africa [13].

HHV-6B uses the cellular receptor CD134 for entry into cells [14], whereas HHV-6A uses CD46 [15]. Like other herpesviruses, these pathogens chronically infect their host and remain latent in a variety of cell types, including peripheral blood mononuclear cells (PBMCs), natural killer cells, bone marrow progenitor cells, salivary glands, bronchial glands, oligodendrocytes, and astrocytes [10, 16, 17]. Although the putative method of latency remains unclear, there is mounting evidence to support subtelomeric chromosomal integration rather than episome formation, a mechanism unique to HHV-6 species among HHVs [18, 19] (Figure 29-1). If viral integration occurs in a germ-line cell, vertical transmission of chromosomally integrated HHV-6 (ciHHV-6) results in offspring with latent HHV-6 in all nucleated cells. This condition of inherited ciHHV-6 is found in ~1% of the population (~70 million individuals worldwide). HHV-6B is responsible for two-thirds of inherited ciHHV-6 cases while HHV-6A accounts for one-third [18]. Importantly, viral integration is not a dead end, as reactivation with associated cytopathic effects can be induced in vitro [20], and a case of apparent inherited ciHHV-6-associated disease was recently described in a child with severe combined immunodeficiency who underwent HCT [21].

HHV-6B accounts for ~98% of HHV-6 species reactivation after allogeneic HCT [22–26]. Studies of HHV-6B detection in diverse populations of allogeneic HCT recipients, primarily using polymerase chain reaction (PCR) assays to detect viral DNA, demonstrate that 40–50% of

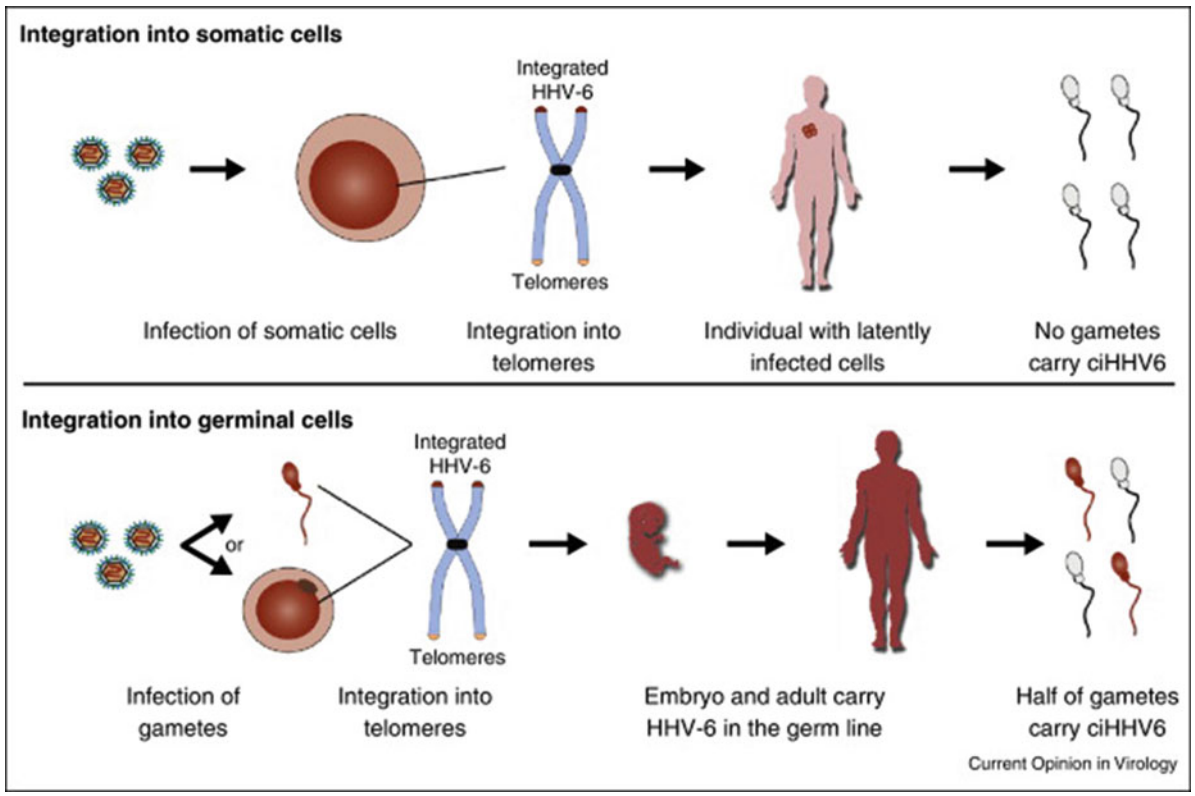

FIGURE 29-1. Chromosomal integration of HHV-6A and B. Human herpesvirus 6A and 6B are able to integrate into the subtelomeric and/or telomeric region of human chromosomes. *Upper panel*: This demonstrates a potential pathway of latency in a naturally infected individual in whom the virus integrates into a chromosome of infected cells. *Lower panel*: This demonstrates the unique condition of inherited chromosomally integrated HHV-6 that occurs when the virus infects and integrates into the chromosome of a gamete that is subsequently fertilized. This will result in an individual with one copy of the entire HHV-6 genome in every nucleated cell and in 50% of their gametes, allowing for vertical transmission. TABLE 29-1. Epidemiology of HHV-6A, HHV-6B, HHV-7, and KSHV infections in HCT recipients

	Population-based seroprevalence	Incidence of reactivation (%)	Risk factors for reactivation after HCT
HHV-6A	Not well studied	0–3[a]	Not well understood
HHV-6B	~95% after infancy	40–50	Cord blood HCT HLA mismatched donor Unrelated donor Acute graft-versus-host disease grades II–IV Receipt of anti-T-cell antibodies Receipt of steroids
HHV-7	~95% after infancy	20–60	Not well understood
KSHV	Sub-Saharan Africa, >30–40% Mediterranean, 10–20% Americas and Asia, <10% Men who have sex with men, 20–40%	0–1	Not well understood

[a]Consider latent inherited ciHHV-6A as a source of viral DNA.

patients have viral reactivation at a median of approximately 3 weeks after HCT (Table 29-1). Given that the majority of people are seropositive for HHV-6B at the time of HCT, most viral detection is likely due to viral reactivation; however, as a number of leukocyte subsets are sites of latency for HHV-6 [16, 17], there is also the possibility of graft-induced (re-) infection with HHV-6 from donor to recipient. The most common risk factors for HHV-6 reactivation include cord blood transplantation (CBT), use of a mismatched or unrelated donor, receipt of anti-T-cell antibodies, acute

graft-versus-host disease (GVHD) grades II–IV, and treatment with glucocorticoids [23, 24, 27–32] (Table 29-1). The highest rates of HHV-6B detection are seen after CBT; in a recent prospective cohort of 125 CBT recipients, reactivation was documented in 94% of patients [25]. CBT recipients also have higher levels of HHV-6 reactivation with median viral loads approximately 1 $\log_{10}$ higher than recipients of other sources of stem cells (i.e., PBMCs or bone marrow) [25, 33]. While use of alternative donor sources and graft manipulation, such as cord blood cells and T-cell depletion, has allowed for expanded access to HCT, later engraftment and delayed adaptive immune reconstitution have resulted in a greater burden of virus-associated complications [34]. A recent study also demonstrated that up to 50% of CBT recipients have long-lasting detection of HHV-6B a median of 4 years post-CBT, despite no significant differences in long-term immune reconstitution [35].

29.2.2 HHV-7

HHV-7, similar to HHV-6B, infects most children within the first few years of life and is thought to be transmitted via saliva [3, 10, 36, 37]. HHV-7 exhibits selective tropism for CD4+ T-cells and uses the CD4 receptor for cell entry [38]. Primary infection rarely comes to clinical attention but is likely another, although less frequent, cause of roseola infantum. Most studies of HHV-7 after HCT have been conducted in pediatric patients, who have a 20–60% incidence of HHV-7 DNA detection, typically during the first 2–6 weeks after HCT [39–41] (Table 29-1). One study reported a lower rate of detection (5.5% of patients) and detection in allogeneic but not autologous HCT recipients [42]. In contrast to HHV-6B, there is no obvious peak time of reactivation, and the vast majority of reactivation events are transient and low-level. Risk factors for HHV-7 reactivation have not been well studied. A prospective study assessing for HHV-7 reactivation with weekly PCR testing for 12 weeks after autologous and allogeneic HCT in 59 pediatric patients showed a negative association with HHV-6 reactivation and an increased incidence after autologous (vs allogeneic) HCT and PBMC (vs cord blood/bone marrow) HCT in univariate models [39]. Another study in 125 pediatric HCT recipients reported a positive association with higher dose of CD34+ stem cells, use of busulfan, related donor, and HHV-6 reactivation.

29.2.3 KSHV (or HHV-8)

KSHV infection is less ubiquitous than HHV-6A, HHV-6B, and HHV-7. Although the timing and precise route of infection are not well understood, exposure to saliva through casual contact among children and young adults is the most plausible route of infection in the majority of individuals [43]. CD19+ B cells appear to be the primary viral reservoir, but other potential reservoirs, such as the endothelium, CD68+ monocyte-macrophage cells, salivary glands, and prostate epithelia have been proposed [6]. There are notable geographic differences in the seroprevalence of KSHV, with the highest rates in sub-Saharan Africa (>30–40%), intermediate rates in Mediterranean areas (10–20%), and lowest rates in Asia and the USA (<10%) [6] (Table 29-1). KSHV infection is evident in 20–40% of men who have sex with men [6–8], and sexual transmission has been demonstrated within this population [44]. Interestingly, KSHV is not detected in appreciable amounts in seminal fluid or the rectum [45].

An epidemiologic study of 187 HCT donor–recipient pairs in Italy found that 13% of donors and 11% of recipients were seropositive for KSHV [46]. KSHV DNA detection in the blood was rare (0–1%) after HCT in this and other studies [47] (Table 29-1). Among solid organ transplant recipients developing KS, more than 80% appear to be seropositive prior to transplant, suggesting viral reactivation as a cause of disease [48]. The natural history of KSHV after HCT is poorly studied and may be higher in certain patient populations.

29.3 Clinical Impact

29.3.1 HHV-6A and B

HHV-6B is a pleiotropic virus that has been associated with many complications after allogeneic HCT (Table 29-2). Whether HHV-6B has a causal role in all of these processes has been controversial due to the challenge implicit in

Table 29-2. Disease associations with HHV-6A, HHV-6B, HHV-7, and KSHV reactivation after HCT

	Epidemiologic associations	Level of in vitro or in vivo support for causation
HHV-6A	Encephalitis[a]	Weak, case reports
HHV-6B	Encephalitis (including limbic encephalitis)	Strong
	CNS dysfunction (not encephalitis)	Moderate
	Fever and rash	Strong
	Myelosuppression	Strong
	Acute graft-versus-host disease	Moderate
	Allograft rejection	Weak
	CMV reactivation	Weak
	Pneumonitis	Weak
	Hepatitis	Weak, case reports
	Increased all-cause mortality	Weak
HHV-7	Encephalomyelitis	Weak, case reports
	Increased level and duration of CMV viremia	Weak
KSHV	Kaposi's sarcoma	Strong
	Bone marrow failure	Weak
	Fever and rash	Weak

[a]Consider latent ciHHV-6A as a source of viral DNA.

attributing disease to a virus latent in diverse cell types. Studies have used a variety of techniques without international standards on an array of sample sources to detect HHV-6, often without distinguishing between species, making direct comparisons problematic. HHV-6A has not been independently associated with any disease after HCT.

29.3.1.1 Central Nervous System Disease

There is sufficient evidence to implicate HHV-6B as a cause of encephalitis, and the most common etiology of encephalitis after HCT, as recently reviewed by Drs. Ward and Ogata [49, 50]. The incidence of HHV-6B encephalitis after allogeneic HCT was evaluated in a meta-analysis of 19 studies and reported to occur in 8.3% of CBT recipients compared to 0.5% of patients receiving stem cells derived from PBMCs or bone marrow [51].

Many studies have defined HHV-6 encephalitis as acute encephalopathy with HHV-6 detected in the CSF or brain, without a more likely explanation identified after extensive evaluation. The more specific syndrome of HHV-6B post-HCT acute limbic encephalitis (HHV-6B-PALE) is characterized by distinct clinical, laboratory, and radiographic features, including amnesia (especially anterograde), seizures, confusion, the syndrome of inappropriate antidiuretic hormone secretion, mild cerebrospinal fluid (CSF) pleocytosis and protein elevation, and medial temporal lobe changes on brain magnetic resonance imaging (MRI) [22, 24, 50–52].

Detection of HHV-6B DNA in CSF is a defining clinical criteria for HHV-6B encephalitis, and at least 85% of affected patients have concurrent detection in the blood [24, 51]. In a review of 48 published cases and case series of patients with likely HHV-6B encephalitis over a 15-year period, 40 of 48 cases had HHV-6B documented in CSF samples [53]. All cases followed allogeneic HCT except for 1 after autologous HCT. Symptom onset occurred after engraftment in the majority of cases following adult HCT but may occur pre-engraftment after CBT [24]. The most common neurologic symptoms were confusion and depressed consciousness beginning at a median of 24 days after HCT, with a range of 15–60 days. Seizures were reported in 40% of cases, although electrographic seizures without obvious clinical findings appeared to occur in a higher proportion. MRI findings were abnormal in 30 of 43 cases and involved the medial temporal lobes in 22 of 30 cases. Typical MRI abnormalities include well circumscribed, hyperintense, nonenhancing lesions involving the medial temporal lobes, and especially the hippocampus, on T2, fluid attenuation inversion recovery (FLAIR) and diffusion-weighted (DWI) MRI sequences [52, 54, 55]. Brain computed tomography scans are typically normal. CSF findings were significant for elevated protein levels in 58% of reported cases, as well as mild lymphocytic pleocytosis in a minority of patients (although leukopenia was likely present at the time of lumbar puncture in many cases) [53]. HHV-6B was identified in 24 of 27 cases that underwent discriminatory testing for HHV-6 species. Additional studies have demonstrated HHV-6B protein expression in the mesial temporal lobes of patients with HHV-6B encephalitis [56, 57].

HHV-6 systemic reactivation with high levels of viremia is the primary risk factor implicated in the development of HHV-6B encephalitis. Patients with HHV-6B encephalitis typically have plasma viral loads 100-fold greater than other viremic patients [29, 58]. Cord blood HCT recipients are at particularly high risk for increased frequency and degree of HHV-6 systemic reactivation [25, 33] with subsequent encephalitis [24, 59]. Among patients with viremia, viral loads $>10^4$ copies/ml are typically seen in the setting of HHV-6B encephalitis. A large retrospective study demonstrated that peak plasma HHV-6B viral loads $\geq 10^5$ copies/ml was 71% sensitive and 94% specific for HHV-6B encephalitis [24]. However, it is important to note that some cases of encephalitis have been reported in the absence of viremia, although this may have been do to lack of or the timing of testing. Finally, not all studies tested patients for inherited ciHHV-6, and inappropriate inclusion of affected patients may have led to a relative increase in observed HHV-6 viral loads (see Sect. 29.3.1.3).

Patients who develop HHV-6B encephalitis have significant morbidity and mortality despite antiviral treatment [60]. Retrospective reviews demonstrate that clinical status improves after antiviral treatment in the majority of patients, but 20–40% of patients have persistent mild-to-moderate neurocognitive deficits and up to 25% have progressive encephalitis resulting in death [52, 53, 61]. Mortality is particularly high after CBT with rates of up to 50% [24].

In addition to overt encephalitis, there is accumulating evidence that HHV-6B may also contribute to less-fulminant CNS dysfunction. A large prospective study of 315 allogeneic HCT recipients that systematically assessed for CNS dysfunction found an independent and temporal association between HHV-6B reactivation and both delirium and neurocognitive decline after HCT [62]. Similar findings were demonstrated in a cohort of 35 CBT recipients [63]. HHV-6B DNA detection in CSF is typically associated with neurologic findings ranging from headache to fulminant encephalitis, but it may also occur in the absence of CNS symptoms in a minority of patients [64–66]. Our understanding of the significance of HHV-6B DNA detection in the CSF continues to evolve but is limited by the lack of routine CSF sampling in asymptomatic HCT recipients early after HCT.

29.3.1.2 Non-Central Nervous System Disease

HHV-6B reactivation has been associated with a number of non-CNS conditions after HCT (Table 29-2), although its precise role in these disorders remains unclear. Of all the non-CNS disease associations, HHV-6B as a cause of

myelosuppression has the most supporting evidence; however, intriguing evidence exists for other outcomes as well.

A number of studies have demonstrated an association of HHV-6B reactivation with myelosuppression and delayed engraftment, particularly involving platelets, in addition to graft failure [30, 32, 67–69]. A recent large prospective trial in 235 consecutive allogeneic HCT recipients showed delayed platelet engraftment among the 48% of patients who developed HHV-6B viremia within 100 days [26]. A retrospective study of 77 CBT recipients found a strong association between HHV-6B reactivation and graft failure in adjusted analyses [70]. In vitro studies have provided plausible mechanistic explanations for these findings, including suppression of thrombopoietin-inducible megakaryocytic colony formation [71] and attenuated lymphocyte proliferation responses in the setting of lytic HHV-6B infection [72]. Interestingly, in the acute care setting, HHV-6 primary infection has been associated with relatively lower platelet counts than that found with other childhood causes of fever [73].

Acute GVHD is another important post-HCT complication that has been associated with HHV-6B reactivation [24, 74, 75]. In a prospective trial of 315 allogeneic HCT recipients with twice-weekly PCR testing, HHV-6B was independently and quantitatively associated with acute GVHD grades II–IV in time-dependent multivariable analyses, and the findings suggested a potential role in each of the organ-specific subtypes [23]. Interestingly, a retrospective study found a bidirectional association between HHV-6 reactivation and acute GVHD [76]. This study also showed that HHV-6B reactivation was associated with rash that clinically imitated skin GVHD in 17 patients; histopathology revealed a lymphoid infiltrate but no evidence of acute GVHD. A causal relationship between HHV-6B reactivation and acute GVHD is supported by in vitro and limited clinical data demonstrating that HHV-6 infection may cause a proinflammatory cytokine response (primarily elevated IL-6 concentrations) [58, 77] or type I immune response [78] that may be involved in the development of acute GVHD. Given the morbidity and mortality associated with acute GVHD, additional study of the causal pathways in the development of HHV-6B-associated acute GVHD is warranted.

HHV-6B reactivation has been variably associated with an increased risk for CMV reactivation and disease after HCT. A recent prospective study of 315 allogeneic HCT patients demonstrated that HHV-6B reactivation was quantitatively associated with increased risk of subsequent CMV reactivation [23]. In a study of 21 allogeneic HCT recipients, HHV-6 reactivation was associated with an absence of CMV-specific lymphocyte proliferative responses, and persistence of HHV-6 detection correlated with need for repeated courses of preemptive antiviral therapy against CMV during the first 6 months after HCT [79]. In contrast, a study of 68 allogeneic HCT recipients found that HHV-6 reactivation was associated with CMV reactivation in univariate analysis but not multivariable analyses [80]. This report additionally demonstrated that detection of HHV-6 DNA in plasma did not seem to affect CMV-specific T cell immune reconstitution as measured by intracellular cytokine staining. The biologic plausibility of a causal link between HHV-6B and subsequent CMV reactivation is supported by in vitro studies demonstrating the immunosuppressive effects of HHV-6B reactivation, potentially through inhibition of IL-12 production [81, 82]. In addition, the generalizability of the association between HHV-6 and CMV reactivation is supported by results from clinical studies of non-HCT populations including critically ill adults and solid organ transplant recipients [83–85].

HHV-6B has been implicated with other end-organ diseases after allogeneic HCT in case reports and small case series. Perhaps the most important area of investigation is its role in pulmonary disease, which remains a leading cause of morbidity and mortality after HCT and is idiopathic in ~10% of patients [86–90]. A number of studies have reported a potential association between HHV-6 and pneumonitis, as first described in two allogeneic HCT recipients with pneumonitis and HHV-6 detection in respiratory specimens and lung tissue by PCR and immunohistochemistry [91]. A retrospective study of lung biopsy specimens from 15 allogeneic HCT recipients with pneumonia found a quantitative association between HHV-6 detection and idiopathic pneumonia syndrome [92]. Several subsequent retrospective studies have had variable results, and HHV-6 has been frequently detected along with copathogens and in control subjects [93–95], raising questions about whether the association is truly causal. In a recent study employing quantitative PCR testing for known and potential pulmonary pathogens in 69 allogeneic HCT recipients with idiopathic pneumonia syndrome (IPS), HHV-6 was detected in 29% of patients, and it was the only pathogen found in half of those patients [96]. Mortality was significantly higher in patients with IPS and HHV-6 detection compared to those without a pathogen, and blood contamination did not appear to be a confounder. Past studies have been limited by small sample size and lack of speciation and quantitative diagnostics with an international standard. Additional study of HHV-6 and lung disease is warranted.

There are limited data suggesting that HHV-6 may be a pathogen in liver disease after HCT. HHV-6 infection and replication in human liver cells has been demonstrated in vitro [97, 98], and multiple studies have implicated HHV-6 as a cause of hepatitis in immunocompetent individuals [99–101]. Three cases of HHV-6-associated hepatitis after allogeneic HCT have been described in patients with hepatitis and temporally associated HHV-6 detection in blood and/or liver tissue, along with histopathological and/or immunohistochemical evidence of active viral replication in the liver [30, 102, 103]. One case was documented to be due to HHV-6B. All three cases improved with antiviral therapy. Given the high incidence of HHV-6B reactivation after HCT and lack of routine screening, HHV-6B may be an underappreciated cause of liver disease after HCT.

No disease has been causally linked with HHV-6A, which is infrequently described in immunocompromised patients and only accounts for 0–3% of reactivation events after HCT [23, 104]. There are a few case reports of HHV-6A encephalitis after HCT [105–107]. With a contemporary understanding of HHV-6 biology, these reactivation events and cases of encephalitis were most likely due to unrecognized inherited ciHHV-6A. Whether HHV-6A was contributory to the patients' illness in those with encephalitis is hard to know with the information provided [50]. However, two recent case reports of patients with inherited ciHHV-6A were highly suggestive of HHV-6A reactivation from the integrated virus with associated encephalitis [108] and hemophagocytic lymphohistiocytosis [21]. Ultimately, HHV-6A detection in the setting of HCT is suggestive of inherited ciHHV-6A, and it appears that viral reactivation from this integrated state can occur, as discussed further in the next section. However, due to the low incidence of HHV-6A reactivation after HCT, it remains unclear if it shares an association with the diversity of complications seen in the context of HHV-6B reactivation.

29.3.1.3 Inherited Chromosomally Integrated HHV-6

Inherited ciHHV-6 is present in approximately 1–2% of the general population (Figure 29-1). Lack of recognition of this condition has led to inappropriate treatment of patients and considerable confusion in the literature, when detection of viral DNA did not correlate with clinical disease [109, 110]. Whether patients with inherited ciHHV-6 can develop HHV-6 reactivation with associated pathogenicity, or other indirect complications, has been a topic of controversy. There is a dearth of studies exploring clinical outcomes in affected individuals. However, an accumulating body of in vitro and in vivo evidence suggests that inherited ciHHV-6 can be the source of pathogenic viral reactivation and other complications, especially in immunocompromised patients.

The prevalence of inherited ciHHV-6 among hospitalized patients was >3-fold higher than in healthy blood donors in one report, suggesting that persons with inherited ciHHV-6 may have more medical complications [111]. In a study of 37 patients with a diagnosis of HHV-6 CNS dysfunction after HCT, there was no obvious enrichment for inherited ciHHV-6 to suggest that patients with this condition have greater risk for disease due to HHV-6 [108]. However, an estimate of the true prevalence was limited by the sample size. A recent report detailed in vivo molecular and virological evidence of HHV-6A reactivation from inherited ciHHV-6A, with associated clinical symptoms of hemophagocytic lymphohistiocytosis, in a child with X-linked severe combined immunodeficiency who underwent HCT [21]. A few case reports and small studies also suggest that inherited ciHHV-6 may directly or indirectly contribute to clinical disease in affected patients [108, 112–114]. However, a retrospective review of 21 cases of patients who had or received stem cells or organs with inherited ciHHV-6 found no clinical disease associations [115].

In vitro experiments have provided clear evidence of HHV-6 transcription and translation from ciHHV-6 cell lines. Researchers have successfully induced lytic genes and capsid mRNA expression by exposing ciHHV-6 cell lines to HDAC inhibitors [20, 116]. Furthermore, these cell lines were demonstrated to give rise to propagating virus with cytopathic effects in an exposed naïve T-cell line, providing evidence of viral fitness. A recent study of 11 immunocompetent and immunocompromised patients with inherited ciHHV-6 used RT-PCR to demonstrate evidence of active viral transcription in 4/11 and HHV-6 antigen detection in 7/10 individuals, although results were not correlated with clinical symptoms [117]. Given the relatively high frequency of inherited ciHHV-6 in the population, it is critical that larger studies evaluate the clinical significance of this condition. Experts have suggested caution in using specimens with inherited ciHHV-6 for human stem cell or organ transplantation [118, 119]. There is an urgent need to address if, how, and when inherited ciHHV-6 may have deleterious effects in its host.

29.3.2 HHV-7

The significance of HHV-7 DNA detection after HCT remains unclear, although the virus is rarely associated with any clinical manifestations (Table 29-2). Some studies suggest that patients with HHV-7 reactivation have higher CMV viral loads or longer duration of CMV detection [40, 120], and a few case reports have implicated HHV-7 as a cause of encephalomyelitis after allogeneic HCT [121–123]. Most studies of HHV-7 in immunocompromised patients have had small sample sizes, often with conflicting results.

29.3.3 KSHV (or HHV-8)

As in other human HHV-associated diseases, KSHV primarily causes disease in immunocompromised subjects due to reactivation of latent infection or transmission of infected cells from the donor. KSHV infection is the cause of Kaposi's sarcoma (KS), which has four clinical presentations: classic, endemic, epidemic or acquired immune deficiency syndrome (AIDS)-associated, and immunosuppression or transplant-associated [7]. In each case, the degree of immunosuppression is a primary factor in the development and progression of disease. While post-HCT KS is rare, there are about 20 reported cases in the literature described primarily after allogeneic HCT [124–127]. In the HCT setting, KS is usually associated with skin lesions and bone marrow failure [124]. A review of 14 cases reports a median age of 46 years (range 7–69), male:female ratio of 2.5:1, and median interval from HCT to KS diagnosis of 8.5 months (range 3–27) [126].

The skin was involved in the majority of patients, and 50% had diffuse disease involving >1 site or multiple organs. Overall mortality was around 35%, although deaths occurred exclusively in patients with diffuse disease, indicating a 70% mortality rate among this patient group.

Clinical manifestations associated with any KSHV reactivation or infection after HCT have been infrequently reported and include fever, rash, hepatitis and bone marrow failure [128, 129] (Table 29-2). Most studies have not found an association between KSHV seropositivity or post-HCT seroconversion and the development of clinical symptoms or increased mortality [46].

29.4 Diagnosis

29.4.1 HHV-6A and B

Diagnosis of clinically relevant HHV-6 species infection or reactivation is challenging due to the high prevalence of primary infection with persistence of the virus in a myriad of cell types [11, 12]. A variety of techniques can be used to test for HHV-6, including serological studies, antigen detection, isolation by culture, and nucleic acid detection. Due to the labor-intensive nature of many of these approaches, in addition to lack of specificity and/or inability to distinguish between HHV-6A and HHV-6B, quantitative viral nucleic acid detection by PCR has become the method of choice. Advantages of this method include its speed, sensitivity, specificity, and ability to distinguish and quantitate species A and B [130–133].

Many studies have demonstrated that detection of HHV-6 DNA in plasma, serum, or CSF correlates well with active viral replication [53, 57, 134]. One study found the specificity of HHV-6 DNA detection in plasma by quantitative PCR to be 84% based on a comparison with viral culture [135]. However, there are a number of important limitations to consider when interpreting results from PCR detection of HHV-6 DNA. *First*, detection of HHV-6 DNA in liquid compartments (e.g., blood, CSF, bronchoalveolar lavage fluid) may significantly underestimate tissue-level viral replication. For example, brain tissue from patients with HHV-6 encephalitis has been shown to have higher levels and prolonged detection of HHV-6 DNA compared to blood or CSF samples [56, 57]. *Second*, sample selection and processing for HHV-6 PCR testing can markedly affect results. For instance, detection of HHV-6B DNA in whole blood or PBMCs does not correlate as well with active viral replication, as the mononuclear cell is a site of latency [17]. The use of serum or plasma is thought to be more representative of cell-free replicating virus, with the caveat that viral DNA may originate from latently infected cells that have lysed during sample preparation [136]. *Third*, the lack of an international standard for HHV-6A and B DNA measurement precludes extrapolation of quantitative levels to other studies, as interlaboratory correlation is known to be poor [131, 137]. The development of an international standard, such as the one for CMV recently made available by the World Health Organization [138], is currently underway. Whether routine screening in all or select HCT recipients will improve outcomes needs further study, and the establishment of viral load thresholds to guide intervention will continue to be limited until standardization in testing assays, sample selection, and sample processing has been accomplished.

The condition of inherited ciHHV-6 adds particular challenges to HHV-6 diagnostics and interpretation of results. Inherited ciHHV-6 is suggested by HHV-6 DNA levels of >5.5 $\log_{10}$ copies/ml in whole blood specimens, corresponding to one copy of HHV-6 per nucleated cell in the sample [18] (Figure 29-1). Other findings consistent with inherited ciHHV-6 include persistent viral DNA detection without a decrease in quantitative levels despite appropriate antiviral treatment. This can be true even when plasma or serum is used due to release of latent viral DNA from cell lysis or contamination, especially if there is a delay in sample preparation and testing [139]. The gold standard for diagnosis of inherited ciHHV-6 is fluorescence in situ hybridization, a labor-intensive procedure with limited availability [139]. Another approach has been to test hair follicles, where any detection of HHV-6 is consistent with inherited ciHHV-6; however, most laboratories are not equipped to test such samples. Droplet digital PCR (ddPCR) is an emerging technique that allows for absolute and precise quantitation of target DNA without the use of a standard curve [140, 141]. This method is particularly well suited for the identification of inherited ciHHV-6 and has recently been developed for this purpose [142, 143]. By concurrently amplifying DNA targets for HHV-6 and a reference human gene for cell count (e.g., human ribonuclease P [RPP30]), a ratio of HHV-6 DNA to cell genome equivalents of ~1 is indicative of inherited ciHHV-6. These assays have high sensitivity and specificity when used with PBMCs and other highly cellular samples, but they can also be utilized with archived plasma, sera, and other samples to aid in retrospective research, although with reduced specificity [142].

Future directions for the diagnosis of active HHV-6 infection include detection of RNA via reverse transcription real-time quantitative PCR (RT-qPCR) [130, 144, 145]. This method of amplifying messenger RNA from PBMCs or other specimens could provide a better approach to distinguish active from latent infections [144], and it may be particularly useful for identifying HHV-6 reactivation in patients with inherited ciHHV-6. One study comparing viral culture with a nested RT-PCR assay for a late protein (*U100*) demonstrated 95% sensitivity and 98.8% specificity of the RT-PCR assay for actively replicating virus in PBMC samples [146]. Additionally, in-depth molecular interrogation for evidence of HHV-6 infection and replication in tissues and other samples involved in end-organ disease is required to identify pathologic and molecular signatures of HHV-6B infection [147].

While the evidence does not yet support routine monitoring for HHV-6B after HCT, patients with acute encephalopathy should have testing of plasma and CSF for HHV-6B. HHV-6B testing may also be considered for patients with end-organ disease that has previously been associated with HHV-6B, especially when no other explanation exists. There is also no basis for routine screening of donors and recipients for inherited ciHHV-6 at this time, although focused testing is important in individuals with findings consistent with ciHHV-6. The implementation of novel diagnostic approaches in well-designed and appropriately powered studies is an essential next step for establishing causality and moving the field forward from studies of association to studies of causation. Large, standardized studies to evaluate the correlation between HHV-6 RNA and DNA detection in blood and tissue with associated end-organ disease will be critical to establish actionable indicators for treatment.

29.4.2 HHV-7 and KSHV (or HHV-8)

As discussed for HHV-6 species, the mainstay for detection of HHV-7 and KSHV in the clinical setting is real time quantitative PCR. There are also no international standards for PCR tests for these viruses. In patients with KS, KSHV viral load in PBMCs correlates with tumor burden, although data in the HCT setting is lacking [48, 148]. Although KSHV viremia is associated with KS and disease progression, diagnosis is predicated on tissue biopsy, which reveals pathognomonic findings. Typical histopathologic features include ectatic, irregularly shaped, round capillary, and slit-like endothelium-lined vascular spaces and spindle-shaped cells accompanied by a variable inflammatory mononuclear cell infiltrate. Kaposi sarcoma cells stain for endothelial cell markers such as $CD34^+$, and immunostaining of anti-HHV-8 antibodies may be useful for diagnosis of early stage disease. Due to the unclear significance of HHV-7 detection in blood specimens after HCT and the low incidence of KSHV-associated disease in this setting, routine screening for these viruses is not currently recommended.

29.5 Treatment and Prevention

29.5.1 HHV-6A and B

Optimal treatment approaches (i.e., single or combination antivirals, dose, duration) have not been rigorously studied. Because of this, there are no widely adopted standard practice guidelines for HHV-6A and B except for treatment of post-HCT HHV-6B encephalitis [149–151]. However, several available antiviral agents demonstrate good in vitro and suggestive in vivo activity against HHV-6A and B, including foscarnet, ganciclovir, and cidofovir [12, 105, 152–154]. Based on these data, treatment recommendations for HHV-6B encephalitis include the use of ganciclovir and/or foscarnet, either alone or in combination [149–151]. Although treatment practices vary, one approach is to use foscarnet (90 mg/kg twice a day) pre-engraftment and ganciclovir (5 mg/kg twice a day) post-engraftment for at least 3 weeks and until clearance of HHV-6 DNA in plasma and CSF by PCR testing (expert opinion).

Prophylactic and preemptive strategies to mitigate HHV-6B reactivation, such as those employed for other HHVs (e.g., HSV, VZV, CMV), have been reported. The use of prophylactic ganciclovir in HCT patients can reduce HHV-6B reactivation in the blood [84] and may reduce associated morbidity in high-risk patients [155, 156]. Other studies have not found an association between reduction in incidence and level of HHV-6B detection and outcomes [157, 158]. Large-scale adoption of this approach is limited by the risk of ganciclovir-induced myelosuppression given the relatively low incidence of serious HHV-6-associated end-organ disease and a limited understanding of the significance of HHV-6B reactivation in the absence of apparent disease. In a retrospective study evaluating the utility of low dose foscarnet (50 mg/kg/day) for 10 days post-engraftment to prevent HHV-6B reactivation in a cohort of 118 allogeneic HCT recipients (unrelated or cord blood donors), high-level HHV-6B reactivation (>10,000 copies/ml) and encephalitis were reduced but did not reach clinical significance [159]. Two small prospective studies of preemptive ganciclovir (5–10 mg/kg/day) or foscarnet (90 mg/kg/day) and one prophylactic trial with foscarnet (90 mg/kg/day) after HCT did not significantly reduce the complications of HHV-6B reactivation [158, 160]. This is perhaps due to the dynamic kinetics of plasma HHV-6 DNA detection and potential delay in time to plasma detection after tissue-level reactivation.

Drug-resistant strains of HHV-6 appear to be exceedingly rare; while in vitro studies support the potential for HHV-6 to develop resistance to antiviral agents, only a few case reports have described the emergence of drug-resistant isolates in the clinical setting [161–164]. However, because the currently available antiviral medications have significant toxicities and all act via similar mechanisms to antagonize DNA polymerase activity, the development of novel therapies is a priority.

A number of new treatment modalities that have activity against HHV-6 species are in various stages of development and testing. Brincidofovir, or CMX-001, is a lipophilic derivative of cidofovir that has generated significant excitement in the field of HCT due to its broad range of activity against many DNA viruses, oral administration, favorable side-effect profile, and high in vitro activity with half maximal effective concentration (EC50) values of 3 and 7 nM for HHV-6A and B, respectively [165]. While this and other available anti-HHV-6 drugs target the viral DNA polymerase, CMV423 is

a novel antiviral agent with potent in vitro activity against the beta herpesviruses through inhibition of a cellular tyrosine kinase involved in viral replication [166]. It has compared favorably to ganciclovir and foscarnet due to its high activity and low cytotoxicity. A variety of other molecules have been reported to exhibit antiviral activity against HHV-6 in cell culture but are in early stages of development [154], and none of these novel agents have been well studied for use against HHV-6 species in the clinical setting. The production of HHV-6 specific cytotoxic T cells for adoptive immunotherapy has been encouraging but is in early stages of development [167–169].

Further testing and discovery of therapies with low toxicity and high efficacy against HHV-6 species is imperative for the implementation of clinical trials exploring the impact of prophylactic, preemptive, and targeted treatment strategies. Prophylactic approaches may be important, as viral detection in liquid compartments such as blood may underestimate tissue-level reactivation. Continued refinement of our understanding of risk factors for HHV-6 reactivation, replication kinetics, and clinical impact may allow for focused treatment of high-risk patients using newly developed agents.

29.5.2 HHV-7

Treatment for HHV-7 has been less well studied given its unclear clinical significance after HCT and in other settings. Like HHV-6 species, acyclovir and other thymidine kinase-dependent drugs are only marginally effective in vitro, while ganciclovir, foscarnet, and cidofovir show similarly potent inhibition of HHV-7 replication in vitro and possibly in vivo [12, 170, 171].

29.5.3 KSHV (or HHV-8)

Treatment of KSHV after HCT is predicated on reduction of immunosuppression, particularly in the setting of localized disease [48, 126]. Chemotherapeutic treatments, such as liposomal anthracyclines (e.g., doxorubicin) and taxanes (e.g., docetaxel), or radiotherapy, might be considered in the setting of diffuse or refractory disease, but the toxicities after HCT should be carefully considered. Sirolimus appears to have antineoplastic activity through its inhibition of the mammalian target of rapamycin (mTOR) and angiogenesis, and it has been reported to contribute to KS regression in one post-HCT patient [8]. Although in vitro studies have demonstrated anti-KSHV activity for ganciclovir, foscarnet, and cidofovir, clinical efficacy in patients with KS has not been demonstrated [48]. This is likely because most tumor cells in KS are latently infected with KSHV, and the anti-DNA polymerase mechanism of these drugs requires actively replicating virus for efficacy.

29.6 Conclusion

- Establishing HHV-6A, HHV-6B, and HHV-7 as causal pathogens in associated diseases is challenging due to their ubiquitous infection of the human population with latency in diverse cell types.
- The importance of HHV-6B reactivation after HCT is underscored by its association with encephalitis and mortality in this setting [23, 26, 172].
- The clinical role of HHV-7 after HCT remains unclear.
- While the incidence of KS due to KSHV after HCT is low, affected patients may suffer significant morbidity, and our ability to predict or prevent development of this disease is poorly understood.
- Actionable interpretation of prior and ongoing studies of these viruses continues to be constrained by existing diagnostic methods and study designs which lead to inconclusive results. Future investigation of both direct and indirect mechanisms by which these viruses contribute to disease, using improved characterization of viral, host, and clinical factors associated with their pathogenesis, will be critical to advance our understanding of their clinical significance.
- As new antiviral therapies emerge [167, 173], the ability to define endpoints and risk-stratify patients is increasingly important. Targeted screening, coupled with low risk prevention and treatment strategies, may improve patient outcomes after HCT. Multicenter randomized controlled treatment and prevention trials using agents active against these viruses are greatly needed to explore a causal link between viral reactivation and adverse outcomes in HCT recipients.

30 Influenza and Parainfluenza Infection in Hematopoietic Stem Cell and Solid Organ Transplant Recipients

Ella J. Ariza-Heredia and Roy F. Chemaly

30.1 Influenza Infection in Hematopoietic Stem Cell Transplant and Solid Organ Transplant Recipients

30.1.1 Overview and Epidemiology

The influenza virus is among the most common human respiratory viruses. It belongs to the *Orthomyxoviridae* family and is a segmented, single-stranded RNA virus in which the individual segments code for critical peptides. Further classification of the virus into subtypes is based on its surface hemagglutinins and neuraminidases [1]. Seasonal influenza activity can begin as early as October and continue into May in the Northern hemisphere. In the USA, influenza activity most commonly peaks between December and February [1]. During the 2014–2015 season, the Centers for Disease Control and Prevention (CDC) reported 125,462 infections (18.1% of specimens tested) (Figure 30-1). The proportion of deaths during this time period attributed to pneumonia secondary to influenza according to the 122 Cities Mortality Reporting System, ranged from 5.0% to 9.3% [2].

Seasonal influenza virus infections in humans cause annual epidemics resulting in millions of cases worldwide and significant health and economic burdens [3]. The seasonal prevalence of influenza infections in immunocompromised patients, including solid organ transplant (SOT) and hematopoietic stem cell transplant (HCT) recipients, closely parallels the community-wide prevalence (Figure 30-1), as demonstrated during local epidemics and the 2009 H1N1 pandemic [1, 3, 4]. Although the overall incidence is low (<5%) [5, 6], influenza infection remains a significant cause of morbidity and mortality among transplant recipients along with respiratory syncytial virus, and parainfluenza [6, 7].

The incidence of influenza infections in HCT recipients is 1.3–2.6%, and significantly higher rates may be seen during the peaks of influenza outbreaks in the community [8]. In SOT recipients, the incidence of influenza infection varies depending on the type of organ transplanted; it is higher among lung transplant recipients than among recipients of other solid organs [9]. In a study involving 3569 SOT recipients, the incidence of influenza infection was 41.8 cases per 1000 person-years after lung transplants, 4.3 cases per 1000 person-years after kidney transplants, and 2.8 cases per 1000 person-years after liver transplants [10] and most studies reported an incidence between 2% and 4% [11–13].

Recent studies reporting on the 2009 H1N1 influenza pandemic have greatly increased our knowledge of the epidemiology of influenza infection in the transplant population [14]. A steady decrease in complication rates has been seen over the past decade, likely for several reasons, including improved supportive care, more sensitive and rapid diagnostics that enable earlier treatment, and better treatment strategies [15].

30.1.2 Clinical Presentation and Prognostic Factors

Influenza is an acute, usually self-limited, febrile illness. The clinical presentation of influenza infection in SOT and HCT recipients does not differ substantially from the typical "flu-like" illness described in the general population [11, 16, 17]. However, transplant recipients may have either atypical presentation limited to shortness of breath or weakness [7] or only constitutional symptoms, sometimes without a fever [12] (Table 30-1). These possibilities reinforce the importance of a high index of suspicion, especially during the respiratory season. In both SOT and HCT recipients, infection with influenza virus may present either with upper respiratory tract infection (URI) or lower respiratory tract infection (LRI), and appears to produce the severest symptoms in the early posttransplant period (<3 months) [8, 9, 13].

In HCT recipients, URI symptoms may consist of rhinitis and cough. Fever is more often described in patients with pneumonia (LRI). Clinical symptoms reported less frequently are muscle aches, sore throat, dyspnea, and sometimes gastrointestinal and neurological symptoms [8, 18].

TABLE 30-1. Comparison of clinical presentations of Influenza and Parainfluenza viruses in Hematopoietic Stem Cell and Solid Organ Transplant recipients

Clinical presentation	Viral infection	
	Influenza [17–20]	Parainfluenza [21–24]
Most common symptoms	Fever, cough, rhinorrhea	Croup, conjunctivitis (better characterized in children) High fever, cough, coryza
Common symptoms	Muscle ache, sore throat, headache, dyspnea	Rhinorrhea, and/or sore throat
Rare symptoms	Gastrointestinal symptoms, neurological symptoms, fatigue	Pneumonitis in absence of upper respiratory infection Parotiditis, epiglottitis, myocarditis, and pericarditis

In cases of LRI, radiographic abnormalities may include typical diffuse ground glass infiltrates, which occur in 14–49% of patients, or air space consolidation resembling fungal or bacterial disease (Figure 30-2) [15, 18, 25].

Studies have investigated many risk factors associated with the severity of influenza infection and post-influenza complications in HCT recipients, including factors associated with the progression to LRI (Table 30-2). LRI occurs in

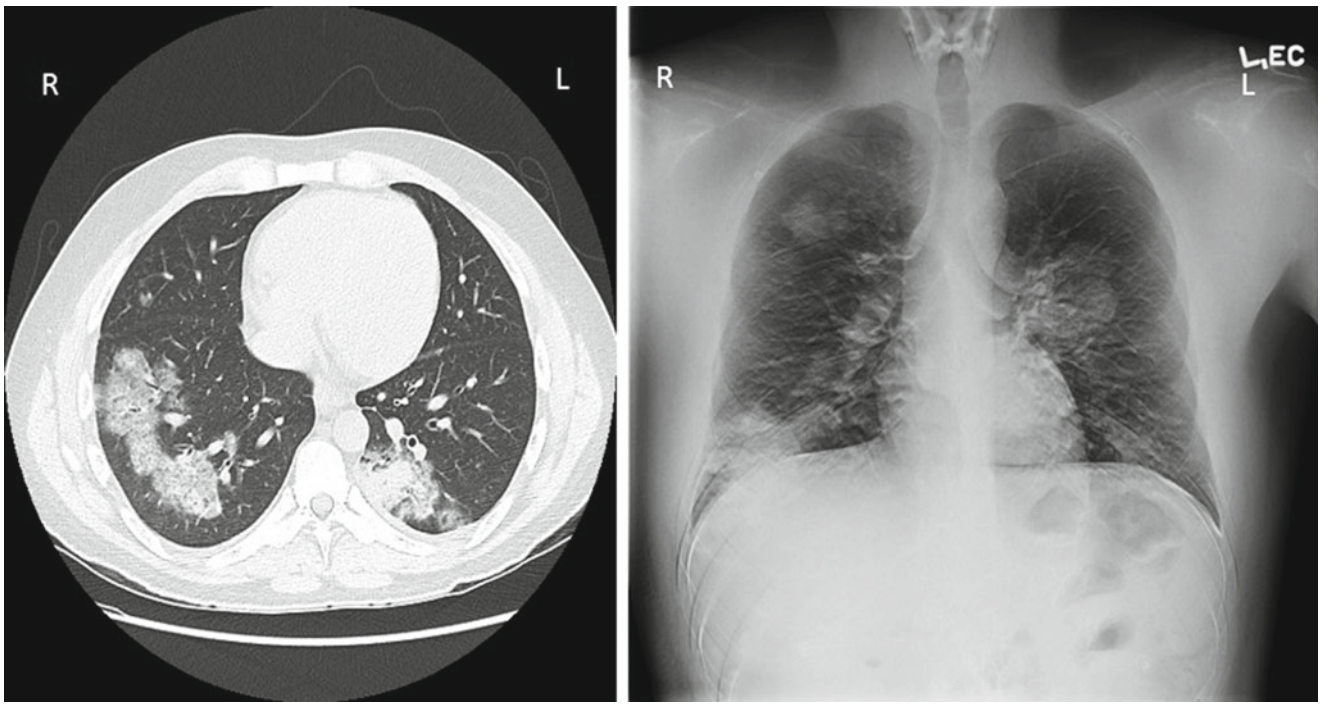

FIGURE 30-2. 29-year-old male with Hodgkin lymphoma status post-Haploidentical HCT Admitted with myalgias, cough, shortness of breath, headache. Nasal wash PCR positive for Influenza A. about 30–50% of HCT patients with influenza [18, 19, 36] and usually develops within a week of the onset of symptoms [8, 11]. At The University of Texas MD Anderson Cancer Center, factors associated with progression to LRI were profound lymphocytopenia, defined as an absolute lymphocyte count of <200 cells/mL (odds ratio [OR], 2.85; 95% confidence interval [CI], 1.01–8.09; $P=0.049$); age older than 65 years (OR, 2.76; 95% CI, 1.34–5.73; $P=0.004$); and neutropenia, defined as an absolute neutrophil count of <500 cells/mL (OR, 2.06; 95% CI, 1.13–3.75; $P=0.016$) [11]. Other studies have also identified lymphocytopenia as a risk factor for progression, although using different upper cutoffs (100–300 cells/mL) [13, 18, 20, 27, 29]. Finally, early antiviral therapy for URI within the first 48 h of presentation has been associated with better prognosis in several studies [8, 29, 31, 36]. Furthermore, studies of HCT recipients with 2009 A/H1N1 infections found that presentation with LRI, age >65 years, and nosocomial acquisition were risk factors for the need for mechanical ventilation [18, 29]. The use of corticosteroids at 1 mg/kg was reported by some authors to have an inverse association with need for mechanical ventilation and progression to pneumonia [29, 37], however these findings are controversial as publications from Fred Hutchinson Cancer Research Center and others, have associated steroid therapy with prolonged viral shedding and in some instances progression to LRI [8, 13, 31]. Moreover, the experience of intensive care departments during the 2009 H1N1 influenza pandemic showed that steroid therapy did not result in better outcomes and was associated with increased risk of super infections, also argues against corticosteroid use [38].

Influenza fatalities in HCT recipients have mostly been associated with respiratory complications, including need for mechanical ventilation, with mortality rates of 6–28% [8, 29, 36, 39]. Mortality can be attributed either to the direct effect of influenza viral infection with subsequent respiratory failure or to superimposed infections with concomitant pathogens, including bacteria, fungi such as *Aspergillus fumigatus*, and other viruses such as RSV [11, 36, 39].

Most of our knowledge of influenza in SOT recipients is derived from reports on the 2009 H1N1 pandemic [17]. However, from studies previous to 2009, presentation with fever in addition to respiratory symptoms strongly suggested influenza infection, as opposed to other viral infections, in SOT recipients [9]. During the 2009 pandemic, constitutional symptoms (e.g., fever, fatigue, malaise, myalgia) and URI symptoms (e.g., rhinorrhea, sore throat) were frequently described, while gastrointestinal (diarrhea), central nervous system (encephalitis), heart (myocarditis), or skeletal muscle (myositis) symptoms were comparatively rare [16, 40] (Table 30-1).

Studies have shown that rates of complications in SOT recipients during the 2009 H1N1 pandemic were generally higher than those observed during previous seasonal influenza outbreaks. Two studies conducted in SOT recipients before 2009, including mostly pediatric SOT recipients and adult renal transplant recipients; in general, they portrayed

[a]Associated with longer viral shedding.

milder, more self-limited illnesses than those described in patients infected with the 2009 H1N1 influenza virus [9, 16]. In contrast, Kumar et al.'s report, on the 2009 pandemic which included 237 SOT recipients from different centers, described a high incidence of pneumonia (31.7%,) and higher rates of admission to intensive care units (ICUs) (15.6%) [17]. Other publications from the 2009 pandemic mirrored these findings, with rates of influenza-associated LRI in SOT recipients as high as 49%, and ICU admission rates of 10–16%, mostly related to respiratory failure [10,

14]. Factors associated with progression in SOT recipients included delayed initiation of antiviral therapy (OR, 3.03; 95% CI, 1.24–7.39; $P=0.015$) [17] and influenza infection occurring within 90 days of transplant (OR, 5.00; 95% CI, 2.10–12.20; $P=0.02$) (Table 30-2) [14, 33].

Influenza-related mortality rates in SOT recipients range from 4% to 9% [9, 10, 41]. Early therapy with oseltamivir has been associated generally with decreased rates of mortality and ICU admission and fewer complicated outcomes in SOT recipients [15, 17]. As in HCT recipients, presentation with pneumonia (OR, 21.6; 95% CI, 2.9–155.8; $P<0.001$) [15] and bacterial, viral, or fungal coinfections are relatively common (incidence, 7–29%) in SOT recipients; these coinfections have been associated with a higher risk of death [15, 17].

30.1.3 Diagnosis

The availability of rapid and sensitive methods to diagnose respiratory viral infections, and influenza in particular, not only allows early diagnosis and initiation of therapy but also limits the risk of nosocomial transmission by facilitating appropriate use of antibiotics and rapid implementation of isolation precautions when necessary [42]. Reliable and accurate diagnosis depends on the quality of the respiratory samples collected for laboratory testing. Nasopharyngeal aspirations, nasal washings, and bronchoalveolar lavages are the optimal specimens, though throat and nasal swabs have been used and can also provide an accurate diagnosis [43]. Respiratory specimens should be collected and placed in viral transport media, preferably at 4 °C, as infectivity is lost at higher temperatures. If a delay of more than 24 h before processing is anticipated, specimens should be frozen [44].

30.1.3.1 Antigen Detection Assays

Antigen detection assays include the enzyme-linked immunosorbent assay (ELISA), immunofluorescence assay, and enzymatic detection by chemical reactions. These tests have quick turnaround times—as fast as 15 min—and do not require specialized laboratory equipment or personnel; thus, they can be used outside certified laboratories in point-of-care settings. Most point-of-care tests distinguish influenza A virus from influenza B virus, but they do not consistently identify avian influenza virus subtypes. Furthermore, these tests have more variable sensitivity (47–93%) than cell culture and molecular assays, though their specificity is acceptable (around 90–95%) [45]. The results of these tests are influenced by the population, the type of specimen, and the timing of collection after presentation [46]. Their sensitivity is greatest during the peak influenza season, when false-positive results are less likely and the positive predictive value is high; however, in immunocompromised hosts, even peak-season sensitivities can be as low as 50% [47]. Thus, given the limited sensitivity of these assays, negative results do not rule out influenza virus infection, and follow-up testing with molecular testing and/or viral culture should be considered to confirm negative results, especially when clinical suspicion is high [38].

30.1.3.2 Molecular Assays

Molecular assays can identify the presence of influenza viral RNA in respiratory specimens: (a) Reverse transcription polymerase chain reaction (RT-PCR) in which purified influenza viral RNA is first reverse transcribed into cDNA, and, the cDNA is then amplified with specific primers, however this technique is time consuming and does not easily yield quantitative results. (b) Real-time quantitative RT-PCR (RT-qPCR) uses chemistry and instrumentation platforms to amplify and simultaneously quantify a targeted DNA molecule with high sensitivity and specificity as well as a rapid turnaround time. (c) Multiplex PCR is a variant of PCR that amplifies multiple DNA targets using more than one pair of primers in a single reaction tube; it is able to distinguish multiple respiratory viruses simultaneously. These assays have high sensitivity (>90%) and specificity (close to 100%) and can yield results in 3–8 h [48–50].

Some molecular assays [1] are able only to detect and discriminate between influenza A and B virus infections; while other tests can identify specific influenza A virus subtypes (A [H1N1] pdm09, seasonal A [H1N1], or seasonal A [H3N2]) [51]. Rapid molecular assays using isothermal nucleic acid amplification are a new type of molecular diagnostic test for influenza.[1] One rapid molecular assay has been approved in January 2014 in Europe, and recently in 2015 by the US Food and Drug Administration (FDA), which differentiates influenza A from B but not subtypes. It can be used in physicians' offices, emergency rooms, or health department clinics and yields results in 15 min [52, 53].

The disadvantages of these molecular techniques include their high cost, which limits their availability, and their inability to distinguish nonviable from viable viruses [54]. Detection of a weak signal may represent a commensal infection, the tail end of a previous infection, or an early evolving infection. In the case of immunocompromised patients, shedding or persistent infection may render viruses detectable by PCR for a prolonged period of time (7–45 days). Therefore, a positive test requires always to be placed into a clinical context [12, 20].

Influenza virus—update can be found at http://www.who.int/influenza/gisrs_laboratory/molecular_diagnosis_influenza_virus_humans_update_201403rev201505.pdf?ua=1. Accessed 28 Aug 2015.

30.1.3.3 Cell Culture

Viral isolation by routine cell culture has been the gold standard for influenza diagnosis. However, it may take 3–10 days before the results are readily available, which may in turn have an impact on patient care [55]. The classic technique uses a series of primary cell lines (human fibroblast and rhesus monkey kidney) and continuous cell lines (A549 human lung carcinoma). The specimens are inoculated onto cell culture monolayers, and the visible cellular changes that occur in response to viral infection are monitored by light microscopy for cytopathic effect (CPE). Based on the specimen source, the time to CPE, the quality of the CPE, and the cell line(s) showing CPE, a preliminary identification of the virus can be made. The presence of a specific virus is confirmed by immunofluorescent staining using virus-specific fluorescently labeled antibodies [56]. A more rapid and sensitive viral culture is the shell vial assay, a modification of tube culture that uses a smaller tube shell vial culture. The sample is centrifuged onto a single layer of cells and viral growth is measured by antigen detection methods. The shell culture can have a turnaround time of 48 h, with sensitivity between 60% and 83% and good specificity, around 90–100% [57, 58].

Viral culture is still an important part of the diagnosis, as it allows assessment of seasonal changes, virus subtype, and potential viral susceptibilities when needed. Unlike the molecular methods and nucleic acid amplification tests, viral culture detects only viable viruses. This can be very useful for patient management because transplant recipients usually experience prolonged viral shedding, even when they are undergoing active antiviral therapy [55].

30.1.4 Management

In both HCT and SOT recipients, antiviral therapy should be initiated promptly and even empirically when influenza infection is suspected, regardless of the severity of the illness. Furthermore, antivirals should be administered even if patients present with symptoms for longer than 2 days, given the known benefit of these drugs in reducing complications [59]. In a study involving HCT recipients, virological response was seen even in patients whose treatment was started 3–6 days after initial symptoms, which is longer than the 48-h treatment window recommended for immunocompetent individuals [20]. Early administration of antiviral therapy has been associated with reduced risks of LRI (adjusted OR, 0.04; 95% CI, 00–02; $P<0001$), hypoxemia (adjusted OR, 014; 95% CI, 00–04; $P<0001$), ICU admission ($P=0.007$), hospitalization ($P=0.049$), need for mechanical ventilation ($P=0.019$), and death at 6 weeks (adjusted HR, 021; 95% CI, 00–10; $P=0049$) [21, 29]. This was also true for SOT patients in whom early initiation of antiviral therapy was associated with lower rates of progression to pneumonia (35% vs. 76%) ($P=0.013$), and delayed antiviral treatment was independently associated with increased risk of admission to ICU (odds ratio [OR] 3.03, 95% CI 1.24–7.39, $P=0.015$) [17].

Other studies in SOT and HCT recipients, as well as in patients with solid tumors have associated delay in initiation of therapy (24 h or more after onset of symptoms), with unfavorable outcomes such as progression to LRI and even death [17, 36, 60]. Most experts recommend continuing antiviral therapy until viral replication has ceased, which typically takes longer in transplant patients than the 5 days of therapy recommended for immunocompetent patients [20]. Therefore, prolonged antiviral therapy may be of benefit in transplant recipients, and experts usually recommend a 10-day course of treatment for posttransplant patients [61].

The two main groups of antivirals for influenza are the neuraminidase inhibitors [oseltamivir, zanamivir, and peramivir (licensed in some countries)], which are active against both influenza A and B [52, 62, 63], and the M2 inhibitors (amantadine and rimantadine), which only act against influenza A [64] (Table 30-3).

Oseltamivir is administered orally; its most common side effects are gastrointestinal (mainly nausea), so it is better tolerated with food. Zanamivir is administered by inhalation and is contraindicated or not well-tolerated in patients with chronic obstructive pulmonary disease and asthma (i.e., underlying airway disease). Intravenous (IV) zanamivir is undergoing evaluation in a phase 3 trial and is available for compassionate use from its manufacturer via an FDA emergent investigational new drug application in the USA [61], and compassionate use program in Europe [65]. In immunocompromised patients, increased doses of oseltamivir (150 mg twice a day, adjusted to renal function) have been used, as was recommended for patients with the H5N1 avian influenza strain. Concerns about absorption in patients with graft-versus-host disease or mucositis also motivated higher dosing. However, the benefit and impact on clinical outcomes of high-dose oseltamivir have not been conclusively demonstrated [66, 67], and we do not advocate this practice at the present time.

Peramivir is available in Japan and South Korea and has been recently approved in the USA but still under evaluation in clinical trials in Europe. Peramivir is active against influenza A and B and is indicated for the treatment of influenza infection in adults. Peramivir is the first neuraminidase inhibitor that is FDA-approved for IV use and is administered as a single IV dose [63]. It should be considered for patients who are unable to tolerate oral or enteric administration of drugs. However, further studies are needed to determine the efficacy and safety of peramivir in immunocompromised patients [62]. Lastly, Lanimavir (formerly CS-8958), which is a new-long acting inhaled neuraminidase inhibitor, has been approved in Japan in 2010 and is currently under clinical trials in the USA and Europe and promises activity against oseltamivir resistant influenza strains, but more clinical data is still required [62].

TABLE 30-3. Currently available medications for treatment of Influenza

Neuraminidase inhibitors Active against influenza A and B viruses				
Antiviral agent	Dosing	Concerns for resistance	Adverse events	Approved for prophylaxis
Oseltamivir	75 mg orally every 12 h for 10 days Requires renal adjustment Approved for children >2 weeks	Some strains of influenza A/H1N1 with H275Y mutations	Gastrointestinal, skin and neuropsychiatric events (Japanese reports) Poor absorption in severely ill patients, patients in ICU, and patients with graft-versus-host disease	Yes
Zanamivir	10 mg inhaled every 12 h (2 5-mg inhalations) Approved for children over 7 years of age	Minimal (case reports on combination with H275Y mutations and I223R and E119 neuraminidase substitutions)	Hyperactive airway; skin and gastrointestinal events	Yes
Peramivir	600 mg IV ×1 dose Requires renal adjustment Approved in Japan, South Korea and the USA for adults over 18 years of age	Potential for some strains of influenza A/H1N1 with H275Y mutation—cross-resistance with oseltamivir	Neurologic events; neutropenia; diarrhea; creatinine kinase elevation	No
Laninamivir	For aults/children age 10, a dose of 2 packages (40 mg of laninamivir octanoate) once a day. Approved in Japan. Phase 2 trials in the USA Approved in Japan Phase 2 trials in the USA	Can be used for oseltamivir-resistant influenza A strains	Gastrointestinal events	No
M2 inhibitors Active against influenza A virus only				
Antiviral agent	Dosing	Concerns for resistance	Adverse events	Approved for prophylaxis
Amantadine (generic)	100 mg orally every 12 h	Currently not recommended for treatment of influenza A (rapid emergence of resistance while on treatment)	Cardiac, neurologic, and gastrointestinal events; neutropenia	No
Rimantadine (generic)	100 mg orally every 12 h	Same as amantadine	Neurological and cardiac events	No

The M2 inhibitors (or amantadanes), amantadine and rimantadine, are not active against influenza B virus because the protein M2 is unique to influenza A viruses [46]. In addition, broad resistance to M2 inhibitors has been described; therefore, amantadanes are no longer recommended as first-line therapy for influenza in the USA unless resistance precludes the use of the neuraminidase inhibitors [68].

The use of adjunctive corticosteroid therapy remains controversial. Some studies have shown that adjuvant corticosteroids may decrease inflammation and thus prevent the development of LRI [69], but at the cost of prolonging viral shedding in immunocompromised patients or even other unfavorable outcomes [8, 70]. Thus, additional studies are needed to determine the role of corticosteroid therapy in patients with severe infection, and its use is not recommended at the present time.

30.1.4.1 Antiviral Resistance

Resistance of influenza 2009 H1N1 and H3N2 strains to the available M2 inhibitors is usually recognized early on and frequently develops over the course of treatment, particularly in immunocompromised patients [71]. The mechanisms of resistance are mostly mediated by mutations at many sites of the target pore of the M2 protein channel. Therefore, amantadine and rimantadine should not be used as first-line therapy or chemoprophylaxis for currently circulating influenza A viruses in transplant patients [68, 72].

Resistance to neuraminidase inhibitors among the influenza viruses is an emerging problem of serious epidemiological and clinical implications. A recent meta-analysis, including 19 studies, reported a pooled incidence rate for oseltamivir resistance of 2.6% [73]. However, higher rates of resistance (up to 16.3%) have been reported from Japanese children in 2004 [74]. Furthermore, during the 2007–2008 season in Europe, increased resistance to oseltamivir (up to 17%) was found to be associated with a specific mutation in the seasonal influenza A/H1N1 virus strains, H275Y, which causes a histidine to tyrosine substitution in the neuraminidase [75]. These resistant strains have been reported worldwide [76, 77] and have elicited concern because they have caused severe clinical disease in patients with cancer, with the potential for nosocomial spread [78]. Strains with H275Y mutations were also reported during the 2009 H1N1

pandemic, and some of these mutations arose after treatment with oseltamivir [78, 79]. Finally, although rare, some instances of oseltamivir-resistant H3N2 strains have been detected worldwide [64]. In immunocompromised patients, the extended duration of viral replication and shedding and the prolonged use of antiviral agents for chemoprophylaxis may explain the development of oseltamivir-resistant influenza A viruses, especially those with H275Y mutations [80, 81].

A small number of oseltamivir-resistant 2009 H1N1 viruses have also shown reduced peramivir susceptibility [82, 83], generating great concern about the use of peramivir in immunocompromised patients with oseltamivir-resistant influenza A infections. Therefore, patients infected with influenza A virus that is suspected or documented to have the H275Y mutation should not be treated with peramivir [78, 84]. The treatment of choice for oseltamivir-resistant influenza with the H275Y mutation is zanamivir, and few reports of good outcomes with the use of zanamivir in HCT recipients have been published [85, 86]. However, it is important to mention that zanamivir-resistant strains of 2009 H1N1 influenza virus have been reported in immunocompromised patients after prolonged antiviral use. These strains showed specific mutations in the neuraminidase (I223R neuraminidase substitutions), occurring in combination with or after the H275Y substitution, that have been associated with reduced susceptibility to zanamivir [87, 88]. Therefore, patients undergoing influenza treatment who do not have an appropriate clinical response within 3–5 days of the initiation of antiviral therapy and/or have a worsening course despite ongoing therapy should raise suspicion of an infection with oseltamivir and/or zanamivir-resistant virus. Several methods for genotypic and phenotypic antiviral susceptibility testing are currently available [64, 89].

It has been suggested that triple combination therapy with oseltamivir, amantadine, and ribavirin or higher doses of oseltamivir (150 mg twice a day, adjusted to renal function) could prevent the emergence of antiviral resistance and treat severe disease [90, 91], but the efficacy and safety of these regimens still need to be determined in clinical trials [67].

30.1.4.2 Antivirals in the Pipeline

New agents for the treatment of influenza are under development. DAS181 (Fludase, Ansun BioPharma, USA) is a recombinant fusion protein that includes a sialidase derived from *Actinomycosis viscosus* that cleaves sialic acid receptors on host cells. This protein has been shown to bind to cells and efficiently remove cell-surface sialic acid residues from respiratory epithelium [92]. Sialic acid is the primary receptor for viral binding and entry into the host cell; therefore, the removal of sialic acid by DAS181 potently inhibits viral infection. Furthermore, by targeting the host cells rather than the virus, DAS181 may be less likely than virus-targeted drugs to induce resistance [93]. In a phase 2 study, DAS181 significantly reduced viral load in participants infected with influenza [93]. More efficacy studies are needed to investigate clinical outcomes and the effect of the medication on viral load and shedding.

Favipiravir (T705, Toyama Chemical, Japan) is an investigational antiviral drug that functions as a nucleotide analogue and inhibitor of the viral RNA polymerase of influenza types A, B, and C, including oseltamivir-resistant strains [64]. Synergy with oseltamivir has been demonstrated in preclinical models [94, 95], and is currently undergoing Phase III clinical trials in the USA, Europe, and Latin America. Nitazoxanide, an antiparasitic agent with a novel antiviral effect [96], has been tested in healthy adults and has been shown to reduce the duration of symptoms after acute uncomplicated influenza infections [97]. In view of the ongoing drift or shift of the influenza A virus and the possibility of new pandemics or serious epidemics, future studies are needed to evaluate combination therapies and even newer agents, such as neutralizing monoclonal antibodies [98] and Toll-like receptor agonists, that elicit broad-spectrum immune response against influenza viruses [99].

30.1.5 Prevention

Person-to-person transmission of the influenza virus may occur through small aerosols, large droplets, or direct and indirect contact. The two basic tenets of influenza infection prevention, therefore, are strict attention to hand hygiene and social distancing [100]. Patients with known or suspected influenza infection should be isolated from other patients using standard and droplet precautions, which include the use of gloves, gowns, and surgical masks when close contact is anticipated and goggles or face shields when appropriate, in particular during aerosol-generating procedures [101].

In general, individuals with influenza infection may become infectious 1 day before symptoms' onset and up to 7 days after becoming sick; however, because immunocompromised patients may have prolonged shedding of the virus, they may be contagious for longer than 7 days. Nosocomial transmission of influenza virus is underestimated, but several outbreaks in transplant and non-transplant units have been reported [81]. Early and accurate diagnosis, by prompting isolation precautions, is of tremendous importance in preventing nosocomial transmission. Other precautionary measures should be established in outpatient settings, where transmission may occur in waiting areas. Screening patients for respiratory symptoms during the winter season at the front desk or at check-in and providing masks and alcohol-based gel for hand hygiene may reduce transmission of influenza virus. In addition, health care workers with flu-like symptoms or with potential respiratory viral infection should be furloughed from direct patient care until influenza and other respiratory viruses are ruled out or they become asymptomatic [66].

For immunocompromised patients, daily chemoprophylaxis with strain-specific anti-influenza agents during outbreaks was recommended in the past. However, this recommendation was called into question by a randomized, double blind, placebo-controlled trial conducted during the 2009 H1N1 pandemic. This study showed that prophylaxis with oseltamivir was effective in reducing influenza burden by 75% in high-risk transplant recipients, but at the price of an increase in oseltamivir-resistant influenza A strains [76, 102–104]. At our institution, we recommend providing empiric therapy for immunocompromised patients with upper respiratory symptoms during the influenza season until molecular testing results by PCR are available and reserving chemoprophylaxis in case of nosocomial outbreaks [61].

Vaccination should be the primary means of prevention of influenza infection. The vaccine should be offered by September or October in the Northern hemisphere and by May in the Southern hemisphere [10, 105]. Several influenza vaccines are currently licensed for use, including inactivated influenza vaccines, which can be administered intramuscularly or intradermal, and live influenza vaccines, which are administered intranasal. Inactivated influenza vaccines currently in use are either trivalent (two strains of influenza A and one strain of influenza B) or quadrivalent (two strains of influenza A and two strains of influenza B). The live attenuated vaccines are contraindicated in transplant recipients and their close contacts because there is a risk of transmission of the live-attenuated vaccine strains [106]. The immunogenicity of influenza vaccine in transplant recipients is variable, depending on the type of organ transplanted, the immunosuppressive regimen used, and the composition of the preparation of the vaccine. Vaccine response in transplant recipients has been found to be lower than that observed in the general population, with antibody response ranging from 20% to 50%, especially during the first year after transplant [107, 108]. However, further studies, including a recent meta-analysis, showed that even when vaccinated patients develop influenza, the severity of the disease is reduced compared to that observed in unvaccinated patients [109–111]. Inactivated influenza vaccine is therefore recommended for all HCT and SOT recipients as well as their household members [10, 109, 112, 113]. Vaccination is usually offered 6 months after transplantation or as early as 4 months after transplantation in case of community outbreaks [112]. Ensuring compliance with vaccination in HCT and SOT recipients and their family members has been challenging, though compliance rates have improved over the years [114, 115]. A patient survey at MD Anderson Cancer Center showed that a strong recommendation by the clinical provider was the best predictor of compliance with influenza vaccination in an immunocompromised population [116]. Likewise, vaccination of health care workers is an essential component of protecting vulnerable patients and should be encouraged and monitored, especially in centers caring for SOT and HCT patients [117].

30.1.6 Long-Term Outcomes

After the 2009 H1N1 pandemic, several studies reported incidences of acute allograft rejection after influenza infection ranging from 9% to 61%, with the highest rates in lung transplant recipients [15]. The stimulation of cellular immunity in response to viral infection may result in enhanced recognition of allogeneic tissue, leading to acute and/or chronic allograft rejection. Furthermore, bronchiolitis obliterans syndrome (BOS), defined as new onset of obstructive disease after transplant (measured by a decline in forced expiratory volume [FEV1] in 1 s), has been described after influenza infection in HCT and lung transplant recipients. However, the relationship of influenza infection with these outcomes is not yet as clear as it is for other viruses, including RSV and parainfluenza virus (PIV), and requires further study [118, 119].

30.2 Parainfluenza Virus Infection in Hematopoietic Stem Cell and Solid Organ Transplant Recipients

30.2.1 Overview and Epidemiology

PIV is a medium-sized, enveloped, single-stranded RNA virus belonging to the *Paramyxoviridae* family. PIVs are divided into two broad classes and four types based on their genetic and antigenic characteristics: respirovirus (PIV-1 and PIV-3) and rubulavirus (PIV-2 and PIV-4). In the general population, most clinical infections are caused by PIV-3 (52%), followed by PIV-1 (26%) and PIV-2 (12%) [120]. Although PIV infections often occur year-round, peak seasonal activity has been reported to occur biennially between late September and December for PIV-1, and during the spring and summer months for PIV-3 [22, 120].

The vast majority of PIV infections occur in infants and children and PIV accounts for 30–50% of the cases of croup (acute tracheobronchitis) [121]. By adulthood, more than 90% of individuals have antibodies to PIV, though they are only partially protected against subsequent infections. Even in the presence of high levels of serotype-specific antibodies, primary infection and reinfection can still occur [12]. Besides children, immunocompromised patients, including HCT and lung transplant recipients, are among the most vulnerable to PIV infections [11, 122]. As in the general population, PIV-3 is the virus type most commonly observed in transplant recipients [23].

In HCT recipients, the incidence of PIV infections has generally been reported to be in the range of 1–7% [21, 61], but a recent report of surveillance in asymptomatic HCT recipients found a much higher incidence of 18% [12]. At MD Anderson Cancer Center, a higher rate of PIV infection in allogeneic transplant recipients (5.5%) was reported when

comparing with autologous population (1.3%) [21]. Most PIV infections occurred during the first year after transplant [123], and in a study from the University of Minnesota where more than half (58%) occurring within the first 100 days [22]. It is possible that the reported high rates of nosocomial transmission, which range from 13% to 41% in different centers, have been in part responsible of early occurrence of PIV after stem cell transplant [12, 21].

In studies from the 1990s, PIV infection in HCT recipients was shown to be strongly related to young age [34, 124]. For example, in Wend et al.'s 1995 report [124], 55% of HCT patients infected with PIV were younger than 18 years of age. More recently, however, the average age of presentation has shifted upward. In Ustun et al.'s longitudinal study [22], which tracked the epidemiology of PIV in HCT recipients for over 30 years, patients 19 years old or younger made up 80% of PIV cases from 1974 to 1992, but only 12% from 2002 to 2010. Similarly, in an MD Anderson Cancer Center study, including data from 2002–2007, the mean age of presentation of PIV infection in over 200 patients with leukemia or after HCT was around 54 years [21].

Limited data are available on PIV infections in SOT recipients. The incidence of PIV infection in SOT patients varies between 1.6% and 11.9%; most of the reported infections have been in lung transplant recipients [125, 126]. The wide difference in the reported incidence rates can be explained in part by the method of detection, time of year, geographic location, and, of course, the type of organ transplanted [122]. Importantly, the majority of PIV infections in lung transplant recipients are described between the first and second years after transplant, mainly reflecting exposure in the community [16, 119, 126].

30.2.2 Diagnosis

As there are no clinical features pathognomonic for PIV infection, microbiological diagnosis is of paramount importance. Viral culture is the gold standard for diagnosis of PIV. The preferred cell lines for PIV culture are monkey kidney cell lines (e.g., LLC-MK2), but commercially available mixed cell culture systems will support growth as well. The culture usually takes 2–10 days; therefore, its clinical value is limited [24]. More rapid diagnostic methods such as antigen detection and molecular testing are commercially available and should be used for immunocompromised patients in particular.

Antigen testing for PIV can be performed with immunofluorescence indirect assays using antisera against each of the PIV serotypes, ELISA, radioimmunoassay. The sensitivity of these tests has been reported as ranging from 28% to 84% [44]. In a study by Sable et al., viral isolation and antigen detection assays using upper respiratory tract specimens showed low sensitivity for PIV diagnosis when compared with tests using specimens obtained by bronchoalveolar lavage [127]. These findings can be explained in part by the relatively low sensitivity of these tests in general and the fact that PIV in adult patients may be shed in low titers [128]. The specificity of immunofluorescence assays, however, has been reported to be approximately 95% [24].

Molecular tests, including PCR techniques, have a sensitivity of 100% and specificity of 95–98% [129]. Multiplex RT-qPCR assay kits using a dual-priming oligonucleotide system are now available; this kit is capable of detecting 12 common respiratory viruses. When interpreting molecular test results, however, it is important to keep in mind that prolonged viral shedding has been reported in immunocompromised patients, including asymptomatic HCT patients [12].

Radiological findings are not pathognomonic, though non-cavitary pulmonary nodules, especially peribronchial ground glass infiltrates and consolidation, have been reported [130].

30.2.3 Clinical Presentation and Prognostic Factors

HCT recipients with PIV infections may present with fever, cough, wheezing, and coryza [34, 85]. Sinusitis may be seen in around 40% of patients [123]. Parotiditis, epiglottitis, and even dissemination to the brain, myocardium, and pericardium have also been reported [131, 132] (Table 30-1). Interestingly, a study by Peck et al. [12] showed that up to 17% of HCT recipients tested positive for PIV when weekly respiratory samples were collected, regardless of whether they showed respiratory symptoms.

Two large studies at Fred Hutchinson Cancer Research Center and MD Anderson Cancer Center demonstrated that the most common presentation of PIV infections in HCT recipients was URI (57–87%), followed by URI and LRI (30%), and LRI without URI (7–15%) [51, 60]. In a prospective study at 37 centers in Europe, progression from URI to LRI occurred in 13–49% of patients; radiographic findings varied and included focal or diffuse interstitial and alveolar interstitial infiltrates (Figure 30-3). Most infections progressed within the first 7 days of presentation [23, 36]. Factors that were associated with progression included low neutrophil count (<500 μg/L) (OR 4.3; 95% CI, 1.9–10.0; $P<0.001$); respiratory coinfections within a month of PIV infection (OR 7.1; 95% CI, 2.7–18.8; $P<0.0001$) [21]; low lymphocyte counts (<200 μg/L) (OR 1.73; 95% CI, 1.1–2.9; $P=0.032$) [23, 30]; and the use of glucocorticoid therapy, dose dependent as follows: dose of 1–2 mg/kg/day (OR, 8.6; 95% CI, 2.6–27.8; $P=0.0003$) and dose >2 mg/kg/day (OR 19.8; 95% CI, 5.2–74.6; $P<0.0001$) [22, 30] (Table 30-2).

Respiratory failure secondary to PIV is a significant and common complication in HCT recipients; it may occur in 19–43% of patients with pneumonia [21–23]. Mortality rates range from 25% to 46%, with higher rates reported in patients who develop LRI (HR, 2.6; 95% CI, 1.3–5.4,

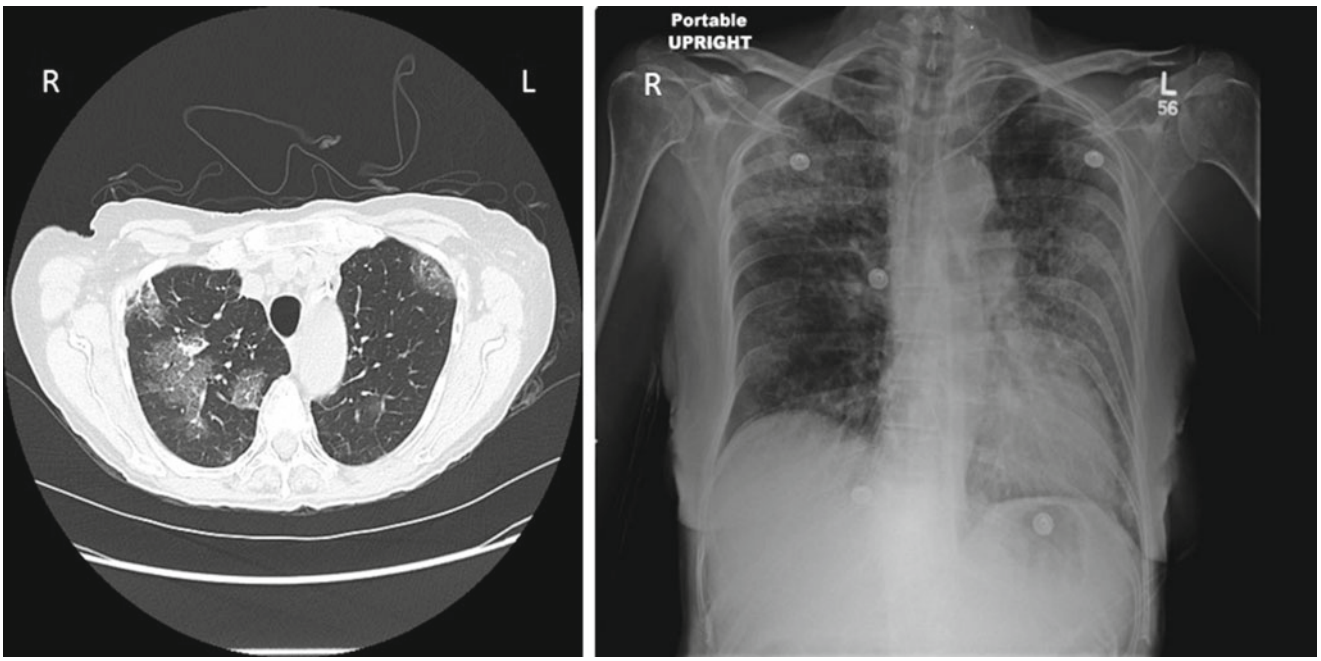

FIGURE 30-3. 68-year-old female with AML DAY+255 Matched-unrelated transplant. Admitted with nasal congestion, cough, dyspnea and fever. Nasal wash was positive for PIV 3. Chest radiograph (*right*) and computed tomography scan of the chest (*left*) showing bilateral ground glass opacities. Abbreviations: *AML* acute myelogenous leukemia, *PIV* parainfluenza virus.

$P<0.01$); who present at age 10–19 years (HR, 4.2; 95% CI, 1.8–9.9; $P<0.01$); who received transplants from a mismatched related donor (HR, 3.8; 95% CI, 1.7–8.5; $P<0.01$); and who developed PIV infection within 3 months after transplant (HR, 2.3; 95% CI, 1.2–4.3; $P<0.01$) [22]. The presence of pulmonary coinfections secondary to *Pseudomonas aeruginosa*, *Staphylococcus aureus*, and *Stenotrophomonas maltophilia* (HR, 2.1; 95% CI, 1.0–4.2; $P=0.04$) and steroid use (HR, 2.0; 95% CI, 1.0–3.9; $P=0.05$) were also associated with higher mortality rates [22, 30, 133].

Reports of PIV in SOT recipients are scarce. Some retrospective studies in adults and children evaluating respiratory virus infections after SOT have reported PIV and influenza to be the most common viruses isolated, with an overall low risk for LRI; however, these infections may be associated with acute allograft rejection [32, 35]. Reported clinical symptoms of PIV infection in SOT recipients are listed in Table 30-1. Vilchez et al. [125] described the clinical presentation of PIV infections in lung transplant recipients as nonspecific, including cough, wheezing, coryza, shortness of breath, and temperature elevation above 38 °C [125]. Various studies have reported time to symptom onset after lung transplant ranging from 260 days to 2 years, mostly reflecting exposure in the community [124, 125]. From 10% to 66% of SOT patients with PIV developed LRI; risk factors for progression included previous anti-lymphocyte therapy, lymphocytopenia, corticosteroid use, and time from transplant to infection (≤1 month) (Table 30-2) [7, 35, 122]. Acute respiratory failure requiring mechanical ventilation occurred in 10–21% of SOT recipients and is associated with a higher risk of death [125, 134]. Reported mortality rates from PIV infection among lung transplant recipients vary from 8% to 20% and are strongly associated with the presence of coinfections with *S. aureus* and *P. aeruginosa* [21, 125].

30.2.4 Management

There is currently no antiviral agent licensed for the treatment of PIV. Management has included supportive care and, in some instances, the use of oral or aerosolized ribavirin with or without intravenous immunoglobulins (IVIGs). New antiviral agents and vaccines in the pipeline might change the paradigm of PIV infection management, particularly in immunocompromised patients.

Ribavirin is a nucleoside analogue that has broad activity in vitro against many RNA and DNA viruses. Aerosolized ribavirin is currently licensed for the treatment of severe RSV infections in young children. Oral and aerosolized ribavirin have also been used for the treatment of PIV; however, the available data remain controversial and not promising [61]. Our experience with PIV infections in HCT recipients at MD Anderson Cancer Center based on retrospective data, has shown that administration of aerosolized ribavirin did not reduce viral shedding, length of hospital stay, clinical response, duration of symptoms, or mortality rate [21]. Furthermore, in other studies there has not been major

difference in outcomes among those who were treated with aerosolized ribavirin and IVIGs from those who were treated with IVIGs alone [135]. Reports on the use of oral ribavirin in HCT recipients have, likewise, shown no impact on mortality rates when compared with supportive care alone [30, 136]. However, in lung transplant recipients with PIV infections, oral ribavirin seems to be associated with some benefits, including lower rates of BOS within 6 months of infection (5% in the ribavirin group versus 24% in the non-ribavirin group; $P=0.02$) [137, 138]. No randomized clinical trials have been conducted on the use of aerosolized or oral ribavirin in transplant patients to date.

Because the hemagglutinin-neuraminidase glycoprotein of PIV is important in membrane attachment, research has focused on the development of selective inhibitors of this major surface glycoprotein. DAS181, a novel sialidase fusion protein, has shown in vivo and in vitro activity against PIV by effectively cleaving sialic acid from respiratory epithelial cells and preventing PIV entry into the cells [61, 93]. DAS181 has been administered on a compassionate use basis for treatment of severe PIV infections in HCT and SOT recipients, with apparent clinical benefit and antiviral effects [93, 139, 140]. There is an ongoing double-blind, placebo-controlled phase 2 trial examining the effects of DAS181 in immunocompromised patients with PIV-related pneumonia. Two new antiviral molecule, BCX 2798 and BCX 2855 (BioCryst Pharmaceuticals, Inc., Birmingham, AL), hemagglutinin-neuraminidase inhibitors, are being evaluated in infected mouse models using a virus similar to PIV, recombinant Sendai virus. BCX 2798 and BCX 2855 were developed through structure-based drug design based on the structure of the lead compound, Neu5Ac2en (2-deoxy-2, 3-dehydro-N-acetyl neuraminic acid), bound to the active site of hemagglutinin-neuraminidase. Neu5Ac2en inhibits most NAs or sialidases and has been shown to reduce virus lung titers and to provide protection against lethal infection in mice [141].

The use of immunomodulation has also been of great interest in the treatment of PIV. Immunoglobulins have long been used in the management of PIV infections in immunocompromised patients, but very few human studies have evaluated the use of IVIGs to treat PIV infection in transplant recipients. In a small cohort of seven subjects with PIV infections after lung or heart-lung transplants, a combination approach using ribavirin, corticosteroids, and IVIG resulted in slower declines in lung function compared to historical controls, as measured by FEV1 [142]. In an animal study using two lots of commercial human-pooled IVIGs to treat PIV-infected cotton rats, Ottolini et al. demonstrated a significant decrease in PIV lung titers with the use of immunoglobulin G. However, they found no effect on inflammatory changes in the lungs [143].

Prince et al., also using a cotton rat model, studied the combination of intranasal topical immunoglobulin G and intranasal topical triamcinolone acetonide; showing a favorable effect on viral load and pulmonary pathology after treatment through 8 days [144]. However, when topical triamcinolone was used alone, virus titers increased more than tenfold [143, 144]. A human study found that higher doses of corticosteroid therapy in HCT recipients were associated with progression to LRI [23]. However, the mechanism of action of the corticosteroids on the pathophysiology of PIV still needs to be elucidated.

30.2.5 Prevention

PIV transmission can occur through contact with infectious fluids, either directly or indirectly through contaminated fomites or through inhalation of airborne particles. Although a few studies have examined whether PIV is transmitted by small droplets, the evidence remains inconclusive. PIV transmission can be effectively controlled by good hand hygiene, disinfection of surfaces, and environmental control of short-range transmission [145, 146]. Several outbreaks have been reported in HCT units, unfortunately due in part to the prolonged shedding of the virus, symptomatic surveillance and isolation precautions have been shown to be ineffective in terminating the outbreaks [147–149]. The recent expansion of knowledge about the need to maintain a high index of suspicion during community outbreaks, recognize asymptomatic shedding, and implement early isolation and contact precautions has reduced nosocomial infection rates from 74% to 27% in the last 30 years [22].

In view of the significant long-term implications of PIV infections in transplant recipients, efforts should focus not only on treatment but also on preventive strategies. Live attenuated PIV vaccines (rHPIV-1/84/del 170/942A) have been developed from human and bovine virus strains, and the results of phase 1 trials in infants, children, and adults suggest that they are safe and immunogenic [150, 151].

In conclusion, PIV is a common infection with high morbidity and potential mortality in transplant patients, as well as long-term effects on the graft and overall outcomes. Further research is needed, in terms of prevention and management including graft outcomes.

30.2.6 Long-Term Outcomes

PIV may activate immunological mechanisms in the lungs; it has been associated with a high rate of acute cellular rejection and risk for BOS in lung transplant recipients [118]. BOS is considered to be the single most important factor limiting long-term survival in lung transplant recipients, in part because its pathogenesis is poorly understood and treatment options are limited [125, 152]. Vilchez et al. [126] report on 24 lung transplant recipients with PIV infections described acute allograft rejection confirmed by trans bronchial biopsy in 82% of patients at the time of diagnosis and BOS in 32% of patients over 18 months of post-PIV-infection

surveillance. However, the interpretation of biopsy results may be difficult in the setting of infection because respiratory viral infections and acute rejection share similar pathological characteristics, including the presence of perivascular infiltrates [153].

In HCT recipients, BOS is one of the most common late-onset noninfectious pulmonary complications [154]. The diagnosis of BOS is based on spirometry measurements, bronchiectasis, and, in some cases, imaging showing evidence of air trapping [155]. At MD Anderson Cancer Center, 922 cases of respiratory viral infections in allogeneic HCT recipients were reviewed. Of those, 304 patients had pulmonary function tests available before and after the respiratory viral episode. The cumulative incidence of BOS was 23%, and BOS was more common following PIV and RSV infections (22%) than following influenza infections (13%) [156]. Similarly, Erard et al.'s [118] report from Fred Hutchinson Cancer Research Center documented significant airflow decline in 86% of the HCT recipients who developed PIV-attributable LRI (adjusted OR 17.9; 95% CI, 2.0–16; $P=0.01$) during the 100 days following transplantation.

30.3 Special Issues in Transplant of Influenza and Parainfluenza

Influenza transmission from organ donor to recipients, while rare, it has been documented in case reports [157, 158]. Lung and intestinal transplant recipients are at higher risk from complications from an infected donor; therefore, potential donors who died in the context of confirmed or suspected influenza infection should be ruled out. For other types of transplantation, organs can be procured as long as the donor received at least 48 h of directed therapy and the recipient is prophylactically treated with neuraminidase inhibitors [159]. Therefore, during the influenza season, a high index of suspicion should be maintained, and potential donors with URI or LRI should be microbiologically tested to rule out influenza or other respiratory viral infections, especially in cases of lung transplantation [159]. Additionally, the transplantation team should inform the potential recipient of the risks and consequences of accepting or not accepting the transplanted organ. To date, there are no reports of solid organ transplant associated PIV transmission, but as for influenza infection, high index of suspicion for donors is encouraged, including microbiological testing when indicated.

Patients who are scheduled to undergo HCT and who develop URI symptoms during the influenza season should be empirically treated for influenza while waiting for test results. A recent study from Fred Hutchinson Cancer Research Center demonstrated how symptomatic patients with upper respiratory viral infection detected before transplant (including influenza and parainfluenza) had an increased overall mortality compared with patients who had no virus detected (unadjusted HR, 3.5; 95% CI, 1.0–12.1; $P=0.05$) [160]. Thus, if at all possible, we recommend postponement of the transplant for 2 weeks or until the illness has completely resolved [61].

Respiratory Syncytial Virus and Human Metapneumovirus Infection in Transplant Recipients

Christian Renaud and Janet Englund

31.1 Introduction

Respiratory viruses may cause serious morbidity and mortality in the immunocompromised host, and the transplant recipient appears particularly vulnerable. The impact of infection with respiratory viruses and the subsequent development of severe lower respiratory tract disease has been increasingly appreciated as respiratory viruses become more readily detectable. Respiratory syncytial virus (RSV) and human metapneumovirus (hMPV) are among the best-documented respiratory viruses causing a wide range of respiratory disease in transplant recipients, ranging from asymptomatic shedding to fatal respiratory failure. Understanding the epidemiology and clinical characteristics of RSV and hMPV permits clinicians to intervene pretransplant, provide appropriate infection control and prevention measures, potentially treat patients, and manage immunosuppressive therapy.

Severe respiratory disease in the seriously immunocompromised host in the mid-twentieth century was originally attributed to infection with opportunistic pathogens such as gram-negative bacteria, fungi, *Pneumocystis jiroveci*, and mycobacteria, as well as cytomegalovirus (CMV) and adenovirus. In the later twentieth century, episodes of acute upper respiratory infection (URI) and LRTI without an identified etiology were often considered to be "idiopathic" pneumonia or attributed to regimen-related toxicity or acute respiratory distress syndrome (ARDS). In the classic 1982 study of 215 non-bacterial, non-fungal pneumonias in 525 allogeneic hematopoietic stem cell transplant (HSCT) recipients, 44% of the episodes of pneumonia remained undiagnosed. The overall mortality rate associated with idiopathic pneumonia in these HSCT recipients was 60%, a strikingly high figure [1]. The potential morbidity of RSV infections was first recognized in immunocompromised children in the 1970s, more than a decade earlier than in immunocompromised adults [2–6]. The recognition of respiratory viruses as an important clinical problem likely reflects the increasing number of severely immunodeficient patients, more aggressive attempts to identify the cause of respiratory illness in high-risk patients, and the increasing ability of clinical virology and pathology laboratories to identify respiratory viruses in clinical specimens.

Although uncommon or atypical pathogens may be responsible for respiratory disease in the transplant recipient, the same viruses that cause typically mild but acute respiratory illness in the general population are responsible for hospitalizations in persons of all ages with underlying medical conditions [7]. These same viruses are also a common cause of respiratory disease in transplant recipients [8–15]. With the widespread availability of sensitive and reliable molecular diagnostic methods, RSV and hMPV have been detected worldwide in transplant recipients and shown to be common causes of respiratory disease in the immunocompromised host [16, 17]. In both the general population as well as in transplant recipients, RSV and hMPV may produce a wide constellation of clinical syndromes ranging from the common cold to bronchiolitis to severe pneumonia, but in contrast to the general population, RSV and hMPV may significantly impact the morbidity and mortality of the transplant recipient.

31.2 Virology

RSV was first identified in 1956 and became appreciated as a major cause of epidemic bronchiolitis and pneumonia in young children in the 1960s [18, 19]. HMPV was first identified in 2001 by molecular techniques in symptomatic children by van den Hoogen et al. as a paramyxovirus causing bronchiolitis and URI in children [20]. Both viruses are classified within the Pneumovirinae subfamily of the Paramyxoviridae family of non-segmented, negative-strand, enveloped RNA viruses [21]. HMPV belongs to the Metapneumovirus genus whereas RSV is a member of the Pneumovirus genus. Both viruses are highly pleomorphic and their sizes vary from 150 to 600 nm. The RSV and hMPV genomes are approximately 13–15 kb in length and closely resemble each other, excluding a few differences in the order of the genes and the absence of the non-structural

P. Ljungman et al. (eds.), *Transplant Infections*, DOI 10.1007/978-3-319-28797-3_31

genes (NS1 and NS2) from hMPV genome. The remaining eight genes code for nine proteins present in both viruses: the nucleoprotein (N protein), the phosphoprotein (P protein), the matrix protein (M protein), the fusion glycoprotein (F protein), the putative transcription factor (M2-1 protein), the RNA synthesis regulatory factor (the M2-2 protein), the small hydrophobic glycoprotein (SH protein), the attachment glycoprotein (G protein) and the viral polymerase (L protein). The RNA core of the virion is associated with P, N, L, M2-1, M2-2 proteins, surrounded by M protein and covered by a lipid envelope. F is the most highly conserved of the envelope glycoproteins within each virus and between RSV and hMPV. The fusion glycoprotein is essential in promoting attachment and fusion of the virus with the cell membrane during viral entry. The fusion protein is the target of many vaccines under development as well as that of monoclonal antibodies such as palivizumab, which is used to prevent RSV disease in preterm infants. By contrast, the G gene is the most variable. Whole genome analysis of both RSV and hMPV has shown the existence of two genotypes, A and B. In hMPV, those two major genetic groups are further divided into subgroups A1, A2, B1, B2 based upon the sequence variability of the G and F genes. Subgroup A2 is again divided into A2a and A2b.

RSV and hMPV infections produce both humoral and cellular immune responses. Humoral immunity protects against reinfection while cellular immunity controls established infection and terminates viral shedding. Protective immunity in immunocompetent hosts is thought to be relatively short-lived. Both viruses interfere with the host's innate immune system resulting into incomplete clearance and partial immunity.

31.3 Diagnosis

Prompt and accurate identification of respiratory viral pathogen is critically important in the transplant recipient because it enables specific infection control precautions to be instituted, the initiation of specific antiviral therapy, impacts the use of immunosuppressive therapy, and potentially affects whether transplantation should proceed [22–24]. Furthermore, identification of a respiratory viral pathogen can assist in avoiding unnecessary therapy, procedures, and surgical procedures (such as open lung biopsy), as well as assist in the identification of a potential cluster or epidemic of infections within the medical unit, hospital, or community. In hospitalized adults (both immunocompromised and immunocompetent), rapid viral diagnosis has been shown to reduce mortality and decrease the length of hospital stay and total cost [25, 26].

Laboratory diagnosis of respiratory viruses including RSV and hMPV has evolved considerably; adequate specimen collection is still essential for the successful identification of viruses in clinical samples. Newer types of nasopharyngeal swabs have shown improved viral diagnostic sensitivity compared to previous swabs, with similar sensitivity to nasal washes when using sensitive molecular methods in patients [27, 28]. For example, nylon flocked swabs and foam swabs increase cell capture within the swab and then release into the transport media, increasing viral recovery [29, 30]. Nasal wash or aspiration methods are superior for isolation of viruses by culture and increase the sensitivity of culture, antigenic assays and quantitative molecular assays [31]. Nasal washes are well tolerated in cooperative adults and offer the advantage of visualizing the quality of the specimen. Bronchoalveolar lavage remains the specimen of choice to diagnose lower respiratory tract infections because of the ability to simultaneously test for potential co-pathogens such as fungi, *Pneumocystis jiroveci*, and bacteria, as well as to document viral infection in the lower airways. Discordance in viral detection between upper and lower respiratory tract samples have been described with both viruses; negative upper tract and positive lower tract specimens in immunocompromised patients are possible but more discordance has been noted for hMPV compared with RSV.

Molecular diagnosis of RSV and hMPV is faster and more sensitive than viral culture or antigen detection, and most laboratories currently use commercial or in-house molecular assays to detect RSV and hMPV (Table 31-1). Many genes have been targeted to detect RSV, including the N, F and L genes, with similar genes also targeted to detect hMPV. Many rapid assays have been approved including some highly multiplexed respiratory panels allowing detection of RSV and hMPV as well as many other respiratory viruses and bacteria. Several different primer sets may be utilized simultaneously in the reaction mix, and the virus identified by the size of the amplicon or following hybridization with a virus-specific probe. Some commercial assays are very rapid and require minimal technical expertise, with only 1–2 h of turn around time [32, 33]. Some laboratories have developed quantitative assays using hydrolysis probe technology with standard curves to help understand the significance of positive results and to follow viral loads under therapeutic management [34–36]. No quantitative commercial assays are yet available. Molecular assays have also been used to detect viral RNA from blood/serum as a prognostic marker [37].

Unlike molecular methods, isolation of virus by culture confirms the presence of a complete infectious unit capable of further multiplication. Positive culture results may be obtained with as little as a single infectious virion, below the threshold of detection for most other detection methods, including some nucleic acid amplification test (NAAT) methods. Another advantage of viral culture is that multiple viruses may be identified from a single sample and viruses can grow independently of point mutations that could potentially create false negative results by NAAT. The major limitations of viral isolation include the time, expense, and expertise required for virus isolation.

TABLE 31-1. Diagnostic tests for common respiratory viruses

Virus	RSV	HMPV	Test advantages
Specimen	Nasopharyngeal aspirate, nasal wash, nasal swab, bronchoalveolar lavage		
Real time RT-PCR assays[a]	Widely available	Widely available	Sensitive, specific, and ability to be rapid (within 1 h); typing, determination of viral load, and sequencing possible
Enzyme-based Immunoassay (EIA[b])	Widely available	Not available in the USA but available in Canada and Europe	Rapid but less sensitive (particularly for low viral loads); relatively inexpensive
Fluorescent antigen detection	Available	Available	Less expensive, rapid; assess quality of specimen; not as sensitive as RT-PCR
Culture (clinical lab)	Central labs only	Limited labs only	Becoming less available; results take time but enables typing and analysis of viral strains

[a]Many viruses can be detected simultaneously by real-time PCR methods [32].
[b]EIA kits are available for RSV only in the USA but for hMPV outside the USA.

A variety of cell lines can be used to grow RSV (Hep-2, A549, RhMK) or hMPV (LLC-MK2, Vero), and detection by cell culture can also be accomplished using several types of cells together, such as the R-Mix cells (mixture of mink lung cells and A549 cells) [38] (Diagnostic Hybrids, Athens, OH). Centrifugation combined with viral antigen detection methods permits more rapid diagnosis [39]. RSV- and hMPV-specific monoclonal antibodies have been used for immunofluorescence (IFA) techniques either directly on respiratory specimens or in cell culture [40, 41]. The sensitivity of IFA is lower than that of NAAT for detection of RSV and hMPV. However, results can be reasonably fast, the method is relatively inexpensive, and importantly, this method also confirms that an appropriate specimen has been properly obtained by looking at ciliated epithelial cells. Sensitivity of IFA when performed by an experienced laboratory is as high as 70–90% of the samples positive by PCR—at least in children [34]. IFA can detect viruses that would be missed by NAAT because of point mutations. IFA positivity also has good clinical correlation while low grade NAAT positivity can be detected for longer periods of time with unclear significance and transmissibility.

Enzyme immunoassays (EIAs) and rapid antigenic diagnostic tests (RADTs) are commercially available for RSV and to a lesser extent for hMPV. These assays lack sensitivity and/or specificity and are not recommended in transplant populations. More than one diagnostic method should be used, since no method is perfect. Molecular assays have the greatest sensitivity—although perhaps at times can perhaps be too sensitive. Paradoxically, rare point mutations causing mismatches have been described causing false negative results of NAAT in transplant units. Viral cell culture requires time, is becoming less available in laboratories, and is more expensive and less sensitive, although it can catch those strains with mismatches and provide information on viral replicative nature while receiving treatment.

31.3.1 Strain Identification and Characterization

Further characterization of RSV and hMPV strains obtained from culture or directly from the clinical specimen is frequently desirable. Antigenic differences among virus strains isolated from different geographic locations or at different times may also be examined. Pools of monoclonal antibodies and "RNA fingerprinting" have been used in the analysis of RSV strains in nosocomial outbreaks [42, 43] but direct sequencing of the F and G glycoproteins is more commonly utilized [44, 45]. Next-generation sequencing is a very promising tool to characterize RSV or hMPV strains during severe infection. This could provide information on phylogenicity to identify outbreaks and also detect mutations that could be associated with antiviral or monoclonal resistance as well as increased virulence. Some human gene alleles in the human genome may increase RSV severity in infants, but little is known yet on these genomic variations in transplant recipients. Next-generation sequencing has the potential to provide information on the virus and the human genomes simultaneously.

31.4 Epidemiology

31.4.1 RSV Epidemiology

31.4.1.1 Hematopoetic Stem Cell Transplantation

RSV is well known to cause annual winter outbreaks in the community (Figure 31-1). Surveillance studies of respiratory viruses from transplant centers have established the high frequency and the significant clinical impact of respiratory viral infections in HSCT recipients overall [8–15, 46, 47] as well as the relative importance of RSV in terms of morbidity and mortality (Table 31-2). A 1988 retrospective review conducted at the Children's Hospital of Philadelphia revealed a

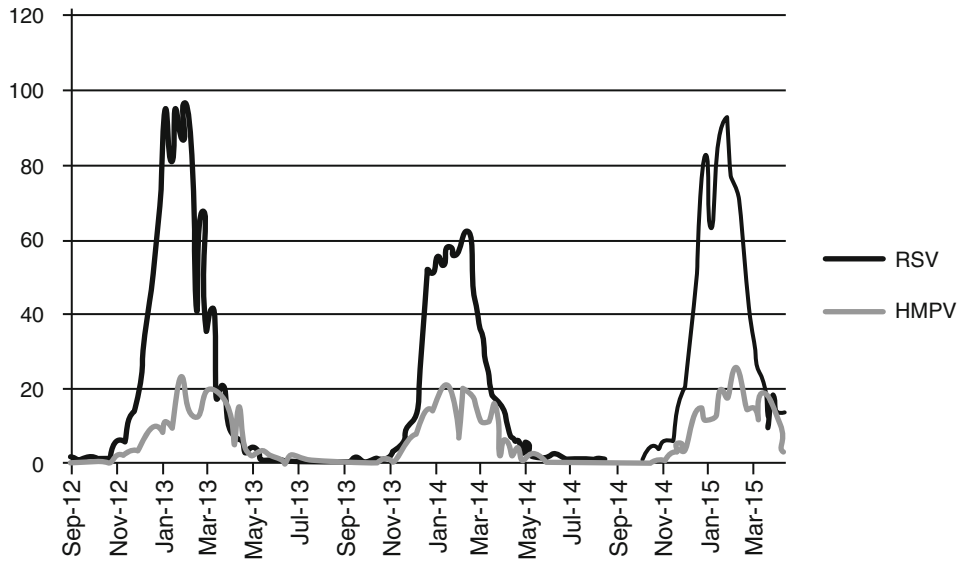

FIGURE 31-1. Seasonality of RSV and hMPV by number of cases/week in outpatient and hospitalized patients, Seattle, 2012–2015.

TABLE 31-2. Lower respiratory tract disease associated with RSV and hMPV in transplant recipients

Virus	Incidence %	Progression to LRTI (%)	Deaths associated with LRTI (%)	Reference
HSCT:				
RSV	1–12	18–55	7–43	[48, 49]
hMPV	3–7	21–40	33–40	[45, 48–50]
SOT:				
RSV-				[51–53]
Lung TX -adults	2–16%	?	10–20%	
Liver Tx (peds)	3–46%	?	12–20%	
	46%	?	?	
hMPV-				[54]
Lung TX	4%	?	33%	

respiratory viral infection in 11 (12%) of 96 pediatric HSCT patients, with only one infection due to RSV [47]. One of the earliest studies demonstrated fatal RSV pneumonia in four of 11 immunocompromised adult HSCT and solid organ transplant recipients with RSV infection [5].

Most studies conducted in the twentieth century utilized classical virological methods that were relatively insensitive for the detection of RSV and/or did not detect recently described respiratory viruses such as hMPV. Thus, these studies likely underestimated the true frequency of RSV overall. Nonetheless, early studies from large transplant centers reported serious sequelae in small numbers of patients who developed pneumonia where RSV was detected [5, 9, 13]. At the Fred Hutchinson Cancer Research Center (Hutch), a prospective surveillance study conducted in 1987 documented respiratory viral infections in 15 (19%) of 78 immunocompromised patients who were followed until hospital discharge [13]; five (33%) patients developed pneumonia and two (13%) patients died (one with RSV, the other with adenovirus). A subsequent prospective surveillance study described 127 viral infections and revealed an overall frequency of viral infections of approximately 4% [11]; 49% of RSV isolates were from BAL. This study demonstrated the relatively high numbers of patients with RSV lower respiratory tract disease, which was higher than rates of LRTI caused by PIV (22%) influenza (10%), or rhinovirus (3%).

Results of viral surveillance in transplant units vary depending on the type of surveillance protocols utilized, time of year surveillance was conducted, type of clinical samples evaluated, and laboratory tests utilized. At the Huddinge University Hospital, Stockholm, a prospective surveillance study conducted among HSCT recipients between 1989 and 1996 detected 39 (7.1%) respiratory viral infections in 545 patients, including RSV in 21% [14]. At M.D. Anderson Cancer Center (MDACC), prospective surveillance conducted using culture techniques among hospitalized adult HSCT recipients during two 6-month winter periods detected 67 (31%) respiratory viral infections in 217 hospitalized patients with acute respiratory symptom. Nearly half of these were due to RSV (33 patients, 49%). The impact of these illnesses was considerable: 20 (61%) patients had RSV infection progressing to pneumonia, and

12 patients with RSV pneumonia died. During the winter period when community viruses were frequent and nosocomial transmission was high, the frequency and mortality of respiratory viral-associated pneumonias was more than four times as high as CMV-associated pneumonia.

Recent prospective studies conducted in transplant centers worldwide continue to demonstrate the importance of RSV and report incidence of infections and risk factors for fatal disease (Table 31-2). A 2005 study from Barcelona, Spain, described the 2-year incidence of symptomatic respiratory viral infections in over 400 patients followed for up to several years posttransplant. Altogether, 29% of allogeneic HSCT recipients and 14% of autologous HSCT recipients had respiratory viruses detected, with 19 patients (4.6%) receiving either autologous or allogeneic transplants having symptomatic RSV disease [55]. Risk factors associated with having a respiratory virus identified included close household contacts with children under the age of 12 years and chronic graft versus host disease. Lymphopenia was identified as a major risk for URI progression. Similar rates have been demonstrated in other centers in the USA [15], South America [56], and Europe [57].

31.4.1.2 Solid Organ Transplantation

Less data is available documenting the impact of RSV in SOT recipients (Table 31-2), RSV has been shown to cause lower respiratory tract disease and has been associated with other complications, such as organ rejection and bronchiolitis obliterans. Lung transplant recipients have the highest rates of RSV lower respiratory tract disease in diverse types of organ transplant. RSV infections in lung transplant recipients have also been associated with organ rejection and progressive bronchiolitis obliterans, both of which have been observed to be seasonally related [58, 59]. Adult renal transplant recipients have also been reported to develop RSV-associated lower respiratory tract disease. The mortality has been low, and most patients have recovered without specific antiviral therapy [5, 60]. RSV infections in pediatric liver transplant recipients have been associated with significant morbidity and some but relatively low mortality [51]. Among 483 pediatric liver transplant recipients cared for at the University of Pittsburgh between 1985 and 1991, 17 (3.4%) children developed RSV infections, three-quarters of which were nosocomially acquired. The majority of the children had lower respiratory tract involvement, and two (12%) children died. Specific antiviral therapy was not administered. The risk factors for more severe disease included onset of infection early after transplant, preexisting lung pathology, augmented immunosuppression prompted by rejection, and younger age. Infections occurring late after transplantation in the absence of rejection were usually not severe.

An intensive prospective approach to determining the incidence and risk factors for respiratory viruses was carried out at the Hutch among 122 HSCT recipients, who were prospectively enrolled between 2000–2004 and tested weekly through 100 days posttransplant using both culture and RT-PCR detection methods [50]. The cumulative incidence estimates of hMPV and RSV at day 100 were similar, at 6.2% and 5.8%, respectively. Multivariable analysis demonstrated that only recipient CMV seropositivity was associated with increased risk for acquisition of a respiratory virus (hazard ratio = 4.1, CI 1.7–10.1, $P = 0.002$).

The frequency of RSV infections and associated morbidity and mortality differs substantially, potentially accounting for the variability reported by different institutions. These differences reflect the intensity of viral surveillances, the time of surveillance, the viruses prevalent in the community, the degree of immunosuppression of the patients, infection control policies, the inclusion of potential as well as actual transplant recipients, surveillance in outpatients as well as inpatients, the types of laboratory assays utilized, and the case definition utilized (i.e., both clinical and laboratory definitions).

31.4.2 HMPV Epidemiology

31.4.2.1 Hematopoietic Stem Cell Transplantation

HMPV has been detected worldwide with a seasonal distribution. Community outbreaks occur yearly mainly in winter and spring (January to May in the northern hemisphere; June to July in the southern hemisphere) (Figure 31-1). Often hMPV outbreaks will be concomitant with or subsequent to RSV outbreaks. HMPV most commonly affects young children less than 2 years old and is second only to RSV as a cause of bronchiolitis. Seroprevalence studies have shown a high percentage of children have contracted the virus by age 5–10 years. However, reinfection can occur later secondary to insufficient immunity or infection with different genotypes. Predominant hMPV strains can vary from location to location and from year to year. Vicente et al. have reported higher virulence by genotype A [61], while Papenburg et al. reported higher virulence by genotype B [62]. However, the interaction or impact of hMPV with other viruses or bacteria remains unclear, particularly in immunocompromised patients.

The importance of hMPV in transplant recipients has not been as well studied as RSV (Table 31-2). It was first reported shortly after the detection of hMPV by Boivin et al. [17]. An early prospective longitudinal study from Spain documented hMPV in both autologous and allogeneic HSCT recipients, with the incidence and clinical impact of hMPV and RSV disease documented to be quite similar [55]. One early prospective study documented hMPV infections in 22 adults with hematologic malignancies that progressed from upper respiratory infection to pneumonia, with a case- fatality rate close to 14% [63]. Lower respiratory tract disease and pneumonia due to hMPV infection in HSCT recipients has been reported to have an overall incidence of 1–4% [48, 55, 64, 65]. A single case series described hMPV-positive nasal

aspirate samples in 86% of 21 adults following HSCT, many of whom were asymptomatic [66]. This study demonstrated very high rates of genetically similar viruses and differs from most other studies due to high rates of genetically identical viruses. These authors suggested that these hMPV infections may have originated in the hospital nosocomially; nonetheless, this study is an outlier compared to other reports of hMPV in transplant centers.

Pneumonia rates following hMPV infection have been reported at 20–28% with mortality rates of 0–4% [67–69]. Among 163 HSCT recipients who underwent BAL for investigation of lower respiratory tract disease with pulmonary infiltrates by radiographic imaging, hMPV was detected in BAL samples from 5 of 163 (3%) patients; four of these five died with acute respiratory failure highlighting the potential severity of hMPV pneumonia [64]. A retrospective cohort study at the Hutch described a high mortality rate of 43% among patients with hMPV pneumonia, a rate similar to RSV pneumonia mortality [49]. Studies from other transplant units continue to document the potential of hMPV to cause severe lower respiratory tract disease, with clinical presentations and outcomes generally similar to RSV [49, 70].

31.4.2.2 Solid Organ Transplantation

The significance of hMPV infection in SOT recipients remains less well defined, with the exception of hMPV disease in lung transplant recipients [70]. Case reports of severe disease have been described following liver and renal transplantation [71, 72]. Rates of hMPV infection in lung transplant recipients have been reported to be similar to those seen in studies of HSCT recipients, varying from 4–6% [57, 73]. In most of these patients, hMPV appears to frequently be the sole pathogen detected. Detection of hMPV in lung transplant recipients may not necessarily signify disease, as was noted in a study of 93 lung transplant recipients undergoing BAL mainly for surveillance purposes; four cases of hMPV was detected in asymptomatic patients [74]. HMPV infection has been found in 4–6% of lung transplant recipients, but prevalence may be higher during nosocomial outbreaks [39, 75]. One study in the setting of a community outbreak identified hMPV in BAL samples from 9 of 26 (35%) patients; their clinical presentation varied from asymptomatic infection to severe disease [39].

Acute allograft rejection was more frequent in the hMPV-infected group than in the non-hMPV-infected group (33% vs. 6%, respectively; $P=0.0257$); and overall mortality was also higher (33% vs. 0%, respectively; $P<0.0025$) [39]. Another prospective study found hMPV infection as frequent as RSV after lung transplantation, and to cause as much pneumonia and acute allograft dysfunction (63% vs. 72%, respectively), but only RSV was associated with chronic allograft dysfunction at 6 months [76]. In another study, 25% of hMPV infections in lung transplant recipients were associated with acute allograft dysfunction compared with 88% for RSV [49]. A meta-analysis of hMPV respiratory infections and allograft rejection, among lung transplantation recipients indicated that detection of hMPV from airway secretions may be a significant posttransplantation occurrence. A total of 2883 samples from 1007 lung transplant recipients, were analyzed for virus detection; 337 samples had viruses identified and 57 (17%) were positive for hMPV. Twenty of these 57 (35%) cases of hMPV had acute rejection within 3 months of viral detection. There were five (9.4%) cases of chronic rejection in association with hMPV. All studies included in the meta-analysis, with the exception of one, identified rejection within 3 months. Another study has also described cases of chronic rejection within 6 months [77].

31.5 Clinical Manifestations

31.5.1 RSV in Transplant Recipients

Disease manifestations of RSV are dependent on many factors including the immunity and immune competence of the host, the time of infection related to transplant, the type of transplant, the age and underlying health of the patient, and the degree and duration of immunodeficiency. RSV infections in HSCT recipients typically follow the same clinical sequence as RSV infections in previously healthy children: signs and symptoms of a URI such as rhinorrhea, sinus congestion, sore throat, or otitis media frequently precede signs of lower respiratory tract disease including cough, wheezing, hypoxia, and pneumonia [5, 6, 9] (Tables 31-3 and 31-4). The presence of wheezing with respiratory symptoms during the respiratory virus season may provide the clue that RSV may be present. Progression of URI to LRI has been associated with patients who are early (<1 month) posttransplant,

TABLE 31-3. Clinical symptoms associated with RSV and hMPV infections in transplant recipients

Upper respiratory tract symptoms:
Rhinorrhea, congestion
Sneezing
Sore throat
Sinus congestion, sinusitis
Otitis media
Lower respiratory tract symptoms:
Cough
Wheeze
Shortness of breath, chest tightness
Systemic symptoms:
Fever
Headache
Myalgia
Hypotension

Table 31-4. Signs, symptoms and viral shedding associated with RSV and hMPV infection in HSCT recipients in a prospective single center institution[a]

Virus	Number of separate clinical episodes	*N* (%) No respiratory symptoms	*N* (%) No systemic symptoms	Viral shedding (median days)	Viral shedding (range, days)
RSV	34	1 (3)	7 (21)	11	2–76
MPV	21	0	4 (19)	24	5–100

Progression, Shedding Patterns, and Clinical Disease Associated with Respiratory Virus Infections after Allogeneic Hematopoietic Cell Transplantation. Presented at American Society of Hematology Annual Meeting, New Orleans, LA; December 7–10, 2013 (Abstract 3278).

those with lymphopenia, or those who are more severely immunosuppressed. In HSCT patients who have recently engrafted, the frequency of progression to LRI tract disease ranges from 25% to 40% [78, 79] (Table 31-2) Pneumonia following RSV infection may be primarily viral, bacterial, fungal, or mixed in origin. Once RSV disease has progressed to respiratory failure, however, the mortality remains high despite the use of antiviral therapy, immunotherapy, or decreased immunosuppressive therapy. Fatality rates of RSV pneumonia range from 20% in more recent case series to over 80% in earlier studies.

Risk factors for the progression of RSV upper respiratory disease to lower tract disease or pneumonia and factors relating to fatal disease have been evaluated. The most common risk factor described in multiple centers using different methods of case ascertainment and viral detection remains lymphopenia. In a prospective multicenter study carried out by the European Group for Blood and Marrow Transplantation, lymphopenia but not neutropenia significantly increased the risk for lower respiratory tract disease [80]. Older age and donor status are also significant risk factors in some studies, whereas CMV serostatus, acute graft versus host disease, time relative to engraftment, and preemptive aerosolized ribavirin at a low dose of 2 h daily were not significant [81]. Investigators from MDACC have demonstrated that season of year, relapse of malignancy, presence of graft versus host disease, increasing age, and lack of engraftment are inpatient risk factors for the development of RSV pneumonia [9, 12, 22, 82]. Recently, large retrospective studies have identified graft source including cord or marrow (adjusted hazard ratio (HR), 4.1, 95% CI 1.8–9.0) and oxygen requirement (adjusted HR 3.3, 98% CI, 15–6.7) to be independently associated with death due to respiratory failure in HSCT recipients [83]. Smoking history, conditioning with high-dose total body irradiation, and an absolute lymphocyte count $< 100/mm^3$ at the time of URI onset are also significantly associated with disease progression [84].

Since initiation of therapy hinges on prompt diagnosis, the possibility of false negative laboratory tests must be considered in individual patients and the diagnosis should be aggressively pursued by other means, such as BAL. Regardless of the therapeutic intervention, high rates of mortality due to RSV pneumonia are documented in seriously immunocompromised patients when therapy has been initiated after the development of respiratory failure (Figure 31-2a). Survival rates remain low for severely immunosuppressed patients who are intubated due to progressive RSV pneumonia unrelated to super-imposed pulmonary hemorrhage, pulmonary edema, or bacterial superinfection [5, 50, 55, 81, 83].

31.5.2 HMPV in Transplant Recipients

HMPV may cause upper or lower respiratory tract infections in HSCT recipients. Asymptomatic shedding from upper respiratory tract has been reported, indicating that not all hMPV infections result in severe lower tract disease [50, 66, 85]. HSCT recipients with hMPV disease in the immediately posttransplant period typically present with respiratory symptoms including nasal congestion, sore throat, cough, or fever. Once lower respiratory tract disease develops, rapidly progressive pulmonary infiltrates frequently accompanied by hypotension, septic shock, or both may be present [64] (Figure 31-2b and c). In a prospective viral surveillance in HSCT recipients where samples for respiratory viruses were obtained weekly, regardless of the presence of respiratory symptoms, a cumulative incidence estimate of hMPV of 6.2% (95% CI, 1.3–11.2) over 1 year was determined; all cases of hMPV had clinical respiratory symptoms identified ranging from mild to more severe disease with single or multiple symptoms [50] (Table 31-4). Among 15 HSCT recipients with hMPV detected by RT-PCR in BAL, 10 (67%) had positive hMPV RT-PCR in nasal wash sampled within 11 days prior to or following the BAL [49]. Viral RNA was detected in the serum of one of these severely immunocompromised HSCT recipients at two time points, 4 days apart, with a viral load of ~8 Log10 copies/ml in each sample. This patient died of severe respiratory disease. In assessing risk factors associated with overall mortality at day 100 posttransplant, the use of bone marrow as the stem cell source, steroid treatment and oxygen use have been associated with overall mortality [49].

Radiographic findings associated with hMPV infection in the HSCT recipient may consist of centrilobular nodules, ground glass opacities, tree-in-bud to diffuse bilateral alveolar infiltrates [86, 87] (Figure 31-2b–f). Centrilobular nodules have been associated with less mechanical ventilation while ground glass opacities tended to be associated with

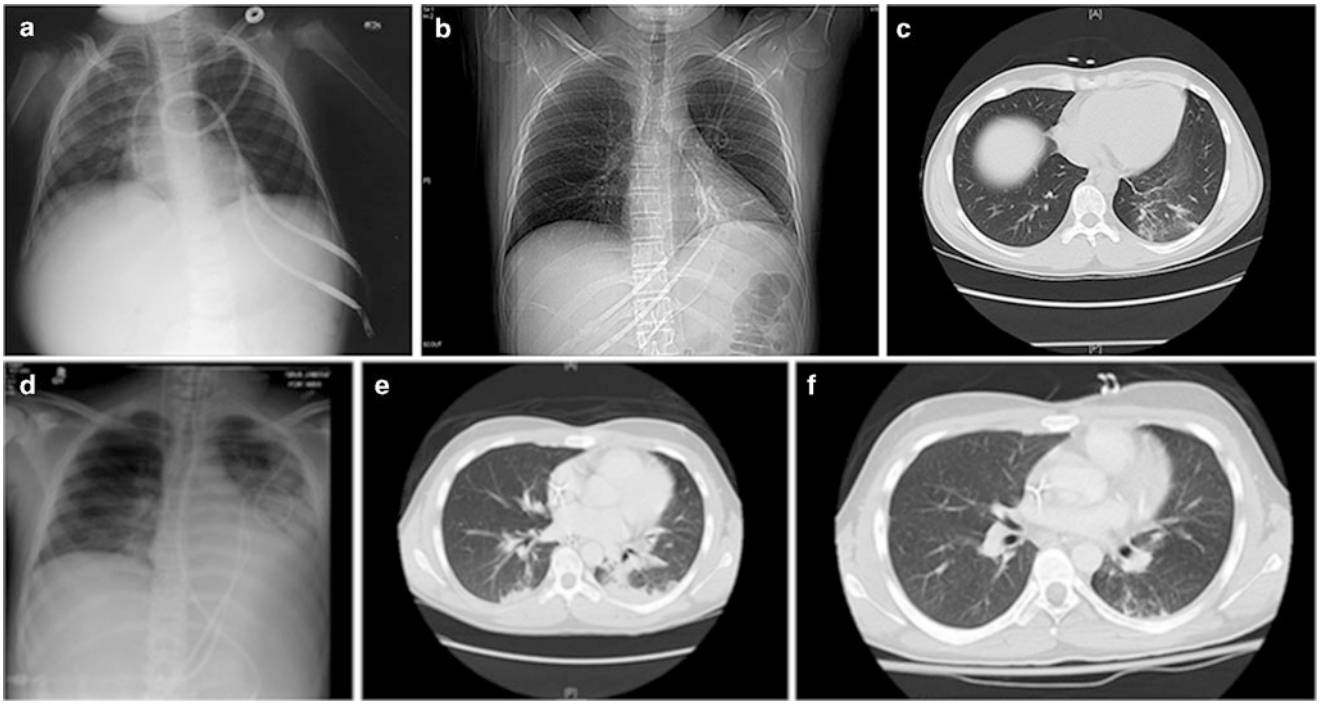

FIGURE 31-2. Chest radiographs of transplant recipients with RSV and hMPV lower respiratory tract disease. (**a**) Three-year-old with RSV pneumonia developing 1 week post HSCT, which proved to be fatal within 2 weeks despite antiviral therapy with aerosolized ribavirin. (**b**) HMPV Lower respiratory tract disease in a 16-year-old boy with ALL and hMPV disease diagnosed day 5 after a matched related BMT. He was diagnosed with hMPV infection on day #5 posttransplant, with clinical findings of mild respiratory distress with cough and abnormal chest radiograph showing interstitial infiltrates. Aerosolized ribavirin and IVIG therapy was initiated. (**c**) Posttransplant day #9: He required intubation due to respiratory failure and acute respiratory distress syndrome, with left sided pneumonia and increasing pleural effusion. He required mechanical ventilation and 50% FiO_2. (**d**) Post Tx day #11: Worsening of left lower basilar consolidation with small left pleural effusion, but oxygen requirement down to 35% FiO_2; not yet engrafted and continued on ribavirin. (**e**) Day #16: Now engrafted and ribavirin discontinued. He was able to be extubated and relatively quickly weaned to room air. (**f**) Patient with improvement post engraftment on day #16 posttransplant. Chest CT shows interval improvement in bilateral patchy groundglass opacities and in left lower lobe consolidation. He received supportive care and 10 days of aerosolized ribavirin therapy, which did not substantially impact viral load, but he improved clinically concomitant with engraftment. He was subsequently extubated and discharged several weeks later.

increased rates of hypoxemia [49]. Alveolar consolidation corresponds to more extensive damage on histological examination. Histological evaluation has also shown hyaline membrane formation, foci of bronchiolitis obliterans and organizing pneumonia and diffuse alveolar hemorrhage.

Variable disease severity has been reported following hMPV infection in SOT recipients. In one study of 114 lung transplant recipients, hMPV was detected in four symptomatic and one asymptomatic patients (4.3%), but viral infection was not persistent and resolved without major complications [88]. In another study, nine lung transplant recipients with hMPV were compared with 17 transplant recipients without hMPV infection; hMPV infection was associated with signs of acute graft rejection and increase overall mortality (three of nine with hMPV-infected patients died and none died in the hMPV-negative group) [54].

31.5.3 Outbreaks

Outbreaks of respiratory viruses occur annually in the community, with potential for patients, families, or health care workers to become infected following exposure outside the hospital. However, nosocomial transmission within the hospital setting becomes a serious concern because of the high rates of morbidity and mortality in immunocompromised patients documented in nosocomial outbreaks. Hospital-based oubreaks of RSV infection in HSCT recipients can occur through introduction of circulating community strains as well as transmission of identical viral strains among patients [42, 44]. Outbreaks of RSV have been associated with high mortality rates ranging up to 45% of infected patients [89, 90]. The transmission of identical strains of RSV within the outpatient setting into the hospital setting

has also been shown [91], demonstrating the importance of infection control measures in both the inpatient and outpatient setting. Nosocomial transmission of hMPV can also occur, with outbreaks possible in both inpatient and outpatient units. In one study, 15 patients were diagnosed with hMPV within 7 weeks in a tertiary care cancer unit [92]. Molecular subtyping revealed infection with genotype A2a virus, implicating nosocomial transmission. Four patients (26.6%) died from hMPV-associated pneumonia and consequent multi-organ failure.

31.6 Treatment and Prevention Strategies

31.6.1 RSV Treatment

Current options for the antiviral therapy of RSV disease in immunocompromised hosts are limited. Large, controlled, therapeutic trials for RSV pneumonia or lower tract disease in immunocompromised patients have not been conducted. Aerosolized ribavirin, licensed in the USA for the therapy of RSV bronchiolitis and pneumonia in infants and young children in 1986, is the antiviral agent currently utilized for the treatment of RSV disease in immunocompromised patients. In general, ribavirin is given as an inhaled aerosolized solution via a face mask in a protective environment, such as a "scavenging tent," to protect health care workers from potential drug contamination. Ribavirin was initially licensed for use when given for 12–18 h/day, but the use of intermittent aerosolized ribavirin given over 2 h, three times daily, was found to have similar effectiveness to 12–16 h/day continuous infusion ribavirin in healthy children [93–95] and has been utilized in adults because of ease of administration and enhanced tolerability. A randomized trial in HSCT patients at risk for LRTI evaluated intermittent dosing of ribavirin given over 2 h three times daily versus continuous ribavirin administration using an adaptive randomized trial design in 50 HSCT patients, with the authors concluding that the intermittent schedule was preferable because of ease of administration and evidence of higher efficacy [96].

Only one randomized, controlled, multicenter clinical trial of aerosolized ribavirin for the prevention of RSV disease progression to LRI has been conducted in HSCT recipients early posttransplant, and despite an enrollment period of several years, only 15 patients were enrolled [97]. None of the ten patients randomized to high dose, short duration aerosolized ribavirin (administered as 2 g/100 ml water given over 2 h three times daily) had disease progression compared to 2/5 control patients, a trend that was not statistically significant ($P=0.08$). Viral loads appeared to be reduced during the ribavirin treatment, but did rebound after cessation of therapy. Data demonstrating effectiveness of ribavirin is mainly retrospective. In an open trial in adult HSCT recipients with "RSV-induced acute lung injury," monotherapy with aerosolized ribavirin was reported to be of benefit if initiated prior to the development of radiographic infiltrates [6]. In another open trial in adult HSCT recipients with radiographically proven RSV pneumonia, combination therapy with aerosolized ribavirin and high RSV-titered IVIG was reported to be of benefit only if initiated prior to the onset of respiratory failure [8, 98]. A retrospective MDACC study of confirmed RSV infections in 280 allogeneic HSCT recipients from 1996 to 2009 utilized multivariable logistic regression to demonstrate that lack of ribavirin aerosol therapy at the upper respiratory tract disease stage was an important risk factor associated with RSV LRTI and all-cause mortality [99]. In a retrospective study of HSCT recipients with confirmed lower respiratory tract RSV infection based on analysis of bronchoalveolar lavage fluid at the Hutch, viral RNA detection in the blood was detected in 30% of 92 patients at a median of 2 days following diagnosis of lower respiratory tract disease [37]. Neutropenia, thrombocytopenia, and mechanical ventilation increased the risk of RSV RNA detection in the plasma or serum but lymphopenia and steroid use did not. The detection of RSV RNA in the serum or plasma increased the risk of overall mortality with an adjusted hazard ratio (AHR) of 2.09 ($P=0.02$).

Data in solid organ transplant recipients is even more limited. Favorable responses have been reported in an open trial of lung transplant recipients with lower respiratory tract disease who received monotherapy with aerosolized ribavirin [58], as well as open trials with oral ribavirin [100–102], although controlled studies have not been performed. Oral ribavirin was found to be well-tolerated, result in less hospitalization, and be less expensive than intravenous or inhaled ribavirin in a retrospective study of 52 lung transplant recipients [102].

The treatment of RSV disease with a combination of antiviral therapy and passively administered immunoglobulin has been investigated in animal models and in children [103–106]. Therapy with IVIG containing high levels of RSV-specific antibodies alone does not seem to be effective in placebo-controlled trials in children who were not immunocompromised [104, 107]. In small open trials at MDACC, combination therapy with aerosolized ribavirin (18 h/day) and high RSV-titered IVIG (0.5 g/kg every other day) was associated with a favorable response in adult HSCT recipients and patients undergoing induction chemotherapy for leukemia who had RSV lower respiratory tract disease in whom therapy was initiated prior to respiratory failure [8, 98]. At the Dana Farber Cancer Institute, combination therapy with aerosolized ribavirin (18 h/day) and RSV-IVIG (1.5 g/kg for one dose) was similarly associated with a favorable response in 2 HSCT recipients with clinically severe RSV pneumonia occurring early following transplant [105]. In subsequent years, MDACC has utilized a combined regimen with similar response, although standard IVIG in frequent and large doses (500 mg/kg QOD) has been substituted for high-titered IVIG.

Other therapeutic options for the treatment of RSV include the use of oral ribavirin, which has been studied in HSCT recipients and found to be safe and less expensive than intravenous or aerosolized ribavirin [100, 108, 109], and is recommended as an option in addition to intravenous and inhaled ribavirin by the European Conference on Infections in Leukemia [94]. Other options include IV ribavirin (an investigational drug, ICN) and topical immunoglobulins administered with aerosolized or intravenous ribavirin [105, 110, 111]. The relative ease of administration of IV ribavirin is attractive, but high rates of mortality (80%) and significant cases of hemolytic anemia (20%) make this option currently problematic. Although the European experience with combination aerosolized/intravenous ribavirin has been favorable [112] and intravenous ribavirin is relatively simple to administer, the high rates of mortality and significant cases of hemolytic anemia make this approach controversial. Monotherapy with IV ribavirin may be more toxic in these patients than has been previously reported in patients with hemorrhagic fevers [113, 114].

The decision to initiate therapy with aerosolized ribavirin with or without immunotherapy for a RSV-URI must take into consideration many factors, including the patient's risk of developing serious lower respiratory tract disease (and specifically, the degree of anticipated lymphopenia), the potential exposure of health care workers to the medication, the psychological and physical discomfort to the patients of aerosol therapy, the adverse effects of aerosolized ribavirin such as bronchospasm, the high cost of these drugs as well as the intensive respiratory therapy needed to safely administer aerosolized ribavirin, and the need for hospitalization with more frequent or prolonged ribavirin dosing regimens.

In patients who have already undergone conditioning therapy and stem cell infusion but have not yet engrafted, the initiation of antiviral therapy at the URI stage may be beneficial. Early studies conducted in the 1990s were small and uncontrolled. One study conducted at FHCRC treated 25 HSCT recipients with upper tract RSV disease with low dose aerosolized ribavirin administered at a high concentration (60 mg/ml) for 2 h each day (total: 2 g/day [8]). Unfortunately, 8/25 patients developed pneumonia, and seven of these died. Another study evaluated combination therapy with aerosolized ribavirin and 500 mg/kg IVIG every other day in 12 patients, two of whom developed pneumonia and died [8, 115]. This "preemptive" strategy, similar to that used in the prevention of CMV disease and CMV pneumonia, is used at some transplant centers for those patients at highest risk of RSV disease progression, such as pre-engrafted patients with RSV detected in the first weeks following transplantation. Other options for preemptive therapy include immunotherapy with IVIG or RSV-specific monoclonal antibodies, although little data on efficacy of immunotherapy is available.

31.6.2 HMPV Treatment

No antivirals for the therapy of hMPV are currently available or routinely utilized. Ribavirin is active in vitro and in vivo against hMPV, although there are no controlled studies or evidence from large retrospective reviews for the treatment of hMPV pneumonia in humans and no drug has yet demonstrated clinical effectiveness in humans [116, 117]. Intravenous, oral or inhaled ribavirin alone or in combination with IVIG has been reported as potentially successful therapeutic options. A retrospective analysis compared the outcome between 13 immunocompromised patients with hMPV pneumonia treated with ribavirin ± IVIG and ten untreated patients. Ribavirin treatment was associated with more hypoxemia and similar mortality, possibly related to late initiation of therapy [49]. A Seattle study describing hMPV lower respiratory tract disease in 55 immunocompromised children, including nine undergoing HSCT and eight SOT recipients, demonstrated that HSCT recipients had more evidence of severe disease [91]. Five of eight HSCT recipients but no SOT recipients had lower tract disease and were treated with aerosolized ribavirin; three had been diagnosed with hMPV pretransplant and during the posttransplant period received both ribavirin and IVIG. Two additional children received aerosolized ribavirin only. Ribavirin was generally administered at a dose of 2 g given three times daily for 5–11 days. Two of the three patients diagnosed with hMPV pretransplant who received ribavirin and IVIG died [91].

31.6.3 Infection Prevention Measures for RSV and hMPV

An aggressive infection control strategy can be effective in reducing the nosocomial acquisition of RSV by transplant recipients [91, 118]. Infection control strategies play a crucial role in the prevention of respiratory viral infection [89, 118–120]. An effective strategy is based on understanding the potential seriousness of these infections in transplant recipients, knowledge of the viruses circulating in the community, and ongoing surveillance in high-risk patients. Continuing education of patients, family members, visitors, and staff regarding the potential seriousness of these infections must be repeatedly emphasized. Frequent and routine clinical screening of high-risk patients for acute upper and/or lower respiratory tract illness or flu-like illness must be conducted, with sampling of respiratory secretions from symptomatic high-risk patients routinely performed both pretransplant and posttransplant. Each health care-acquired infection should be viewed as a sentinel event warranting an investigation and reaffirmation or modification of the preventative strategy.

Infection control strategies should be designed to prevent spread by multiple modes of transmission [90, 91]. Multiple

respiratory viruses may circulate in the community concurrently and can be spread by different means. Infection control measures may need to be intensified during community or hospital outbreaks, and the intensity and duration of infection control measures should be tailored to the risk of serious disease in different subsets of transplant recipients, and to what works in the "real world." Guidelines for the prevention of opportunistic infections among HSCT recipients have been issued by the Centers for Disease Control and Prevention (CDC), the Infectious Diseases Society of America, and European and American Societies for Blood and Marrow Transplantation. The guidelines clearly present evidence-based recommendations rated by the strength of the recommendation and the quality of the supporting evidence, similar to guidelines previously issued for the prevention of opportunistic infections in those with human immunodeficiency virus [120]. Preventive strategies for HSCT recipients, their household contacts and other close contacts, and health care workers are clearly outlined in this document.

The prevention of nosocomial acquisition of respiratory viral infections in HSCT recipients has been demonstrated in one prospective study comparing rates of infection in patients cared for in a "protected environment" with patients cared for on a transplant unit where infection control measures were strongly encouraged, but not rigidly enforced [9]. The effectiveness of infection control interventions has also been demonstrated by the dramatic decline in the frequency of nosocomial CRV infections among HSCT recipients cared for in this transplant unit after the implementation of an aggressive, multifaceted infection control strategy [118]. Although this intensive multifaceted approach has been effective, modified versions of this strategy have also been effective. For instance, the Seattle Cancer Care Alliance (SCCA) adult inpatient transplant unit uses a similar strategy with the exception that health care workers and other visitors do not wear masks when entering the patient room [91]. However, these workers are intensively screened for signs and symptoms of respiratory illnesses prior to entering the unit, and restricted from entering the unit if they are symptomatic. Similarly, HSCT recipients with respiratory symptoms are not transferred to other units, but are cared for on the transplant unit using modified droplet precautions with all persons entering the room wear gloves, gown, and mask, and the door to the room is kept closed. It may not be feasible to so intensively protect patients for the duration of increased susceptibility to respiratory viral diseases. Protective strategies are costly and cumbersome, and pose unpleasant restrictions on the freedom and quality of life of the patient and their families. This problem is further compounded by the growing trend to discharge patients early from the hospital and to perform outpatient HSCT or posttransplant care. Transplant recipients residing in the community and followed frequently in the outpatient setting are another group in which infection control practices must become priority [91].

The prevention of exposure to respiratory viruses is particularly challenging among high-risk transplant recipients living in the community because respiratory infections are so prevalent and so contagious. Examples of protective measures for outpatients include washing hands frequently and thoroughly, avoiding close contact with individuals suffering from respiratory illnesses, and encouraging close contacts to vigorously practice respiratory hygiene. In many cases, such as individuals living with children, such efforts may be nearly impossible. Consideration of removing day care exposures for young children or decreasing exposure to transplant recipients to children (including siblings), can and should be discussed with families. The rigor and duration of prophylactic measures need to be individualized based on the immunologic status of the patient and the risk for serious disease, the needs of the patient, and quality-of-life issues.

31.6.4 Passive Immunoprophylaxis

Passive immunization with immunoglobulin, immunoglobulin products, and humanized monoclonal antibodies have been actively studied in the pediatric infant population. Palivizumab, a humanized monoclonal antibody directed against the RSV F protein, is licensed for the prevention of RSV disease in premature infants and infants with congenital heart disease, and is administered as a monthly injection during the 4–5 months of RSV season. The cost of this therapy has led to new guidelines for use in the pediatric population [121]. Similar interventions have been utilized to attempt to decrease the morbidity of serious RSV disease in HSCT recipients but direct proof of effectiveness has not yet been demonstrated [115]. For example, passive immunoprophylaxis in immunocompromised patients has been evaluated in an open trial conducted [122] using high-titered human RSVIG. In this adult study, significant antibody titer increases to other respiratory viruses were extremely variable, although the subset of patients with the lowest titers appeared to receive the greatest increase in viral-specific antibody. The cost of this potential therapy remains quite high. The monoclonal RSV antibody palivizumab (Synagis) has been studied in an open label study in adult HSCT recipients [123]. Immunoprophylaxis with monoclonal RSV antibodies would be prohibitively expensive in older children and adults, but may have the potential to protect against RSV infection, based on pediatric studies.

New antibody products, including long-lasting monoclonal antibodies with enhanced activity against RSV, are under development and if available at a less expensive price, could potentially provide protection against RSV for patients in the pretransplant and immediate posttransplant phase. Newer monoclonal antibodies that have the potential to neutralize against both RSV and hMPV have also been described, offering hope for newer preventive modalities that may protect against both these viruses [124].

31.6.5 Pretransplant Screening

Screening of transplant recipients for respiratory viruses prior to transplant is not routinely recommended based on current US and international transplant guidelines [94, 125]. However, the assessment of viral shedding or infection in symptomatic transplant candidates prior to transplant is recommended. Delay of transplant based on detection of RSV or hMPV may be warranted depending on the evaluation of the risk and benefits of continuing on with transplantation. Consequences of postponing transplantation should be considered, including progression of underlying malignancy, logistical issues regarding the donor availability, and accessibility of services for the patient. An early study of RSV diagnosed prior to HSCT demonstrated that delaying transplant reduced the risk of pneumonia following transplant [23]. More recently, a large prospective study conducted in 458 patients at the Hutch demonstrated that nearly 25% of subjects had respiratory viruses detected pretransplant [24]. Overall, patients with a virus detected prior to transplant had fewer days alive and lower survival at day 100 (AHR 2.4; 95% CI 1.3–4.5) compared with patients who did not have viruses. In HSCT recipients who had respiratory symptoms and a virus detected prior to transplant (mainly adults), an increased overall mortality was seen compared with patients without respiratory viruses detected. Higher rates of pretransplant infection and sequelae of infection were seen in pediatric patients. Detection of respiratory viruses in asymptomatic patients was not associated with increased mortality. This data strengthens current guidelines that recommend patients with respiratory symptoms prior to transplant should be tested for respiratory viruses and transplant delayed, when feasible. However, this study was performed chiefly in adults. The higher rates of respiratory viruses documented in children pretransplant make routine screening of pediatric patients worthy of further investigation.

31.6.6 New Antivirals

Experimental approaches to the therapy of RSV antiviral therapy include novel fusion inhibitors [126], nucleoside agents, small RNA inhibitory molecules [109], and high-titered monoclonal antibody preparations. Two promising RSV antivirals that have shown efficacy in challenge studies in healthy adults include the Alios compound AL8176 (Alios Biopharma, South San Francisco, CA), an oral anti-RSV nucleoside designed to inhibit RSV replication by acting on the viral polymerase, and the Gilead Sciences compound GS5806 (Gilead Sciences, Foster City, CA), an orally bioavailable RSV fusion inhibitor [126, 127]. Clinical trials of these agents in healthy young children with RSV have been proposed [128]. An international multicenter, placebo-controlled clinical trial of GS5806 was initiated in July 2014, and remains ongoing in adult HSCT recipients with documented RSV infections (Clinicaltrials.gov identifier NCT02135614). Other antiviral agents are under development.

31.6.7 Vaccines

No RSV or hMPV vaccine is currently available. In general, active immunization of transplant recipients will be unlikely to prevent severe disease seen in the first several months posttransplant. However, prevention of RSV infection in families, staff, and nosocomial spread of virus by the use of vaccines holds true promise to benefit transplant recipients themselves. Promising advances in new vaccines directed against both RSV and hMPV have been reported over the past decade, with progress evident in both RSV fusion-protein based vaccines and live attenuated vaccines. Advances in the understanding of the pre- and post-fusion nature of the RSV F protein [129] has led to increased work in developing protein-based vaccines appropriate for older children, adults, and pregnant women.

Advances in technology and better molecular understanding of RSV and hMPV have resulted in new potential RSV candidate vaccines [130]. At least 12 RSV vaccines are in clinical studies in phase 1 or 2 clinical studies, with one RSV F vaccine under study in pregnant women. Examples of live RSV vaccine candidates under study include live-attenuated vaccines relying on genetic manipulation of the RSV genome [131], vectored virus vaccines utilizing the chimpanzee adenovirus or vaccinia virus Ankara [132], or chimeric viruses containing a backbone of attenuated parainfluenza with the F gene of RSV added [133, 134]. A chimeric hMPV vaccine containing a backbone of avian hMPV and F genes of the hMPV [135]. Although live viral vaccines are unlikely to be given to transplant recipients pretransplant or early posttransplant, they offer hope for the potential control of RSV and hMPV disease in family members and health care workers the future.

32 Rhinovirus, Coronavirus, Enterovirus, and Bocavirus After Hematopoietic Cell Transplantation or Solid Organ Transplantation

Alpana Waghmare and Michael Boeckh

32.1 Rhinoviruses

32.1.1 Epidemiology

Human rhinoviruses (HRVs), the viruses predominantly associated with the common cold, are highly prevalent in both immunocompetent and immunocompromised individuals. Prior to the development of sensitive molecular viral detection assays, influenza, respiratory syncytial virus, and parainfluenza virus were the most common and most concerning respiratory viral pathogens detected in hematopoietic cell transplant (HCT) recipients [1]. Due to the development of polymerase chain reaction (PCR) assays for viral detection, HRVs are now known to be the most common viruses detected from respiratory specimens in HCT recipients and can account for 25–40% of cases of viral respiratory infections in these patients [2–4] (Figure 32-1). Due to their high prevalence and their ability to cause progressive infection, HRVs are also a significant cause of lower respiratory tract infection (LRTI) in HCT recipients (Table 32-1). HRV infection is also common in solid organ transplant (SOT) recipients, although the incidence is not known among SOT recipients as a whole. In lung transplant recipients, data from older retrospective and prospective studies suggests an incidence of 35–55% among patients with positive respiratory samples [5–7] (Figure 32-2). In a recent prospective surveillance study of 112 lung transplant recipients, HRVs represented 62% of all positive samples [8]. Among symptomatic lung transplant recipients, HRV represented 34% of all respiratory viruses detected [9].

HRVs are members of the Picornaviridae family and are classified into three species, HRV-A, HRV-B, and HRV-C, based on similarity in genome organization, capsid features, and conserved sequences [10]. The total number of genotypes continues to grow as new genotypes are characterized; currently at least 160 unique genotypes are described. Due to poor growth in traditional viral culture models, HRV-C was only recognized after the development of molecular diagnostic techniques. Thus, HRV-C is not a novel species, but rather one that has been circulating unnoticed due to lack of an appropriate diagnostic assay. There are several biologic characteristics of HRV-C that differentiate the species from HRV-A and HRV-B. HRV-A and HRV-B both use ICAM-1 or LDLR for cell attachment and entry, whereas it appears that HRV-C may utilize a distinct receptor, cadherin-related family member 3, that is associated with asthma susceptibility [11, 12]. Additionally, HRV-C species are stable at higher temperatures and readily infect upper and lower airways, whereas HRV-A and HRV-B species tend to be more limited to the sinuses and upper airways [13, 14]. These biologic characteristics are thought to play a role in variations in clinical outcomes observed among the different species.

32.1.2 Clinical Characteristics

Most immunocompetent patients with HRV present with an afebrile, self-limited syndrome characterized by rhinorrhea, nasal congestion, and malaise, and less frequently sore throat, mild cough, and hoarseness [15–19]. HRV may also be associated with exacerbations of sinusitis, chronic bronchitis, and asthma, and with lower respiratory tract syndromes and atypical pneumonias in otherwise healthy people, including the young and the elderly [20, 21]. The specific mechanisms by which HRVs produce lung diseases are not well understood. HRVs are also implicated in asthma and chronic obstructive pulmonary disease (COPD) exacerbations, but again the mechanisms are poorly defined.

With the widespread availability of PCR diagnostics, data are emerging on the incidence and clinical relevance of HRV infections in immunocompromised patients. Early studies relied on culture to detect HRV, a specific but insensitive method because the standard viral culture systems are not optimized for HRV detection, especially HRV-C [22]. For example, a Fred Hutchinson Cancer Center surveillance study from 1987 to 1992 detected HRVs in 29 specimens, and only one was from a lower respiratory tract specimen [2]. A prospective 5-year study at MD Anderson Cancer

TABLE 32-1. Summary of clinical manifestations of rhinoviruses, coronaviruses, enteroviruses, and bocavirus

Virus	Upper respiratory tract infection	Lower respiratory tract infection	Other manifestations	Treatment	Comments
Human rhinovirus	++++	++		Supportive care	May be associated with severe disease in immunocompromised hosts
Coronavirus	+++	+	Gastrointestinal disease in children	Supportive care	Recent outbreaks of severe acute respiratory syndrome (SARS) and middle east respiratory syndrome (MERS)
Enterovirus	++	+	Neurologic disease (poliomyelitis, meningitis, encephalitis), cardiac disease, muscle disease, eye infections	Supportive care	Sporadic outbreaks described, including Enterovirus-D68
Bocavirus	++	?		Supportive care	

Center cultured specimens specifically for HRVs at lower temperatures with roller culture methods, and reported that HRV infections were associated with substantial morbidity and mortality in 7 of 22 (32%) myelosuppressed patients [23]. In that study, approximately one third of the adult HCT recipients who developed symptomatic HRV infections prior to engraftment had progression of upper respiratory tract symptoms to LRTI, and all cases with pneumonias were fatal. Lung biopsies and autopsies revealed findings consistent with interstitial pneumonitis and/or ARDS, but no in situ evaluation was performed to definitively assess HRV infection. Similar reports with evidence of LRTI based on radiographic and BAL findings continue to be noted [24–26], but it remains unknown if pneumonia is a direct cause of viral invasion of the lung tissue or by host responses in the lung. Evidence for in vitro and in vivo replication in lower respiratory tract has been shown in experimental infection, where HRV was isolated from human volunteers after intranasal HRV challenge by in situ hybridization [27]. The use of RT-PCR continues to provide new information about the frequency of HRV infection. In a study of BAL samples from 77 HCT recipients that were tested using RT-PCR, HRV was detected in six patients (8%), mortality rate was very high (83%) and two of the six patients showed persistent HRV infection. However, all of the HRV-infected patients had significant coinfections and it was not certain whether HRV

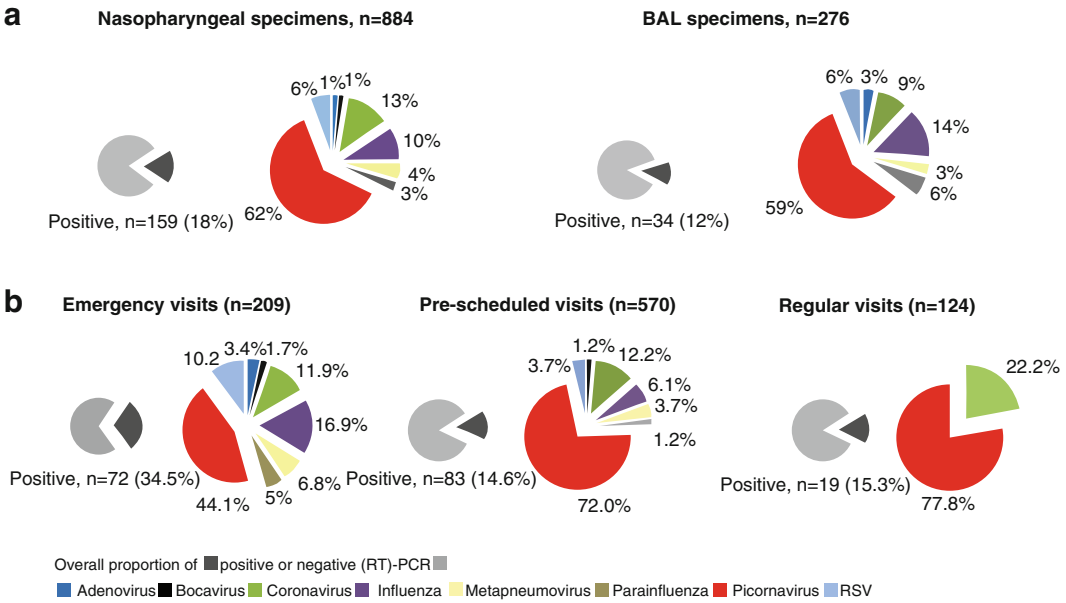

FIGURE 32-2. Distribution of viruses in lung transplant recipients. (**a**) Viruses recovered in upper and lower respiratory specimens. (**b**) Viruses recovered according to visit type. Reproduced from Thorax, Pierre Olivier Bridevaux, J.D. Aubert, P. M. Soccal, J. MazzaStalder, C. Berutto, Incidence and outcomes of respiratory viral infections in lung transplant recipients: A prospective study, 69, pages 32–38, copyright 2014, with permission from BMJ Publishing Group Ltd.

infection was the direct cause of poor prognosis [25]. In a small cohort of patients with hematologic malignancy, LRTI was associated with hypoalbuminemia and bacterial co-pathogens were seen in 25% of patients [28].

Recent studies have shown that immunocompromised adults with HRV demonstrated similar hospital admission rates, intensive care unit admissions, and mortality rates as patients with pandemic H1N1 influenza [29]. Several reports have linked HRV infection to severe respiratory failure and even death [23–25]. Furthermore, recently presented data suggest that LRTI associated with HRV leads to a mortality rate comparable to that of RSV, influenza virus, and PIV [30], independent of the presence of co-pathogens. Risk factors for mortality following HRV LRTI included bone marrow stem cell source, oxygen requirement at time of diagnosis, and steroid use ≥1 mg/kg prior to diagnosis [30]. Other factors that may influence clinical severity include the presence of HRV RNA in blood, viral load, and HRV species type; however, no data exist in immunocompromised patients to date. HRV viral RNA was detected in the sera of 30 (12%) of 243 pediatric patients with severe HRV respiratory infection, with HRV-C being the predominant species [31]. In healthy pediatric patients, increased respiratory viral load has been associated with HRV LRTI and HRVC has been implicated as a more virulent pathogen [32–34]. Others, however, have shown lack of correlation between HRV-C and oxygen requirement, length of hospitalizations, and coinfections [35]. The predominance of HRV-C in HCT recipients has also been described in small studies, with higher rates of pneumonia in patients with HRV-C detected from the upper respiratory tract [36]. In a small cohort of patients with hematologic malignancies, the rate of LRTI was not different between patients infected with HRV-A, HRV-B, or HRV-C [28]. The relative risk of HRV-C infection in the immunocompromised population remains unknown, and more research is needed to define the role of strain differences on outcomes.

Detection and diagnosis of respiratory viral infections prior to transplant is a common clinical concern that has until recently only been evaluated in small cohorts for certain viruses [37–40]. In a large, prospective surveillance cohort of allogeneic HCT recipients, detection of HRV pretransplant was associated with significantly fewer days alive and out of the hospital, and significantly higher mortality at 100 days posttransplant [41]. Further, larger prospective studies are needed to determine risk factors for posttransplant complications, the role of viral load and symptom burden at the time of transplantation, and the need to potentially delay transplantation for patients with HRV present prior to transplantation. Ultimately, the issue of viral causality of disease and evaluation of prophylactic and treatment modalities will need to be addressed. The impact of HRV infection prior to SOT is not known.

Like HCT recipients, SOT recipients are exposed to highly immunosuppressive regimens that leave them susceptible to respiratory viral infections. Lung transplant recipients have the added disadvantage of altered lung immunity due to factors such as impaired ciliary clearance, poor cough reflex, and abnormal lymphatic drainage. These factors can predispose to lower respiratory tract infections. The impact of HRV on outcomes in lung transplant recipients can range from

asymptomatic infection to severe disease. In a pooled analysis of all respiratory viruses detected in lung transplant recipients, viruses were detected five times more frequently when respiratory symptoms were present [42]. A correlation between higher symptom scores and higher rhinovirus load in the upper respiratory tract has been demonstrated, although even asymptomatic patients can have relatively high viral loads [43]. The relative rate of progression from upper to lower tract disease for HRV specifically is not known, although the effect on lung function has been evaluated in aggregate for all respiratory viruses and suggests a decline in forced expiratory volume (FEV1) of −5% to −30% [42]. For HRV specifically, the FEV1 loss was similar to that seen in other respiratory viruses [8]. The correlation between respiratory viral infections and acute rejection, chronic rejection, and bronchiolitis obliterans syndrome (BOS) remains somewhat unclear, with several conflicting findings when respiratory viruses were evaluated in aggregate [6–8]. A recent large cohort of 250 lung transplant recipients, however, showed an independent association between respiratory viral infections (34% HRV) and chronic lung allograft dysfunction in multivariate models [9]. This association was influenced by time, with more of an effect within a shorter period following respiratory infection. Larger, prospective studies investing individual viruses are needed to clearly assess the impact on these outcomes.

32.1.3 Diagnosis

Unlike paramyxoviruses, HRV infection cannot be diagnosed based on characteristic histopathologic changes or changes in cell morphology. In the past, cell culture was used to diagnose HRV infection using multiple cell lines at low temperatures of 33–34 °C, often in rolling tubes. The cell lines utilized for the detection of HRVs may detect enteroviruses; HRV isolates are distinguished from enteroviruses by their lability in acid (loss in viral titer following exposure to a pH of 5). There are no commercially available antigen-detection assays or simple kits for the detection of HRV.

RT-PCR has dramatically improved the ability to both detect and characterize HRVs, with current assays at least two to three times more sensitive than conventional culture methods [44]. Some PCR assays are able to distinguish between enteroviruses and HRVs instead of the acid lability assays [45]. Typing of HRVs based on PCR amplification sequence variations in 5′-noncoding region also has been described [46]. New standardized methods to detect more of the over 100 strains of HRV have now been described [47]; however, commercially available multiplex respiratory viral PCR panels contain primer/probe sets that can cross-react between enterovirus and HRV strains. New strains and types of HRV are being detected frequently and more diseases associated with HRV are being described using new and diverse molecular methods.

32.1.4 Treatment Options

There are no approved antivirals for the treatment of HRV infections. Several agents have been evaluated in preclinical and clinical trials for the treatment of HRV infection in immunocompetent hosts, including capsid binding inhibitors, protease inhibitors, and RNA synthesis inhibitors [48]. None of these agents have been evaluated in immunocompromised hosts. Given the high prevalence and potential severity of HRV infection in this population, there is a great need for drug development and clinical trials for the prevention and treatment of LRTI. Outside of transplant recipients, there is a potential need for intervention in other populations such as patients with asthma or COPD to prevent disease exacerbation [49, 50].

32.2 Coronaviruses

32.2.1 Epidemiology

CoVs are a frequent cause of the common cold, but little is known about the role of CoVs in immunocompromised patients [51] (Table 32-1). Human group 1 (subtypes 229E and NL63) and human group 2 (OC43 and HKU1) CoVs were originally reported as causes of human respiratory illnesses. The availability of more sophisticated diagnostic tools, such as RT-PCR, has facilitated the detection of CoVs in normal and immunocompromised persons. These improved molecular methods of viral discovery facilitated the recent identification of the novel Group 1 and 2 human CoV subtypes—NL63 in 2004 [52] and HKU1 in 2005 [53]. A more accurate clinical epidemiology of CoV infection is beginning to emerge. It is now known that all four known subtypes of CoV circulate simultaneously [54], and that in addition to the common cold, CoV is associated with upper respiratory tract infection and LRTI in persons with and without underlying conditions [55, 56]. In lung transplant recipients, CoVs appear to be the second most common respiratory viruses after picornaviruses with a detection rate of 13–27% of positive samples [5–7] (Figure 32-2). In a prospective surveillance cohort of lung transplant recipients, coronaviruses were detected in 13% of all positive samples, again only second to picornaviruses [8].

Two additional CoVs associated with outbreaks are the severe acute respiratory syndrome-associated CoV (SARS-CoV) and the recently described Middle East respiratory syndrome-CoV (MERS-CoV). The SARS outbreak originated in Guangdong Province in China in 2002 and was characterized by a life-threatening, atypical pneumonia and was spread by close contact with infected humans, mostly to household contacts and health care workers [57]. SARS-CoV is not currently circulating in the world with the most recent human cases of infection reported in China in 2004 [58]. MERS-CoV first emerged in the Arabian Peninsula in 2012, and since then travel-associated cases have been found

in a number of countries outside the region [59]. In adults, the fatality rate is estimated to be 40%; in children asymptomatic infection is common but patients with underlying medical conditions are at increased risk [60, 61]. There is little data on the incidence of SARS-CoV and MERS-CoV in immunocompromised hosts, although immune suppression is considered a risk factor. SARS-CoV has been described in liver transplant recipients and in patients with myelodysplastic syndrome [62, 63]. MERS-CoV has been described in patients on chronic immunosuppression and in renal transplant recipients with a broad range of clinical presentations [64, 65]. Other CoVs have been reported to cause pneumonia in children and immunocompromised patients treated for hematologic malignancies [66–68]. The role of coronavirus virus infection prior to transplantation is not known.

32.2.2 Clinical Characteristics

Although most CoV infections result in relatively mild upper respiratory tract infection, these viruses have been associated with more severe LRTI (e.g., bronchiolitis and pneumonia) in patients who are immunosuppressed, have asthma, or are premature. In one retrospective study carried out over 1 year, CoV was detected in six immunocompromised children—five with acute lymphocytic leukemia and one renal transplant recipient [54]. Five patients were febrile at the time coronavirus was present, with fevers lasting 1–7 days. All patients initially presented with rhinorrhea and nasal discharge; two children had cough as a presenting symptom. Chest radiographs of only one of the three children were abnormal; LRTI based on decreased oxygen saturation, tachypnea, and abnormal chest radiograph was present in only one child with leukemia, who was significantly neutropenic and lymphopenic at the time CoV was detected. CoVs have been associated with LRTI in HCT recipients with sometimes fatal outcomes [66, 67, 69–71]. The clinical characteristics of SARS-CoV and MERS-CoV infection in HCT and SOT patients are not well described, and presentation can range from mild symptoms to respiratory failure and death [62–65, 72].

32.2.3 Diagnosis

Until the advent of RT-PCR, techniques for the detection of CoV were limited and the reliable identification of CoV was problematic. Early detection techniques isolated two subtypes—OC43 and 229E, originally using organ cultures of human embryonic trachea, with morphology determined using negative staining with electron microscopy [73]. With the advent of molecular detection methods and increased interest in CoV detection during the SARS outbreak, new strains of CoVs have been discovered and new RT-PCR assays developed that facilitate further studies of these viruses. Based on RT-PCR assays, four strains of non-SARS CoVs (OC43, 229E, NL63, and HKU1) appear to cocirculate during the non-summer months in temperate climates, and are associated with symptomatic disease in immunocompromised hosts [54]. Guidance on RT-PCR and serologic assays for the confirmation on MERS-CoV can be found on the World Health Organization website [74].

32.2.4 Treatment Options

There are no approved antivirals for prophylaxis or treatment of CoV infections and supportive care remains paramount in managing patients infected with coronaviruses. Though several antivirals were used during the SARS-CoV epidemic, no clear benefit could be established on systematic review [75]. Oral ribavirin was evaluated in retrospective studies for the treatment of MERS-CoV in immunocompetent individuals; decreased survival was noted in one study when compared to matched controls [76, 77], however, larger prospective studies are needed to show true efficacy. Shedding of all coronaviruses may persist for up to months, and routine infection control practices are encouraged.

32.3 Enteroviruses

32.3.1 Epidemiology

EVs are part of the picornaviridae family of viruses and can be associated with severe illness in immunocompromised hosts. EVs include polioviruses, coxsackieviruses, and echoviruses; these are now all classified into four species: *Enterovirus A* (EV-A), EV-B, EV-C, and EV-D. Risk for infection and subsequent poor outcomes appears to be heavily influenced by age, although factors such as sex and socioeconomic status play a role in the general population. EV activity can be either sporadic or epidemic, and several outbreaks have been described. EVs are typically found during the summer and early autumn in temperate climates.

Enterovirus-D68 (EV-D68) was first identified in California in 1962 [78] and has since been associated with several small outbreaks, both in the US and internationally, from 2009 to 2013 [79–84]. In the summer of 2014, several hundred cases of severe respiratory illnesses in children in the United States were found to be associated with EV-D68 infection [85], and several additional clusters have been described worldwide [86–96].

32.3.2 Clinical Characteristics

EVs can cause a wide spectrum of illnesses in immunocompetent individuals including asymptomatic infection, poliomyelitis, meningitis, encephalitis, cardiac disease, muscle disease, eye infections, respiratory infections, exanthems, and neonatal disease. The most frequently described manifestation

in immunocompromised patients is respiratory disease, although the incidence and spectrum of disease is not known. According to one study, EVs can be associated with lower respiratory tract infection and mortality; however, larger studies are needed to establish specific risk factors for worse outcomes [97].

Most confirmed cases of EV-D68 infection have been in children, occurring primarily in patients with underlying lung disease such as asthma or a history of wheezing. EV-D68 was also associated with several cases of acute flaccid paralysis in children during the 2014 outbreak in the United States, although definitive causation has not yet been established [98, 99]. The impact of EV-D68 infection in immunocompromised hosts is not known; however, the association between EV-D68 and severe illness was described in eight adult immunocompromised patients with presumptive EV-D68 infection including HCT recipients [100]. Additionally, one recent report of adults with confirmed EV-D68 infection included solid organ transplant recipients [87].

32.3.3 Diagnosis

Depending on the clinical scenario, EVs can be detected from a number of clinical specimens including cerebral spinal fluid, serum, respiratory specimens, cardiac tissue, and stool. EVs may be identified in throat samples as well as fecal specimens and cerebrospinal fluid. Commercial multiplex PCR assays contain primer/probe sets that may cross react between rhinoviruses and enteroviruses. A specific EV-D68 RT-PCR has been developed by the CDC and has been made publically available [101].

32.3.4 Treatment Options

There are no approved antivirals approved for the treatment of EVs. Intravenous immunoglobulin (IVIG) has been used in the treatment of neonatal enteroviral sepsis, but the effect on clinical outcomes is highly dependent on the presence of specific neutralizing antibodies and timing of administration [102, 103]. Pleconaril, an oral capsid inhibitor with activity against picornaviruses, has been evaluated in treatment of enteroviral infections including meningitis, neonatal sepsis, and respiratory infections [104–108] but is not available for treatment. Other capsid binders, protease inhibitors, and polymerase inhibitors are in various stages of development, but none are currently available for treatment of enteroviral infections [109]. No studies have shown efficacy in immunocompromised hosts.

32.4 Bocavirus

Human bocavirus (HBoV) is a newly identified human parvovirus that was originally identified by random PCR amplification/cloning technique on pooled respiratory secretions from hospitalized children with respiratory tract symptoms [110]. This virus was named "human bocavirus," due to its relatedness to the genome organization of two other parvoviruses, bovine parvovirus and minute virus of canines, in the family Parvoviridae. This virus continues to be detected in young children with a winter seasonality [111–113]. The relationship of HBoV and respiratory disease in immunocompromised patients is not yet clear. Preliminary evidence to date demonstrates case reports of disseminated HBoV infection with involvement of the respiratory tract, blood, and stool in several patients, sometimes associated with GVHD and prolonged viral shedding in the feces [114, 115]. Other studies have reported little evidence linking this virus with pulmonary pathology or severe respiratory disease in HCT or lung transplant recipients [116–118]. Further research is necessary to link this virus with the disease in the transplant recipient. No specific antiviral therapy is available.

32.5 Future Directions and Unmet Needs

Respiratory viruses are a significant concern following HCT and SOT and can be associated with substantial morbidity and mortality, even among viruses traditionally not concerned pathogenic. New, sensitive diagnostic assays allow for routine detection of rhinoviruses, enteroviruses, coronaviruses, and bocavirus, and additional data on the epidemiology, risk factors, outcomes of infection, and the impact of different viral strains are desperately needed. Preliminary studies suggest that detection of these viruses prior to transplant may affect outcomes, but additional studies are needed to explore this important clinical area. Furthermore, as new antivirals are being developed, it will be important to identify high-risk patients that may benefit from treatment. Finally, a better understanding of these viruses will be able to inform better infection prevention strategies that will remain the mainstay of viral control.

Adenovirus Infection in Allogeneic Stem Cell Transplantation

Susanne Matthes-Martin

33.1 Introduction

Adenoviruses (HAdVs) are nonenveloped lytic DNA viruses capable of infecting most mammalian species. To date 67 different human serotypes with varying tissue tropism have been identified, which are divided into seven subgroups or species (A–G) according to their oncogenic potential in rats, hemagglutinating properties, and DNA homologies [1–6].

About half of the serotypes have been associated with clinical symptoms, others are found rarely and may not cause disease [7]. HAdV is highly resistant even in moisture-free environments and remains infectious at room temperature for up to 3 weeks [7, 8]. HAdV is stable at low pH and resistant to gastric and biliary secretions, allowing the virus to replicate and achieve a high viral load in the gut [7].

HAdV is transmitted from person to person by viral shedding in feces, respiratory secretions, and tears of infected individuals. Infection occurs by receptor-mediated endocytosis. Receptors interacting with HAdV include the coxsackieadenovirus receptor, CD46, sialic acid residues, and lactoferrin [9, 10]. Upon entering early endosomes the virus particles gain access to the nucleus, and viral proteins enter the MHC class I and II processing pathways. Finally the replication of viral DNA leads to viral assembly, host cell lysis, and escape from the host cell [9].

Due to the fact that recombinant adenoviruses are increasingly being used as gene transfer vectors in humans, innate and adaptive immune responses to HAdV have been extensively studied. HAdV is recognized through intracellular and extracellular receptors, which trigger interferon-γ (INF-γ), tumor necrosis factor (TNF), interleukin-1 (IL-1), IL-2, and macrophage inflammatory protein production. Besides the direct antiviral effect of these cytokines by inhibiting assembly and maturation of adenoviral particles, they recruit and activate innate effector cells [11–14]. Finally HAdV-specific cytotoxic T-cell clones (mostly $CD4M^+$ cells) are able to lyse infected target cells using a perforin-dependent mechanism [15–17]. One of the most important T-cell targets is the adenoviral hexon protein, which contains the generic antigenic component common to all adenoviruses [18]. Leen et al. characterized 40 CD4- or CD8-restricted hexon epitopes and showed that most of them are shared among different HAdV subspecies suggesting that HAdV-specific T cells can recognize different serotypes [19, 20]. It is supposed that the exposure to different species during childhood and the resulting crossreactive cytotoxic T lymphocytes (CTLs) leads to a broad HAdV immunity in adults [20–23]. By cytokine flow cytometry and INF-γ ELSPOT HAdV-specific T cells are detectable in healthy individuals [24].

However, HAdV disposes of several mechanisms for immune escape. HAdV encodes proteins that block responses to cytolytic and proinflammatory cytokines, intrinsic cellular apoptosis, as well as innate and adaptive cellular immune responses [25–28]. Moreover, antigen presentation by MHC class I molecules is inhibited by blocking their transport to the cell surface [29].

Clinical manifestations in immunocompetent hosts include upper respiratory disease (subgroups C and E), gastroenteritis (subgroups A, D, and F), or conjunctivitis (subgroup D) and are self-limited in most cases although severe manifestations including encephalitis, myocarditis, and pneumonia have been observed sporadically [30–33]. HAdV infections occur mainly in young children; however, outbreaks of HAdV infections in adults, in military camps and in medical facilities have been described [31, 34–37]. In a US population-based epidemiological study, Gray et al. identified several risk factors for severe HAdV disease: age less than 7 years, chronic disease, recent transplantation, and infection with type 5 (subgroup C) and type 21 (subgroup B) [38]. Asymptomatic HAdV infection can persist lifelong in lymphoepithelial tissues [39].

Sites of HAdV persistence include tonsillar and adenoidal T-lymphocytes, and the gastrointestinal tract [39–41]. Diagnostic approaches include virus isolation from either conventional or rapid cell culture, serologic tests, direct fluorescent assay or enzyme immunoassay, and conventional or

P. Ljungman et al. (eds.), *Transplant Infections*, DOI 10.1007/978-3-319-28797-3_33

real-time polymerase chain reaction (PCR) techniques [5, 6, 42, 43]. Whereas conventional cell culture is relatively time-consuming, enzyme immunoassay and rapid cell culture are efficient and sufficiently sensitive for the diagnosis of adenovirus enteritis and upper respiratory disease in immunocompetent children [43]. In immunocompromised patients, however, PCR-based assays have been established as a standard diagnostic tool for rapid, specific, quantitative, and highly sensitive detection of HAdV in any diagnostic material [42, 44–49]. The analysis of peripheral blood samples of immunocompetent children with HAdV-associated respiratory disease and of healthy controls showed that HAdV DNA may be detected in about 40% of children with respiratory HAdV infection for a median period of 4.5 days and occasionally in healthy individuals at a very low level [50].

In neonates and immunocompromised patients, HAdV can cause lethal organ damage [51]. One of the first lethal HAdV infections published was the case of a child with severe congenital immunodeficiency [52]. HAdV infections in patients receiving chemotherapy seems to be a rare event, but lethal disseminated HADV disease has been described in this condition [53–59].

In adult HIV patients, acute diarrhea is frequently associated with HAdV positivity in stool, whereas in HIV positive children HAdV does not seem to be an important cause of diarrhea [60, 61]. There are only sporadic reports on severe or lethal HAdV infections in HIV patients [62, 63].

33.2 Diagnostics

During the last years real-time PCR assays for detection and quantification of HAdV has become the gold standard in the context of allogeneic HSCT [5, 42, 44, 46, 47, 64, 65]. The difficulty of targeting the wide range of serotypes with major genetic differences between the species has been overcome by designing primer/probe combinations derived from the hexon and the VA RNA region [45, 47, 49]. There are a number of commercial kits available. In-house quantitative PCR seem to be comparable to those achieved with commercial kits [49, 66, 67]. The most commonly identified species in the context of HSCT are C (serotypes 1, 2, 5, 6), followed by A (serotype 31) and B (serotypes 3, 11, 34), although in rare instances D and F can be detected [68–71]. Sequential or simultaneous infections with different species have been described occasionally [1, 68–71].

As it has been shown that detection of high levels of HAdV DNA in peripheral blood predicts disseminated HAdV disease, a quantitative HAdV PCR-screening in peripheral blood samples has become standard in many centers [44, 46, 47, 70, 72–74].

The screening for HAdV in the stool and molecular monitoring of viral load in serial stool specimens facilitate early detection of impending invasive infection [1, 66, 74, 75]. It is important to bear in mind, however, that inhibitors of PDR amplification may be present in stool specimens and the implementation of appropriate controls is necessary to prevent false negative results. In the guidelines published in 2012 by the European Conference of Infections in Leukemia (ECIL) monitoring with quantitative PCR of HAdV load in peripheral blood on a weekly basis for all patients with at least 1 risk factor is recommended and the duration of monitoring should be adapted to degree of immune reconstitution [76].

33.3 Incidence

Shields et al. were the first to describe the impact of HAdV on allogeneic hematopoietic stem cell transplantation (HSCT) [53]. During the last decade, HAdV infection in the context of allogeneic stem cell transplantation has been increasingly recognized as a major cause of transplant-related mortality (TRM) especially in children undergoing allogeneic HSCT. Whether this "increase" is due to a higher percentage of T-cell–depleted grafts and highly efficient peritransplant immunosuppression or due to the fact that with the use of highly sensitive PCR techniques HAdV is increasingly being diagnosed remains open.

The first study based on HAdV-PCR screening in stool, urine, and throat swab samples was performed by Chakrabarti et al. in a cohort of 76 adult HSCT patients [77]. A number of screening studies have been performed since then, mainly in pediatric HSCT patients, revealing an overall incidence of HAdV infection between 12% and 42%. Although 55–60% of the infected patients remained asymptomatic, an incidence of lethal disease between 0.9% and 7% has been observed [1, 47, 70, 72, 73, 77–84]. The broad range of reported incidences may be due to the differences concerning the diagnostic samples (peripheral blood, feces, urine) and the diagnostic approach (culture, PCR). The reported screening studies based on PCR screening in peripheral blood since the year 2000 are summarized in Table 33-1.

TABLE 33-1. Screening studies on incidences of HAdV viremia and HAdV-related mortality [1, 47, 70, 72, 78, 82–84, 86, 94, 95, 109]

33.4 Risk Factors

Several risk factors for HAdV infection and, more importantly, HAdV disease have been identified.

33.4.1 Patient Characteristics

Although HAdV infections are more frequently reported in children, recent screening studies revealed incidences of viremia between 5% and 12% [70, 72, 84–86]. Within the pediatric HSCT patient cohort, however, younger age seems to be a significant risk factor [75, 81]: Although similar rates of HAdV infections are observed in adult HSCT patients, the clinical impact of HAdV infections in adult HSCT patients remains controversial [72, 84, 87–90]. Recipient and/or donor serostatus do not have an impact on the occurrence of HAdV infection [91, 92]. However, HAdV PCR positivity in nasopharyngeal aspirate preceding hematopoietic stem cell transplantation or HAdV infection prior to SCT seem to be a very strong risk factor for adenovirus DNAemia in pediatric patients [93, 94].

33.4.2 Donor and Graft

Patients transplanted with unrelated cord blood, and patients transplanted from unrelated donors (who usually receive in vivo or ex vivo T-cell–depleted grafts and have a higher incidence of severe GvHD) have an increased risk for HAdV infections and disease [83, 95–98]. This underlines the impact of prolonged immunosuppression on posttransplant HAdV infection, attributable either to in vivo or ex vivo T-cell depletion, prolonged lymphopenia, or to GvHD-associated immunosuppressive posttransplant therapy [78, 82, 99]. In a study published by van Tol et al. the risk of HAdV infection, disease, and lethal outcome increased with the degree of T-cell depletion from 8%, 2%, and 0% (<2 log T-cell depletion) to 29%, 18%, and 7% (>2 log T-cell depletion) and 71%, 42%, and 42% (>3 log T-cell depletion), respectively [81]. Lee et al. found in a restrospective case finding study in 624 adult and pediatric patients a tenfold increased incidence of HAdV disease in patients receiving T-cell depleted grafts [79]. Analyzing patients with or without ATG-containing conditioning regimens (irrespective of the graft manipulation), Runde et al. reported a significantly higher incidence of HAdV infection in patients receiving ATG [92]. Several groups have addressed the question of whether the mode of T-cell depletion (i.e., ex vivo, in vivo, specific antibodies) has an impact on the risk of HAdV infection: Lion et al. compared patients who received pretransplant ATG and an unmanipulated graft with those who received ATG and an ex vivo T-cell–depleted graft and found a significantly higher incidence of HAdV infection in patients with ex-vivo T-cell depleted grafts; 8 of 11 patients who experienced lethal disease had received ex vivo T-cell–depleted grafts [47]. Myers et al. compared the incidence of HAdV infection and HAdV disease in pediatric patients with either ATG- or alemtuzumab containing conditioning regimens: patients receiving alemtuzumab had a significantly higher probability at 6 months of HAdV infection (35% vs. 13%) and HAdV disease (14% vs. 2%) compared to patients receiving ATG [80], although the impact of serotherapy on the incidence of HAdV infections may be influenced by the dose and length of exposure [100]. The impact of alemtuzumab containing conditioning regimens on HAdV disease in adult patients is being discussed controversially: Sive reported a HAdV associated mortality of only 7%, whereas Avivi and others found a high HAdV-related mortality of 50%, despite a comparable infection rate [77, 84, 85, 88, 89].

33.4.3 Graft-Versus-Host Disease

Severe acute graft-versus-host disease (GvHD) requiring intensified or prolonged immunosuppressive treatment seems to be associated with an increased risk for HAdV infection and disease [1, 60, 79, 80, 85, 92, 96]. The lack of correlation of HAdV infection with GvHD reported in two large screening studies may be due to the fact that these included a large proportion of patients who had received a T-cell–depleted graft [47, 77]. Patients undergoing T-cell–depleted HSCT usually do not experience GvHD but have an increased risk of HAdV infection, which may result in a statistically similar incidence of HAdV infection and disease in patients with or without GvHD. Excluding patients with T-cell–depleted grafts from the statistical analysis reveals a significant correlation between severe GvHD and HAdV infection and disease.

33.4.4 Delayed Immune Reconstitution

There is an obvious correlation of delayed T-cell reconstitution and the risk of HAdV infection [77]. The association of HAdV infection with low T-cell counts has been confirmed in several studies [81, 83, 94, 101]. van Tol et al. showed in a homogenous group of patients with comparable immunosuppressive therapy and comparable risk for GvHD that individuals with delayed T-cell recovery have a significantly higher risk of HAdV infection and, more importantly, progression to disease [81] The monitoring of qualitative (detection of HAdV-specific T-cells) instead of quantitative (total T-cell count) seems to be a more elegant approach to evaluating the risk for progression from HAdV infection to HAdV disease [81, 95, 101, 102]. The detection of HAdV-specific T cells either by IFN-γ ELIspot assays, CD40L upregulation or multimer staining may help clinicians to identify those patients who are shedding HAdV or display HAdV viremia but are at low risk for HAdV disease [102–105].

33.5 Transmission and Reactivation

Viral infections in the context of allogeneic stem cell transplantation are supposed to be the result of transmission by the stem cell graft, endogenous reactivation, nosocomial, or community-acquired transmissions.

It has been suggested, that HAdV infections may be donor derived because donors of HSCT patients developing HAdV infection were seropositive and HAdV could be detected in the graft in rare occasions. However, this could not be confirmed in other studies [92, 95, 106]. The fact that different HAdV serotypes are detectable simultaneously or sequentially in a number of HAdV-infected patients does not support the hypothesis of transmission via the stem cell graft [1, 68, 71, 107].

Although HAdV disease usually occurs between 2 and 3 months posttransplant, screening studies in the pediatric setting showed that the median time point of the first HADV detection in peripheral blood is day +15 [1, 108]. As HAdV is usually detected for the first time when patients are still nursed under strict protective isolation measures, and no seasonal distribution can be observed, community-acquired infections are unlikely in most patients.

However, several HAdV outbreaks in HSCT units have been described, some with and some without evidence of nosocomial origin [109–112].

Several findings support the hypothesis that HAdV infection post transplant is caused by endogenous viral reactivation in most cases. In contrast to immunocompetent patients, adenovirus infections in immunocompromised patients present no seasonal variation [37]; high titers of HAdV antibodies against a certain serotype in the recipient prior to SCT have been shown to be associated with HAdV infections with the same serotype after SCT [113]; infectious HAdV strains detected in children before transplant are identical with the strain isolated after HSCT [1, 39, 81, 114]. This is supported by the observation that adenoviral DNA is highly prevalent in lymphocytes from the gastrointestinal tract and HAdV viremia is preceded by viral shedding in stool in most cases [1, 41, 46, 115, 116]. Once infection has occurred, viral load can increase rapidly with a viral doubling time of 1–3 days [117]. In an adult transplant patient, it has been shown that subsequent virus replication in the colon, bone marrow, and liver was the origin of HAdV DNAemia [118].

33.6 Definitions of HAdV Disease

As HSCT patients, especially those who are severely immunosuppressed due to T-cell depletion or GvHD, frequently have several possible causes for their symptomatology, it may be difficult to attribute specific symptoms or even lethal organ failure exclusively to HAdV in the context of GvHD or other viral and fungal infections. With the perception that HAdV is an important pathogen in the HSCT setting, several attempts have been made to clearly define HAdV infection and disease [115, 119, 120]. It is an established consensus that infection is defined as the detection of HAdV by any method at any site. Definite disease has classically been defined as clinical symptoms compatible with HAdV infection together with either detection of HAdV in tissue culture or histologic evidence; probable disease was defined by most authors as appropriate symptoms, together with either the presence of HAdV in the absence of other recognizable causes or with the HAdV isolation from tissue site with or without histologic evidence. Disseminated disease has been defined by some authors as HAdV viremia, by others as multiple organ involvement in the presence of two or more HAdV-positive PCR assays in PB and other sites tested, in the absence of other identifiable causes [1, 81]. HAdV-related death is usually defined as the detection of HADV in biopsy specimens at autopsy [77, 119].

Taking into account that highly sensitive PCR techniques have become the diagnostic gold standard for HAdV in the context of allogeneic HSCT, ECIL the following definitions have been recommended by ECIL [76]:

- Systemic infection/viremia: Positive HAdV PCR, virus isolation, or antigen detection in peripheral blood.
- Local infection: Positive HAdV PCR, virus isolation, or antigen detection in biopsy material or in body fluids other than peripheral blood.
- Probable disease: HAdV infection plus corresponding symptoms and signs without histological confirmation.
- Proven disease: HAdV infection plus corresponding symptoms related to the infection and histological confirmation of HAdV in the appropriate location.

33.7 Clinical Manifestation

To date, the pathogenetic mechanism of HAdV disease is not completely understood. It has been shown in several animal models that innate cellular immune responses and the respective proinflammatory cytokines largely contribute to the HAdV-associated organ damage, especially in the liver [121, 122]. The binding of HAdV to circulating platelets, which causes their activation/aggregation and subsequent entrapment in liver sinusoids may also contribute to hepatic symptoms and the frequently observed hemorrhagic events [123]. Additionally, HADV seems to be able to induce auto- or alloimmune mechanisms [124].

The first symptoms of HAdV disease in HSCT patients frequently are diarrhea, fever, elevated liver enzymes, and secondary pancytopenia.

However, it has been shown in screening studies that the detection of HAdV in stool samples is associated with enteric symptoms in only 20–30%[1, 81].

The spectrum of HAdV-associated disease in HSCT patients ranges from mild enteritic or respiratory symptoms to severe hemorrhagic enteritis, hemorrhagic cystitis, nephritis, hepatitis, pneumonia, encephalitis, myocarditis, pancreatitis, and lethal multiple organ involvement, which frequently is associated with hepatic failure [31, 73, 85, 87, 89, 90, 125–128]. Although not all patients who are HAdV PCR positive in peripheral blood become symptomatic, all reported lethal cases developed viremia and it has been shown in several studies, that increasing or high viral load is associated with lethal HAdV disease [1, 70, 72, 79, 83, 84, 90]. There is frequently an asymptomatic interval of several weeks between the detection of HAdV viremia and the progression to invasive disease. The occurrence of HAdV viremia prior to day + 50 seems to be associated with a poor outcome [74]. Finally there is a significant correlation between HAdV infection and disease and overall TRM [129]. In a mouse model, it has been shown that in the presence of HAdV, lipopolysaccharide-induced TNF production rises dramatically in peripheral blood, liver, spleen, and lung, and lethality increases after lipopolysaccharide challenge. This observation suggests that HAdV infection might increase the septic mortality and thus indirectly contribute to TRM [130, 131].

33.8 Prevention and Therapy

33.8.1 Prevention

Strict isolation and hygiene measures in HSCT patients shedding the virus are absolutely necessary in order to prevent horizontal transmission and nosocomial outbreaks. Sodium hypochlorite for 10 min or 85% ethanol for at least 2 min can inactivate HAdV [132, 133]. The CDC guidelines recommend contact precautions such as private room, masking, gowning, and gloving in order to minimize the risk of transmissions to other patients and contamination of surfaces [134].

No randomized trials on the use of immunoglobulins as prophylaxis for HAdV infections are available. It has been shown however, that immunoglobuline prophylaxis does not have any impact on the incidence of post-transplant CMV infection [135].

In some pediatric HSCT centers, patients with positive HAdV-PCR in stool prior to T-cell–depleted HSCT receive one dose of cidofovir prior to conditioning, thus taking the opportunity of treatment prior to deletion of the host immune system (R. Handgretinger, personal communication).

33.8.2 Pharmocological Therapy

For three commercially available antiviral agents—ganciclovir, ribavirin, and cidofovir—in vitro efficacy against different HAdV serotypes has been shown [136, 137].

Ganciclovir displays some in vitro activity against HAdV, and one study showed a correlation between HADV infection and the absence of prophylactic or preemptive ganciclovir treatment [138].

Ribavirin is a purine nucleoside analogue with in vitro activity against most HAdV isolates from species A, B, and D, and in all isolates from species C [136]. Although viral clearance has been described in a retrospective analysis of immunocompromised children with severe HAdV disease, no therapeutic benefit could be observed in a cohort of pediatric patients with HAdV viremia [139, 140].

Cidofovir, a cytosine analogue that inhibits DNA polymerase activity with comparable in vitro activity against different HAdV subgroups, has become standard treatment for HAdV infections [141, 142]. It is used as induction therapy in a dose of 5 mg/kg/week and 5 mg/kg every 2 weeks thereafter. Cidofovir-associated nephrotoxicity, cytopenia, and uveitis may contribute substantially to the HAdV-associated morbidity [119]. Hyper-hydration and the concomitant administration of probenecid is mandatory in order to reduce nephrotoxicity. Patients treated with cidofovir must undergo frequent monitoring of renal and especially tubular function. Dose reduction (1 mg/kg three times weekly) seems to be associated with less nephrotoxicity, but the effectiveness remains open [91, 143].

Cidofovir seems to be associated with viral clearance and clinical recovery in non-immunocompromised patients with HAdV pneumonia [144].

Although successful treatment of HAdV infection and disease following HSCT with cidofovir has been reported in several retrospective and prospective studies, the therapeutic value in the context of HSCT and—more importantly—severe lymphopenia remains open. No randomized trials are available and published data are based on extremely heterogenous patient populations concerning T-cell depletion and the presence of severe GvHD, different time-points of infection (ranging from pretransplant infection and very early disease up to more than 200 days posttransplant), different treatment regimens, and a variety of concomitant measures such as withdrawal of immunosuppression or DLI. Retrospective analyses revealed that up to 40% of HSCT patients receiving cidofovir for viral infections other than HAdV develop HAdV viremia during cidofovir treatment [74, 119]. The antiviral effect of cidofovir treatment seems to be strongly influenced by T cell reconstitution [145, 146].

The outcome of patients treated for HAdV viremia with cidofovir is summarized in Table 33-2.

The compound brincidofovir (CMX001; 1-O-hexadecyloxypropyl-cidofovir) is an orally bioavailable lipid conjugate of cidofovir, was able to eradicate disseminated HAdV infection in a mouse model and its safety has been demonstrated in healthy volunteers [147, 148]. However, data on the clinical effectiveness in the context of HAdV is still very limited [149, 150].

Table 33-2. Outcome of cidofovir treatment for patients with HAdV viremia: HAdV-related mortality [1, 47, 74, 84, 87, 88, 96, 108, 109, 116, 145, 161–166]

The results of a prospective double blind placebo controlled phase II trial on preemptive treatment for HAdV viremia (The HAdv Halt Trial, https://clinicaltrials.gov/ct2/show/NCT01241344) have not been published to date.

A prospective study on the preemptive treatment with CMX001 in children with high viral load in stool samples is currently under way.

33.8.3 Adoptive Transfer of HAdV-Specific T Cells

Feuchtinger et al. showed that patients who cleared HAdV infection displayed HAdV-specific T cells until day 200 post-HSCT at significantly higher frequencies than patients who failed to control HADV infection [104]. Heemskerk et al. found that the survival of patients with HAdV viremia was associated with an increase in lymphocyte counts together with the presence of HADV-specific $CD4^+$ T-cell responses and increases in titers of neutralizing antibody [101]. The fatal outcome of HAdV disease despite pharmacological treatment, together with the findings that outcome is mainly related to HAdV-specific immunoreconstitution, suggests that the recovery of HAdV-specific immunity is critical for successful antiviral therapy.

These observations and the fact that the transfer of virus specific T cells is feasible and successful in other posttransplant viral infections have prompted several attempts to select donor-derived HAdV-specific T cells [151–153].

HAdV-specific T-cells are supposed to be cross-reactive with all HAdV subtypes, because the hexon is the immunodominant T-cell target among HAdV capsid proteins, and contains multiple epitopes conserved among different serotypes [19, 24]. In vitro experiments showed that HAdV-specific T cell can be generated by HAdV-pulsed dendritic cells and that cytotoxic T cells raised against HAdV species C can lyse cells infected with species B [18, 151, 154]. Feuchtinger et al. isolated HAdV-specific T cells through an INF-γ secretion and capture assay and could show specific antigen responses of both $CD4^+$ and, to a lesser extent, $CD8^+$ T cells by INF-γ expression and cytotoxicity assays upon restimulation with different HAdV strains [153].

In general, the selection of HAdV-specific T-cells is based either on long-term expansion [107, 155], magnetic separation of virus-specific T-cells using the IFN-γ-capture assay [156] or multimers [103].

Other promising approaches are the allodepletion of donor T cells to improve immune reconstitution concerning all common viruses, the generation of third party T-cells specific for the three most prevalent viruses in the context of HSCT by transduction with a clinical grade HAdV vector and restimulation with irradiated EBV-transformed lymphoblastoid cell lines or the transfection of γ/δ donor-T-cells with adeno-specific T-cell receptor by electroporation [157–159].

In a pilot-study Feuchtinger et al. treated six patients with HAdV viremia with virus-specific donor T cells generated by INF-γ secretion assays [156]. In three of four evaluable patients the infused T cells underwent an in vivo expansion and the viral load decreased in peripheral blood after adoptive T-cell transfer. In vivo expansion of specific T cells was dose independent, suggesting that even very low numbers of HAdV-specific donor T cells expand easily in vivo in the presence of viremia.

Although only few clinical phase I/II trials have been published so far, they showed impressive clinical results concerning reduction of viral disease without inducing severe GvHD. Clinical trials and trial results are summarized in Table 33-3.

33.9 Preemptive Treatment Strategies

In the view of the fact that HAdV viremia is frequently followed by lethal disease, the availability of highly sensitive screening methods and a “window of opportunity” between detection of HAdV and HAdV disease, early preemptive treatment in patients at risk is strongly recommended. However, considering the substantial toxicity of cidofovir and the high percentage of patients shedding HAdV in stool without becoming symptomatic, preemptive treatment for all patients with PCR-positive stool or blood samples is not recommended. Taking into account the high risk of HAdV viremia in patients with high viral loads in stool, preemptive treatment strategies based on quantitative PCR in stool samples may be considered [1, 75]. As severe lymphopenia and delayed immunoreconstitution are risk factors for HAdV disease, all guidelines and algorithms strongly recommend

TABLE 33-3. Adoptive therapy with HAdV-specific T-cells [107, 155, 156, 159, 167–171]

	Method	Donors/infused cell number	Outcome
Feuchtinger et al. (2006)	Interferon-γ capture	Stem cell donors (unrelated) 1–50/10E3/kg	GvHD 1/9, HAdV 1/6 resolved
Leen et al. (2009)	Culture with transduced EBV-transformed B lymphoblastoid cell lines	Stem cell donors (unrelated and haplo) 10E6–10E8/m^2	GvHD 0/12, HAdV 2/2 resolved
Uhlin et al. (2012)	Selection with HLA multimers	Third party 3×10E4/kg	GvHD nr, HAdV 0/1 resolved
Gerdemann et al. (2013)	Short-term plasmid-stimulated culture (CMV, ADV, EBV)	Stem cell donors (unrelated and haplo) 0.5–2×10E7/m^2	GvHD 0/10, HAdV 5/5 resolved
Quasim et al. (2013)	Interferon-γ capture	Stem cell donors (unrelated and haplo), third party 1×10E4/kg	GvHD 1/5, HAdV 3/5 resolved
Leen et al. (2013)	Culture with transduced EBV-transformed B lymphoblastoid cell lines	Third party 2×10E7/m^2	GvHD 8/45, HAdV 14/17 resolved
Geyeregger et al. (2014)	Short-term culture of HAdV stimulated donor T-cells	Stem cell donors (haplo) 1×10E4/kg	GvHD 1/2, HAdV 1/2 resolved
Di Nardo et al. (2014)	Interferon-γ capture	Stem cell donors (haplo) 1×10E5/kg	GvHD 0/1, HAdV 1/1 resolved
Feucht et al. (2015)	Interferon-γ capture	Stem cell donors (sibling, unrelated, haplo) 4×10E3/kg	GvHD 0/30, HAdV 22/30 resolved

TABLE 33-4. Screening and preemptive treatment strategies [1, 76, 120, 142]

	Patients to be screened	Diagnostics	Preemptive treatment with cidofovir	Immunotherapy
Matthes-Martin et al. (2012)	Allo HSCT with ≥1 risk factor	Weekly PB	If ≥1 risk factor	Reduce IS if possible
Lion et al. (2010)	All pediatric allo-HSCT	Weekly PCR screening in feces	All: viral load >10E6/g feaces	Reduce IS if possible
	If viral load >10E6/g faeces	Weekly PCR screening in PB	Increasing viral load despite treatment	HAdV CTLs
Lindemans et al. (2010)	All pediatric allo-HSCT	Weekly PCR screening in PB	High-risk patients: viral load >10E2	Reduce IS if possible
	PCR positive patients	Twice weekly	Intemediate-risk patients: viral load >10E3	Reduce IS if possible
			Low-risk lymphopenic patients: >10E3	Reduce IS if possible
			Low-risk patients: >10E4	Reduce IS if possible
			Increasing viral load despite treatment	HAdV CTLs
Chakrabarti et al. (2004)	All allo-HSCT	Weekly: PB	Any	Reduce IS if possible
		Weekly: feces, urine, throat	If symptomatic: any	Reduce IS if possible
			If asymptomatic and lymphopenic: any	Reduce IS if possible
			If asymptomatic and immuosuppressed: any	Reduce IS if possible
			If no improvement	HAdV CTLs

the reduction of immunosuppressive therapy, whenever possible [76, 120, 142, 160]. All proposed treatment strategies today, recommend third-line therapy with virus-specific T-cells. This should, however, be performed exclusively in the context of prospective trials and restricted to experienced centers until it is confirmed that the transfer of HAdV-specific T-cells is feasible, safe, and effective.

Several algorithms for preemptive treatment in case of DNAemia have been proposed with the aim to prevent HAdV-associated mortality on one hand and overtreatment on the other hand. Published preemptive treatment strategies are listed in Table 33-4.

Acknowledgments. We thank Thomas Lion who contributed to the diagnostic section. We would also like to thank Andreas Heitger, Rene Geyeregger, and Stephan Ladisch for carefully reading and editing the manuscript and Helmut Gadner for his continuous support—without him this work would not have been possible.

34
Adenovirus Infection in Solid Organ Transplantation

Marian G. Michaels, Michael Ison, and Michael Green

34.1 Epidemiology

Adenoviruses are nonenveloped, double-stranded DNA viruses [1]. There are 57 immunologically distinct types of adenoviruses that are further classified into one of seven (A–G) subgroups based on hemagglutinin properties, DNA homology, oncogenic potential in rodents, and clinical disease (Table 34-1) [2, 3]. Infections due to adenovirus occur throughout the year without significant seasonal variation. The highest incidence of adenoviral infection occurs in children between the ages of 6 months and 5 years [2, 4, 5], although outbreaks have been noted historically among military recruits, adolescents at summer camp, and sometimes nursing home residents [6, 7]. Explanations for the infrequent incidence of disease in the very young or in older individuals include the presence of transplancentally acquired maternal antibody in the young infant and the development of neutralizing antibody to the most common adenoviral strains (serotypes 1, 2, and 5) in the majority of children older than 5 years [2]. A risk factor for infection in the preschool age group is the increased likelihood of person-to-person spread resulting from intimate contact between children in the absence of well-developed sanitary habits, especially those in day care or other closed environments [4]. Similarly, it is thought that the relative lack of hygiene and crowding in military barracks is the cause of the increased risk of adenoviral spread among recruits.

Adenovirus has been reported in recipients of all organ types and recipients of bone marrow transplantation with wide ranges depending on the organ transplanted, the age of the patient and the type of study [2–27]. In general infection has been seen more commonly in children compared to adult organ recipients [8, 23, 28]. Presumably, this difference is due to adults having preexisting immunity against adenovirus. However, serological evidence of previous infection does not confer complete protection against invasive adenovirus disease (e.g., adenovirus hepatitis has occurred in pediatric LT recipients with type-specific antibody) [10]. In addition, it is sometimes difficult to attribute specific disease states to the finding of adenovirus since it can be shed asymptomatically for long periods of time even in the normal host [2] Descriptions of adenoviral infections associated with specific types of SOT are provided later in this chapter.

34.2 Mode of Transmission

Adenovirus is typically transmitted person-to-person via direct contact, airborne droplets, or fomites. Among transplant recipients, disease is most frequently described as occurring within the first few months after transplantation. Although outbreaks of adenovirus infections among transplant recipients have been reported [12], attempts to document nosocomial person-to-person spread in two large series were unsuccessful [8, 13]. Adenovirus has not been reported to spread through the use of blood products, thereby eliminating another potential source of viral transmission, though the possibility of transmission via stem cell products has been raised. These facts, as well as the stereotypical timing of adenoviral infection within the first several months after transplantation [8, 13, 14], have led to the suggestion that reactivation of latent virus and/or donor organ-associated transmission are the major sources of early infection in transplant recipients. In support of this hypothesis is the capacity of adenovirus to remain latent and the striking similarities, in terms of both timing of infection and relationships between serostatus and severity of disease [10], that exist between adenovirus and cytomegalovirus. Of greatest similarity is the significant increase in organ-specific adenoviral disease in the transplanted organ. However, the early diagnosis of adenovirus may in part also be biased by more frequent testing early after transplantation.

34.3 Clinical Disease

A number of clinical reports of adenovirus infection after SOT have been published [8–11, 14–27, 29–34]; a summary of their findings is shown in Table 34-1. While manifestations can vary by organ type, several general comments

P. Ljungman et al. (eds.), *Transplant Infections*, DOI 10.1007/978-3-319-28797-3_34

Table 34-1. Adenovirus serotypes associated with specific symptoms in immunocompromised hosts

Host	Disease state	Common serotype
Immunocompromised hosts	Persistence in urinary tract Persistence in colon Pneumonitis, hepatitis	4, 11, 34, 35 42–49
AIDS	Gastroenteritis, pneumonitis, hepatitis, encephalitis	1, 2, 5, 11, 26, 28, 29, 30, 37, 43–47
Bone marrow/stem cell transplant	Gastroenteritis, pneumonitis, hepatitis, hemorrhagic cystitis, encephalitis, disseminated disease	1–3, 5, 7, 11, 31
Liver transplant	Gastroenteritis, hepatitis, pneumonitis, disseminated disease	1, 2, 5, 7, 31
Renal transplant	Hemorrhagic cystitis, pneumonitis, gastrointestinal disease	11, 34, 35
Lung transplant	Pneumonitis, disseminated disease	2, 5[a]

[a]Serotyping often not reported in the literature.

Table 34-2. Definitions of adenovirus infection and disease

Adenovirus disease status	Definition
Asymptomatic infection	Detection from stool, urine, respiratory secretions or blood by culture, antigen test, or PCR in the absence of signs or symptoms of illness
Possible adenovirus infection	Detection in above sites or in the cerebrospinal fluid or bronchoalveolar lavage in the presence of signs or symptoms of illness but with concurrent infection or rejection of the affected organ
Probable adenovirus infection	Same as possible but without concurrent infection or rejection of the affected organ
Proven adenovirus invasive infection	Biopsy proven with histologic evidence of adenovirus in tissue
Disseminated adenovirus Infection	More than two organ systems infected not including blood

Modified from Florescu DF, Hoffman JA and the AST Infectious Diseases Community of Practice, Adenovirus in solid organ transplantation, Am J Transplant. 2013;13(Suppl 4):206–11. doi:10.1111/ajt.12112.

pertain to all organs. First, as mentioned previously, confirming that observed clinical symptoms are due to adenovirus can be difficult as this virus can shed asymptomatically or be carried latently. Definitions categorizing clinical manifestations of adenovirus after transplantation have been proposed by the American Society of Transplantation Infectious Diseases community of Practice [28]. These include asymptomatic shedding, symptomatic disease, or disseminated disease; Table 34-2 expands this to include possible, probable, and proven disease [28].

34.3.1 Liver Transplantation

Historically, adenovirus had been recognized as the third most important viral pathogen (after cytomegalovirus (CMV) and Epstein–Barr virus (EBV)) in children undergoing liver transplantation, accounting for infection in 10% of 484 pediatric LT recipients under cyclosporine A in our center in the 1980s [8]. We subsequently observed a dramatic decrease in the incidence and severity of adenovirus infection after the introduction of tacrolimus-based immunosuppression. A review of more recent experience in the literature appears to support this decline in the importance of adenovirus in this population. Key epidemiologic observations from the earlier series of adenovirus in pediatric liver transplant recipients under cyclosporine-based immune suppression included the development of disease in younger recipients (median age of l 3.0 years; range 0.8–17.2 years) and the development of infection early after transplant [8–11]; the median time of adenoviral isolation was 25.5 days after LT in our series, with severe infections typically presenting in the first 50 days [8]. Symptomatic disease, ranging from self-limited fever, gastroenteritis, or cystitis to devastating illness with hepatitis or pneumonia, was observed in 60% of pediatric LT recipients with evidence of adenoviral infection [8]. Hepatitis was the most common form of invasive infection, and was associated with prolonged high-grade fevers. Eight of 14 pediatric LT recipients with adenoviral hepatitis recovered including four who lost their graft during the course of the disease and underwent successful retransplantation. One of the four had a mild episode of recurrent disease. Adenovirus pneumonia was also seen in this series affecting 8 of 48 pediatric LT recipients; 6 of these 8 children died, including 2 with concurrent hepatitis. Serotypes 1, 2, and 5 were the most common isolates in this series [8] with serotype 5 being the primary cause of hepatitis and serotype 2 associated with the most cases of pneumonia. The use of OKT3 was identified as a risk factor for symptomatic disease [8]. The presence of donor/recipient serologic mismatching was associated with development of both infection and more severe disease [9, 10].

A single report describes the experience with adenovirus infection in adult LT recipients [9]. Eleven of 191 (5.8%) adult recipients of LT had positive cultures for adenovirus in this series. However, only 7 of the 11 were thought to have developed symptomatic disease. In three of the seven symptomatic cases, disease was limited to the urinary tract. Disseminated disease associated with pneumonia was observed in three patients. The remaining patients developed fulminant hepatitis. Death was attributable to adenovirus in one case of disseminated disease with pneumonia and in the case of fulminant hepatitis. The mean time to isolation of adenovirus by culture was 66 days after transplant, while the mean time to onset of symptomatic disease due to adenovirus was 55 days (range 3–180 days) after transplant. A second report describing results of surveillance for adenovirus in adult SOT recipients

found that 8.3% of 121 liver recipients had AV detectable by PCR in their blood in the first 12 months after LTx. However, the majority were asymptomatic, and progression to significant disease did not occur [10].

34.3.2 Renal Transplantation

The reported experience of adenovirus infections after RT is limited to case reports that have accumulated over the last 25 years [27] The most frequently reported clinical syndrome has been hemorrhagic cystitis due to adenovirus types 7, 11, 34, and 36 [14, 19–22, 27]. Generally, episodes are self-limited despite the fact that many of these patients were initially treated as having rejection with augmented immunosuppression. Hemorrhagic cystitis sometimes accompanied with adenovirus nephritis may be confused with renal rejection. Patients with adenovirus nephritis generally present with persistent fevers, microscopic or macroscopic hematuria, and elevated serum creatinine [35]. More serious illness, consisting of interstitial pneumonia has been less frequently reported but is associated with a higher rate of fatal, disseminated disease [16–18]. Additionally, a single case of fatal hepatitis due to adenovirus type 5 has been reported following RT [15].

Similar to adenoviral infections after pediatric LT, the vast majority of adenovirus infections after RT have developed within the first 6 months after transplantation (range 17 days to 9 months; median 2.5 months) [14–22, 27]. However, all the reported cases of adenoviral infection in RT recipients have occurred in adults (range 17–61 years; median 30.5 years) [14–22]. The early timing after transplantation and the predilection for infection of the transplanted organ has again led to the hypothesis that these cases may be due to donor associated transmission. This may represent publication bias, though, as clinical experience suggests milder, self-limited infections can occur throughout the entire post-transplant period.

34.3.3 Cardiac Transplantation

There is less information about adenoviral infection following cardiac transplantation compared to other organ types [26]. However, adenovirus genome has been identified by polymerase chain reaction in endomyocardial biopsy specimens of 8 of 40 pediatric cardiac transplant recipients who had histologic evidence of inflammation indistinguishable from rejection [36]. Of interest, several of the children with this finding had recent or concurrent histories of upper respiratory tract infections. Two of the eight patients presented with cardiogenic shock and were felt to have histologic evidence of high-grade rejection. They were treated for rejection with improved clinical status, and adenovirus could not be identified on subsequent biopsies. Whether adenovirus was the sole cause of the inflammation, a promoter of rejection, or an innocent bystander in these patients was not established in this report. An additional report among pediatric heart transplant recipients identified an association between detection of adenoviral genome copies in myocardial biopsy specimens and adverse clinical events including coronary vasculopathy and graft loss [37]. As with the previous report, causal relationships between the presence of adenoviral DNA and the subsequent development of these adverse events remain to be proven. Anecdotal case reports of adenovirus disease after heart transplantation have been published in both adults and pediatrics [30, 31].

34.3.4 Lung Transplantation

Adenovirus disease after lung transplantation appears to have higher morbidity and mortality than seen with adenovirus and other organ types. Ohori et al. reported the outcome of four cases of adenovirus pneumonia among 308 lung transplant recipients at the University of Pittsburgh [23]. As noted with other organ transplant recipients, the incidence was much higher among children (3 of 40) than among adults (1 of 268) [23]. Disease occurred in the first 6 weeks following transplantation and was uniformly fatal. Dissemination beyond the respiratory tree was not demonstrated despite the performance of an autopsy in each of the patients. The authors speculated that the presence of ischemic harvest injury predisposed their patients to the development of adenovirus pneumonitis.

Bridges et al. reported their experience with adenovirus infection in pediatric lung and heart-lung transplant recipients [32]. Adenovirus was identified in the lung of 8 of 16 patients occurring between 1 and 458 days following transplantation. Adenovirus was associated with early, fulminant infection in two patients. Perhaps as importantly, these and other investigators found that adenovirus infection of the transplanted lung was significantly associated with respiratory failure leading to graft loss or death and with the histologic diagnosis of obliterative bronchiolitis [32, 38].

34.3.5 Intestinal Transplantation

Several reports have documented a very high rate of adenoviral infection among pediatric intestinal transplant recipients with rates ranging from 20.8% to 100% [24, 25, 33]. In contrast, only limited experience with adenovirus infection has been reported in adult intestinal transplant recipients [34]. At least one of the reports of high rates of adenoviral infection may be confounded by the fact that viral cultures were obtained as part of routine screening of graft biopsies and not all of infected patients were symptomatic. The interpretation of a positive adenovirus culture or histologic finding is made difficult by the frequent absence of any associated symptoms

in ITx recipients with positive results. For patients demonstrating symptoms at the time of recovery of adenovirus, high stool output, alone or in the presence of fever, were the most common symptoms found in these patients [24, 25]. While one report found no difference in all cause mortality rates for pediatric ITx recipients with and without adenovirus infection [33], mortality attributable to adenovirus was reported in the three series [25, 26, 34]. Adenovirus can also present as an invasive disease with risk factors including failure to clear virus, isolating, virus from more than one site and intensified immunosuppression.

34.4 Diagnosis

Presumptively diagnosing adenovirus infection after transplantation can be difficult. Typical manifestations seen in patients with disease due to adenovirus, such as fever, hepatitis, or pneumonitis may represent infection with adenovirus but can also be from a number of other pathogens, and also can be seen with rejection. Accordingly, the presence of high-grade fevers and symptoms suggestive of infection should prompt a diagnostic evaluation aimed at identifying all such possibilities. Adenovirus can be found through the use of antigen detection, culture, nucleotide amplification tests, or histopathology [1, 2, 39]. Rapid antigen detection kits are commercially available but their sensitivity and specificity in the SOT population is unstudied. While traditional viral cultures are available, they are used less frequently in the era of shell vial assays and nucleic acid–based real-time polymerase chain reaction (PCR) assays. These latter tests permit more rapid diagnosis and increase sensitivity for adenovirus [1, 39]. Unfortunately, finding of a positive test for adenovirus is not definitively diagnostic of symptomatic disease as adenovirus can be asymptomatically shed for prolonged periods of time in urine, upper respiratory secretions, and stool [2, 39]. Accordingly, recovery of adenovirus should always prompt an effort to identify any additional or alternate potential explanations for symptoms present concurrently. Detection of adenovirus at two or more sites has been found to be predictive of invasive disease in bone marrow transplant (BMT) recipients [3, 39]; this has also been observed after pediatric LT [8]. Nucleic acid amplification can use quantitative or qualitative PCR for detection adenovirus in multiple specimen types. The relative sensitivity of PCR assays is dependent on the specimen, the primers used, and the characteristics of the method; as such, not all nucleic acid tests will detect all adenovirus serotypes. Preliminary experience suggests that quantitative nucleic acid detection of adenovirus genomes in blood appears to have prognostic significance and can be used to monitor response to therapy [40–45].

Given the concerns regarding sensitivity and specificity for the above-mentioned diagnostic tests, it is not surprising that histologic evaluation remains the gold standard for the diagnosis of invasive adenoviral disease [1, 2, 39]. Adenoviral infection is associated with a typical cytopathic inclusion ("smudge cells"). The presence of the virus within tissue may also be identified through the use of confirmatory histochemical stains. Most experts would consider the presence of adenovirus in a histologic specimen in association with a compatible clinical syndrome to be diagnostic of disease attributable to adenovirus.

34.5 Treatment

There currently is no FDA-approved therapy for the treatment of adenoviral infection. For some patients with more limited disease, such as kidney transplant recipients with hemorrhagic cystitis or interstitial nephritis, management can often be accomplished with reduction of immunosuppression alone. In general, all patients with adenovirus infection should have immunosuppression reduced to speed recovery of infection along with general supportive care. Although the role of antiviral agents is unproven, therapy has resulted in reduced progression of disease and reduced mortality in patients with disseminated infection or those with more severe manifestations of infection. A number of agents show variable in vitro activity against adenoviruses. However, interpretation of these results is limited by the use of different techniques, cell lines, and viral isolates [39, 46, 47]. There are case reports and series describing the use of cidofovir [30, 46–51], ribavirin [44, 52–55, 74], and ganciclovir [29, 56–59] in the treatment of adenoviral infection after SOT or BMT. Ribavirin use is associated with significant toxicity [39, 41, 46], and its activity against adenovirus may be limited to subtype C viruses [60]. To date, ribavirin has not been documented to reduce viral titers in monitored patients [8, 44, 60], and most experts recommend against the use of ribavirin in the treatment of adenovirus [3, 39]. Likewise, data to support the use of ganciclovir for the treatment of adenovirus is limited and is generally not used for the treatment of severe infections.

Of all proposed antiviral agents for adenovirus, cidofovir and its lipid ester, brincidofovir (CMX001) have the best evidence to support its use [3, 46, 48–51, 61–63]. In studies using molecular monitoring of infected patients, most, but not all, patients demonstrated a virologic response to cidofovir therapy, which correlated with clinical improvement [42, 43]. Failure to have a one log or greater decline in viral loads in the first 2 weeks of treatment was associated with progression of viremia and death secondary to symptomatic disease [42]. Typically, one of two regimens of cidofovir has been used for the management of adenoviral disease: 5 mg/kg q1–2 weeks or 1 mg/kg three times a week [39, 41, 49–51, 53]. Patients are usually hydrated before and after treatment and receive probenecid with doses to prevent nephrotoxicity. Although the regimen of 1 mg/kg three times per week is associated with less nephrotoxicity [49], the efficacies of the two regimens have not been directly compared. Additionally, the 1 mg/kg three times per week regimen is associated with

breakthrough CMV and herpes simplex virus (HSV) infections [64, 65]. More recently, brincidofovir (CMX001) has been demonstrated to have excellent oral bioavailability with improved in vitro and in vivo activity against adenovirus (5 to greater than 2500-fold more potent against adenovirus, in terms of IC50 values, than the unmodified parent compound) [66–68]. Further, brincidofovir is associated with no significant nephrotoxicity or bone marrow toxicity, although dose-limiting diarrhea has been described [61, 63, 66, 67]. In a prospective study of brincidofovir for the management of adenovirus in 13 immunocompromised patients with adenovirus, eight patients had a ≥ 1 $\log_{10}$ drop in viral load after the first week of therapy and nine had demonstrated a virologic response by week 8. Patients with a virologic response had a longer survival than those without a response (median 196 days versus 54.5 days; P = .04) [61]. A phase 3, open label study of brincidofovir is currently studying the safety and efficacy of this novel compound in patients with adenovirus (clinicaltrials.gov identifier NCT02087306).

The use of antibody preparations, including polyclonal immunoglobulin with high titers against respiratory syncytial virus (Respigam, MedImmune, Inc. Gaithersburg, MD), have been used in a few cases with unclear benefit [51] but has biologic plausibility [69, 75].

Finally, the use of adoptive immunotherapy has been reported for the treatment of life-threatening adenoviral infections after T-cell-depleted BMT [70, 71]. However, efforts to apply similar strategies for EBV in SOT recipients have yet to be proven successful. Accordingly, while the use of this strategy for BMT recipients may become a therapeutic option, it is not applicable to SOT recipients at this time. Nonetheless, large-scale production of a panel of adenovirus-specific and multivirus-specific T cells has been demonstrated and shows promise as an emerging therapy [72, 73].

35 Human Polyomavirus and Papillomavirus Infection and Disease Posttransplant

Hans H. Hirsch

35.1 Introduction

Infectious complications are accentuated in transplant patients as the result of the immunosuppression needed to disable alloimmune reactions between graft and host such as graft rejection or graft-versus-host disease. For viral infections, the intensity of immunosuppression not only correlates with a higher frequency of infectious episodes, but also with an increased level and duration of viral replication during such episodes, and consequently a greater likelihood of organ manifestations [1–5]. Moreover, virus-induced organ pathology is favored when virus-infected cells and immune effectors meet in an allogeneic constellation [1]. Thus, after solid organ transplantation (SOT), liver, lung, and kidney transplants appear to be more prone to complications from hepatotropic, pulmotropic, and nephrotropic viruses, respectively, whereas after allogeneic hematopoietic stem cell transplantation (HCT), excess pathology can arise in virtually every organ targeted by viral infection. Thus, in addition to immunosuppression, virus replication inside infected host cells is less effectively controlled if viral epitopes are presented in the context of a MHC-I versus T-cell receptor mismatch. Moreover, mounting an antiviral immune response in this allogeneic constellation bears an increased risk for allosensitization, chronic inflammation, and smoldering viral replication, which together or alone may be correlates of the so-called "indirect" viral effects [6, 7]. This rule of thumb also applies to human papillomavirus (HPV) and human polyomavirus (HPyV) infections, which show an aggravated clinical course in transplant recipients. HPV and HPyV share some similarities in morphology being nonenveloped icosahedral particles of 40–55 nm in diameter, in host range being restricted to the humans as well as in their oncogenic potential. Since 2002, however, HPV and HPyV are no longer grouped together as *papova* viruses, but are now recognized as distinct virus families called *papillomaviridae* with 39 genera and *polyomaviridae* with 4 genera including more than 70 species [8–10].

35.2 Human Polyomavirus (HPyV) Infection

The discovery of PyV dates back to the 1950s with the identification of an infectious agent causing multiple tumors in newborn mice, hence providing the name (Greek: poly, multiple; -oma, tumor) [11]. Since then, PyVs have been detected in a variety of vertebrates including rodents, birds, cattle, monkeys, and primates. Today, 13 PyVs has been detected in human specimens, which differ in age-dependent seroprevalence rates, associated pathology, and presumably host cell tropism (Table 35-1) [12, 13].

PyV are fairly resistant to environmental inactivation and endure temperatures of up to 50 °C for 1 h [8, 14]. The PyV genome is a circular double-stranded DNA of about 5100 base pairs containing a short noncoding control region (NCCR) of 400 bp bearing the origin of viral genome replication as well as promoter/enhancer elements controlling expression of the early viral gene region (EVGR) and the late viral gene region (LVGR) in opposite directions from the NCCR. The EVGR encodes the regulatory the small T-antigen (sTag) and large T antigen (LTag), which is highly conserved and often targeted in immunohistochemical diagnosis of PyV disease. The LVGR encodes the viral capsid proteins Vp1, Vp2, Vp3, as well as the small regulatory agnoprotein. Human PyV (HPyV) genomes are 50–85 % homologous both at the nucleic acid and the amino acid level. These similarities need to be taken into account when using molecular and immunologic assays for research and diagnostics [15, 16].

Based on serological studies, primary BKPyV transmission seems to occur efficiently in children below 10 years of age, reaching an IgG seroprevalence of at least 90 % by early adolescence [17–20]. In healthy blood donors, the average seroprevalence is 82 % and declines with increasing age [19, 21]. In dialysis patients, lower antibody titers have been

[a]Patient name should not be identified.

observed [22]. By contrast, and despite a certain degree of cross-protection [19, 23], JCPyV seroprevalence continues to increase during adult life to an average of 58 % indicating continued exposure and primary infection during adult life [18, 19, 24]. In HIV-seropositive patients, JCPyV IgG have been reported in more than 90 % suggesting a risk for increased transmission associated with HIV infection [25, 26]. For KIPyV, WUPyV, and MCPyV, slightly lower seroprevalence, though similar age dependence, has been determined (Table 35-1) [20, 27, 28]. For SV40, seropositivity seems to be <5 % arguing against a significant SV40 circulation in human populations despite documented vaccine contaminations in the 1960s and possibly ongoing exposure in zoological parks and animal facilities.

Primary HPyV infections have not been linked to specific symptoms or signs indicating that they are largely subclinical or run an unspecific, e.g., flu-like course. Transmission presumably occurs via mucosal surfaces exposed through ingestion, inhalation, or inoculation of virion-contaminated fluids. For BKPyV and JCPyV, kidney and urinary tract have been identified as the principle sites of persistence. Importantly, reactivation and asymptomatic urinary shedding of BKPyV and JCPyV is observed in healthy blood donors at median rates of 7–10 % and 19–33 %, with urine viral loads of 3.5 and 4.6 $\log_{10}$ genome equivalents per mL (Geq/mL), respectively [19, 29]. Thus, the detection of BKPyV or JCPyV in the urine per se is not an indicator for disease. For KIPyV and WUPyV, respiratory transmission is strongly implicated, but the specifics are still unresolved including aspects of latency, reactivation and the high rate of coinfection with other viruses [30, 31]. WUPyV DNA was identified in 43 samples obtained from 2135 patients with acute respiratory tract infections. Of those, 31 were also positive for other respiratory viruses [32]. Screening of immunocompetent individuals with respiratory tract infection detected KIPyV and WUPyV in 1–7 % without pronounced seasonality, but preferably in pediatric patients [33, 34]. Using KIPyV VP1-specific PCR, positive results were obtained in 1 % (6 of 637) nasopharyngeal aspirates from patients with respiratory tract disease and 0.5 % (1 of 192) stool samples from patients with gastroenteritis [35]. KIPyV could not be detected in urine, serum, whole blood or isolated leukocytes. MCPyV, HPyV6, and HPyV7 have been detected in a relatively large proportion in skin samples from otherwise healthy individuals [36–38]. Thus, the MCPyV-associated skin carcinoma is likely to require cofactors besides MCPyV infection such as failing immune control, older age, and sun exposure, but possibly also coinfection and interaction with other polyomaviruses [12]. At this point, the clinical significance of HPyV infection in immunocompetent individuals is still unclear.

In patients with impaired immunity, HPyV replication appears to be relaxed, and the prevalence of BKPyV replication and urinary shedding significantly increases to 50–80 % [39, 40]. High-level BKPyV viruria defined as decoy cell shedding or the equivalent of >7 $\log_{10}$ Geq/mL is observed in more than half of these patients [39, 41–47]. Molecular and kinetic data from kidney transplant patients support the model of BKPyV latency and reactivation in renal tubular epithelial cells followed by amplification in the urothelial cell compartment [43]. The respective increases in JCPyV shedding are less pronounced in immunodeficient populations [19, 25, 41, 48], and JCPyV viremia remains an exception [48–50]. For KIPyV and WUPyV, tenfold higher detection rates have been reported in immunosuppressed patients [51–53]. In fact, all significant, pathologically defined HPyV diseases have occurred in individuals with impaired immune functions. Despite the environmental stability and the high HPyV loads in urine and respiratory secretions, there is so far only one report of nosocomial transmission clusters, opening the question about specific infection-control measures for patients at high risk [54], which are currently not deemed necessary without further evidence [55].

35.3 HPyV Diseases in Transplant Patients

The key HPyV diseases posttransplant are PyV-associated nephropathy (PyVAN), PyV-associated hemorrhagic cystitis (PyVHC), and PyV-associated progressive multifocal leukoencephalopathy (PML) (Table 35-1). PyVAN and PyVHC are primarily associated with BKPyV, but a minority of cases are implicating JCPyV [48, 50, 56, 57]. Conversely, progressive multifocal leukoencephalopathy is primarily mediated by JCPyV [24], but a few cases may be caused by BKPyV [58]. In addition, a variety of gastrointestinal or typically proliferative skin disorders have been linked to other HPyVs causing diarrhea, or Merkel cell carcinoma, *Trichodysplasia spinulosa*, and pruritic keratinocyte plaques (Table 35-1).

35.4 BKPyV

35.4.1 Polyomavirus-Associated Nephropathy (PyVAN)

The incidence of PyVAN ranges from 1–10 % in kidney transplant recipients with a peak in the first 6 months posttransplant [39]. PyVAN is typically asymptomatic with no other sign than progressive renal allograft failure. Testing for BKPyV replication demonstrates decoy cells in urine cytology, urine viral loads of >7 $\log_{10}$ Geq/mL and, at the same time, detectable plasma BKPyV loads (probable PyVAN) [39, 43, 59, 60]. Plasma BKPyV loads have been used as a surrogate marker of the disease, which becomes more likely with increasing duration and level, e.g., above 4 $\log_{10}$ Geq/mL (presumptive PyVAN). The definitive diagnosis of proven PyVAN requires allograft tissue showing typical

cytopathic changes in renal tubular epithelial cells, which are confirmed by immunohistochemistry for large T-antigen, Vp1 or agnoprotein expression or by in situ hybridization [61–64]. Immunohistochemistry has mostly relied on cross-reacting antibodies raised against the SV40 LTag. Although BKPyV causes more than 95 % of cases, this cross-reactivity is actually advantageous since rare cases of JCPyV-mediated PyVAN are detected as well [48, 50]. Classification of the histological features has been recommended in order to predict the risk of subsequent graft loss and enhance the comparability of clinical studies (Table 35-2; for details, see [59, 60]).

The limitation of the histological diagnosis resides in the (multi-)focal nature of PyVAN, causing false negative biopsy results in 10–30 %, which may be even higher early in the disease when serum creatinine concentration is still at baseline levels [59, 63]. Also, the distinction of PyVAN from acute interstitial rejection is difficult and may require adjunct histological evaluation of vascular rejection including staining for C4d [13, 60]. The differential diagnosis of tubular cytopathology with intranuclear inclusion and interstitial nephritis/tubulitis includes adenovirus and cytomegalovirus nephritis. Of note, high-level BKPyV viruria with urine loads of >7 $\log_{10}$ Geq/mL are found 30–60 % of kidney transplant patients and precedes by approximately 6 weeks the detection of plasma BKPyV loads in a subpopulation of patients (10–20 %) and PyVAN [39].

The risk factors of PyVAN include donor characteristics (such as female gender, deceased donation, ischemia–reperfusion injury, high BKPyV-specific antibody titers as a marker for recent exposure, HLA-mismatches), recipient characteristics (such as older age, male gender, low or absent BKPyV-specific T-cell activity), and posttransplant factors such as acute rejection and antirejection treatment with high cumulative steroids, depleting anti-thymocyte globulin, intensified immunosuppressive rescue protocols, and tacrolimus–mycophenolate–prednisone combinations [39, 47, 59, 65–67]. Though multiple and diverse, these entities may indeed reflect complementing factors in PyVAN pathogenesis, the central feature being a disrupted balance between BKPyV replication in renal tubular epithelial cells and BKPyV-specific cellular immune control [68, 69]. Studies of plasma BKPyV load kinetics in kidney transplant patients undergoing surgical graft removal or clearing BKPyV replication following reduced immunosuppression indicated a short BKPyV half-life of 2–12 h in plasma as well as in urine [43]. Thus, stable steady-state levels actually result from a >99 % replacement of the plasma virus load every day [43]. The resulting cytopathic loss can be estimated as in the order of 1–10 million tubular epithelial cells leading to extensive denudation of the tubular epithelial cell layer with necrosis, urine leakage, ensuing inflammation, and eventually tubular atrophy and fibrosis (Figure 35-1). By contrast, the multilayered urothelial cell layer remains largely intact in kidney transplant patients despite high urine viral loads and hence without concomitant denudation, inflammation, and clinical signs [43]. Thus, BKPyV viruria and viremia remain the most consistent marker for screening, early intervention, and monitoring outcome. In view of the limited sensitivity of allograft biopsies and the higher specificity of plasma BKPyV loads compared to urine BKPyV loads, a diagnosis of probable and presumptive PyVAN has been used to guide preemptive treatment (Table 35-2).

TABLE 35-2. PyVAN diagnosis

- Possible PyVAN
  - High-level PyV replication
    Urine viral load >7 $\log_{10}$ Geq/mL, mostly BKPyV, rarely JCPyV; decoy cells
  - Plasma BKPyV load not tested or undetectable
- Probable PyVAN
  - High-level PyV replication
    Urine viral load >7 log Geq/mL mostly BKPyV, rarely JCPyV; decoy cells, PyV particles in three-dimensional aggregates (“haufen”) by electron microscopy of urine, BKPyV VP1 mRNA > 6 $\log_{10}$ copies/ng total RNA
  - Plasma BKPyV load detectable
- Presumptive PyVAN (“laboratory-confirmed”)
  - Plasma BKPyV load increasing to >4 $\log_{10}$ Geq/mL for >3 weeks
- Proven PyVAN
  - PyVAN-A: Mild viral cytopathic changes in ≤25 % of tubules with minimal interstitial inflammation, tubular atrophy, and interstitial fibrosis <10 % of the biopsy core. Risk of kidney graft loss <10 %
  - PyVAN-B: Variable viral cytopathic changes in 11–>50 % of tubules, significant inflammatory infiltrates with tubulitis, but only mild tubular atrophy and fibrosis in ≤25 % of the biopsy core
    PyVAN-B1 moderate interstitial inflammation in 11–25 % of biopsy: allograft function slightly impaired, risk of graft loss 25 %
    PyVAN-B2 significant interstitial inflammation in 26–50 % of biopsy: allograft significantly impaired, risk of graft loss 50 %
    PyVAN-B3 extensive interstitial inflammation in >50 % of biopsy: allograft significantly impaired, risk of graft loss >75 %
  - PyVAN-C: Moderate to severe tubular atrophy and interstitial fibrosis affecting >25 % of renal parenchyma, viral cytopathic changes variable and inflammatory infiltrates variable, ranging from <10 % to >50 %: Allograft function significantly impaired, progressive failure, and risk of kidney graft loss >80 %

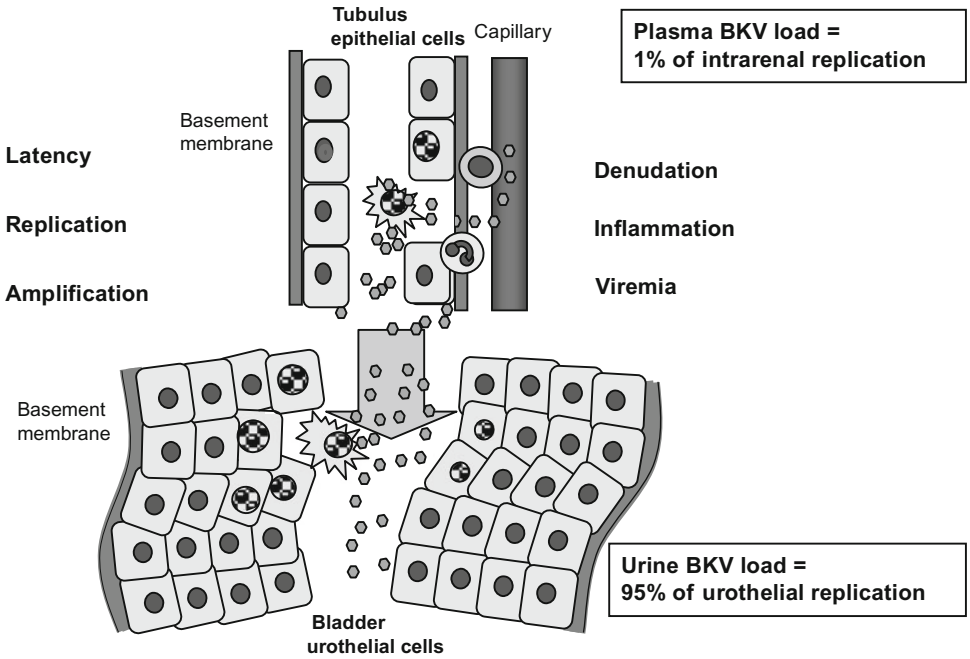

FIGURE 35-1. PyV replication and pathology in nephropathy.

Screening for BKPyV replication identifies kidney transplant patients before extensive tissue damage and irreversible loss of renal graft function has occurred [39, 70, 71]. Protocol biopsies are suboptimal for this purpose since approximately one third of cases are missed, which then run a worse course [70]. Testing urine for BKPyV replication by urine cytology (decoy cells) or quantitative PCR allows to rule out PVAN with a high negative predictive value of >95 %, but the positive predictive value is low. Patients with high-level urinary BKPyV replication should be tested for plasma BKPyV DNA load. If plasma BKPyV loads are positive and increasing to >4 $\log_{10}$ Geq/mL, reducing immunosuppression should be considered even in the absence of a positive histology [59, 72–76]. Until an internationally accepted calibrator for standardizing BKPyV loads has been implemented across laboratories, the relevance of this threshold has been debated. Unlike the experience with cytomegalovirus loads, however, external quality assurance programs in Europe indicate that 95 % of the 120 participating laboratories deviate less than 0.5 $\log_{10}$ Geq/mL from one another. At least six prospective studies supported the feasibility and safety of this preemptive approach without progression to PyVAN and without an excess of acute rejection episodes [72, 76, 77]. Currently, a minimal screening is recommended in 3 monthly intervals during the first 2 years posttransplant, or when an allograft biopsy is performed [13, 59, 60]. This basic approach has been expanded to monthly screening up to month 6 posttransplant and then 3 monthly in some centers. Modeling data suggest a benefit at PyVAN rates of >2.1 % when assuming adverse events in 10 % of cases [78]. However, screening may be beneficial already at lower rates given the good outcomes in dedicated centers [59, 72–76].

The treatment of PyVAN relies on timely reduction of immunosuppression [60]. Specific antivirals are lacking, but have been used as adjunct therapy [79]. There are no clinical studies comparing one strategy with another, but there is general consensus, that PyVAN should be treated by reducing tacrolimus to trough levels to <6 ng/mL (3 ng to 5 ng/mL), mycophenolate mofetil dosing be reduced to less than 1000 mg per day (or equivalent) or even discontinued, and prednisone reduced to 10 mg or less per day [59]. For cyclosporine, trough levels of 100–125 ng/mL have been proposed. Currently, no recommendation can be made whether or not calcineurin inhibitors or antiproliferative drugs should be reduced first. In the preemptive situation, both approaches have been successful [13]. Studies of BKPyV-specific immunity in kidney transplant patients and in vitro studies using BKPyV-specific cellular immunity indicate that the calcineurin inhibitor concentration is most critical and that for patients with definitive PyVAN, reducing calcineurin inhibitors might be more effective as a first step [80]. Biweekly plasma BKPyV loads are commonly used as a surrogate marker for tubular epithelial cell replication. Plasma BKPyV loads respond earlier than urine BKPyV loads, and a decline of >2 $\log_{10}$ Geq/mL is associated with the emergence of BKPyV-specific T-cell activity in peripheral blood [69, 81, 82]. Clearance typically takes 8–12 weeks. Some centers add low-dose intravenous cidofovir at 0.25 mg to 1.0 mg/kg bodyweight to this intervention (cave renal and ocular toxicity; [79]). In vitro studies indicate that concentrations of 40 µg/mL are needed for a 90 % inhibition [83], but peak serum concentrations of only 5 µg/mL have been observed in vivo [84]. Accordingly, several studies have been disappointing [85, 86]. Similarly, the use of fluoroquinolones for prohylaxis or treatment has not been effective [86, 87].

Switching from mycophenolate to leflunomide, a pyrimidine synthesis inhibitor used for treating rheumatoid arthritis, has been advocated because of its presumed virostatic properties [88, 89]. Similar to cidofovir, randomized controlled trials for leflunomide efficacy are lacking. Since leflunomide must be viewed as a less potent immunosuppressant than mycophenolates, it is currently impossible to attribute the clearing of BKPyV replication and nephropathy to improving BKPyV-specific immunity or to a combined effect with antivirals [90]. More recently, switching to mTOR-inhibitors has been proposed as a possible intervention with a direct inhibitory effect on BKPyV replication, while preserving BKPyV-specific immune activation [80, 91–94].

Retransplantation after allograft loss due to PyVAN can be considered, but recovery of BKPyV-specific immunity should be taken into account [95, 96]. Clearance of plasma BKPyV or at least a decline of >2 log Geq/mL may be used as an indicator [81]. Surgical removal of the affected first graft is not a prerequisite, but this may be advisable for preemptive retransplantation to avoid rapid reinfection of the new graft and to allow unambiguous attribution of BKPyV screening assays to the new transplant. No specific recommendation for immunosuppression has been made other than targeting the lower end of normal. Whether or not induction treatment for retransplantation increases the risk of PyVAN recurrence is not known [95, 96].

PyVAN has been sporadically diagnosed in autologous kidneys in non-renal SOT or HCT despite similar or even more intense immunosuppression suggesting that factors specific to kidney transplantation must be operating [13, 97–101]. Most patients were identified with advanced inflammatory PyVAN-B stage and progressed to terminal renal failure with dialysis-dependence despite reducing immunosuppression and/or addition of cidofovir. Where examined, significant viremia and viruria was noted in most of these patients as reported for kidney transplant recipients. Larger studies indicate however that PyVAN is an exceptional complication in non-renal SOT. Thus, non-renal SOT and allogeneic HCT with creeping serum creatinine concentrations, PyVAN should be considered in the differential diagnosis and testing for BKPyV viremia be performed, but universal screening for BKPyV replication is presently not warranted [41, 102, 103]. Less than 5 % of PyVAN may be caused by JCPyV. The clinical presentation of JCPyV-PyVAN is indistinguishable from BKPyV-PyVAN, with comparable cytopathic changes in renal tubular epithelial cells and corresponding signs of inflammation [48, 50, 56]. Thus, the diagnosis of JCPyV-PyVAN requires high-level JCPyV loads in urine (>7 $\log_{10}$ Geq/mL), absence of BKPyV replication, compatible histopathology changes (PyVAN-A, -B, or -C), and the exclusive detection of JCPyV in the allograft, e.g., by PCR. The NCCR in JCPyVAN is typically not rearranged unlike the JCPyV genomes in PML. Of note, JCPyV viremia is rare and usually of low viral load and cannot be used as a sensitive marker for screening and monitoring. With some exceptions of late diagnosis, kidney allograft function was often preserved and histological clearance was observed following reduced immunosuppression [104]. Urine JCPyV loads declined, but remained persistently detectable at levels similar to immunocompetent individuals [19, 48, 50].

35.4.2 Polyomavirus-Associated Hemorrhagic Cystitis (PyVHC)

PyVHC complicates 5–15 % of allogeneic HCT around 3–6 weeks posttransplant (late onset) and is associated with higher costs in the early transplant period [105] and an overall poorer survival [106, 107]. Most patients are hematologically stable and have engrafted. However, cystitis with urinary urgency and often disabling pain, and macrohematuria with clots require hospital admission and dedicated inpatient care with analgesia, forced diuresis, bladder irrigation, and urologic intervention for bleeding and relief of postrenal failure. PyVHC should be distinguished from other causes of hematuria and/or cystitis [108, 109]. This may be sometimes difficult because of overlapping patient characteristics and risk factors [110]. Hemorrhagic cystitis with severe hematuria (grade II–IV) has been reported in up to 5 % of 1906 patients after HCT by Seber et al. [111] with allogeneic HCT, patient 10–30 years of age, cyclophosphamide, busulfan, and graft-versus-host disease [111]. This included early-onset hemorrhagic cystitis which occurs prior to engraftment and is largely attributed to urotoxic conditioning regimens with cyclophosphamide, ifosfamide, busulfan, and/or TBI and [40, 108, 112, 113]. It is important to note that BKPyV viruria reaching high viral loads of >7 $\log_{10}$ Geq/mL is observed in 50–80 % of HCT patients, but less than one fifth develop PyVHC [40, 112, 114]. Clearly, high-level BKPyV replication with viruria is necessary, but not sufficient for the diagnosis of PyVHC. Similarly, hematuria is quite frequent after allogeneic HCT [40] and may be due to different causes such as thrombocytopenia, coagulation disorders, and graft-versus-host disease.

The diagnosis of PyVHC requires the triad of cystitis, hematuria (grade II or more), and high-level BKPyV replication with urine loads of >7 $\log_{10}$ Geq/mL (Table 35-3). In addition, other diagnoses should be excluded including other infections and bleeding disorders [40, 54, 79, 112, 115]. Cystoscopy may be indicated for local hemostasis and clot removal to treat post-renal failure, but is rarely performed for a histological diagnosis because of bleeding complications. Similarly, imaging studies such as ultrasound, computer tomography, or magnetic resonance imaging searching for posttrenal obstruction may reveal thickened bladder and ureter walls, but are not required for the diagnosis [116]. Urine BKPyV loads may be higher (e.g., greater than 9 $\log_{10}$ Geq/mL) in cases with PyVHC than in asymptomatic patients, but the levels frequently overlap [45, 46, 117–119]. BKPyV viremia has been associated with an increased risk of PVHC.

TABLE 35-3. Polyomavirus-associated hemorrhagic cystitis (PyVHC) Diagnosis

Triad of	
1. Clinical signs of cystitis	
(a) Dysuria, urge, frequency, lower abdominal discomfort	
2. Hematuria of Grade II and higher	
(a) *Grade I* microscopic hematuria (>100 erythrocytes per high-power field)	
(b) *Grade II* macrohematuria	
(c) *Grade III* macrohematuria with clots	
(d) *Grade IV* macrohematuria with urinary obstruction and post-renal failure	
3. Laboratory markers of high-level PyV replication in urine	
(a) Urine viral load >7 $\log_{10}$ Geq/mL	
(b) Plasma viral load detectable, often >4 $\log_{10}$ Geq/mL	
(mostly BKPyV, rarely JCPyV >7 $\log_{10}$ Geq/mL; or decoy cells)	
• Exclude major contribution of other diagnosis or factors	
Urotoxic	Early-onset HC
Hematological	Bleeding disorder, low platelets, graft-versus-host disease
Infectious	Bacteria; virus, e.g., cytomegalovirus, adenovirus; fungus; parasite
Malignant	Local or metastasizing (e.g., urothelial carcinoma)
Mechanical	Catheter, urologic intervention

BKPyV loads were been detected in sera of one-third of HSCT recipients in the first 100 days after HSCT and sustained serum BKPyV loads of >4 $\log_{10}$ Geq/mL were significantly associated with PyVHC [54, 106, 120, 121]. At present, validation of urine BKPyV load kinetics or plasma BKPyV is lacking regarding their use for diagnosis and for their potential use to trigger preemptive interventions.

Risk factors for PyVHC include allogeneic HCT, acute GvHD, unrelated donor, myeloablative conditioning, cord blood HCT, and a higher BKPyV recipient antibody titer before HCT [106, 109, 118, 122]. In fact, BKPyV replication represents secondary reactivation in seropositive patients, even in children [123], but the role of the mismatch of seronegative donor (D−)/seropositive recipient (R+) is unknown. However, in some cases of presumed nosocomial BKPyV transmission, pediatric allogeneic HCT recipients with low or absent BKPyV IgG developed PyVHC, and the disease only resolved when BKPyV antibody responses increased, independent of systemic or intravesical cidofovir treatment. Nevertheless, there is currently not enough evidence to support routine testing of HCT recipients or donors for the presence of BKPyV-specific antibodies.

The pathogenesis of PyVHC is not well understood. Urotoxicity of the conditioning protocol, particularly by cyclophosphamide and ifosphamide, is known to activate local inflammation through oxygen radicals, TNFa, IL-1b, and NFkB signalling as well as outright DNA and cell damage of urothelial, submucosal and smooth muscle cells [124]. These factors also enhance BKPyV replication via transcription factor binding sites such as NFkB and AP1 contained in the BKPyV noncoding control region, while at the same time, BKPyV-specific immune control is ablated. Forced diuresis, mesna, and reduced intensity protocols decrease the overall urotoxicity of conditioning, but may still lead to significant local exposure, particularly in the bladder causing limited local urothelial damage with erosion, edema, vascular congestion, and impaired regeneration [125]. In such a structurally and functionally altered environment, high-level BKPyV replication may significantly add to the urothelial cytopathology which, in contrast to kidney transplant patients showing a similarly high cytopathic wear, leads to urothelial denudation, urine leakage, inflammation, and hematuria [43]. Inflammation may be further aggravated postengraftment due to an immune reconstitution inflammatory syndrome [126–128]. The role of local toxicity is consistent with the reduced rate of PyVHC after reduced intensity conditioning. The preferential manifestation of PyVHC in allogeneic HCT as compared to autologous HCT has suggested a contributory role of graft-versus-host disease. On the other hand, neutropenia is often shorter in autologous HCT. Thus, we postulate the following sequence of events (Figure 35-2): (1) Reactivation of BKPyV replication from latency in renal tubular epithelial cells; (2) Limited damage of the urothelial transitional cell layer by urotoxic conditioning; (3) High-level BKPyV replication in the urothelial cell layer through cell damage and regeneration and similar lack of antiviral immune control; (4) significant denudation, hemorrhage, and inflammation; and (5) Exacerbation upon recovery of immunity post-engraftment [43, 126, 127]. Local urothelial denudation and inflammation may also facilitate the leakage of BKPyV into the circulation thereby explaining the diagnostic potential of plasma BKPyV loads [120, 121, 129]. Despite being an attractive model of PyVHC to researches in the field [130], detailed studies are needed for validation and hopefully the development of rational therapies.

The treatment of PyVHC is unresolved despite an array of published case reports and a variety of approaches. The reported response rates are high, but are based on small uncontrolled case series only, the course of which cannot be distinguished from

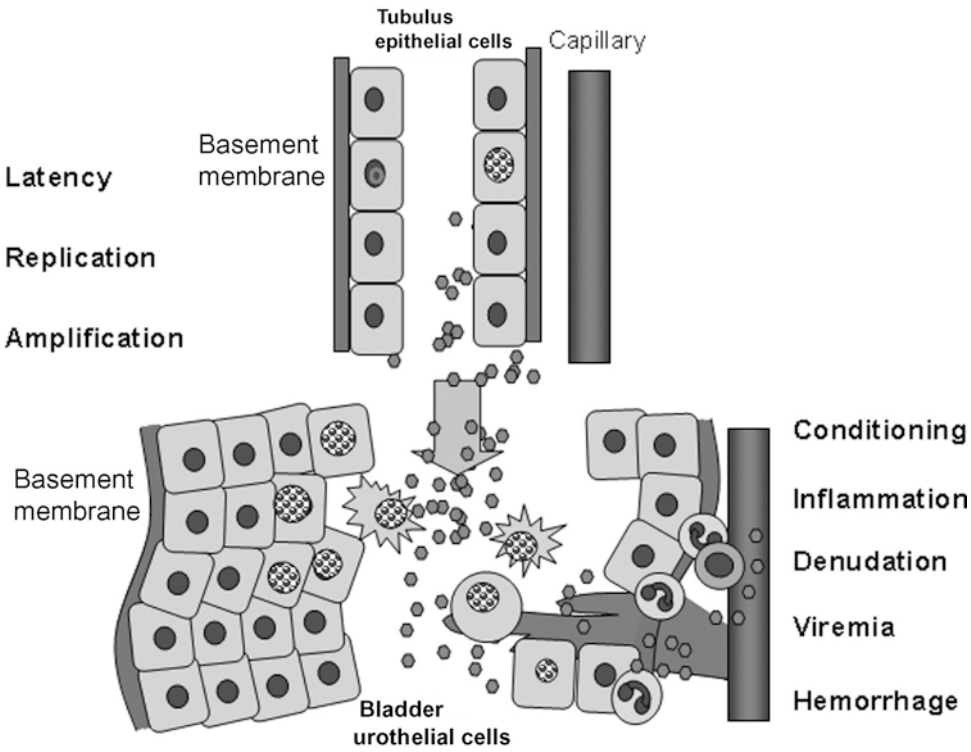

FIGURE 35-2. PyV replication and pathology in hemorrhagic cystitis.

spontaneous recovery. The mainstay of therapy is symptomatic with analgesia, hyperhydration, diuresis, and continuous bladder irrigation to prevent clot formation and urinary tract obstruction, platelet and erythrocyte substitution. Local treatment with alum, formalin or hyperbaric oxygen has been reported as beneficial. Urologic intervention may be performed for clot evacuation and for uncontrolled bleeding which may require cystectomy [131, 132]. Treatment with steroids, especially in patients with graft-versus-host disease may also alleviate the inflammatory component of PyVHC and reduce pain, but at the same time enhance BKPyV replication by direct activation through viral glucocorticoid response elements and impaired antiviral immune control. Reducing immunosuppression as proposed for treating PyVAN may increase inflammation. Thus, antiviral treatment seems urgently needed to break out of this double-blind pathology. Intravenous cidofovir as biweekly dosing of 5 mg/kg body weight together with probenicid or as lower dose of 0.25 mg, 0.5 mg or 1 mg/kg body weight given once to three times per week has been reported [79, 109, 133–135], but again, evidence from randomized controlled trials is lacking. In a retrospective survey in Europe, a presumed response to intravenous cidofovir was associated with younger age (<15 years), non-cord blood stem cell source, and total body irradiation as part of the conditioning regimen [134]. Intravesical cidofovir instillation (5 mg/kg in 60–100 mL saline) has been described as a therapy option, but was neither well tolerated nor effective in our experience. Fluoroquinolones such as ciprofloxacin or levofloxacin may inhibit BKPyV replication in vitro and reduce the peaking of urine BKPyV loads in HSCT patients in vivo, but randomized controlled studies are lacking [79], and a recent study in kidney transplant patients showed no effect [87]. In addition, fluorquinolones are already widely used as antibacterial prophylaxis during neutropenia and seemingly resistant BKPyV isolates have been reported [79, 136]. Thus, there is currently no established treatment for PyVHC other than symptomatic support with pain management, hyperhydration, and intravesical irrigation. Accordingly, no strategies regarding screening for urine BKPyV load or BKPyV viremia can be recommended. A summary of recent findings and recommendations have been presented at the sixth European conference for Infections in Leukemia [137].

PyVHC has been rarely reported in other patients including SOT patients, patients receiving chemotherapy or with HIV-AIDS receiving antiretroviral therapy, and even in one presumably immunocompetent individual with primary BKPyV infection [129, 138–142]. One case of PyVHC involving JCPyV has been reported in a patient with hereditary ataxia telangiectasia [143].

35.5 JCPyV

35.5.1 Progressive Multifocal Leukoencephalopathy (PML)

PML is a demyelinating disease of the central nervous system (CNS) that is primarily caused by lytic replication foci of JCPyV in oligodendrocytes. PML has been initially described in patients with chronic lymphatic leukemia and Hodgkin's lymphoma about 50 years ago [24, 144–146] and

PyV particles were seen by electron microscopy in a patient with chronic obstructive lung disease treated with corticosteroids [147]. PML is observed after HCT as well as after SOT. The incidence rates have not been determined, but must be lower than 0.1 % when extrapolating observations in HIV-AIDS populations where rates of up to 1 % and more have been reported [148, 149]. PML may occur more frequently and earlier after HCT, typically within the first year (range 1–20 months) as compared to a median of 23 months in SOT patients (range 1–132 months) [150–152]. It is postulated that this reflects the more pronounced immunodeficiency in HCT resulting from the underlying disease and its treatment as originally described [144] before as well as after HCT. Conversely, PML may occur rarely and only several years after kidney transplantation, with first symptoms appearing at a median of 37 months (range 5–120 months) [150–161]. While being consistent with lower immunosuppression after kidney transplantation, this may also indicate a cumulative risk from immunosuppression and JCPyV (re-) exposure. The case of a patient should be noted who developed PML 6 months after kidney retransplantation, but after having been immunosuppressed for his first transplant functioning for as long as 20 years [152].

PML is typically suspected when patients present with neurologic deficits (Table 35-4). If compatible findings in magnetic resonance imaging (MRI) are seen in an immunocompromised patient, the diagnosis becomes very likely. The deficits start frequently focally and compromise defined motor functions and sensory deficits particularly vision, as well as ataxia and are accompanied by initially subtle changes in mental status, memory, and speech [24]. Fits are rare HIV-AIDS, but may be more frequent with partial immunity in HIV-AIDS patients treated with antiretroviral therapy and in transplant patients. For a radiological diagnosis, magnetic resonance imaging (MRI) is preferred over computer tomography to reveal multiple lesions in subcortical areas, cerebellum and brain stem, which over time become confluent. These lesions are characterized in MRI by increased signal intensity in T2-weighted images without mass effect (improved signal contrast in fluid-attenuated inversion recovery and suppression of CSF signal intensity; hypointense in T1-weighted MRI) as well as signal in diffusion-weighted imaging. The growing experience from MRI surveyance of multiple sclerosis patients treated with the monoclonal integrin inhibitor natalizumab has lead to identification of presymptomatic lesions in some patients indicating a change in the diagnostic paradigm of PML. The key laboratory study is the detection of JCPyV DNA in cerebrospinal fluid (CSF) which has a high positive predictive value of >95 %, but only a limited negative predictive value of 50–80 % [162]. Therefore, other etiologies should be evaluated as well, including parvovirus B19, EBV, CMV, and HHV6 encephalitis/ventriculitis and toxoplasmic encephalitis. Other CSF parameters are not or only mildly altered including protein (<100 mg/dL) and cell counts, usually with normal lactate and glucose concentrations. The definitive diagnosis of proven PML requires the histological detection of enlarged oligodendrocytes with nuclear inclusions in the periphery of demyelination lesions, which stain positive for JCPyV by immunohistochemistry or in situ hybridization (Table 35-4). In addition, lipid-laden macrophages and enlarged multinucleated astrocytes are seen. Inflammatory cells are typically missing in early stages, but in HIV-AIDS patients treated with antiretroviral therapy, inflammatory infiltrates are increasingly noted which may indicate an immune reconstitution inflammatory syndrome (IRIS), as also seen especially after discontinuation of natalizumab combined with plasmapheresis. IRIS is associated with clinical deterioration and new contrast enhancement in MRI and even epileptic fits. Biopsies for histopathology studies are considered when JCPyV is not detected in CSF and/or the epidemiological risk is unclear, and/or the clinical or radiological presentation is atypical. The key differential diagnosis in transplant patients is calcineurin inhibitor-induced leukoencephalopathy (cyclosporine, tacrolimus), which may present with radiologically similar lesions. Also, demyelination due to chemo/radiotherapy, other viruses, acute limbic encephalitis, CNS lymphoma, toxoplasmic encephalitis, and graft-versus-host disease ought to be considered, while multiple sclerosis is unlikely in the transplant setting. The course

Table 35-4. Diagnosis of progressive multifocal leukoencephalopathy (PML)

- Probable
  - focal neurological deficits *plus*
  - MRI showing corresponding T1 hypointense, T2 hyperintense lesions in subcortex cerebellum and brain stem, no significant contrast enhancement, no mass effect
  - Patients with inherited, acquired, or iatrogenic immune dysfunction
- Presumptive ("laboratory-confirmed")
  - Probable criteria plus

  - JCPyV-positive immunohistochemistry or in situ hybridization in the periphery of demyelinated lesions in brain tissue (biopsy, autopsy)
- Significant contribution of other (coexisting) pathology excluded

of PML is followed clinically and by MRI. JCPyV load in CSF has been proposed as a marker of severity and treatment response, but requires repeat lumbar taps. With few exceptions [163], JCPyV load in plasma is mostly low or undetectable, and urine JCPyV load cannot be used for screening or diagnosis as it is unrelated to the overall course [164].

The risk factors of PML have not been defined in transplant patients, mostly because of the sporadic onset in diverse clinical backgrounds. In analogy to PML in HIV-AIDS, profound long-standing cellular immunodeficiency and insufficient intracerebral antiviral immune surveillance are viewed as the key pathological mechanism [165]. This would also account for the occurrence of PML in patients treated with anti-T-cell reagents such as natalizumab, efalizumab, or FTY720 used for treating autoimmune diseases such rheumatoid arthritis, multiple sclerosis, inflammatory bowel disease, or psoriasis [166]. In HIV-AIDS, the median CD4 cell count at PML diagnosis is typically below 100 per microliter (median 60), but cases with higher CD4 counts occur [149]. A detailed study of HIV-positive PML non-survivors indicated that the overall counts were not decisive, but selectively impaired JCPyV-specific T-cell responses [26]. In the study [26], a protective role of antibodies, and consequently intact B-cell repertoires, was suggested which may also explain the occurrence of PML cases after anti-CD20 depletion using rituximab [167]. However, the vast majority of PML cases after rituximab had also been treated with antiproliferative drugs [167]. Of the eight transplant patients diagnosed with PML after rituximab (four autologous HCT, three allogeneic HCT, one kidney), all seven HCT patients had received alkylating agents [167].

The pathogenesis of PML is characterized by the uncontrolled replication of JCPyV in oligodendrocytes. The multifocality of PML pathology is reminiscent of PyVAN and suggests hematogenous spread. Expanding lesions reflect local cell to cell spread. However, it is not resolved whether or not JCPyV reaches the central nervous system during a primary infection and is later reactivated in the brain, or whether PML is the result of secondary reactivation in the periphery reaching the brain via lymphocytes [168]. The increasing JCPyV seroprevalence with age argues that significant JCPyV exposure occurs during adult life, which as primary or secondary replication could be the starting point of PML in severely immunocompromised individuals [19, 24]. A recent report of primary JCPyV infection and PyVAN argues that this can be case at times [50].

The treatment of PML is hampered by the lack of effective antivirals. Cidofovir and cytarabine have been explored in HIV-AIDS patients without convincing results [169–171]. Other attempts have explored serotonin uptake inhibitors (risperidone, mirtazipine), and mefloquine and chlorpromazine have been shown in vitro to interfere with JCPyV infection via the blockade of the 5-HT2a receptor or endocytosis, respectively [172]. The success of combination antiretroviral therapy in HIV-AIDS patients with PML indicates that recovering JCPyV-specific immunity must be an integral component of treatment [149]. However, discontinued immunosuppression may put transplant patients at risk of organ- and life-compromising alloimmune reactions, the only exception being kidney transplantation where organ function can be replaced by dialysis. It is important to realize that PML is mostly diagnosed because of the occurrence of clinical deficits, hence representing an advanced stage of disease with diminished treatment success. Moreover, recovery of JCPyV-specific immunity may not be achievable in sufficient time following reduced immunosuppression. Recent case reports suggest that administration of cytokines without or with PML-specific JCPyV VP1 mutant might be worth testing in clinical trials [173, 174]. Unfortunately, an early marker of PML risk is presently lacking that could guide an early intervention similar to BKPyV viremia in PyVAN after kidney transplantation.

35.6 KIPyV and WUPyV

The role of KIPyV and WUPyV in transplant patients is only emerging. In retrospective PCR study of respiratory secretions from 200 immunocompromised patients from France, KIPyV and WUPyV were detected in 8 % and 1 %, respectively [175]. KIPyV was significantly more frequent (18 %) among 45 allogeneic HCT patients tested. In several of these patients, stool samples were found positive for KIPyV [175]. Data from a large prospective study of more than 200 allogeneic HCT patients reported detection rates of 17 % for KIPyV in respiratory secretions, yet without seasonal variation and without prominent respiratory symptoms, but frequent detection of other potential pathogens [176]. Thus, the data suggest that WUPyV and KIPyV may play a role in mostly non-severe respiratory tract pathologies. Clearly, the association with respiratory and gastrointestinal disease requires further study [177]. A significant step in this direction may come from novel antibodies used for immunohistochemistry of lung pathologies, that would be instrumental in better defining KIPyV and WUPyV disease [178, 179].

35.7 MCPyV

35.7.1 Merkel Cell Carcinoma (MCC)

MCC is a rare, cutaneous malignancy first described in 1972, showing the neuroendocrine characteristics of the epidermal Merkel cells that transmit the sensation of touch. The incidence of MCC is increased in immunocompromised populations including those with hematologic malignancies such as chronic lymphatic leukemia, HIV-AIDS, and SOT. Transplant Tumor registries have reported an incidence of MCC in the last two decades with estimated incidence rates of 0.1–0.9 % [180]. Recent data from Finland identified three cases in 4200 renal transplants, all of whom died within 0.5–2.1 years [181]. The risk of MCC increases with duration and intensity of immu-

nosuppression posttransplant. The mean age at diagnosis in SOT patients is 47 years. MCC is aggressively metastasizing in lymph nodes, lungs, liver, and bone, with a mortality rate of 56 % and accounts for 4 % of all skin cancer fatalities after SOT [182]. Treatment is not validated, but should be aggressive with local surgery and significant reduction or discontinuation of immunosuppression, which may lead to regression of MCC metastasis in line with immunologic sensitization to tumor antigens including possibly MCPyV LTag truncations [182–184].

MCC has a predilection for the dermis in sun-exposed areas, and local metastasis is rapid and determines outcome. MCC presents as three types (trabecular, intermediate, small cell, mixed) of which the intermediate type showing large tumor nests is most prominent and frequently diagnosed, while the trabecular type of bridged tumor cell strands or the loosely collagen infiltrating small cell type a rare. Mixed differentiation involving squamous, glandular, and melanocytic suggests a likely common tumor stem cell origin. Moreover, the presence of MCC within other malignancies such as squamous cell cancer and basal cell cancer has been described and complicates the diagnosis [182]. Immunohistochemistry for cytokeratin 20, neuron-specific enolase, and epithelial membrane antigen is positive, while S100, CD45, and laminin staining is frequently negative.

The pathogenetic role of MCPyV support the association with Merkel cell carcinoma, but not with other non-melanoma skin cancer types or prostate carcinoma [185–187]. In the original description, MCPyV-DNA could be amplified in eight of ten MCC tumors by using MCPyV-specific PCR and Southern hybridization. In a control group, only 5 of 59 samples were positive, indicating a positive association between MCPyV-DNA and MCC [188]. In another recent report, MCPyV was detected by PCR in 54 % of 13 MCC, but in only one case of 37 keratoacanthomas, and not in any of 85 squamous cell carcinoma, 28 Bowen's disease, and 6 actinic keratosis [185]. Thus, the association of integrated MCPyV is strong, but not all exclusive. The identification of truncated LTag fusion transcripts as well as small and middle Tag in MCC is in line with activated host cell proliferation, inactivation of apoptosis and genomic instability as key events transforming an infected Merkel cell precursor [182–184]. The predilection of sun-exposed areas in chronically immunosuppressed individuals suggests additional DNA damage and local immunodeficiency. The need for cofactors is also supported by the high seroprevalence and the detection of MCPyV in the general and at risk population [189].

35.7.2 Other PyV-Associated Pathologies

Relevant PyV pathologies include BKPyV-associated ureteric stenosis [190, 191], BKPyV-associated pneumonitis [192], BKPyV-associated CNS disease, some presenting as meningoencephalitis, as systemic disease, or PML [58, 193–198]. More recently, detection of WUPyV has been reported in an HIV-1 infected patient with clinical and radiological signs of PML [199]. Oncogenic transformation by HPyVs may result from uncoupling of EVGR-driven host cell activation from LVGR expression leading typically to host cell lysis and release of viral progeny [200, 201]. As discussed previously, corresponding genetic accidents involving the noncoding control region and/or chromosomal integration are more likely in chronically immunosuppressed individuals exposed to persisting high-level PyV replication in a genetically unstable host cell [127, 129]. These genetic alterations of virus and host cell may then lead to BKPyV carcinoma [202–205]; JCPyV-associated colon cancer after liver transplantation [206]; or after PyVAN in kidney transplants [50]. In the recent years, a number of other intriguing case reports have implicated several new HPyVs in human diseases, with a predilection for the skin (TSPyV, HPyV7, NJHPyV13) [38, 207, 208], or the gastrointestinal tract (HPyV10, MXPyV, MWPyV, STLHPyV11) [37], as summarized in Table 35-1. In the years to come, a more detailed understanding of these HPyVs and their potential pathologic role in transplantation can be expected [13].

35.8 Human Papillomavirus (HPV) Infection

The infectious nature of warts was described in the nineteenth century, followed by demonstrating a viral etiology through the transmission by cell-free extracts in the early twentieth century (Latin: *papilla*, "nipple"; Greek: *-oma*, for tumor). Members of the *papillomaviridae* family are widespread among higher vertebrates, but are considered to be species-specific. Today, more than 100 HPV genotypes can be distinguished by sequencing the major HPV capsid protein L1 [8, 10]. Clinical concepts largely use the distinction between cutaneous, mucous, and anogenital HPV illustrated by their most frequent representatives representatives (Figure 35-3).

HPV virions are non-enveloped icosahedral capsids of 45–55 nm diameter and therefore slightly larger than PyV particles, but are similarly resistant to environmental inactivation. The double-stranded viral DNA genome has approximately 7900 bp. The upstream regulatory region (URR) drives the expression of the early viral E genes (E1, E2, E4, E5, E6, E7), followed by expression of the late viral L or capsid genes (L1, L2) (Figure 35-4). The E3 does not code for a protein, and some E genes are missing from certain HPV types. Overall, HPV E proteins coordinate viral gene expression, maintenance and replication within the host cell and delay host cell differentiation (acanthosis, koilocytosis, parakeratosis, hyperkeratosis). E1 and E2 participate in replication and maintenance of the episomal HPV genome. E5, E6, and E7 have the potential to promote malignant transformation through a variety of activities including inhibition of apoptosis, p53 inactivation and degradation, inhibition of

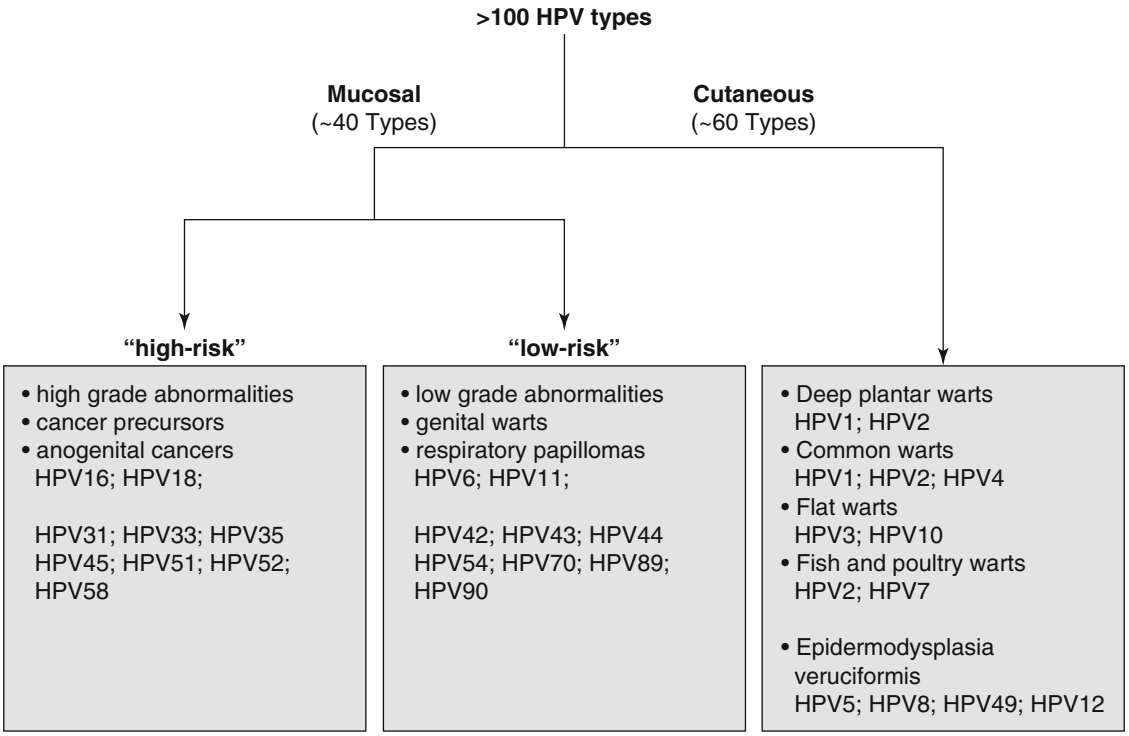

FIGURE 35-3. HPV types and tropism.

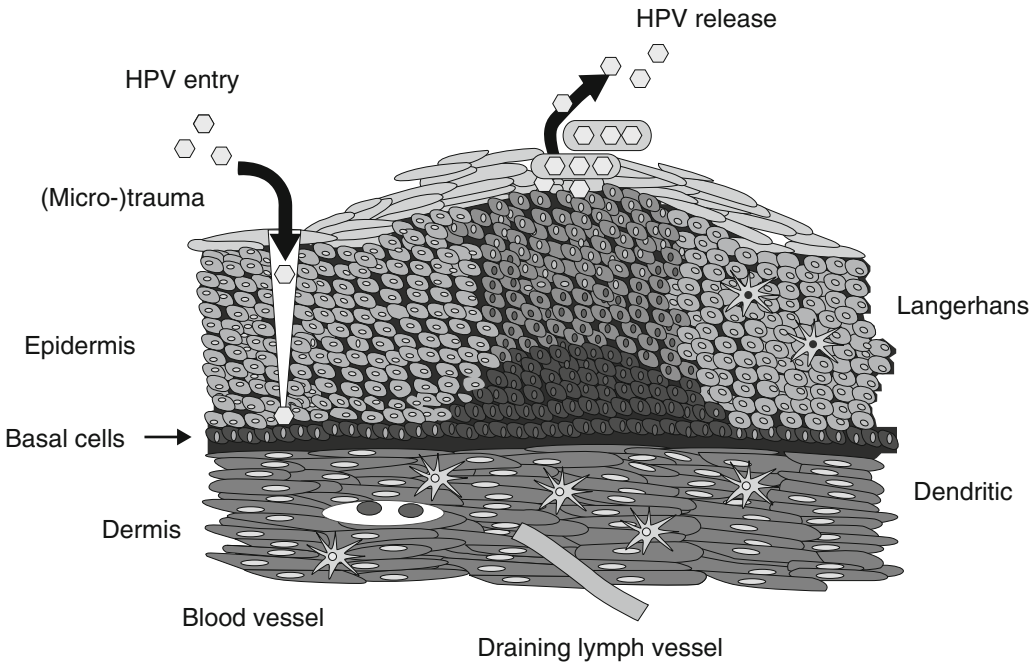

FIGURE 35-4. HPV infection and pathology in the skin. (Micro-)trauma facilitates access of HPV to basal cell layer. Expression of early E genes (*red*) increase proliferation rate to expand the infected cell pool and delay differentiation-driven late L gene (*green*) expression and virion assembly in keratinocytes.

keratinocyte differentiation, and interfering with pRb 107 and 130 inhibition of the E2F transcription factor required in the S-phase of the cell cycle [209, 210]. Deregulated expression of E6 and E7 is linked to malignant transformation and frequently follows the integration of the HPV DNA genome [209, 210]. The HPV virion mainly consists of two structural proteins called L1 of 54 kDa being the major capsid protein sufficient to form virus-like particles bearing the type-specific neutralizing epitopes, and L2 of 63 kDa that binds to the viral DNA and facilitates entry into the nucleus.

HPV infections occur worldwide with little geographic variation. Most data are available for cervical variants detected in women. HPV16 and HPV18 are the most common types in the Western world, whereas HPV52 seems to be more common in Eastern Asia. Cutaneous HPV infections can be detected in healthy skin in more than 80 % of the general population. In a US survey of >4000 persons, the seroprevalences of HPV types 6, 11, 16, and 18 among female subjects were 17.0 %, 7.1 %, 15.6 %, and 6.5 %, respectively [211]. Among males, the seroprevalences were lower for each type, i.e., 6.3 %, 2.0 %, 5.1 %, and 1.5 % for HPV6, 11, 16, and 18, respectively [211]. Comprehensive studies covering 37 HPV serotypes in an Australian cohort of 390 individuals and 34 HPV serotypes in 441 European SOT patients identified seropositive response to at least one HPV in more than 80 %, a dominance of cutaneous beta-HPV types, and demonstrated stability of the antibody response over 48 and 18 months, respectively [212, 213]. A systematic review of HPV infection in heterosexual men reported detection ranges of 1.3–72.9 % with more than half of the studies' rates >20 % [214]. For male college students, higher rates than those reported for females were found [215]. Risk factors for detectable HPV were younger age at first sexual contact, greater number of lifetime and recent sexual partners, higher frequency of sexual intercourse, consistent condom nonuse. Mucosal HPV types in women are most commonly found with sexual activity with an average of 25 %, with similar risk factors as outlined above. Typically, multiple HPV coexist in about 25 % of women including the high-risk types HPV16 and HPV18. Similar data exist for men, but generally smaller study populations. Cervical infections are frequently cleared within 6 months, but persistence is a risk factor for progression to higher grade cervical intraepithelial neoplasia (CIN) and cervical carcinoma. The HPV detection rate increases in immunocompromised patients including HIV, cancer, chemotherapy, and particularly transplantation [216, 217]. In a long-term study from the Netherlands, beta-HPV seropositivity at transplantation in a population of mostly kidney and kidney–pancreas recipients significantly predicted the development of keratinocyte cancer and basal cell carcinoma after 22 years with hazard ratios of 2.9 (95 % CI 1.3–6.4) and 3.1 (95 % CI 1.2–8.0), respectively, and borderline trends for squamous cell carcinoma (hazard ratio 2.9, 95 % CI 0.99–8.5) [218]. The increased risk for HPV-related malignancies may actually start during the period of the underlying disease, at least for renal transplantation, as suggested by an observational cohort study from Denmark. Comparing 12,293 patients with end-stage renal disease patients with 229,524 controls, the age-, gender-, and comorbidity-adjusted risk was 2.41-fold higher (95 % CI 1.83–3.16) for any HPV-related cancer [219].

In immunocompetent individuals, the frequency of clinical HPV manifestations is much lower than the molecular detection rates of the viruses. This indicates that cofactors are required for the clinical manifestations which include failure of specific immune responses, host genetic factors, (micro-) trauma, sunlight, and other injuries (Figure 35-4). In transplant patients, a special role has been attributed to calcineurin inhibitors leading to impaired p53-mediated DNA damage responses, which together with sun exposure promotes genetic alterations in inflamed skin with activated regenerative responses [210, 217]. Benign common warts affect up to 20 % of school children, which then regress, often spontaneously. Risk factors for plantar warts are heated swimming pools and lack of protective footwear. Flat warts are found in up to 10 % among 10-year-olds, whereas plantar warts affect mostly adolescents. Recurrent respiratory papillomatosis in its juvenile form is linked to vaginal delivery and low-risk HPV6 and HPV11, especially in young mothers with condylomata acuminata. The adult form has been linked to a higher number of sexual partners and oral sex. Examples for host genetic factors are mutations in the loci EV1 and EV2 on chromosome 17 and 2, respectively, which encode for transmembrane channel proteins EVER1/TMC6 and EVER2/TMC8 in the endoplasmic reticulum for the precancerous epidermodysplasia verruciformis [220]. Progression to cancer is observed in 30–50 % of affected individuals after 40 years of age [221]. Anogenital warts are frequently caused by HPV6 and HPV11. In men, the preputial cavity or the penile shaft is more frequently affected when uncircumcised or circumcised, respectively. In women, the vaginal introitus is mostly affected and less frequently the vulva. Cervical intraepithelial neoplasia (CIN) and its progression to cervical cancer is linked to HPV16 and HPV18 and has defined cytological (Papanicolaou grades I–V) and histological changes (CIN1, mild dysplasia, CIN2, moderate dysplasia; CIN3, severe dysplasia and carcinoma in situ; invasive cancer across the basal membrane). CIN1 undergoes regression in 90 % of cases, whereas persistence of CIN2 and CIN3 is associated with progression to invasive cervical cancer 60–70 % of cases [222].

35.9 HPV Disease in Transplant Patients

35.9.1 Warts, Precancerous Skin Lesions, and Non-melanoma Skin Cancers

Cutaneous warts and precancerous kin lesions are quite common in SOT patients and increase form 15 % at the time of transplantation to >80 % after 20 years. Sun-exposed areas in the face, neck, forearms, and hands are most commonly seen,

and HPV1 and 2 are most frequently detected [216, 220, 223]. Actinic keratosis in sun-exposed areas, mostly in the face, is associated with HPV5 and HPV8, and affect up to 40 % by 5 years post-SOT may be clinically indistinguishable from precancerous changes or squamous cell carcinoma [220]. Improved detection combining PCR and histological assessment revealed a high rate of active beta-HPV replication in the skin of kidney transplant patients [224] suggesting that surveillance and treatment strategies can be improved. Despite local treatment with liquid nitrogen, electrocoagulation, CO_2 laser, and interferon-alpha, recurrences are frequent. Surgery is commonly avoided for early stages because the role of skin lesions for infection and spread of HPV. An interesting case of presumably donor-derived HPV-positive plane lesions on the hand and forearm of a double hand transplant recipient was reported recently, which increased with increasing tacrolimus concentrations and responded to topical cidofovir treatment [225]. Similarly, rapid progression of flat warts and genital wart have been described in cases after allogeneic HCT in keeping with the contributory role of the allogeneic constellation between host cell and immune effectors [226, 227].

Skin malignancy was documented in 187 cases (19.2 %; mean age 56 years) of a cohort of 976 kidney transplant patients from England amounting to 141 events per 1000 patient years with a mean time to diagnosis of 8 years post-transplant [228]. In two-thirds, skin cancer was in highly sun-exposed areas, with multiple lesions in more than half of the patients. Squamous cell carcinoma was the first and most frequent type in more than half of the affected patients (71.4 /1000 patients at risk), followed by Bowen's disease (23.1 %; 32.5/1000); basal cell carcinoma (15.9 %; 22.4/1000), keratinic actinosis (6.6 %; 9.26/1000); malignant melanoma (0.4 %; 0.53/1000). Risk factors identified were increasing age at transplantation, total time of exposure to immunosuppression, increased creatinine levels at 1 year, and deceased donor graft. Higher rates have been observed in Spain and Australia [220, 221, 228]. In other studies, an association with certain HLA-type has been reported, whereby HLA-A11 decrease, and HLA-B27 and -DR7 increase HPV susceptibility [220, 221]. The HPV types associated with squamous cell cancer are mostly HPV2, HPV5, HPV8, and, interestingly, even HPV16 and HPV18, which are not found in the epidermis of immunocompetent individuals. Lymph node metastasis can occur in about 10 % patients providing an important argument for regular clinical screening and early treatment of precancerous lesions to avoid late presentation (Figure 35-5). Treatment is directed at the physical local destruction of lesions by keratinolytic therapies (salicylic acid), chemical (podophyllotoxin, trichloroacetic acid) or physical means (cryotherapy, laser, surgery). Through this local tissue destruction, opportunities for new HPV infections may be generated, but at the same time, activation of professional antigen-presenting cells (Langerhans, dendritic cells) may actually be the first step of immune activation. Local imiquimod, a toll-like receptor activator and local interferon-alpha therapy may also act along this rationale. Local cidofovir cream may be an adjunct therapy. Therefore, as HPV pathology is largely governed by exposure to immunosuppression, reducing immunosuppression to the lower limits should be considered, or, in case of life-threatening progression of infections, immunosuppression should be discontinued.

FIGURE 35-5. Squamous cell carcinoma due to HPV in a kidney transplant recipient (courtesy of Peter Itin, MD, University Hospital Basel, Switzerland).

35.9.2 Mucosal Epithelial Cancer

The incidence of invasive cervical cancer also increased after transplantation by three- to fivefold. In kidney transplant patients, however, an excess of cervical cancer incidence was already noted during renal replacement therapy prior to transplantation, as compared to patients before renal replacement therapy [219, 229]. In a large US-based study, the standardized incidence ratios in SOT patients were compared to the general population and a 3.3- to 20.3-fold increased risk of in situ HPV malignancies was identified. This rate increased further with time posttransplant, and implicated the HLA-B44 for susceptibility, whereas the HLA-DRB1:13 was linked to resistance [230]. Higher tacrolimus levels were associated with a higher risk of oropharyngeal cancers, but a lower risk of anogenital cancers, whereas no association with cervical cancers was found. After allogeneic HCT, however, an increased risk of cervical dysplasia has been found in women surviving more than 3 years after allogeneic HCT. Two-thirds of women with normal gynecological findings prior to transplant developed cervical abnormalities, and 25–33 % developed high-grade intraepithelial lesions posttransplant. Importantly, vulvovaginal chronic GVHD was consistently the most significant risk factor in several studies [231, 232]. Although the efficacy of vaccination after allogeneic HCT is known to be limited, HPV vaccination is recommended at 6 and 12 months posttransplant for girls aged 12–17 years of age, and

may be extended to female and male adults [233]. In SOT, suboptimal immunogenicity of the quadrivalent HPV6, 11, 16, and 18 vaccine was observed, when given early posttransplant to lung transplant patients and those with higher tacrolimus levels [234].

In deterministic Markov models, costs and health outcomes of cytology screening and HPV vaccination after kidney transplantation were investigated. Annual screening for cervical cancer by Papanicolaou cytology was considered cost-effective. The role of HPV vaccination in transplantation could not be well evaluated due to lack of data on vaccine efficacy in this setting [222, 235]. After allogeneic HCT, patients requiring continued immunosuppressive therapy for chronic graft-versus-host disease had the highest risk of HPV-related malignancies (odds ratio 4.6 $P=0.019$) underscoring the importance of regular gynecologic assessment before and after transplantation for early treatment [236, 237]. More extensive lesions require surgical resection (conization) and for invasive cancer appropriate staging and chemotherapy together with improved immune functions. The role of therapeutic vaccines in early and late stage is an area of considerable research [222]. Patients after allogeneic HCT are also at risk for oral cavity malignancies. In a systematic review, 64 cases of oral malignancy were identified which were diagnosed 5–9 years posttransplant and primarily affected the tongue, the salivary gland, the lip, and the buccal musosa [238]. Although in most cases, specifics of HCT were lacking, total body irradiation and chronic graft-versus-host disease implying corresponding immunosuppressive treatment appeared as notable risk factors. Since chronic graft-versus-host-disease affects approximately 40 % of allogeneic HCT patients and in practically all cases the oral mucosa, precancerous and cancerous changes may be difficult to diagnose [239] and a classification for HCT patients has been recently proposed (Grade 0: No involvement; Grade I: erythema and/or hyposalivation; Grade 2: lichenoid changes; Grade 3: ulceration, tumor) [238]. Given the potential role of HPV in this setting, systematic studies are clearly needed to evaluate their contribution.

35.10 Conclusion

HPV and PyV are long established viral companions of human populations, but represent a significantly emerging clinical problem in a world of rapidly changing epidemiology among immunocompetent individuals. The increasing number of severely immunocompromised patients, particularly those after successful SOT and HCT, exacerbates their pathogenic potential. Awareness of the pathogenesis, risk factors, and diagnostic tests may hopefully enable the development and better use of appropriate preventive and therapeutic measures.

Hepatobiliary Infections After Solid Organ or Hematopoietic Cell Transplantation

Anne M. Larson and George B. McDonald

36.1 Introduction

The frequency as well as severity of hepatobiliary infections has declined in transplant recipients, due to molecular diagnostic methods, antimicrobial prophylaxis, and preemptive therapies for viral infections [1, 2]. Current drugs in development aimed at viral liver infection have the potential to make these infections rare events after transplantation [3–5].

36.2 Hepatobiliary Infections After Solid Organ Transplantation

Lifelong immune suppression places SOT recipients at risk of infection due to bacterial, viral, and fungal pathogens [1, 6, 7]. Most SOT-related hepatic and gastrointestinal issues relate to graft dysfunction, adverse effects of medications, infections, or malignancy [8–10]. Infectious complications cause significant morbidity and mortality in the 6 months following SOT [11, 12]. Up to 16% of SOT recipients will develop infections after 6 months posttransplant [12, 13]. Anti-infective prophylaxis, more intense surveillance, and preemptive treatment reduces the frequency of these infections [14]. If untreatable life-threatening infection should develop after kidney transplant, immunosuppressive drugs can be discontinued and the patient maintained on dialysis. This option is unavailable to recipients of other organs. Liver infections can develop following any SOT, either isolated to the liver or as part of a systemic infectious process. The transplanted liver presents unique infectious complications related to the liver transplant surgery itself [15].

36.2.1 Viral Infections

Viral hepatitis B (HBV) or C (HCV) infection that is present prior to orthotopic liver transplantation (OLT) can reinfect the new graft with varying long-term consequences. Opportunistic viral infections are more likely to develop after the first month, with herpesvirus infections predominating [11].

36.2.1.1 Hepatitis Viruses A, B, C, D, E

The most common causes of liver injury after SOT are chronic HBV or HCV. Chronic HEV infection, however, is now being identified as a source of posttransplant liver injury and chronic hepatitis (4–6% in Europe) [16, 17]. The prevalence of HCV or HBV infection ranges from 5% to 66% of kidney transplant (KT) and kidney-pancreas transplant (KPT) recipients, depending on country of origin [18]. The effect of HCV on patient and graft outcomes remains somewhat controversial [19, 20], with studies showing inferior outcomes in KT patients who are HCV or HBV-infected [21–24]. A meta-analysis showed that the presence of anti-HCV antibody carried a relative risk of 1.79–1.85 for death and 1.56 for graft failure [23, 25, 26]. HCV-infected patients are at greater risk for developing chronic rejection of the kidney, proteinuria, other infections, glomerulonephritis, and new-onset diabetes, all of which contribute to inferior patient and graft survival [18]. Cirrhotic patients who undergo KT have a significantly worse 10-year survival than those without cirrhosis.

HCV antiviral therapy with interferon-alpha and ribavirin was not possible after KT due to increased risk of allograft rejection, but improved outcomes are expected with direct-acting antiviral drugs for HCV infection. HBV antiviral therapy has significantly improved clinical outcomes following KT and KPT [27, 28]. Antiviral medications should be considered in HBsAg-positive KT patients. Without this protection, acute HBV exacerbation frequently occurs and is often severe [29]. The duration of HBV antiviral prophylaxis following renal transplantation remains unclear [28].

Recurrence of HCV and HBV infections following OLT is common [30–33]. HCV replication in the liver allograft begins within the first postoperative week [34], followed by

P. Ljungman et al. (eds.), *Transplant Infections*, DOI 10.1007/978-3-319-28797-3_36

ALT elevation within the first 6 months, then by accelerated fibrosis progression with decreased 5- and 10-year survival compared to OLT recipients without HCV [35, 36]. Approximately 2–6% of HCV-infected recipients develop a rapidly fatal form of recurrence—fibrosing cholestatic hepatitis C [37, 38]; up to 75% develop signs of liver damage; and 30–40% will progress to cirrhosis within 5 years with accelerated graft loss [35, 36, 39–42]. Risk factors for worse outcomes from recurrent HCV include donors >50 years, coinfection with CMV or HIV, and possibly other factors (donor steatosis, presence of ischemia–reperfusion injury or cold ischemia time) [34]. Eradication of HCV would be ideal, preferably before OLT, to prevent infection in the allograft. Interferon alfa-based therapies were poorly tolerated by patients with end-stage liver disease—only 40% of OLT candidates were able to receive therapy and the cure rates were 20–30% [34, 43]. In 2011, the protease inhibitors telaprevir and boceprevir plus interferon–ribavirin were found to improve the cure rate in advanced HCV infection to 50–60% overall; many cirrhotic patients did not tolerate this therapy [34]. Boceprevir and telaprevir increased the $AUC_{cyclosporine}$ by 2.7-fold and $AUC_{tacrolimus}$ by 17-fold, necessitating careful management of immunosuppression [43, 44]. Newer DAAs have now been developed, with cure rates over 90%, and these will revolutionize the treatment of HCV infection in the OLT setting [4, 45–50]. At the time of this writing, the field is rapidly evolving and multiple DAAs are being FDA- and EMEA-approved. We recommend this website for continuously updated information: http://www.hcvguidelines.org.

In the past, patients transplanted for chronic HBV infection developed rapid reinfection of the liver graft, with significant morbidity from fibrosing cholestatic hepatitis B, even in the setting of grafts from HBcAb-positive donors [51]. If antiviral prophylaxis is not given, de novo hepatitis B develops in as many as 58% of recipients receiving an HBcAb-positive graft [51]. HBV recurrence is prevented in >90% of OLT recipients with Hepatitis B immune globulin (HBIG) and antiviral medications. Prophylactic antiviral therapy needs to be continued indefinitely; oral antiviral medications with a high barrier to resistance are used (entecavir, tenofovir) [52, 53].

Although acute hepatitis E virus (HEV) infection is generally self-limited in immunocompromised patients, chronic HEV infection can lead to significant liver injury, advanced fibrosis and cirrhosis [54, 55]. Graft loss after OLT has been reported. Ribavirin monotherapy (600 mg daily) for 3 months is effective for chronic HEV infection [56, 57], and responses have been seen with acute HEV infection [58]. Hepatitis E virus infection has been identified following LT in about 2% of recipients [57].

There are limited data regarding outcomes of HCV- and HBV-infected patients in the setting of heart transplant (HT), lung transplant (LT), and heart–lung transplant (HLT). Reports are conflicting, with some suggesting no difference in mortality, significantly increased all-cause mortality, or increased liver related deaths after HT in HCV-infected patients [59–64]. Data are even more limited in the setting of LT and HLT. Chronic HCV infection remains a contraindication to LT in most centers, although 2–3% of patients transplanted are listed as being seropositive for HCV [60, 65]. Newer DAAs will change the approach to these patients, but have not been tested in these patients as of this writing. The presence of HBV following HT, LT, and HLT does not appear to affect posttransplant survival to 5 years [64, 66]. Antiviral management is the same as that for other recipients with HBV infection.

36.2.1.2 Herpesviruses—HSV, VZV, CMV, EBV, HHV

Cytomegalovirus (CMV)

The seroprevalence of cytomegalovirus in US adults is about 50% (range 30–97%) [67, 68]. CMV is the dominant viral pathogen occurring within the first year after SOT [69–71]. CMV infection is defined as the presence of viral replication (detection of viral proteins or virus in any body fluid or tissue specimen), while CMV disease is defined as infection accompanied by clinical signs and symptoms [72–74]. CMV disease is further classified as CMV syndrome (fever, malaise, neutropenia or thrombocytopenia, and detection of CMV in the bloodstream) or tissue-invasive CMV disease.

CMV tends to invade the grafted organs and thus, presents differently with each organ type [75]. Several factors predispose to CMV infection [69, 70]: (1) Increased immunosuppression (e.g., antilymphocyte antibody or high-dose mycophenolate mofetil therapy) [11]; (2) CMV-negative recipients who receive a CMV-positive graft [69, 70, 76]; and (3) graft rejection with intensified immunosuppression or coinfection with immunomodulating viruses (i.e., HHV-6, HHV-7), bacteria or fungi [11, 77, 78]. In the absence of prophylaxis, symptomatic CMV disease occurs in up to 60% of SOT recipients, with a peak incidence 4–6 months after transplantation—once antiviral prophylaxis has been discontinued [67, 79]. About 80% of CMV disease in SOT recipients is gastrointestinal [80].

CMV disease prevention is with either antiviral prophylaxis (ganciclovir or valganciclovir) or preemptive therapy (treating if CMV viremia develops) [70, 81]. CMV antiviral prophylaxis delays the onset of infection—many recipients will develop infection after prophylaxis is discontinued [12]. CMV drug resistance has been reported with both strategies. CMV disease is generally treated with valganciclovir, ganciclovir, foscarnet, or cidofovir [73, 82].

Renal recipients are at less risk for CMV than other SOT recipients, with an incidence of infection between 8% and 32% [83–86]. Gastrointestinal and liver CMV disease can be seen. The development of CMV replication is associated with renal graft rejection with a hazard ratio of 1.58

(95% CI, 1.16–2.16, $p=0.02$) [87, 88]. In high-risk candidates, antiviral prophylaxis for 3–6 months is preferred to the preemptive approach [73].

The risk of CMV infection or disease following OLT depends on the serologic status of the donor/recipient pair—highest in a seronegative recipient receiving a seropositive donor (D+/R-) [69, 89]. Recipients can also develop reactivation of endogenous CMV, become superinfected by the donor's CMV (D+/R+), or develop CMV from another source [90]. In high risk OLT recipients, level I evidence supports the use of antiviral prophylaxis for 3–6 months [73]. After OLT, hepatitis is the most common manifestation of CMV, generally occurs beyond the first month, and can be more severe than in recipients of other organs [91–94]. Chronic graft dysfunction is an independent risk factor for late CMV disease (HR 6.5, 95% CI 1.7–24.6) [13]. CMV-infected OLT patients are seldom jaundiced but often have elevations in serum aminotransferases (usually <5-times normal), which can be confused with rejection. The diagnosis can usually be confirmed by detection of CMV DNA in the bloodstream but a liver biopsy may be needed. The histologic picture is of an acute hepatitis, with lobular microabscesses (neutrophils), microgranulomas, and rarely cells containing intranuclear or cytoplasmic inclusions, and positive IHC. Asymptomatic low-level CMV viremia usually does not require antiviral therapy but the exact threshold that would trigger therapy is not known [95]. CMV has been associated with an increased risk of acute or chronic graft rejection [87, 96]. The proposed mechanism is that CMV causes hepatic inflammation leading to T-cell activation, altering the state of graft tolerance and triggering rejection [97, 98]. The hazard ratio for development of acute graft rejection within 4 weeks of detection of CMV replication is 2.21 (95% CI, 1.54–3.17, $p<0.001$) in OLT recipients [87]. Residual viral DNA persists in the hepatocyte and biliary epithelium following antiviral therapy, contributing to chronic allograft rejection [99]. CMV is also a risk factor for invasive fungal and bacterial infections, leads to activation of HHV-6 and EBV, and may accelerate hepatitis C virus pathogenesis [96, 100, 101].

Recipients of LT and HT can develop CMV infection (15–25%), usually presenting as pneumonitis, but hepatic CMV infection remains a cause of morbidity [76]. Within 4 weeks of detection of CMV replication, there is an increased risk of graft rejection in HT (hazard ratio 2.6, 95% CI, 1.34–4.94, $p<0.001$) (HR 5.83, 95% CI, 3.12–10.9, $p<0.001$) [87]. Antiviral prophylaxis is recommended for 3–6 months after HT and 6–12 months after LT and HLT.

Intestinal transplant are at highest risk of CMV infections, perhaps because of the amount of lymphoid tissue in the transplanted organ and the intensity of immunosuppression needed [73]. Hepatobiliary disease is not common in this setting, but can occur. Antiviral prophylaxis is indicated for the first 3–6 months following transplantation.

Herpes Simplex Viruses

The Herpes simplex viruses (HSV1 and HSV2) characteristically represent reactivation of latent virus within the recipient. The seroprevalence in the USA for HSV1 is 44–80% and 2–26% for HSV2 [102]; seroprevalence rates are higher in other regions. Manifestations of HSV or VZV infection can develop in ~70% of SOT recipients if antiviral prophylaxis is not used [103]. HSV has tropism for squamous epithelium (nose, mouth, esophagus, genital mucosa), but can involve the intestinal epithelium and liver. Primary HSV infection can be more severe and prolonged in the SOT recipient. HSV reactivation is often asymptomatic; symptomatic lesions may be more invasive or take longer to heal after SOT. Rarely, disseminated HSV can occur, presenting with fever, leucopenia and hepatitis [103, 104]. Severe HSV hepatitis presents with serum ALT levels >5 times normal and may rapidly progress to acute liver failure and death. Histologically, there is significant coagulative necrosis and intranuclear inclusions within the hepatocytes; the diagnosis is readily made by PCR of blood samples and by biopsy PCR or immunohistochemistry. Disseminated disease (including HSV hepatitis) should be treated with intravenous acyclovir. Viral resistance to acyclovir is ranges from 3.6% to 6.3% [104].

The incidence of HSV-related infection in the year following KT/KPT transplant is ~6% [105] and is generally asymptomatic and self-limited, presenting as stomatitis, hepatitis, or pneumonia, and rarely, disseminated disease with severe hepatitis, which is often fatal [106, 107]. Primary infection from the renal graft is rare, especially in an era of acyclovir prophylaxis [107–109]. HSV disease in HT, LT, and HLT recipients presents in similar fashion to KT recipients, with mucocutaneous lesions and only rare instances of aggressive disseminated disease or acute liver failure. HSV1 and HSV2 infections are relatively rare after OLT, but can lead to organ specific disease with hepatic involvement, sometimes culminating in acute liver failure and death; the onset can be very early in the postoperative period (20 ± 12 days) [12, 110, 111]. Given the rapidity of its onset, HSV hepatitis after OLT is most likely a reactivation of the virus; patients present with fever, elevated serum ALT (without jaundice), right upper quadrant pain, leukopenia, and possibly mucocutaneous lesions (31%) [111]. Liver biopsy may need to be performed to exclude acute cellular rejection. Early therapy with intravenous acyclovir significantly improves survival—62% survival in treated patients compared with no survival if untreated [104, 107, 111, 112].

Varicella Zoster Virus (VSV)

VZV may cause hepatitis, with onset between 4 and 12 months after SOT [113]. Primary VZV infection may lead to severe end-organ damage, but few adult SOT recipients are at risk for primary infection because of high seroprevalence

[114]. Reactivated disease generally presents as localized shingles (cutaneous herpes zoster), usually during the first 5 years following transplantation. More rarely, a disseminated, non-dermatomal rash can be seen. Severe, often fatal, disseminated VZV can lead to hepatitis (~50%), pneumonitis (29%), and disseminated intravascular coagulation [114]. LT and HLT recipients have the greatest risk of VZV disease followed by HT, KT, and OLT [115–117]. Prophylaxis with acyclovir, valacyclovir, valganciclovir, or famciclovir reduces early recurrence of VZV following SOT [118]. VZV hepatitis presents with elevated serum ALT (often markedly elevated), fever and abdominal pain in a patient with cutaneous zoster, but an abdominal prodrome without skin lesions can occur. Diagnosis is made by PCR of blood samples or lesions. Histologically, liver biopsies show coagulative necrosis and inflammation [119].

Epstein-Barr Virus (EBV)

EBV infection can be either primary or secondary, with presentations ranging from asymptomatic viremia to infectious mononucleosis and posttransplant lymphoproliferative disorder (PTLD) (see also Chap. 26) [120]. The majority of infections in adults are secondary to viral reactivation and are generally self-limited, resolving with supportive care [121]. Primary infection is often symptomatic and associated with more severe disease, particularly hepatitis (antiviral therapy may be required) [122–124]. EBV infection can also lead to EBV-associated posttransplant lymphoproliferative disorder (PTLD), with an incidence that varies from 0.6% to 16% depending on the organ transplanted and whether the recipient is an adult or a child [125]. PTLD is more likely in those with greater immune suppression [126, 127]. If PTLD involves the liver or the biliary tract, then symptoms of liver injury or obstruction can be seen [128].

Human Herpesviruses 6, 7, and 8

Infection by HHV-6, -7, and -8 are common, but clinical disease is rare after SOT (e.g., <1% of SOT recipients) [129–131]. HHV-6 infects >95% of the general population; variant B is the most common in SOT recipients, with reactivation developing about 2–8 weeks after SOT. The majority of infections are asymptomatic and short-lived infection, but presentations can include fever, rash, bone marrow suppression or tissue invasive disease (hepatitis, encephalitis, pneumonitis, and colitis). HHV-6 may cause a hepatitis-like picture, with elevated ALT, fever, and lymphocytic infiltration and, in liver recipients, graft dysfunction [130, 132–134]. Reports of acute liver failure have been described. Some have shown increased mortality in OLT recipients with HHV-6 reactivation compared to those without [135]. HHV-6 has also been associated with opportunistic fungal infections, earlier and more severe recurrence of HCV, CMV infection, and graft rejection [136]. Diagnosis is by PCR in serum or tissue; serologic testing is of limited use [130, 137]. HHV-6 can be chromosomally integrated, potentially complicating a diagnosis. Prophylactic and antiviral therapy is similar to that in CMV—ganciclovir, foscarnet, or cidofovir, based predominantly on in vitro data [138]. Monitoring for reactivation of HHV-6 and HHV-7 after OLT has not been shown to be beneficial [139].

HHV-8 (Kaposi's sarcoma-associated herpesvirus) is oncogenic [12, 140]. HHV-8 can also lead to Castleman's disease, lymphoproliferative disorders, and primary effusion lymphomas (a form of non-Hodgkin's lymphoma) [141, 142]. Primary HHV-8 infection may also cause fever, bone marrow suppression (leukopenia), and rash, which generally lasts about 10 days [131]. HHV-8 can rarely cause hemophagocytosis, myelosuppression, and multiorgan failure in the SOT recipient [143, 144]. A fourth of Kaposi's sarcoma cases involve the lungs, gastrointestinal tract, and the liver [131].

36.2.1.3 Adenovirus

Adenovirus liver infection after SOT is more common in children than adults, can result from primary infection or reactivation, and may be disseminated or localized [145–148]. OLT patients on high dose immunosuppression are at greatest risk of infection. Adenovirus hepatitis can be severe and acute liver failure may result. PCR for adenovirus DNA in blood, plus a consistent clinical picture, usually suffices for diagnosis. Liver histology shows microabscesses and poorly formed macrophage granulomas in addition to coagulative necrosis [149]. Adenovirus infection after SOT has been successfully treated with cidofovir (the current standard of care) and with ribavirin and intravenous immunoglobulin [145, 150, 151].

36.2.2 Bacterial Infections

36.2.2.1 Common Bacteria

The risk of hepatobiliary bacterial infection (cholangitis or liver abscess) depends on the organ transplanted, with OLT recipients more susceptible because of biliary duct manipulation and potential for biliary tract contamination [152, 153]. The infectious complication rate between deceased donor and living donor OLT is similar at about 67%; however, those receiving a deceased donor liver are more likely to have intra-abdominal infections, usually developing within the first 2–3 months following transplantation [12, 152, 154, 155]. Over time, the pattern of bacterial infection changes [1, 153]. The most common infectious agents in the first 3 months following OLT are gram-negative rods (~50%), gram-positive cocci (44%), and *Candida* species (6%) [156].

Two to six months after OLT, viral infections predominate and opportunistic infections may occur [1, 152]. During this period, less common bacterial infections (*Listeria monocytogenes*, *Norcardia* species, and reactivation of latent infection, including *Mycobacterium* species) can be seen [152]. Six months or more following OLT, bacterial infections are generally related to environmental exposure, late biliary complications, and allograft dysfunction [13, 152].

Risk factors for infection after OLT include preoperative use of antibiotics, surgical-technical issues, steatosis, ischemia–reperfusion injury, and volume of intraoperative blood transfused [12, 152, 157]. The presence of serum endotoxin pretransplant is predictive of risk of bacterial infections post-OLT [158]. The use of antibiotics prior to transplantation in these patients has led to multi-drug resistant organisms, particularly enterococci, *Staphylococcus aureus*, and non-albicans *Candida* species [159, 160]. Hepatobiliary infections after OLT range in frequency from 18% to 37%; are frequently related to complications of the surgical procedure; and surgical site infections are closely related to intraoperative conditions and postoperative events [161]. Surgical site infections after OLT are associated with graft loss and death [152, 153, 162, 163]. The biliary tract is responsible for up to 34% of bacteremias seen following OLT. Biliary leakage and stricture formation, generally at the anastomotic site, are the most common of the biliary abnormalities [164, 165]. Reconstruction of the biliary tree with anastomoses either directly duct-to-duct or via Roux-en-Y can lead to both anastomotic and non-anastomotic strictures, risk factors for cholangitis, especially after Roux-en-Y anastomosis [12, 152, 153, 166]. Both bacteriobilia and fungibilia in OLT recipients undergoing endoscopic retrograde cholangiography for biliary complications are associated with worse survival, even with successful endoscopic treatment [167].

Following OLT, the biliary tree is exclusively dependent upon the hepatic artery for its blood supply. Loss of arterial flow results in bile duct necrosis with leakage and development of intrahepatic bilomas, abscesses, and perihepatic fluid collections. Hepatic artery thrombosis leads to ischemic bile duct injury in 5–8% of OLT recipients presenting with either mildly elevated liver enzymes or bacterial cholangitis or acute liver failure necessitating urgent retransplantation [168–171]. Portal vein thrombosis can also lead to hepatic ischemia and severe hepatic dysfunction if it occurs early in the posttransplant course; later, signs of portal hypertension develop, also a predisposing factor for infection.

Immunosuppression increases the risk of cholelithiasis and cholangitis in non-liver SOT recipients, especially among diabetic patients [172, 173]. The development of cholangitis in this setting carries an increased risk of mortality. Some have advocated for cholecystectomy in these patients regardless of symptoms to minimize further biliary complications in HT and HLT recipients [173, 174]. Bacterial infections following intestinal transplantation are common, often associated with mucosal disruption and bacterial translocation; approximately 17% are from an intraabdominal source and cholangitis has been reported [175].

36.2.2.2 Mycobacteria

The incidence of *M. tuberculosis* infection following SOT (especially KT) is higher than the incidence in the normal population, especially in areas where the prevalence is high [176–178]. Tuberculosis has been reported as early as 2 weeks to as late as 2 years after SOT, usually secondary to reactivation of latent infection. Isoniazid prophylaxis prior to, during and after transplantation can be used with minimal hepatotoxicity [179]. Although the majority of patients develop pulmonary disease (51–73%), disseminated disease, including intra-abdominal infection, is seen in 38% [12, 176, 178, 180, 181]. Hepatic tuberculosis presents with fevers, night sweats, weight loss, and cholestatic liver tests. Non-tuberculous mycobacterial infections (e.g., *Mycobacterium avium* intracellulare, *M. chleonae*, *M. mucogenicum*, *M. triplex*, and *M. xenopi*) are rarer and less likely to affect the hepatobiliary system after SOT [12, 182]. LT recipients are at higher risk of non-tuberculous mycobacterial infection than other SOT patients [183]. Treatment of tuberculosis is complicated by interactions between rifampin and the calcineurin inhibitors (cyclosporine, tacrolimus), whose doses must be increased by two- to fivefold according to blood levels [12, 184]. The use of rifabutin as an alternative to rifampin has shown promise [176].

36.2.3 Fungal Infections

Fungal infections usually develop after the first month after SOT, particularly after discontinuation of fungal prophylaxis, which has decreased the incidence of early fungal infections and subsequent mortality [185]. OLT recipients have the highest incidence (7–42%), followed by pancreas (18–38%), HT and HLT (15–35%), and then KT (0–14%) [186]. Liver involvement is generally secondary to disseminated infection or cholangitis, especially after OLT, where fungal abscesses may develop from *Candidal* species (*C. albicans, C. tropicalis*), with a 12-month cumulative incidence after SOT of 1.9% [187]. Molds such as Aspergillus and zygomycetes are increasing in incidence [100, 187–190].

36.2.3.1 Candida Species

Candidal infections after SOT are most frequently seen in the blood, urinary tract, and in the abdomen; blood cultures do not reliably confirm the presence of invasive disease [191]. Risk factors for invasive candidiasis include prophylactic antibiotics, KT, lengthy operative procedures, ≥40 units of

blood products, prolonged ICU stays, Candida colonization, Roux-en-Y anastomosis, early surgical reexploration, and CMV infection [192, 193]. In the absence of prophylaxis, invasive infections occur in up to 42% of OLT recipients, and *Candida* species account for 60% to >80% [100, 188, 194, 195]. The route by which candidal organisms reach the liver, spleen, and kidneys is via gastrointestinal "persorption," where yeast forms pass through tight junctions into the portal circulation [196]. OLT recipients have significant *Candida* gastrointestinal colonization; antifungal prophylaxis should be given to all adult OLT recipients to prevent invasive disease [197]. About 4% of KT or KPT recipients develop intestinal fungal infections, most often candidal. Pancreas recipients with enteric drainage are at greater risk of fungal infection compared to those with bladder drainage. Small intestine graft recipients develop invasive *Candida* infection at rates as high as 28% [198]. Risk factors include graft rejection, high immunosuppression, anastomotic disruption, abdominal reoperation, and multivisceral transplantation [191]. Prophylaxis is generally administered for at least 4 weeks until the small bowel anastomosis has healed.

Anti-fungal therapy in SOT recipients is similar to that in non-SOT patients [199]. Therapy is generally continued for at least 4 weeks. Invasive lines and catheters should be removed if at all possible when candidemia is present. Azole antifungal medications can have drug–drug interactions with calcineurin inhibitors. Antifungal prophylaxis has reduced the risk of invasive disease and mortality but has led to infections with non-*Candida albicans* species, including *C. glabrata* and *C. krusei* [200–202].

36.2.3.2 Molds and Other Fungi

Invasive aspergillosis (usually *Aspergillus fumigatus*) can develop in SOT recipients, most commonly in LT recipients followed by KT, OLT, and HT recipients, generally in the lungs, secondary to inhalation of spores [203]. Hepatic involvement is not common and isolated hepatic aspergillosis is even rarer, presenting as multiple abscesses within the liver parenchyma, although single abscesses may form [204, 205]. Invasive aspergillosis after KT occurs later than after OLT, associated with the presence of chronic lung disease and chronic heart failure [206]. After OLT, *Aspergillus* accounts for about 25% of invasive fungal disease, especially following biliary tract infection [200, 207, 208]. Hepatic artery mycotic aneurysms have been described. LT and HLT recipients have the highest incidence of fungal infection in the SOT setting and non-candidal species predominate as a major source of mortality [209–211]. These infections generally involve the transplanted organ and not the hepatobiliary system. Mortality is lower in SOT recipients with invasive Aspergillosis (34.4%) compared to HCT recipients (57.5%) [203]. *Cryptococcus neoformans* is the third most common fungal infection seen following OLT and can infect any SOT recipient, usually presenting as pneumonia (46%) and meningitis (36%) [12]. Hepatobiliary involvement is infrequent, although disseminated disease, including peritonitis, can occur. *Histoplasma capsulatum*, a rare cause of granulomatous liver disease when disseminated, is generally asymptomatic in the immunocompetent host. Clinical infection in SOT recipients is uncommon (<0.5%) [212]. Infection can be primary or due to reactivation, and can progress to disseminated disease with multiorgan involvement and death in ~10% of infected SOT recipients [212–214]. A urinary histoplasma antigen test is the most sensitive diagnostic study. Coccidioides species can also disseminate in immunocompromised hosts [215].

Mucormycosis is more common after HCT than SOT; OLT recipients have an incidence of 0–1.6% [216]. Rarely, mucormycosis can involve the liver, sometimes presenting with Budd–Chiari syndrome [217]. Patients with iron overload syndromes, prior triazole antifungal use, renal failure or diabetes are risk factors; SOT recipients with mucor infections face 49–71% mortality [218].

Pneumocystis jiroveci causes pulmonary disease in SOT and generally develops after prophylactic medications have been discontinued [219]. Hepatobiliary involvement has not been reported.

36.2.4 Differential Diagnosis of Hepatobiliary Problems in SOT Patients

Hepatobiliary problems after SOT can be due to infections or noninfectious problems (especially after OLT), or to a combination. The approach to diagnosis and treatment is based on imaging, molecular diagnostics, and clinical experience ("Man sieht nur, was man weiß. Eigentlich: Man erblickt nur, was man schon weiß und versteht," Johann Wolfgang von Goethe[1]). Table 36-1 displays the major causes of hepatobiliary disease after SOT.

36.3 Hepatobiliary Infections After Hematopoietic Cell Transplantation

36.3.1 Viral Infections

The clinical and histologic manifestations of hepatic viral infection after HCT are not uniform, but range from fulminant hepatic failure (HSV, VZV, adenovirus, HBV) to more indolent, chronic inflammation (HCV, HBV) to a cholestatic

[1] "*You only see what you know. Actually: One sees only what one already knows and understands*."

TABLE 36-1. Hepatobiliary diseases after solid organ transplant, by clinical presentation and by cause [15, 23, 39, 91, 103, 106, 164, 165, 168, 169, 172–174, 217, 220–237]

	Hyperbilirubinemia	Abdominal pain	Elevated liver enzymes (ALT, AP)	Liver failure	Ascites
Infectious causes	HBV, HCV, HEV infection Fibrosing cholestatic hepatitis B or C Herpesvirus, adenovirus hepatitis Bacterial cholangitis Infection-related hyperbilirubinemia (cholangitis lenta)	Cholecystitis Biliary obstruction with cholangitis Fungal, bacterial abscess Acute viral hepatitis Peritonitis after bile leak (OLT)	Viral hepatitis Fungal, bacterial abscess EBV lymphoproliferative disease	Decompensation of cirrhosis Fibrosing cholestatic hepatitis B or C Fulminant viral hepatitis (HSV, VZV, adenovirus)	Budd–Chiari syndrome caused by mold infection Fulminant viral hepatitis
Noninfectious causes	OLT rejection DILI Vascular injury (OLT) Biliary tract obstruction Recurrent hepatocellular carcinoma (OLT) Hemolysis, RBC transfusions, Gilbert syndrome, renal insufficiency	Biliary obstruction (stone, stricture, tumor) Cystic duct obstruction Acute pancreatitis Budd–Chiari syndrome Sinusoidal obstruction syndrome	DILI (azathioprine, sirolimus, CNI) Biliary obstruction Rejection (OLT)	Hypoxic hepatitis Hepatic vascular injury (OLT) Sinusoidal obstruction syndrome Budd–Chiari syndrome	Cirrhosis Fulminant hepatic failure, nonviral Nodular regenerative hyperplasia

HBV hepatitis B virus, *HCV* hepatitis C virus, *HEV* hepatitis E virus, *OLT* orthotopic liver transplant, *DILI* druginduced liver injury, *RBC* red blood cell, *EBV* Epstein-Barr Virus, *CNI* calcineurin inhibitor, *HSV* herpes simplex virus, *VZV* varicella zoster virus.

picture (HCV, as fibrosing cholestatic hepatitis, or CMV biliary disease). Liver biopsy is rarely performed for viral diagnosis, as most hepatic viral infections can be identified by tests for viruses in blood samples. Antiviral treatment is available for almost all common viruses that infect the liver after HCT.

36.3.1.1 Hepatitis Virus Infections Before Transplant

Hepatitis Viruses in Potential Transplant Recipients

Hepatitis C virus. HCV RNA testing might be needed for HCT candidates with negative anti-HCV test results whose history indicates increased risk for HCV infection (e.g., intravenous drug abuse) or whose B cells cannot mount an antibody response [238]. HCV-infected HCT candidates requiring HCT can proceed with HCT with an HCV-infected donor, provided that recipient has full understanding of the risk that long-term consequences of HCV infection after HCT. However, such an approach may be associated with a higher rate of virologic failure (e.g., genotype 3 infection, Q80K NS3 polymorphism) [239]. Data are lacking regarding pre-HCT treatment of HCV-infected HCT candidates [5, 240]. Direct-acting antiviral (DAA) therapy before HCT might be considered for (1) patients with chronic HCV infection; (2) patients with HCV-related cirrhosis and/or portal hypertension; and (3) patients with an HCV-related lymphoproliferative disease [240, 241]. It is not known whether the efficacy of DAA therapy is affected by dysfunctional immunity (following chemotherapy or biologic therapy for cancer) or whether eliminating HCV before HCT improves the outcome of transplant by reducing the risks of post-HCT fatal sinusoidal obstruction syndrome, liver decompensation, fibrosing cholestatic hepatitis, or recurrent lymphoma.

Hepatitis B virus. The major risks faced by HBV-infected patients include fatal sinusoidal obstruction syndrome following some myeloablative regimens if hepatic inflammation or fibrosis is present; liver decompensation if cirrhosis is present at baseline; and fulminant hepatitis B or fibrosing cholestatic hepatitis B (seen only when antiviral prophylaxis has been forgotten or HBV is activated in a patient with occult HBV) [242, 243].

Staging of liver disease in candidates with chronic viral hepatitis. The presence of advanced fibrosis or cirrhosis may have a significant impact on HCT eligibility, risk of hepatocellular carcinoma, and the choice of conditioning regimen [244, 245]. Screening for hepatocellular carcinoma should be carried out before referral for HCT. Detection of advanced fibrosis and cirrhosis may require liver biopsy if transplant decisions would be affected by such findings. Two alternatives to biopsy have not been well-studied in HCT candidates: (1) Analysis of blood test panels (aminotransferases, platelet count, coagulation parameters, gamma-glutamyl transpeptidase, total serum bilirubin, haptoglobin, and gamma globulins) is not recommended in HCT candidates [5]; (2) Vibration-controlled transient elastography may be useful. In patients with chronic HCV infection, elastography has an estimated sensitivity of 70% and specificity of 84% for a diagnosis of significant fibrosis and an estimated sensitivity of 87% and specificity of 91% for a diagnosis of cirrhosis [246]. Elastography data in HCT candidates, particularly those with malignant infiltration or extramedullary hematopoiesis, are limited [247, 248].

Preventing Passage of Hepatitis Viruses from Infected Donors

The risk of viral passage from donors infected by HBV differs from that of HCV-infected donors, as the former can have HBV confined to the liver, whereas HCV-infected donors are always viremic and invariably transmit HCV to uninfected recipients [249]. Prevention of passage of HCV from an HCV-infected donor to the HCT recipient does not require a sustained virologic response in the donor, just the disappearance of HCV from extrahepatic reservoirs (peripheral blood stem cells and marrow cells) [250–253]. When there are oncologic imperatives for moving quickly to transplant, DAAs can clear extrahepatic HCV from donors more quickly than interferon and ribavirin without significant toxic effects on the donor marrow [252]. If time does not permit treatment of an HCV-infected donor, the use of HCV-infected hematopoietic cells for an HCV-uninfected recipient is not absolutely contraindicated because new DAAs can provide a virologic cure in the majority of transplant survivors after recovery and immune reconstitution.

HBV-infected donors who are viremic (serum HBV DNA+) will transmit virus to their recipients [240, 242]. When equally HLA-matched donors are available, an uninfected donor is preferred. If the most suitable donor has chronic hepatitis B, treating that donor with entecavir or tenofovir may prevent passage of virus [254, 255]. HBV persisting in donor peripheral blood stem cells may have to be eliminated to prevent passage [255, 256]. HB_sAg negative, anti-HB_c-positive donors can be used if their serum and peripheral blood stem cells are HBV DNA-negative. HBV-naïve recipients of cells from an HBsAg positive, serum HBV DNA-negative donor should be monitored for HBV DNA after transplant. Hepatitis B vaccination of HBsAg-negative recipients prior to the start of conditioning therapy, using double doses of HBV vaccine, may also be beneficial if there is a risk of passage from an infected donor [257]. When both donor and recipient are infected by HBV, the recipient should be treated with antiviral drug prior to conditioning therapy. Donors with occult hepatitis B (undetectable serum HBV DNA, HBsAg-negative but anti-HBc positive) can also be used; however, in HBV-endemic countries, 6–15% rates of viremia in such patients have been reported [258]. An entity termed "false occult HBV" has been described in Europe in patients with isolated anti-HBc but HBV DNA+ in 2.8% of cases; in some viremic patients, HBsAg mutants, missed by standard multivalent assays, were found [259]. If time permits, both donor and recipient should receive entecavir therapy and be vaccinated prior to conditioning therapy and the recipient should be given entecavir prophylaxis for up to a year after transplant [254, 260]. A donor who is naturally anti-HBc positive may be the preferred donor if the recipient is HBsAg positive or anti-HBc positive, as adoptive transfer of immunity can effect clearance of virus [261]. A similar result may be obtained by immunizing donors before cell harvest and infusion into HBV-infected recipients [261, 262].

Hepatitis D virus, which infects only patients with HBV infection, has not emerged as a significant cause of post-HCT liver disease, perhaps because pharmacologic control of HBV addresses HDV coinfection. Current recommendations are to exclude HDV-infected donors [240]. Recent recognition of the prevalence of hepatitis E virus in both endemic and non-endemic areas has led to awareness that this virus can be transmitted from infected donors and from blood product transfusions to recipients [263, 264]. Treatment of infected donors with ribavirin should be a feasible method of preventing transmission of HEV [58]. Donors infected by hepatitis A virus should not be harvested until they reach a non-viremic state. Screening of donors by serum ALT and anti-HAV IgM tests will detect HAV infection [265].

36.3.1.2 Viral Liver Infections Through the First Year After Transplant

A sudden rise in serum ALT following HCT is usually due to a noninfective cause such as zone 3 hepatocyte necrosis in SOS (peaking around day 20), hypoxic liver injury (as in septic or cardiac shock or respiratory failure), acute biliary obstruction (choledocholithiasis), drug-induced liver injury, or the acute hepatitic presentation of GVHD [242, 266]. If a likely cause is not apparent, acute viral hepatitis should be suspected; HSV, VZV, adenovirus, and HBV can lead to fatal fulminant hepatic failure after HCT whereas hepatic infections caused by CMV and HCV are seldom severe, with the exception of fibrosing cholestatic hepatitis C [242, 267]. With routine use of prophylactic acyclovir/valacyclovir, acute hepatitis due to HSV and VZV is now rare; however, HHV-6 and HHV-8 reactivation and HEV as causes of hepatitis have been reported after HCT [268, 269]. When there is uncertainty about the cause of rising serum ALT levels, serum PCR tests for herpesviruses, adenovirus, HCV, HBV, and, in some circumstances, HEV should be performed [263, 264]. If acyclovir is not being given to a patient with rapidly rising serum ALT, it should be started empirically, particularly if the patient presents with abdominal complaints typical of VZV infection [270].

Adenovirus. Adenovirus hepatitis should be suspected if the patient has concomitant pulmonary, renal, bladder or intestinal symptoms but may present with just fever, raised serum ALT, and hypodense regions in the liver on abdominal CT scan along with features of bone marrow suppression [271]; the most effective treatment is cidofovir when given early in the course of infection but many cases of adenovirus hepatitis are rapidly fatal [272–275]. However, not all patients who are excreting adenovirus and not all viremic patients progress to liver and multiorgan involvement [276]. New agents for prevention and treatment are in development [3, 275].

Herpes simplex virus. Before effective antiviral prophylaxis, HSV activated from latency caused infections far beyond its tropism for squamous epithelium, affecting the lungs, liver, and gastrointestinal mucosa. Hepatic presentation was that of rapidly rising serum ALT, followed by jaundice and liver failure. In a 15-year study of over 6000 patients undergoing HCT during 1992–2007, no cases of severe HSV hepatitis were seen [266].

Varicella zoster virus. In visceral VZV infection, abdominal distention, severe pain, fever, and rising serum ALT levels may precede cutaneous manifestations by up to 10 days [270, 277]. High-dose empiric acyclovir should be started on clinical suspicion while serum is analyzed by PCR for VZV DNA. A common presentation of disseminated VZV is that of enigmatic abdominal pain 2–6 months after HCT, after discontinuation of acyclovir—an indication for intravenous high-dose acyclovir while a definitive diagnosis is sought (VZV DNA in serum). In the first 100 days after HCT, severe VZV hepatitis occurred in 4 of ~2500 patients, all during the 1990s, and none since 1998 [266].

Cytomegalovirus. Liver and biliary CMV infections are now extremely rare after HCT [266, 278]. Even during an era when CMV disease was common, liver CMV infection was almost never a serious medical problem. An autopsy study of 50 patients from the 1980s examined liver tissue by viral culture, immunohistochemistry, and in situ DNA hybridization. Among patients who were seropositive at baseline, viremic during life, with CMV pneumonia and positive CMV cultures of the liver at autopsy, all had CMV-infected liver cells, including hepatocytes, endothelial cells, Kupffer cells, and bile duct epithelium, along with multifocal lobular granulomas [279]. In contrast, CMV infected liver cells were rarely found in the absence of disseminated CMV disease [279]. Patients with CMV in the liver cells did not have a typical clinical picture or laboratory results that were different from HCT patients without liver CMV at autopsy [279]. CMV infection of the gall bladder mucosa and the ampulla of Vater can lead to clinical problems (cholecystitis and biliary obstruction, respectively) [280].

Hepatitis B virus. Fulminant hepatitis and fibrosing cholestatic hepatitis B may develop during immune reconstitution in patients at risk, but can be prevented with prophylactic antiviral agents [281]. Entecavir is currently the drug of choice for this indication because of superior efficacy and fewer mutations [282]. If severe hepatitis from HBV reactivation does occur, usually because a diagnosis of HBV was not made prior to HCT, antiviral therapy with the most potent antiviral drug available (entecavir or tenofovir or both drugs simultaneously [283]) should be initiated immediately; however, progression to fatal liver failure is not uncommon [284]. Fulminant hepatitis B has also been reported following discontinuation of prophylactic antiviral therapy, and all patients, particularly those with high pre-transplant HBV DNA levels, should be monitored following antiviral drug withdrawal [285, 286]. In patients who acquired HBV as infants, the infection may be completely occult during transplant screening (negative serum tests for HBV antibodies, antigen, and DNA); after transplant, viral activation and clinical hepatitis during immune suppression can occur [243].

Hepatitis C virus. Hepatic manifestations include (1) an increased risk of fatal sinusoidal obstruction syndrome among patients with chronic HCV infection who receive sinusoidal endothelial cell toxins [242] as part of conditioning therapy [239]; (2) hepatic inflammation occurring at 3–6 months after HCT, coincident with immune reconstitution and discontinuation of immunosuppressive drugs [239]; (3) liver decompensation among patients who had cirrhosis at the time of transplant [287–289]; and (4) rarely, fatal fibrosing cholestatic hepatitis C in patients receiving mycophenolate mofetil [267]. Extrahepatic manifestations of HCV infection after HCT have been suggested by epidemiologic studies, including an excess of deaths related to bacterial infections and to liver disease [288, 289]. It is not clear whether excess mortality in these reports is due to HCV per se, the presence of undetected hepatic fibrosis and portal hypertension at HCT, or both. Other studies find no increased mortality in follow-up of HCV-infected survivors of HCT, to 10 years [239, 290].

Increases in titers of HCV RNA occur in both cancer patients receiving chemotherapy [240, 291, 292] and in HCV-infected HCT patients, but with the exception of fibrosing cholestatic hepatitis C [267], this viremia is not commonly manifest as a clinical illness. Upon immune reconstitution, there may be increases in serum ALT in ~30% of infected HCT patients [239, 290]. There is little utility in measuring titers of HCV RNA after HCT in patients already known to be infected.

The alternative to pre-HCT therapy for HCV is to treat after HCT, following immune reconstitution if feasible, using DAAs [5]. Sustained virologic response rates of 70–96% have been observed in patients who received DAAs during immunosuppressive therapy after liver transplant, suggesting that similar results would be seen in HCT survivors [46]. DAA therapy after HCT can be deferred, as the natural history of HCV infection in this setting is usually benign, with three exceptions: patients with fibrosing cholestatic hepatitis C [267]; patients with cirrhosis whose condition is deteriorating [287]; and patients who underwent HCT for HCV-related lymphoproliferative disorders [5, 240, 241]. Therapeutics for HCV treatment are rapidly evolving; we recommend this website for continuously updated information: [http://www.hcvguidelines.org]. Monotherapy with a DAA is not recommended regardless

of HCV genotype. Telaprevir-based and boceprevir-based regimens are not recommended for treatment of any patient with HCV infection. HCT recipients are characteristically receiving multiple drugs that have pharmacologic interactions with DAAs or toxic effects that overlap with those of DAAs. Such interactions have not been extensively studied in HCT recipients; what is known is summarized in a recent ASBMT review [5]. Metabolism by CYP450 enzyme, specifically the CYP3A4 isoform, is the major metabolic pathway of approved DAA HCV therapies [293–295]. When a calcineurin inhibitor or sirolimus is used with a protease inhibitor, it is reasonable to empirically reduce the dose of the immunosuppressive agents and monitor their levels more frequently because of major CYP3A4 and P-glycoprotein drug–drug interactions. The field of DAA therapy for HCV infection is rapidly evolving, and attention must be paid to drug–drug interactions in HCT recipients [5].

Hepatitis E virus. HEV may result in chronic infection in immunosuppressed individuals including HCT recipients [17, 269, 296]. In contrast to water-borne HEV due to genotype 1 and 2 found in the developing world, HEV genotype 3 (HEV3) is found in mammalian reservoirs including domestic pigs, wild boar and deer in Europe, North America, and China [268]. Diagnosis is by detection of anti-HEV antibodies and HEV RNA. Oral ribavirin has been shown to be effective therapy [58].

36.3.1.3 Hepatitis Virus Infections in Long-Term Transplant Survivors

Sporadic liver infection by herpesviruses can be seen in long-term survivors whose antiviral prophylaxis has been discontinued, especially those who remain on immune suppressive therapy for chronic GVHD. The more common infections are with hepatitis viruses.

Hepatitis C virus. Between 5 and 10 years after HCT, serum aminotransferase elevations were seen in 57% of HCV-infected patients, without excess mortality [239, 297, 298]. In some patients, however, the duration of HCV infection before HCT can only be estimated, and the extent of fibrosis at the time of HCT unknown; this circumstance can lead to progressive liver disease that becomes apparent following HCT [288, 289, 299]. In the time period from 10 to 40 years after HCT, HCV is the leading cause of cirrhosis, and the time to cirrhosis is shorter in HCT survivors than in other patients with chronic HCV infection [299, 300]. About one-third of HCV-infected 40-year survivors of HCT develop end-stage liver disease (cirrhosis, hepatocellular carcinoma, or liver transplant). Compared with the general population, patients who survive over 10 years post-HCT have an eightfold risk of developing a new solid malignancy; the risk of HCV-related hepatocellular carcinoma is particularly elevated in this cohort. Transplant survivors with risk factors for hepatocellular carcinoma should undergo surveillance with 6 monthly liver ultrasound scans according to international guidelines [301, 302]. Partial liver transplant from the original hematopoietic cell donor has been described [303, 304]. All HCV-infected long-term survivors should be offered DAA therapy to delay the development of cirrhosis and prevent long-term consequences of chronic HCV infection (lymphoma and other lymphoproliferative disorders) [240, 305, 306].

Hepatitis B virus. The serologic pattern of HBV infection may be atypical in HCT survivors as a consequence of immunosuppression. Clearance of HBsAg may be observed, and is particularly likely if the donor was anti-HBs positive because of prior HBV infection [261]. Patients who remain HBsAg-positive after HCT are at risk of flares of hepatitis activity, particularly at times of reduction of immunosuppression; these patients should be taking oral antiviral agents such as tenofovir or entecavir. All long-term survivors with chronic hepatitis B should be regularly monitored to assess virologic and disease status, and the need for antiviral therapy [307–309]. Long-term survivors with chronic hepatitis B do not seem to have an increased rate of progression to cirrhosis compared with non-HCT patients, and effective antiviral treatment should essentially prevent any disease progression. However, HBV viral status should be reassessed prior to reintroduction of chemotherapy [240, 310, 311]. Biologic agents, such as rituximab used in the treatment of B-cell malignancy, have a particularly high risk of reactivation of occult hepatitis B (HBsAg negative and anti-HBc positive), and prophylactic antiviral therapy is recommended [240].

Hepatitis E virus. Hepatitis E virus (HEV) is one possible explanation for enigmatic elevations of serum ALT in long-term survivors, but has been little studied. HEV can cause chronic infection in HCT survivors who remain on immune suppressive drugs because of chronic GVHD [17, 269, 296]. Oral ribavirin has been shown to be effective therapy in other situations [58].

36.3.2 Bacterial Infections

Pyogenic liver abscesses and granulomatous hepatitis caused by mycobacteria are rare after HCT. In contrast, bacterial infections of the biliary tree are not rare, owing to a high prevalence of gallbladder microlith and stone formation, leading to bactibilia and the potential for cholecystitis and cholangitis [280, 312].

36.3.2.1 Bacterial Infections Before Transplant

Liver disease is a common complication of oncology practice [310]. The most common liver presentation of bacterial infection is not liver infection per se, but the effect of inflammatory mediators (interleukin-6, TNF-alpha) on hepatocyte transporters of conjugated bilirubin (cholangitis lenta, also known as hyperbilirubinemia related to infection) [221]. Liver abscesses and biliary infections are almost always overt illnesses; more subtle presentations can be seen with granulomatous liver disease caused by mycobacteria, nocardia, and a long list of rarer organisms. Cholecystitis and cholangitis, usually related to stones, sludge, and bactibilia, must be dealt with before the start of conditioning therapy.

36.3.2.2 Bacterial Infections Through the First Year

Bacterial liver abscesses are rare in HCT recipients; however, latent mycobacterial infection (including bacille Calmette-Guerin) may reactivate within the liver with prolonged immunosuppressive therapy [313, 314]. Disseminated clostridial infection and gall bladder infection with gas-producing organisms may lead to air in the liver and biliary system. Biliary sludge (calcium bilirubinate and crystals of calcineurin inhibitors) is very common in the weeks following HCT [315]. Passage of sludge down the bile duct may cause epigastric pain, nausea, abnormal serum liver enzymes, "acalculous" cholecystitis, acute pancreatitis, and bacterial cholangitis [280, 316]. Acute cholecystitis is frequently without larger gallstones [317]. Cholecystitis in this setting may also be due to leukemic relapse with gall bladder involvement or infection by CMV, fungi, rarely by other organisms such as Hemophilus influenza, and occasionally by mucosal edema caused by acute GVHD. Biliary obstruction is a rare event, caused by a variety of disorders (common bile duct calculi or inspissated biliary sludge; GVHD of the ampullary mucosa; lymphoblastic infiltration of the common bile duct, gall bladder, and ampulla of Vater in EBV lymphoproliferative disease; CMV-related biliary disease; dissecting duodenal hematoma complicating endoscopic biopsy; and leukemic relapse [chloroma] in the head of the pancreas) [280, 317]. In patients undergoing autologous HCT, biliary strictures are commonly due to recurrent malignancy [318]. Endoscopic retrograde cholangiopancreatography is indicated in patients with clinical evidence of bacterial cholangitis and radiologic evidence of biliary obstruction and allows for biliary stenting or dilatation with acceptable risk [317, 318].

36.3.2.3 Bacterial Infections in Long-Term Transplant Survivors

Long-term survivors have an increased incidence of gallstones related to the formation of calcium bilirubinate microliths (biliary sludge) following myeloablative conditioning therapy [312, 315]. Biliary sludge, gallstones, and crystals of calcineurin inhibitor medications may cause cystic duct obstruction, common bile duct obstruction, acute pancreatitis, and their associated bacterial cholangitis and biliary sepsis [280].

36.3.3 Fungal Infections

Fungal liver abscesses were formerly very common, difficult to prevent, and treatable only with an amphotericin B–bile salt formulation that made patients ill and caused renal failure [319]. Now, pretransplant screening and antifungal prophylaxis throughout the HCT process has almost eliminated fungal liver abscesses and biliary fungal infections as major problems [320]. Use of toxic amphotericin formulations have been largely abandoned in favor of far less toxic azole, echinocandin, and liposomal amphotericin drugs. Fungal liver abscesses present with fever, tender hepatomegaly, and increased serum alkaline phosphatase levels; resistant *Candida* species or molds should be suspected if abscesses occur despite prophylaxis [320]. High-resolution CT scan or MRI may demonstrate multiple fungal abscesses, and serologic tests for fungal antigens may be useful for diagnosis [321]. However, the sensitivity of imaging tests for military fungal lesions is poor [322]. Return of neutrophil function after HCT can effect resolution of previously treatment-refractory Aspergillus infection [323]. Non-sterile herbal remedies contaminated by molds and ingested may lead to liver abscesses in survivors [324].

36.3.4 Differential Diagnosis of Hepatobiliary Problems in HCT Patients

After transplant, patients with liver abnormalities have infection as the cause far less commonly than noninfectious causes. Occam's Razor is frequently disposable in the transplant setting, as there are often multiple simultaneous causes of liver abnormalities. Table 36-2 provides an overview of hepatobiliary problems after HCT.

TABLE 36-2. Hepatobiliary diseases after hematopoietic cell transplant [5, 242, 310]

Disease	Frequency	Timing	Diagnosis	Treatment	Prevention
Sinusoidal obstruction syndrome	<10% (regimen-dependent)	Onset before day +20	• Hepatomegaly, ascites, weight gain, jaundice, multiorgan failure in severe cases • Imaging • WHVPG, histology • Note atypical presentations (acute hepatitis, anasarca)	• None proven • Defibrotide (uncontrolled observations)	• Assess patient risk before conditioning starts • Choose "liver-friendly" conditioning regimens
Cholestasis of sepsis (cholangitis lenta)	Common in neutropenic patients	Following sepsis or neutropenic fever	• Exclude other causes of cholestasis • Inferential diagnosis	Treat underlying infection	• Infection prophylaxis or expectant treatment • Ursodiol
Acute GVHD	• ~20% of allograft recipients • Rare after autograft	Day +15 to 100	• Confirm GVHD in skin, gut • Exclude other causes of cholestasis • Histology	• Prednisone 2 mg/kg/day • Ursodiol	• Optimal donor selection • Complete GVHD prophylaxis • T cell depletion protocols • Ursodiol
Acute viral hepatitis	Uncommon when prophylaxis is used against herpesviruses, hepatitis B	HSV, day +20 to 50 Adenovirus, day +30 to 80 VZV, day +80 to 250 HBV and HCV, during immune reconstitution	• Pretransplant serology and PCR results • PCR of serum for specific viruses • Liver histology/PCR/immunostains now uncommonly needed	• HSV, VZV: acyclovir • Adenovirus: cidofovir • HBV: entecavir or tenofovir	• HSV and VZV infection: acyclovir prophylaxis for all patients • If patient is at risk for HBV infection: entecavir, choose HBV immune donor • Avoid MMF in patients with HCV infection • Consider treatment of HCV with DAA drugs before conditioning
Fungal abscess	Rare when prophylaxis is used	Day 10–60	• Hepatic pain, fever • Liver imaging • Serum fungal antigen	• Antifungal drugs	• Pretransplant screening • Oral antifungal prophylaxis for all patients
Drug-liver injury	Common	Any time	• Clinical evidence	• Discontinue drug	• None
Ischemic liver disease	Confined to patients with septic or hemorrhagic shock or respiratory failure	Day 0–50	• Clinical evidence	• Restore cardiac output, blood oxygenation	• Early treatment of sepsis, bleeding
Biliary obstruction	• Transient biliary sludge, common • Stones, chloromas rare	Day 15–60	• History, examination • Biliary ultrasound	• Papillotomy ± stent if obstruction persists	• None
Idiopathic hyperammonemia	• Rare	Day 10–50	• Venous blood ammonia	• None proven	• Unknown, probably genetic defect
Chronic hepatitis C	• Formerly common	After day 80	• HCV RNA in serum • Elevations of serum AST, ALT after immune reconstitution	• DAA HCV therapy after full immune reconstitution	• Screen hematopoietic cell donors • Consider treatment of HCV with DAA drugs before conditioning
Iron overload	Very common	Pretransplant • Long-term follow-up after transplant	• MRI specific for iron quantitation • Transferrin saturation • Marrow iron quantitation • Liver iron quantitation	• May not be necessary • Phlebotomy, chelation if iron burden is very high	• Avoid medicinal iron supplements
Chronic GVHD	Common after allografts	After day 80	• Prior acute GVHD history • Chronic GVHD in other organs • Consistent ALT, alkaline phosphatase • Histology	• Immunosuppressive drug therapy • Ursodiol	• Screening for chronic GVHD at day 80

Fungal Infections

37
Yeast Infections After Haematopoietic Stem Cell Transplantation

Jason A. Trubiano, Sharon C.-A. Chen, and Monica A. Slavin

37.1 Introduction

Invasive fungal disease (IFD) caused by yeasts and yeast-like pathogens complicates both autologous haematopoietic stem cell transplantation (auto-HSCT) and allogeneic haematopoietic stem cell transplantation (allo-HSCT). The most commonly isolated yeasts vary according to both geographic location and prophylaxis practices. Nonetheless, invasive candidiasis (IC), which includes bloodstream infection (candidemia) and deep-seated tissue infection, continues to be the most common yeast infection after HSCT [1]. The aetiology, risk factors, diagnostic approaches and treatments for IC, cryptococcosis and infectious due to other yeasts will be described.

37.2 Epidemiology, Risk Factors, and Clinical Features of Yeast Infections in HSCT

37.2.1 Candida Infections in HSCT

IC in haematology and HSCT patients is associated with significant morbidity, mortality and hospital/patient centred costs [2–6]. Historically IC has occurred in up to 17 % of allogeneic HSCT patients, with 11 % of infections being disseminated, but the latter has been reduced by widespread use of azole prophylaxis and changes in conditioning and transplant regimens [7]. A recent report of the incidence of IC in patients with a haematological malignancy was 1.4 cases/1000 admissions [8]. After HSCT, the incidence of IC was 1 % and 1.1 % at 6 and 12 months, respectively, from the Transplant Associated Infections Surveillance Network (TRANSNET) database from multiple US centres [6]. A similar incidence in HSCT recipients was described by The European Organization for Research and Treatment of Cancer (EORTC) with a fungaemia incidence of 1.55 % of which 90 % of infections were due to *Candida* spp. [9]. Nonetheless, in some stem-cell transplant centres low rates of IC have been demonstrated, even in absence of fluconazole prophylaxis [10]. The higher rates of IC seen in some HSCT antifungal prophylaxis studies may be attributable to differences in conditioning regimens and other local practices [11, 12].

The traditional candidemia risk factors are neutropenia, intra-abdominal source, older age, corticosteroid use, hypogammaglobulinemia, APACHE II score, total parenteral nutrition (TPN), intensive-care-unit (ICU) admission, recent HSCT (<6 months), recent abdominal surgery and antibacterial therapy [13–16]. Candidemia may result from gastrointestinal colonisation and translocation or in some cases central venous catheter (CVC) colonisation [17]. Colonisation with *Candida* species, primarily *Candida albicans*, *Candida krusei* and *Candida glabrata* occurs in approximately 8–44 % HSCT recipients and is higher in allo-HSCT than auto-HSCT but colonisation rates do not appear to reflect rates of IC [18–20]. A shift in the epidemiology of IC has been observed with non-*albicans Candida* species, especially *Candida parapsilosis*, *C. krusei* and *C. glabrata*, collectively responsible for 54–87.4 % of candidemia cases [8, 9, 14, 15, 21–25]. Specifically, *C. glabrata* and other non-*albicans Candida* spp. are more commonly found in HSCT compared to solid organ transplant (SOT) recipients [26]. In haematology patients, including HSCT recipients, *C. glabrata* is an increasingly important pathogen associated not only with the traditional candidemia risk factors but also with prior azole exposure [24, 27].

Breakthrough candidemia, defined as a positive blood culture for *Candida* species after ≥3 days of antifungal therapy [28], accounts for up to 50 % of IFD in HSCT patients. In HSCT patients, candidemia is more likely to be associated with fluconazole, echinocandin or multidrug resistance depending on prior exposure to antifungals [14, 15, 28–30]. Multidrug resistant *Candida* species are currently uncommon but associated with increased mortality [28, 29].

Legend: The proportion of reports for each pathogen.

–: Not reported.

+: Infrequently reported.

++: Commonly reported.

+++: Very commonly reported.

[a]Including abdominal collections.

[b]CNS, Central Nervous System—Meningeal, epidural or cerebral disease.

[c]Includes any ocular and retinal disease.

[d]Includes myocarditis, pericarditis and valvular disease.

However, overall despite shifts in the epidemiology and resistance patterns of *Candida* spp., morbidity and mortality outcome measures in candidemia have not dramatically changed [2, 9, 13, 14, 21, 23]. IC remains an independent predictor of mortality in HSCT recipients with recent mortality rates of IC estimated at 30–70 % [1, 15, 22, 31–33]. The clinical syndromes of IC in HSCT recipients are shown in Table 37-1.

Disseminated IC is rare, likely due to more widespread use of antifungal prophylaxis [34]. It is a distinct clinical syndrome of persistent fever after neutrophil recovery, raised ALP and target lesions, abscesses or nodules seen on imaging of liver, spleen, kidneys or lungs. Notably, biopsy culture is often negative although yeasts and granulomata may be seen on histology [35].

37.2.2 Cryptococcosis in HSCT

Yeast-like fungi of the *Cryptococcus neoformans* complex are ubiquitous encapsulated fungi that primarily enter hosts via the respiratory tract, with potential for dissemination especially in immunocompromised hosts. Cryptococcosis is primarily caused by *C. neoformans* and *Cryptococcus gattii,* both of which have been reported to cause infection in haematology patients. Invasive disease due to non-*neoformans Cryptococcus* spp. is rare [36, 37].

Cryptococcosis is less frequent in HSCT compared with SOT recipients [38]. In HSCT recipients it accounts for <1 % of all IFD, possibly due to use of antifungal prophylaxis [6, 11, 39–42]. In those few cases reported in HSCT, incidence appears higher in auto-HSCT than allo-HSCT [11, 37, 38, 41, 43]. Whilst pulmonary and central nervous system (CNS) disease remain the most common sites of infection, unusual presentations including panniculitis have been reported [42] (see Table 37-1).

37.2.3 Uncommon and Endemic Pathogens in HSCT

Yeasts that are infrequently encountered in HSCT recipients include *Malassezia* spp., *Rhodotorula* spp., *Saccharomyces* spp. and *Trichosporon* spp. [44]. However, some previously uncommon and more intrinsically antifungal resistant yeasts such as *Trichosporon* spp. are emerging related to patterns of prophylaxis use and may present as breakthrough infections [45–47]. They may be associated with central venous or arterial line use, particularly *Rhodotorula* spp, and occur more frequently in warm moist climates leading to geographic variations in incidence [46, 48]. The crude mortality of these emerging pathogens can be upward of 70 % [39]. *Malassezia* spp. classically causes tinea versicolor and skin colonisation. *Malassezia* spp. IFD typically occurs at 30–50 days post HSCT, resulting in pulmonary, catheter-related fungaemia and cutaneous disease [49–51]. *Malassezia* species require long-chain fatty acids for growth and therefore have a predilection for individuals receiving lipid containing intravenous parenteral nutrition and are usually susceptible to amphotericin B. Lipid enriched media may improve isolation from patient samples [52, 53]. The mortality associated with *Malassezia* infections in this population remains low [50]. *Geotrichum* spp. rarely causes invasive disease in HSCT, the reported clinical syndrome predominately fungaemia [54–57]. *Saccharomyces* spp. whilst a known gastrointestinal tract coloniser of HSCT recipients also remains an infre-

quent cause of IFD [18, 58–61]. When *Saccharomyces* spp. IFD occurs, it is often at 43–180 days infection post HSCT [61]. Whilst many clinical isolates remain susceptible to the azoles and the echinocandins, resistance to fluconazole has been reported [62, 63].

Rhodotorula spp. infections have been reported in HSCT with increased frequency in the Asia-Pacific region, typically associated with line-related fungaemia and low mortality (9–13 %). *Rhodotorula mucilaginosa (Rhodotorula rubra)* is the most commonly isolated species, followed by *Rhodotorula glutinis* and *Rhodotorula minuta* [64]. *Rhodotorula* spp. are intrinsically resistant to fluconazole, echinocandins and amphotericin B [65]. *Rhodotorula* spp. invasive disease is typically associated with neutropenia, CVC and auto-HSCT and treatment includes central line removal [66–68].

Trichosporon spp. colonises the skin and gut of humans, and in HSCT most often causes fungaemia. Invasive disease in HSCT was first described in 1977, and since then has been increasingly reported. The most frequently encountered species are *T. asahii* and *T. beiglii* [69]. *Trichosporon* spp. are usually resistant to echinocandins and less susceptible to amphotericin B than to azoles. It has a high mortality (42–76 %), improved however by azole therapy and neutrophil recovery [39, 70]. Whilst fungaemia is the most common presentation for invasive trichosporonosis, other clinical features can include skin or hepatosplenic lesions and pulmonary infiltrates [39].

Dimorphic fungal pathogens are also important pathogens to consider in HSCT recipients who have lived in or visited endemic areas. The TRANSNET endemic fungal pathogen surveillance study identified only two cases of coccidioidomycosis and four cases of histoplasmosis in HSCT recipients [71]. In this study only 9 % of endemic pathogens were from HSCT recipients, with the remainder occurring in SOT recipients [71]. Importantly infections can occur many years after HSCT and are also associated with the use of tumour necrosis factor alpha inhibitors [72]. For blastomycosis, coccidioidomycosis and histoplasmosis, isolated pulmonary disease is reported in 36 % of patients and disseminated disease in the remainder [71]. In allo-HSCT the incidence of *Coccidiodes,* in Arizona, an endemic area, was estimated at 2.6 %, associated with pulmonary involvement in 80 % and 45 % mortality [73]. In four other cases of Coccidioidomycosis in allo-HSCT the mortality was 75 % [74, 75]. Disseminated disease sites include bone marrow, liver, gastrointestinal tract, kidney, spleen, skin and nodal disease. The median time from transplantation to infection with an endemic pathogen in HSCT is estimated at 274 days. Frequent testing for infection in higher risk patients should be performed with appropriate serology and PCR and antifungal prophylaxis considered [71, 73].

Histoplasmosis has been reported in immunocompromised hosts including solid organ transplant recipients and HIV infected, but reported in only a small number of HSCT recipients, primarily allo-HSCT [71, 76–79]. It is even less reported than coccidioidomycosis [73, 75]. It is also important to note that cases have also been reported in patients who reside outside endemic areas [76]. Blastomycosis and paracoccidioidomycosis have been reported in haematology cohorts but not HSCT recipients [80].

37.3 Diagnostics

Routine culture-based diagnostics including cultures of blood, cerebrospinal fluid (CSF) and tissue biopsy where applicable are recommended for diagnosis of suspected IC and cryptococcosis, and all yeast infections. A fungal culture allows antifungal sensitivity testing to be performed. Blood cultures, although specific for invasive IC, lack sensitivity (50–83 %) overall and are limited by relatively delayed time to positivity (2–3 days) [1, 81, 82]. The time to positivity (TTP) can be a clue to *Candida* species, a TTP less than 56.5 h had a negative predictive value (NPV) of 92 % for *C. glabrata* [83]. In a single centre retrospective review the mean time to detection from blood cultures of *C. albicans* was 35.3 h and for *C. glabrata* 154 h [84]. It is important to note that whilst the isolation of *Candida* spp. from a sterile site is significant, isolation from non-sterile sites (including bronchoalveolar lavage) may reflect colonisation rather than invasive disease. The isolation of *Cryptococcus* however from any culture, even from a non-sterile site, should be considered reflective of invasive disease unless proven otherwise.

37.3.1 Non-culture-Based Diagnostics

37.3.1.1 1,3-β-D-Glucan (BDG)

BDG is a cell wall component of several fungal pathogens, including *Candida*. It however is not present in *Cryptococcus* species. BDG could be a useful test for diagnosis of IFD in HSCT recipients when combined with adjunctive clinical, radiological and microbiological findings. The majority of BDG studies use one of the four commercially available assays, based upon two-three times per week surveillance testing. BDG is now recommended by several guideline groups for the diagnosis of IC [85–95], however the utility of BDG has not been extensively studied in HSCT cohorts. A review of BDG by European Congress for Infections in Leukemia (ECIL) examined a heterogeneous group of 10 studies utilising BDG in haematology cohorts, demonstrating no clear difference between assays and variable sensitivity (50–100 %), specificity (45–100 %) and NPV (73–100 %) [87, 88]. Improvement in specificity (100 %) is demonstrated by obtaining two consecutive positive BDG results, at the expense of sensitivity (45–65 %) [89, 91, 95]. In a recent study of haematology patients including HSCT, BDG had insufficient sensitivity to detect breakthrough candidemia [96]. In a small number of case reports BDG has remained

positive after clinical resolution of IC [97, 98]. Moreover, in HSCT patients receiving concurrent immunoglobulin replacement, false positive BDG tests have been reported [99, 100]. In cases of rare invasive yeast infection, such as trichosporosis, BDG is often falsely negative [70]. We therefore suggest that BDG be used only in settings where serial testing is available and interpreted in conjunction with clinical, microbiological and radiological evidence of IFD.

37.3.1.2 T2 Diagnostics

T2 magnetic resonance (T2MR) technology is being increasingly used for the diagnosis of IC [101]. T2MR is a self-contained instrument that detects and amplifies Candida DNA from whole blood [102]. A recent multicentre study of over 1800 patient blood cultures, 250 of which were spiked with *Candida* spp., including HSCT recipients (43 % cohort), demonstrated a sensitivity of 91 %, specificity of over 98 % and NPV of 99 % for *Candida* spp. [102]. The median time to a negative result in this study was 4.4 h compared with 2–5 days for routine blood cultures [102]. Whilst T2MR remains promising, its role in HSCT centres is currently ill defined.

*37.3.1.3 **Candida** PCR*

Candida specific and panfungal PCR have been employed for the diagnosis of IC, however methodologies are yet to be standardised and validated. *Candida* PCR has been demonstrated to detect IC prior to standard culture methods, however the evidence for routine use of this diagnostic modality in HSCT and its performance in the presence of antifungal prophylaxis is absent [103, 104]. Using data extrapolated from mixed patient population studies Avni et al. demonstrated in a meta-analysis that the sensitivity and specificity of *Candida* PCR in cases of candidemia was 100 %, whilst in suspected IC the sensitivity was 91 % and specificity 95 % [104]. Others have shown that PCR is more sensitive than blood cultures for diagnosis of intra-abdominal infection, although HSCT recipients were not included in this study [105]. Greater validation is required in at risk groups such as HSCT recipients before widespread clinical use.

37.3.1.4 Cryptococcal Diagnostics

The presence of the polysaccharide capsule surrounding *C. neoformans* has led to the development of the cryptococcal antigen assays (CrAg) that detect the antigen in serum and CSF. CrAg detection is included in the EORTC/MSG criteria for diagnosis of IFD [87]. Whilst the test specificity when performed on serum or CSF is excellent (92–100 %) [106, 107], the sensitivity of CrAg whilst higher than blood cultures is lower (77–95 %) in the relatively small number of studies in haematology/HSCT patients [107–111]. Due to paucity of data regarding serum CrAg use in HSCT, it cannot be used as a stand-alone test to exclude cryptococcal disease or monitor response to therapy. Interestingly a false positive cryptococcal antigen has been reported in case of invasive trichosporonosis due to the cross-reactive capsular antigen [112].

The Cryptococcal lateral flow assay (LFA) has 97 % concordance with enzyme immunoassay antigen detection and an overall sensitivity and specificity for cryptococcosis of 97–100 % and 99.6 %, respectively [113–116]. Its rapid nature, low cost and "point-of-care" deliverability in conjunction with subsequent validation on sera and CSF specimens make it an attractive diagnostic for cryptococcal disease. Potential use of the assay on urine samples has been demonstrated primarily in HIV cohorts, allowing for earlier detection of invasive disease in the future [114, 117–119].

37.3.1.5 Matrix-Assisted Laser Desorption/ Ionisation-Time of Flight Mass Spectrometry (MALDI-TOF MS) for Yeast Identification

The use of MALDI-TOF MS has been increasingly reported for rapid identification of yeast species including directly from blood cultures [120, 121]. It detects mass patterns of organisms from clinical isolates, comparing against reference strains, allowing species identification within minutes [120]. In a small number of studies MALDI-TOF MS has been used to simultaneously identify *Candida* spp. and to determine susceptibility to triazole antifungals and the echinocandins [122, 123]. In candidemia MALDI-TOF has been successfully employed to detect fungaemia, more rapidly than methods based on culture and molecular diagnostic methods [124]. Correct identification of *Candida* spp. by MALDI-TOF has been referenced at 95–98 % [120, 121, 125]. The utility of MALDI-TOF MS in routine diagnostics in haematology patients has not been extensively validated, although remains promising.

37.4 Antifungal Resistance

Laboratory testing for susceptibility to antifungal drugs is a vital component of the diagnostic approach to invasive yeast infection. Patterns of resistance may vary between centres. Whilst *C. albicans* almost exclusively remains fluconazole sensitive, increasing resistance in non-*albicans Candida* spp. has been observed. Prior fluconazole therapy and echinocandin use correlated with fluconazole and caspofungin resistance, respectively [126]. The risk factors for fluconazole resistant *Candida* spp. in HSCT were identified to be prior fluconazole use, *C. glabrata* isolation, prior amphotericin B therapy, diabetes, CMV antigenemia and non-

Hodgkin's lymphoma on multivariate analysis of the TRANSNET study [26]. In cancer patients including HSCT and gastrointestinal surgery, triazole therapy and advanced age (age > 65) are associated with fluconazole resistant *Candida* spp. [7].

Fluconazole resistance has been increasingly noted in *C. glabrata* [1, 8, 14, 22, 26, 127, 128]. This is compounded by concomitant echinocandin resistance associated with fluconazole resistance phenotypes in some countries, independent of prior azole exposure [28, 129]. The emergence of multidrug resistant *C. glabrata*, involving azoles and echinocandins is cause for concern, associated with increased all-cause mortality [29, 129, 130]. Fluconazole susceptible dose-dependent (SDD) *C. glabrata* isolates have been successfully treated with fluconazole therapy in HSCT recipients [24, 131]. The resistance patterns of uncommon yeasts are outlined in Table 37-2.

There are no standardised antifungal susceptibility breakpoints for *Cryptococcus* spp. In many centres routine susceptibility testing is not performed considering resistance to first line therapies (amphotericin B and 5 flucytosine/fluconazole) is infrequently reported [1, 132].

37.5 Impact of Antifungal Prophylaxis on Invasive Yeast Infections Post HSCT

The widespread use of azole prophylaxis in HSCT patients has significantly reduced the incidence of IC and patient mortality (Figure 37-1) [7, 9, 133, 134]. Fluconazole prophylaxis to day 75 after HSCT has reduced candidemia and improved overall survival in HSCT recipients, even if colonised [7, 20]. When triazole or echinocandin antifungal prophylaxis is employed, the incidence of *Candida* spp. colonisation is decreased significantly [135]. There have been few head-to-head studies demonstrating efficacy of one agent over the other, with minor differences in occurrence of IC noted in a systematic review and meta-analysis [136]. Prophylaxis strategies are risk stratified in regard to known host factors, corresponding with either Candida directed prophylaxis (fluconazole) or mould active therapy (i.e. itraconazole, voriconazole, posaconazole).

Although 400 mg/day fluconazole was used in the randomised placebo controlled trials of prophylaxis [7], in one observational study low dose fluconazole therapy (200 mg) prevented *C. glabrata* or *C. krusei* infection in allo-HSCT but not autologous HSCT patients [25]. However, 200 mg or even 400 mg daily may not achieve adequate pharmacokinetic targets to treat invasive infection with less susceptible isolates [137]. Risk factors for acquisition of fluconazole resistant candidemia not surprisingly include recent gastrointestinal surgery and fluconazole/triazole exposure [14]. However, one study found no increase in the proportion of *C. glabrata* positive cultures in patients receiving fluconazole prophylaxis [135]. *C. krusei* is inherently resistant to fluconazole and is isolated twice as frequently in subjects receiving fluconazole compared to those receiving posaconazole or itraconazole [135]. Prolonged fluconazole prophylaxis in HSCT patients with GVHD is also associated with increased risk of *C. albicans* resistance [135].

Voriconazole prophylaxis was better tolerated but equally effective at reducing IFD, including IC, when compared with itraconazole (1.3 % vs. 2.1 %) in allo-HSCT [138]. *C. glabrata* and *C. krusei* breakthroughs have been noted in HSCT recipients receiving primary or secondary voriconazole prophylaxis [27, 139–141]. In myeloablative HSCT recipients at standard risk for early death or relapse, one randomised, double-blind study of voriconazole and fluconazole concluded that fungal-free survival rates (the primary endpoint) were similar at 180 days [142]. Notably, fluconazole and voriconazole were similarly tolerated with the same proportion of withdrawals due to adverse events (AEs) at a similar median time. *Candida* infections occurred in 1 % of patients on each arm [142].

Breakthrough IC, in particular that due to *C. glabrata* has also been noted in allo-HSCT recipients receiving posaconazole prophylaxis [135, 143, 144]. In some centres *Candida* spp. was the most common breakthrough IFD seen in HSCT recipients [135, 144].

Echinocandin prophylaxis in HSCT is not reported to be associated with high rates of breakthrough yeast infections [45]. Nonetheless breakthrough infections due to *Candida* spp., including *C. parapsilosis, C. tropicalis* and *C. glabrata* have been reported, even after short periods of echinocandin exposure [12, 19, 128, 145, 146].

37.6 Treatment

The treatment principles for IFD in HSCT are similar to those guidelines provided for general haematology and oncology populations [1]. Practical points and empirical treatment for IC in HSCT are outlined in Figure 37-2 and doses of antifungals commonly used to treat IC are shown in Table 37-3. Early initiation of empirical therapy, usually with an echinocandin followed by targeted step-down antifungal therapy is vital, as delayed therapy is associated with inferior outcomes [147–149]. In addition, delay in catheter removal in *Candida* blood stream infections is associated with increased mortality [150–152]. However, in neutropenia the gastrointestinal tract is a potential source of *Candida* infection and line removal may not always be required in such cases [17]. The incidence of ocular candidiasis in patients with candidemia (12.5–26 %) necessitates ophthalmologist review in all cases of candidemia [153–155]. The role of echocardiography to examine for *Candida* spp. endocarditis has long been debated. A recent prospective cohort study demonstrated an overall *Candida* spp. endocarditis

TABLE 37-2. Summary of suggested antifungals for invasive yeast infections in HSCT

Yeast	Primary clinical syndromes	First line	Second line	Minimum duration	Comments
Candida spp.	Candidemia (see Figure 2)	Echino[a]	Azole[a,b]	2W	1. Echinocandins not recommended for urinary or ocular candidiasis 2. If no surgical intervention for endocarditis, then lifelong suppressive fluconazole
	CNS (meningitis/abscess)	5FC + L-AMB	Azole[c]	4–6W	
	Retinitis	AMB or Azole[c]	L-AMB or Azole[d]	4–6W	
	Endocarditis	5FC + L-AMB	Echino + L-AMB	6W	
	Intra-abdo collection	Azole[b]	Echino[a]	2–4W	
	Hepatosplenic[e]	Azole[b]	L-AMB/Echino	16–26W	
	Cystitis/pyelonephritis	Azole[b]	L-AMB +/− 5FC	2W	
	Osteomyelitis	Azole[b] or L-AMB[a]	Echino[a]	26–52W	
	Septic Arthritis	Azole[b] or L-AMB[a]		6W	
C. neoformans	CNS	I: L-AMB +5FC	High dose L-AMB[f]	2W	1. L-AMB preferred over AMB 2. Voriconazole can be considered for salvage therapy
	Pulmonary (mild)	C: Azole[c]	–	8W	
	Pulmonary (severe)	M: Azole	–	26–52W	
		Azole[b]	–	26–52W	
		Same as "CNS"		26–52W	
C. gattii	CNS	I: L-AMB +5FC	–	6 W	1. Azole induction not recommended 2. For mild lung disease may consider azole for 6–12 months
	Pulmonary	C: Azole[b]		52–78W	
		I: L-AMB +5FC		2W	
		C: Azole[b]		26–52W	
Histoplasma spp.	Pulmonary or disseminated	L-AMB	AMB OR Azole[b,d]	4–6W (induction) 52W (consolidation)	1. Step down from L-AMB to itraconazole 200 mg bd-tds. 2. For non-CNS/non-disseminated disease can consider itraconazole first line
Coccidioidomycosis	Pulmonary or disseminated	L-AMB	AMB Azole[g]		1. For mild disease can consider fluconazole or itraconazole
Geotrichum spp.	Fugaemia and disseminated	Azole[d]	L-AMB	2W	1. Variable susceptibility to fluconazole
Malassezia spp.	Cutaneous disease	Azole[d]	Azole[b]	1–2W	1. Variable AMB susceptibility 2. No echinocandin susceptibility data 3. Intraconazole susceptible
Rhodotorula spp.	Fungaemia, pneumonia or invasive disease	L-AMB	Azole[d]	2W	1. Intrinsic resistance to fluconazole and echinocandins
Saccharomyces spp.	Fungaemia	Azole[d]	L-AMB/Azole[b]		1. Variable fluconazole susceptibility 2. No echinocandins data
Trichosporon spp.	Fungaemia, pneumonia or invasive disease	Azole[d]	Azole[b]	2W	1. Increasing rates of fluconazole and AMB resistance. 2. Limited evidence for combination therapy 3. Echinocandins have poor activity.

Adapted from references [1, 39, 51, 54, 56, 65, 68, 70, 71, 73, 161, 164, 166, 167, 176–180].

Abbreviations: *L-AMB* liposomal amphotericin B, *AMB* Amphotericin B, *Min duration* minimum treatment duration, *W* weeks, *Echino* echinocandin, *5FC* 5-Flucytosine, *CNS* central nervous system, *I* induction, *C* consolidation, *M* maintenance.

[a]If echinocandin started, follow with azole if susceptible (fluconazole > voriconazole).

[b]Fluconazole preferred if susceptible.

[c]Fluconazole 800 mg OR 12 mg/kg daily.

[d]Voriconazole preferred if susceptible.

[e]Disseminated disease.

[f]Liposomal Amphotericin 6 mg/kg daily.

[g]Fluconazole or voriconazole preferred.

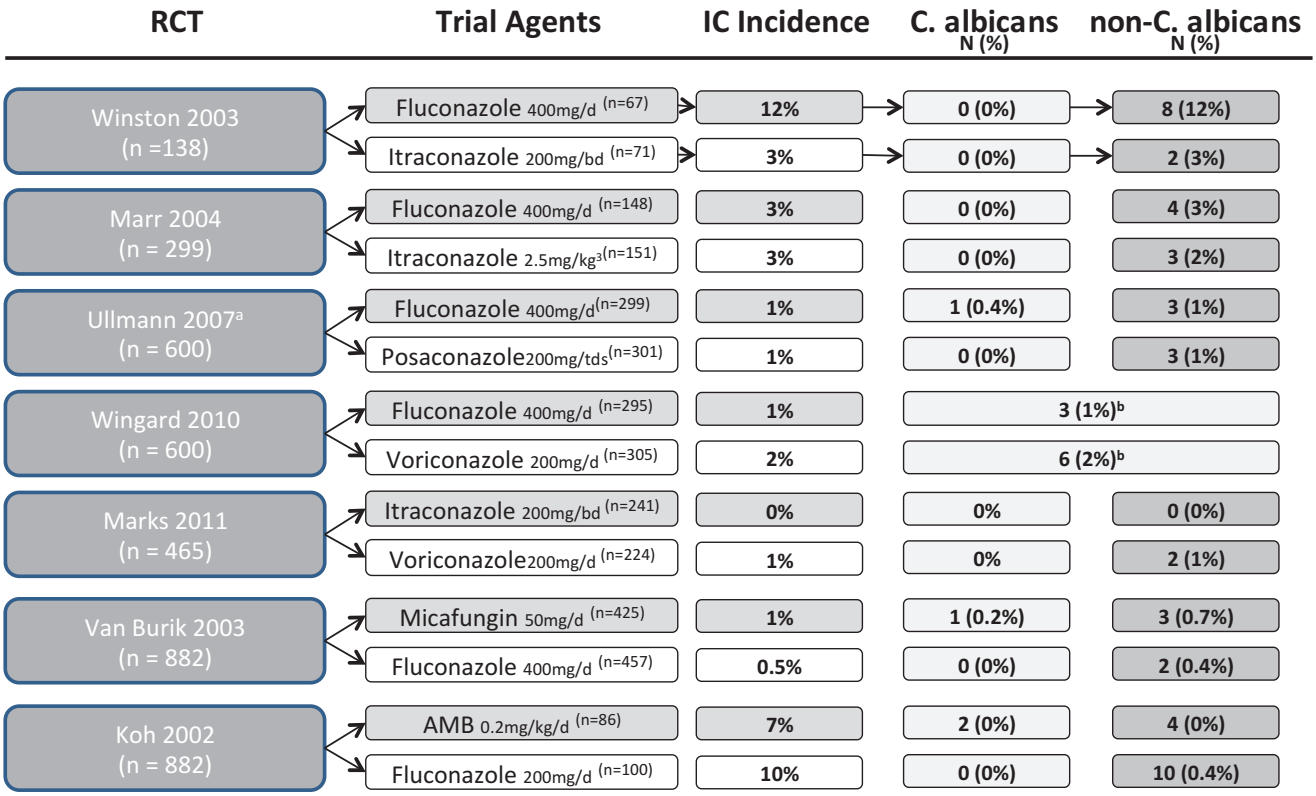

FIGURE 37-1. The incidence of IC in seven contemporary randomised control trials of antifungal prophylaxis in allo-HSCT recipients. *Abbreviations*: *RCT* randomised control trial, *N* study number, *IC* invasive candidiasis, *AMB* amphotericin B, *d* daily, *bd* twice-daily, *tds* three-times-daily. Maintenance dosing for agents listed. [a]Ullman et al. included only allo-HSCT with severe GVHD. [b]Missing information regarding *Candida* spp. References [133, 134, 138, 142, 175].

incidence of 4.2% [156]. When transoesophageal echocardiogram (TOE) is performed routinely in most centres, the incidence has been reported at upwards of 17% [157]. Echocardiography should be strongly considered, especially in the setting of prosthetic valves.

Hepatosplenic or disseminated candidiasis may require prolonged treatment and be complicated by prolonged fever. It has been suggested that this entity may represent an immune reconstitution inflammatory syndrome (IRIS) and some authors have suggested use of corticosteroid treatment [34]. IC is not a contraindication to HSCT [158]. Where neutropenia is expected to resolve granulocyte infusions have been used in conjunction with antifungal therapy to bridge a period of profound neutropenia but in the absence of a randomised trial efficacy is uncertain [159, 160].

The initial antifungal treatment choice is dependent on the causative species, site of infection, presence/absence of candidemia, host factors, prior azole exposure, and local hospital epidemiology. It is imperative to differentiate *Candida* spp. colonisation from IC, in particular isolation of *Candida* spp. from urinary and upper respiratory tract sources in the absence of clinical or radiological evidence of disease. Although *Candida* spp. colonisation, especially from multiple sites, may suggest candidemia, alone it does not warrant therapy.

The treatment of cryptococcosis in HSCT is outlined in the 2010 IDSA guidelines and is summarised in Table 37-2 [161]. The treatment in HSCT should not differ from recommended guidelines, although the data primarily stem from HIV/AIDS patients [1, 161, 162]. In all patients with cryptococcosis, a CSF opening pressure should be measured and a CSF specimen obtained for CrAg testing and culture. There is however limited evidence regarding the approach to patients who have recently completed treatment for cryptococcosis and about to undergo HSCT. From a small retrospective study, Zuniga et al. demonstrated that adequately treated cryptococcal disease was not a contraindication to transplantation [163]. For *C. gattii* infections a longer induction therapy is recommended due to risk of treatment failure [164]. In treatment of cryptococcal infections after HSCT, the possibility of IRIS with rapid reduction of immune suppression should be considered [165]. The treatment of other rare and emerging yeast infections is summarised in Table 37-2. The recommended antifungal dosing schedules are summarised in Table 37-3.

Invasive candidiasis general principles

1. Remove implicated central venous catheter in cases of candidemia
    a. If catheter or device CANNOT been removed consider echinocandin (biofilm activity)
2. Avoid delays in empirical antifungal therapy - Delays associated with increased mortality
3. Avoid using an echinocandin alone in patients with evidence of retinal candidiasis[a]
4. Renally excreted agents more effective in patients with Candida pyelonephritis, cystitis or fungal ball[b]
5. Strongly consider ophthalmic examination and echocardiography in all candidemia patients
6. Repeat blood cultures to ensure fungaemia clearance on therapy and determine duration of therapy

Considerations when choosing Empirical treatment for candidemia

1. Tailor empirical therapy to local epidemiology
2. Consider patient clinical status and prior antifungal exposure and colonisation:
    a. If patient haemodynamically stable & non-neutropenic, treatment choices include:
        i. Echinocandin (micafungin, caspofungin or anidulafungin)
        ii. Voriconazole
        iii. L-AMB
        iv. Fluconazole[c]
    b. If haemodynamically unstable OR neutropenic, or recent azole exposure or prophylaxis treatment choices include:
        i. Echinocandin (micafungin, caspofungin or anidulafungin) -
        ii. L-AMB
        iii. Voriconazole
    c. If recently colonised with Candida spp. consider its known susceptibility when employing empirical therapy for presumed invasive candidiasis.
    d. If recent echinocandin exposure or concerns with echinocandin resistance
        i. L-AMB
        ii. Voriconazole

Abbreviations: L-AMB, liposomal amphotericin B
[a]An azole such as fluconazole or voriconazole achieves levels in vitreous fluid but echinocandins do not
[b]Fluconazole & 5-flucyotsine are renally excreted whilst echinocandins are not
c 12mg/kg loading then 6mg/kg ongoing

FIGURE 37-2. Practice points and empirical therapy for invasive candidiasis and candidemia in HSCT. *Abbreviations*: *L-AMB* liposomal amphotericin B. [a]An azole such as fluconazole or voriconazole achieves levels in vitreous fluid but echinocandins do not. [b]Fluconazole & 5-flucyotsine are renally excreted whilst echinocandins are not. [c]12 mg/kg loading then 6 mg/kg ongoing.

TABLE 37-3. Treatment doses for commonly used antifungals in invasive candidiasis

Agent	Dose & frequency	Route
Fluconazole[a]	Loading—12 mg/kg OR 800 mg daily (single dose) Maintenance—400 mg OR 6 mg/kg daily	IV or oral
5-Flucytosine[a,b]	Loading—Nil Maintenance—25 mg/kg four-times-daily	IV or oral
Liposomal amphotericin	Loading—Nil Maintenance—3–5 mg/kg daily	IV
Voriconazole	Loading—6 mg/kg twice-daily for 2 doses Maintenance—4 mg/kg twice daily	IV or oral
Caspofungin	Loading—70 mg daily (single dose) Maintenance—50 mg daily	IV
Micafungin	Loading—Nil Maintenance—100 mg daily	IV
Anidulafungin	Loading—200 mg daily (single dose) Maintenance—100 mg daily	IV

[a]Require dose adjustment in renal impairment.
[b]Suggest performing trough levels to achieve clinical efficacy (>25 mg/L) and peak levels to avoid toxicity (<100 mg/L).

Yeast Infections After Solid Organ Transplantation

Todd P. McCarty and Peter G. Pappas

38.1 Candida

38.1.1 Epidemiology

Candida is a genus of yeast found in abundance worldwide. There is a wide variety of species found throughout the environment, however only about 15 of these are commonly pathogenic in humans. In addition to causing disease, the yeast can be found throughout the body as a part of the normal human microbial environment.

The Transplant-Associated Infection Surveillance Network (TRANSNET) study reported in 2010 that *Candida* comprised more than half of all documented invasive fungal infections in SOT recipients [1]. *Candida albicans* was the predominant species, however was the etiologic pathogen in approximately 50% of *Candida* cases. *C. glabrata* comprised a quarter while the remaining cases were primarily caused by *C. parapsilosis*, *C. tropicalis,* and *C. krusei*. Polymicrobial infection occurred in almost 10%. The Prospective Antifungal Therapy (PATH) registry followed a broader group of patients and saw a similar distribution of species overall, however when looking at solely solid organ transplant recipients, observed *C. glabrata* to be the most common species at nearly 40% [2]. They also demonstrated similar findings of *Candida* being the most common cause of fungal infection in solid organ transplant (SOT) recipients [3]. A follow-up study from the PATH registry looking solely at non-albicans species observed *C. glabrata* to cause over 60% of non-albicans candidiaisis (Table 38-1) [4]. A similar population-based monitoring program, the SENTRY Antimicrobial Surveillance Program, demonstrated *C. albicans* as the most common with *C. glabrata* second, however at a lower frequency (less than 20%) compared to TRANSNET and PATH Alliance [5]. One key difference between the studies, however, is that while TRANSNET and PATH were confined to North America, SENTRY was a worldwide study. The SENTRY breakdown by region shows their North America rates by species to be similar to the other studies, with much lower rates of *C. glabrata* in the other parts of the world [6]. *C. parapsilosis* supplants *C. glabrata* as the second most common species in their Latin America isolates.

38.1.2 Pathogenesis

As the most common species, the majority of work looking at pathogenesis and virulence has focused on *C. albicans. C. albicans* has an ability to exist along a spectrum from budding yeast to a walled hyphal structure [7]. One primary mode of virulence is the ability of the yeast to adhere to surfaces, including human cells, and convert to the hyphal form for the purposes of invading tissue [7]. Indeed, altering genetics to prevent the transition from yeast to hyphal phase has been shown to decrease pathogenicity [8]. The ability to adhere to surfaces is also an important contributor to human disease with the ability to form biofilms on prosthetic surfaces, including a concurrent upregulation of resistance mechanisms [9]. The adherence of fungal cells to a surface and formation of a biofilm prompt the development of "persister cells" that are highly resistant to antifungals [10].

38.1.3 Clinical Manifestations

38.1.3.1 Superficial Infections

As SOT recipients have their immune system influenced by pharmacologic immunosuppression, in particular glucocorticosteroids, *Candida* is presented with the opportunity to transform from commensal to pathogen. The spectrum of superficial disease ranges from cutaneous to mucous membrane and can occur in a variety of sites. Additional co-morbid conditions can contribute to the development of oropharyngeal thrush or vaginitis, such as concurrent antibiotic use (e.g., prophylaxis) and diabetes. Oropharyngeal thrush can progress to a more invasive form of mucosal disease, specifically,

P. Ljungman et al. (eds.), *Transplant Infections*, DOI 10.1007/978-3-319-28797-3_38

Table 38-1. Species distribution in candidemia among patients with solid organ transplants

	TRANSNET	PATH alliance
Species	*N*=264	*N*=292
C. albicans	131 (50%)	97 (33%)
C. glabrata	78 (30%)	112 (38%)
C. parapsilosis	23 (9%)	33 (11%)
C. tropicalis	12 (5%)	16 (5%)
C. krusei	14 (5%)	8 (3%)

Candida esophagitis. A more severe infection such as this must be dealt with promptly as potential complications ranging from stricture to perforation and death have been reported [11, 12].

38.1.3.2 Candidemia

Candidemia is the most common manifestation of invasive candidiasis amongst transplant recipients based on data from the TRANSNET cohort [1, 13]. The following risk factors are well understood to place patients at risk for invasive candidiasis: neutropenia, chemotherapy, colonization with *Candida*, broad-spectrum antibiotics, central venous catheter, hemodialysis or renal failure, critical illness, parenteral nutrition, mechanical ventilation, surgery, and advanced age [14]. It is not uncommon for the SOT recipient to meet one or more of these factors.

Liver transplant recipients are at particularly increased risk of candidemia with a variety of potential factors taking into account pre- and post-transplant variables. Using a focused algorithm of creatinine greater than 3 mg/dL, transplant operative time greater than or equal to 11 h, retransplantation, receipt of more than 40 units of blood products, or early fungal colonization, the presence of two or more factors identified a group of patients in whom 67% developed an invasive fungal infection with *Candida* being the most common genus [15]. Since the establishment of the Model for End-stage Liver Disease (MELD), this has now been evaluated for its contribution to predicting infectious complications [16, 17]. In multivariate analysis including other known risk factors for invasive fungal infections (IFIs), an elevated MELD score has been shown to have increased odds for developing all types of IFIs including invasive candidiasis and candidemia [17].

38.1.3.3 Urinary Tract Infection

Candida is an uncommon pathogen in the urinary tract; however, it is a frequent colonizer in certain patients. Patients with urinary catheters, diabetes, on broad-spectrum antibiotics, or prolonged hospitalization are all prone to *Candida* isolation from urine culture specimens. Renal transplant recipients, in particular, pose a dilemma over what to do with positive culture results in the setting of manipulation of the urinary tract and possibly the placement of a ureteral stent. Prosthetic materials are one of the situations where *Candida* can evolve from colonizer to pathogen. Studies to determine the true incidence of candiduria in renal transplant recipients are inconclusive, however it probably approximates 10%, not dissimilar to the hospitalized population as a whole [18, 19]. These studies have failed to show a substantial benefit to treating a positive *Candida* urine culture in the absence of symptomatic probable or proven disease. Infection can be severe with pyelonephritis having been reported [20, 21].

38.1.3.4 Intra-Abdominal

Candida has long been known to be a colonizer of the gastrointestinal tract, and therefore controversy has persisted over whether its presence in peritoneal culture represents colonization versus invasive infection [22]. In particular, complicated nosocomial peritonitis appears to be an instance of true infection [23]. Liver, small bowel, and pancreas transplant recipients can be of increased risk and, if certain criteria are met, may warrant fluconazole prophylaxis to prevent invasive candidiasis. This will be discussed in more detail below.

38.1.3.5 Pulmonary

Candida as a cause of primary pneumonia is exceptionally rare. While pulmonary disease does occur, it is generally in the form of hematogenous spread from other sources. This generally appears radiographically as septic emboli. *Candida* frequently occurs as a colonizer either of the respiratory tract or, in the mechanically ventilated, the endotracheal tube given the organism's propensity to adhere to surfaces. Studies have failed to find an association between microbiologic growth of *Candida* from bronchoscopic specimens and an impact mortality or other outcomes [24, 25]. An exception to this statement is limited to anastomotic tracheobronchitis in lung transplant recipients. This is a well-described entity and can be caused by a wide variety of organisms, including *Candida* [26]. A single center study looking at the causes of tracheobronchitis in 272 heart–lung or lung recipients found 15 anastomotic infections, of which *Candida* was the most common pathogen, having been diagnosed in eight of the patients [27].

38.1.3.6 Ocular

Involvement of the eye is an uncommon but well-recognized complication of disseminated invasive candidiasis. Clinical manifestations range from chorioretinitis to full-blown endophthalmitis. Rates as high as 26% for ocular spread associated with candidemia have been reported. Historically *C. albicans* is more likely than other species to cause ocular involvement based on its innate invasive potential, while *C. parapsilosis* is the least likely compared to other species [28, 29]. There are no prospective studies looking at rates of ocu-

lar candidiasis in solid organ transplant recipients; however, it has been reported in the SOT population [26, 30, 31]. It does appear to be an uncommon complication, as one series reporting all ocular infections from a cohort of heart transplant recipients had no cases caused by *Candida* [32].

38.1.3.7 Donor-Derived

Presence of *Candida* in the gastrointestinal tract raises the potential for transmission in the process of the intra-peritoneal organs [33]. Additionally, the presence of candidemia prior to or at the time of death of the donor would raise the potential for transmission. While not strictly a donor-derived complication, there are numerous case reports of *Candida* contaminating the preservation fluid in transport from donor to recipient [34–39]. A study of graft-site candidiasis deriving from organ recovery in renal transplant recipients found renal arteritis to be the most common complication [40].

38.1.4 Diagnosis

Culture is currently the gold standard of diagnosis. While it is difficult to interpret a culture positive for *Candida* species from a non-sterile site, sterile cultures are indicative of an invasive process and should be treated with the utmost urgency. Given the benefits of early and effective treatment and the variation of anti-fungal sensitivities based on species, efforts are underway to develop more reliable means of rapid diagnosis and species identification.

Matrix-Assisted Laser Desorption/Ionization Time-of-Flight (MALDI-TOF) is one means of rapid identification that can lead to faster adjustment of antifungal treatment. MALDI-TOF has been shown to identify *Candida* species with accuracy equal to or greater than conventional methods [41]. Additionally, the technology has been shown to drastically decrease time to identification, in particular for the non-albicans *Candida* species [42]. To run the assay, a pure culture specimen must undergo preparation specific to the brand of MALDI-TOF in use. While this earlier identification can be beneficial in making empiric adjustments in treatment, it does not impact the time to diagnosis of invasive candidiasis since it still requires a positive culture.

Peptide nucleic acid fluorescent in situ hybridization (PNA-FISH) can be performed directly from a positive blood culture bottle prior to being plated for isolation of pure colonies with a very high level of sensitivity and specificity for *C. albicans* [43]. Commercially available multi-species kits now exist but have some limitations in their ability to distinguish completely to the species level with pairing of species to a single color fluorescence [44]. The test can be run directly from positive blood culture bottles or from subcultured colonies. While this has the potential to provide some identification data even faster than MALDI-TOF, it is still reliant on *Candida* growing in culture.

Table 38-2. Performance of non-culture based diagnostic assays for candidemia and/or invasive candidiaisis

Assay	Sensitivity	Specificity
(1 → 3)-β-D-glucan	57–97%	44–93%
PCR	73–93%	90–96%
T2Candida®	88–94%	98.9–99.9%

The most recent technology to become available is the T2Candida® assay. Based on magnetic resonance technology, the assay is able to identify to a paired species level (*C. albicans/C. tropicalis*, *C. krusei/C. glabrata*, and *C. parapsilosis*) from a whole blood specimen without waiting for a positive culture [45]. The technology can identify a positive signal within hours of the obtaining the whole blood specimen, thus having the potential to identify candidemia much sooner and lead to earlier initiation of appropriate therapy. Additionally it has an excellent negative predictive value for candidemia which could be used to de-escalate or stop unnecessary anti-fungal therapy very quickly (Table 38-2).

Non-fungemic invasive candidiasis remains a challenge to diagnose [46]. An assay to detect (1 → 3)-β-D-glucan (BDG), a component of the *Candida* cell wall, in serum or plasma has been shown in a meta-analysis to have a sensitivity of 76.8% and specificity of 85.3% for proven or probable invasive fungal infections from any organism [47]. Studies restricted to candidiasis have sensitivities ranging from 57% to 97% while the specificity was 44% to 93% [48]. Part of the variation in specificity is due to the presence of the protein in the cell wall of most fungi, not solely *Candida*. Thus, the assay is less specific than some other assays and is considered to be "pan-fungal" by many experts. One study restricted to liver transplant recipients showed improved performance with a sensitivity of 83% and specificity of 89% [49]. Conversely, the test performs poorly in lung transplant recipients with one study having a sensitivity of 71 and 59%, noting mold colonization of the lungs and hemodialysis raised levels of BDG [50]. A meta-analysis of polymerase chain reaction (PCR) for the diagnosis of candidiasis has shown good performance characteristics in the blood culture negative population with sensitivity ranging from 73% for culture negative candidiasis to 93% for proven/probable candidiasis [51]. Specificity for both groups was over 90%.

38.1.5 Treatment

Multiple guidelines exist to assist the clinician with ensuring appropriate treatment across the spectrum of invasive candidiasis [52–55]. Overall, treatment of the solid organ transplant is the same as treatment for the non-transplant patient. As such, the focus here will be on selected types of infection.

Candidemia initial regimen should be based on both severity of illness and the potential for a resistant isolate, in particular *C. glabrata* and *C. krusei*, but most experts agree that

echinocandins are preferred as initial therapy for most patients with candidemia [55]. For empiric therapy, echinocandins are generally preferred in the critically ill, those with a recent history of or present fluconazole use, or colonization with a resistant isolate. The TRANSNET study, performed between 2000 and 2006, documented an overall fluconazole resistance rate at that time of 16%, with *C. glabrata* and *C. krusei* comprising 30% of all isolates [13]. Lacking those risk factors, fluconazole is a reasonable option for empiric therapy in the non-acutely ill person. Once the species and susceptibilities are determined, targeted therapy can be chosen. Treatment should continue for at least 14 days from the first negative culture with an attempt to influence source control, in particular the removal of intravascular catheters [55].

For candiduria, the decision to treat should be on the basis of symptoms and/or findings consistent with a urinary tract infection. If the patient is asymptomatic but neutropenic or undergoing a urologic procedure, then treatment is warranted. The kidney(s) should be assessed for the presence of a fungal ball and surgical removal of the obstruction pursued if found. Echinocandins are poorly excreted into the urine, therefore fluconazole is the treatment of choice for most *Candida* urinary tract infections. If a fluconazole-resistant isolate is isolated, then a lipid amphotericin-B preparation can be used, with or without flucytosine [55].

Ocular candidiasis is another circumstance where echinocandins fall short in their ability to penetrate a particular tissue. Again, lipid amphotericin-B products and fluconazole are the agents of choice. Consultation with ophthalmology should be obtained early to assess the need for aggressive surgical intervention with vitrectomy [55].

Treatment of end-organ infection, such as pulmonary, intra-peritoneal, or cardiovascular candidiasis should be driven by species identification and susceptibilities. Duration of therapy will need to be tailored to the individual patient on the basis of ability to drain the infected material and reverse the source of contamination.

There is emerging evidence of the development of resistance to echinocandins, in particular in *C. glabrata. C. parapsilosis* has been noted to have, on average, higher minimum inhibitory concentrations against the echinocandins, but there is little correlation to these values and clinical response to therapy with echinocandins [56–60]. Rates of resistance appear to vary significantly across centers. The presence of azole and/or echinocandin resistance should be explored among patients failing to respond as expected to either of these therapies.

The other aspect of treatment is monitoring for drug–drug interactions (DDIs). While the echinocandins have minimal DDIs, fluconazole and other azole agents are well documented to have many potential DDIs, and care should be taken to adjust immunosuppressant dosing, especially with use of the calcineurin inhibitors, cyclosporine and tacrolimus, and the mTOR inhibitors, everlimus and sirolimus [61, 62].

38.1.6 Prophylaxis

There is a subset of intra-abdominal transplant patients who are high risk for invasive candidiasis. Criteria to determine high-risk is best established in liver transplant recipients; defined as *Candida* colonization, 40 or more units of cellular blood products transfused, retransplantation, choledochojejunostomy, and prolonged operation, having two or more of these factors warrants prophylaxis [54]. Additionally, a MELD score >30 has been shown to increase the odds of a post-transplant infection of any type [63]. There were few documented fungal infections in this study; however, the broader use of MELD has overlapped with the growing use of anti-fungal prophylaxis. This confounds the assessment of the value of MELD as a predictor of invasive fungal infection (IFI), but nevertheless, a high MELD score should be considered a risk factor for IFI and taken into consideration when deciding to give anti-fungal prophylaxis in the early post-transplant period.

A meta-analysis of antifungal prophylaxis of any sort demonstrated a decrease in all types of candidiasis and improvement of mortality attributable to fungal infections, but without an impact on overall mortality [64]. Fluconazole has been shown to be superior to both nystatin and placebo in preventing infections caused by *Candida* and is well tolerated [65, 66]. Caspofungin has demonstrated efficacy but has not been studied in a randomized, comparative trial [67]. Anidulafungin has been shown to be equally effective for antifungal prophylaxis when compared to fluconazole in a randomized, controlled trial of 200 liver transplant recipients that met the criteria for needing prophylaxis [68]. A 2008 survey of liver transplant centers in North America showed three quarters of programs used targeted prophylaxis among high-risk recipients, and fluconazole was the most commonly used agent [69]. Prophylaxis should be discontinued no more than 4 weeks after transplant unless there are ongoing concerns for invasive candidiasis.

There are no clinical trials to assess the role of antifungal prophylaxis in small bowel transplants; however given its presence as a colonizer in the gastrointestinal tract and high rate of infection, fluconazole is commonly used for this purpose [70]. Pancreatic transplantation also carries a high rate of fungal infection with one study showing the benefit of fluconazole prophylaxis on decreased candidiasis and infection free survival [71].

38.2 Cryptococcus

38.2.1 Epidemiology

Cryptococcus is an encapsulated budding yeast capable of causing a disease with a variety of manifestations. *Cryptococcus neoformans* has long been the predominant disease causing species, but the emergence of *Cryptococcus gattii* throughout the world is becoming a formidable challenge.

Originally recognized in Australia and Papua New Guinea, *C. gattii* has now been reported across the globe [72].

Comprising 8% of all IFIs in the TRANSNET dataset, the 146 cases of cryptococcosis were the third most common fungal pathogen in solid organ transplant (SOT) recipients [1]. The incidence of cryptococcosis in that study was approximately 0.2% of all solid organ transplant patients. Literature reviews of reported cases have shown a much higher incidence in SOT recipients, ranging from 1.56 to 2.8, but these represent cumulative estimates, whereas the TRANSNET data are based on calculated annual incidence [73, 74]. Cryptococcosis is rare in stem cell transplant recipients. The TRANSNET study identified only 6 cases among 16,200 enrolled stem cell transplant recipients [75]. While infection can occur any time after transplant, multiple studies show a median time to infection of 19–21 months post-transplantation [1, 74, 76]. Infection in the first month raises the possibility of pre-existing infection in the recipient or donor-derived infection [77, 78].

38.2.2 Pathogenesis

Primary infection in humans occurs through inhalation of infectious particles, though uncertainty remains over just what type of particle begins the cascade that ultimately leads to active disease. Current data suggests humans are exposed at a high rate at a young age with the organism remaining dormant for a prolonged period of time before later causing disease [79–81]. This is not uniform worldwide, however, as a study of exposure rates in children from the Philippines and two regions of New York demonstrated high variability in serologic positivity among children from the Bronx, NY, Dutchess County, NY and the Philippines [82]. A study to determine pre-transplant exposure to *Cryptococcus* in SOT recipients who were diagnosed with disease exhibited evidence of antibody responses in 52% [83]. That group also developed cryptococcosis much earlier in the post-transplant period, 5.6 months from the time of transplant rather than 40.6 months in the group that did not have evidence of pre-transplant antibodies against *Cryptococcus*. These data suggest that most cases of post-transplantation cryptococcosis are due to a reactivation event.

The polysaccharide capsule plays a key role in its ability to cause disease and evade the host immune system. It has been shown to inhibit phagocytosis and reduce the production and effectiveness of the innate immune response, including cytokines and the complement pathway [84]. Once phagocytosed and intracellular, the capsule enhances the ability of the yeast to survive oxidative stress [85]. Inoculation of a mouse with a capsule deficient strain of *Cryptococcus* leads to an increased inflammatory response and minimal production of invasive disease compared to a capsular *Cryptococcus* strain [86]. Further evidence of the importance of the capsule in the virulence of *C. neoformans* is found in the animal model. When one deletes the *CAP59* gene responsible for capsule formation, this causes a loss of virulence in a mouse model of cryptococcal meningitis; the transformation of the avirulent strain with a plasmid containing the *CAP59* gene restores its virulence in this model [87].

38.2.3 Clinical Manifestations

Cryptococcus causes a variety of clinical syndromes. In the solid organ transplant population, there is a higher frequency of isolated pulmonary disease when compared to the human immunodeficiency virus (HIV) population [88]. Disseminated disease remains a frequent occurrence with the bloodstream, central nervous system (CNS), skin and soft tissue, and urinary tract as potential sites of disease.

38.2.3.1 Pulmonary

As the primary site of most infections, the lungs are the most common site of disease, and patients can present either with primary or reactivation disease. Pulmonary disease in the SOT population can range from an asymptomatic nodular infiltrate to lobar consolidation, a mass-like infiltrate, cavitary disease, or diffuse nodular infiltrates [89, 90]. Studies of cryptococcosis in SOT recipients have found that 25–39% of cases will have disease limited to the lungs [1, 88, 89]. Higher doses of steroids have been associated with a higher rate of symptomatic and disseminated diseases [89, 91]. Duration of symptoms prior to diagnosis spans a wide range, with one study of solid organ transplant recipients reporting the presence of symptoms from 1 to 97 days [92]. Severity of illness can range from asymptomatic disease to fulminant respiratory failure [93]. Compared to HIV patients, SOT recipients have a higher rate of pulmonary disease with less CNS involvement [88]. However, the diagnosis of pulmonary disease should prompt a search for infection elsewhere, in particular a lumbar puncture to assess for involvement of the CNS [94].

38.2.3.2 Central Nervous System

As noted above, central nervous system involvement occurs at a lower frequency in SOT patients compared to HIV patients, but it remains the most common site of extrapulmonary involvement among SOT patients with cryptococcosis, occurring in 44–62% of these patients [1, 88, 95, 96]. While presenting symptoms vary, asymptomatic meningeal disease likely occurs rarely, patients can present acutely with symptoms occurring for only 2 days to several weeks [97]. Abnormal mental status, fungemia, late-onset disease (defined as more than 24 months post-transplant), and a serum cryptococcal antigen titer >1:64 have been found to be associated with an increased risk of CNS involvement [95].

Focal parenchymal lesions with or without evidence of meningitis may occur in SOT recipients [98]. Focal parenchymal lesions without meningitis are an uncommon manifestation of disease in this population. In one study, 10% of patients had focal parenchymal lesions while 13% had meningeal enhancement. Additionally, the presence of a focal meningeal lesion was associated with higher CSF cryptococcal antigen titers compared to parenchymal lesions [98]. Finally, among those with CNS infections, the presence of abnormal neuroimaging findings at diagnosis was more likely to meet the diagnostic criteria for immune reconstitution inflammatory syndrome later in their treatment course [99].

38.2.3.3 Bloodstream Infection

Rates of blood culture positivity indicating disseminated disease vary, in part due to a lack of consistent collection of the blood cultures. One study of 178 cases had 38% of blood cultures grow *Cryptococcus*, however cultures were only collected on 39 patients [74]. Other studies have shown lower rates of bloodstream infection, with the Cryptococcal Collaborative Transplant Study Group showing 21% overall but significantly more common in CNS disease with 36% of patients who were fungemic [76, 98]. Positive blood cultures were also associated with increased 90-day mortality [76]. A separate single-center study of cryptococcal meningitis in SOT recipients demonstrated similar observations with 39% of patients with CNS disease having positive blood cultures [97].

38.2.3.4 Skin and Soft Tissue

Cutaneous and subcutaneous infection is the third most common form of cryptococcosis in the SOT population, comprising 10–18% of cases [88, 100]. Appearance varies greatly, from cellulitis to abscess and ulcer formation to deep nodular and panniculitis lesions having been reported in a variety of anatomic locations [100]. Clues that should make the clinician suspect cryptococcosis rather than a bacterial etiology should include the following: bilateral or disseminated lesions, a nodular component to palpation or appearance, atypical anatomic location, tissue necrosis, and failure to respond to conventional anti-bacterial agents.

38.2.3.5 Urinary Tract

The prostate and urinary tract are known reservoirs for fungal infections, however reports of cryptococcal infection there in SOT patients are rare. Involvement of the prostate and the kidney have both been reported [101, 102].

38.2.4 Diagnosis

Multiple reliable means of establishing a diagnosis of cryptococcosis exist: cryptococcal antigen assay of bodily fluid (primarily serum and cerebral spinal fluid), routine and fungal culture, and characteristic findings on histopathology and/or cytology of pathologic samples.

38.2.4.1 Cryptococcal Antigen

A variety of types of antigen assays to detect the capsular polysaccharide antigen exist. The most experience has been developed with latex agglutination and enzyme immunoassays, although more recently a lateral flow assay with potential utility as a point-of-care test has been developed [103–105]. All methods display a high degree of sensitivity and specificity, approaching 100% depending on the sample type and clinical syndrome. One group in whom the assay performs less well is the lung transplant population, where the serum assay may have decreased sensitivity [89, 106].

38.2.4.2 Culture

Cryptococcus species do not require specialized media for reliable culture, growing readily on standard bacterial media such as blood agar as well as standard fungal media such as Sabouraud's dextrose agar [107]. Certain types of media can be used to increase the sensitivity of culture, with brain heart infusion agar potentially improving the yield [108]. The organism can be cultured from tissue or bodily fluid collected at the site of disease, whether it be a tissue biopsy, blood culture, pulmonary specimen, cerebral spine fluid, or urine. The time to positive culture result for *Cryptococcus* tends to be slower than for bacterial or other yeast organisms, usually 3–5 days before growth is evident [107].

38.2.4.3 Histopathology

Microscopic examination of specimens, either of tissue or fluid, can be an important addition to prompt diagnosis and determining sites of involvement. Several stains can be helpful to distinguish *Cryptococcus* from other fungal infections. India ink has classically been used to highlight the capsule of these yeasts in cerebrospinal fluid. The potential difficulty with this simple test is in successfully identifying the yeast from CSF lymphocytes [107]. With increasing use of easier to perform and interpret antigen tests, however, the India ink is being used less frequently. Gomori methanamine silver (GMS) stain is positive but non-specific for most fungal organisms, and mucicarmine stain of tissue is useful in highlighting the capsule and distinguishing *Cryptococcus* from *Histoplasma, Blastomyces*, and *Candida*.

38.2.4.4 Species Identification

With the increasing recognition of *C. gattii* as a cause of human disease and the comparative difficulties in treating this organism, attention must also be placed on proper species identification with the diagnosis of cryptococcosis. The two main species can be differentiated when grown on agar that is supplemented with L-canavanine, glycine, and

bromthymol blue (CGB agar). *C. gattii* isolates turning the agar blue, while the agar remains yellow with *C. neoformans* isolates [109]. Genetic typing to determine *C. neoformans* or *C. gattii* is generally used with more specialized labs being able to determine the specific subtype of *C. gattii* for epidemiologic purposes and potentially tracing acquisition to a particular exposure [108].

38.2.5 Management

The management of cryptococcosis in SOT recipients is largely based on more recent data generated from the HIV epidemic which has been extrapolated to the SOT population, and abundant retrospective studies specific to post-organ transplantation. Once the diagnosis of cryptococcosis is established, the extent of the infection should be established, in particular to discern whether there is CNS involvement. A lumbar puncture to measure opening pressure and collect cerebrospinal fluid for microbiologic diagnosis is essential in all patients with proven or suspected cryptococcosis. Elevated opening pressure is frequent but not universal. As discussed above, cerebrospinal fluid can be tested for the presence of cryptococcal antigen, stained and microscopically examined for the presence of yeast, and cultured. The presence or absence of involvement in the CNS guides the type and duration of antifungal therapy.

Early studies in HIV patients suggested that amphotericin-B and fluconazole as monotherapy were similar in treating cryptococcal meningitis, however later studies have shown that the combination of amphotericin-B with flucytosine shortens time to sterilization of the CSF and improves outcomes when compared to other interventions [110–112]. Additionally, a prospective study in solid organ transplant recipients noted improved mortality in transplant recipients with cryptococcal meningitis when a lipid formulation of amphotericin was used rather than amphotericin-B deoxycholate [113]. Disseminated disease and fungemic patients also benefit from initial therapy with amphotericin-B, however no specific trials have investigated this. Treatment of isolated, extra-neural disease can be monotherapy with fluconazole, depending on disease severity, with an avoidance of the potential nephrotoxic consequences of amphotericin-B. Similarly, duration of therapy depends on disease location and severity. When amphotericin-B products are being used for induction of disseminated, CNS, or severe disease it should be in conjunction with flucytosine for a minimum of 2 weeks if this regimen can be tolerated [94, 114]. This could potentially be extended if the patient is slow to respond and still with significant symptoms or evidence of disease at 2 weeks. If amphotericin is given without flucytosine, induction should continue for at least 4 weeks [94, 114]. Following the completion of induction therapy, the patient can be transitioned to a fluconazole consolidation phase for 8–10 weeks dosed at 6–12 mg/kg (generally 400–800 mg) daily though dose adjusted, if needed, for renal function [94, 114]. Finally, therapy can be completed with a further 6–12 months of fluconazole maintenance at a lower dose of 200–400 mg daily. For mild to moderate, localized, extra-neural disease that does not require amphotericin-B induction, fluconazole should be given for 6–12 months at 400 mg daily [94, 114].

Other potential options for treatment that have been studied in some fashion are the extended-spectrum triazoles including voriconazole, posaconazole, and isavuconazole, however there are insufficient clinical data to support their use in this setting.

Calcineurin pathways exist in *Cryptococcus* as a means for governing growth and are key in allowing the fungus to grow at higher temperatures, such as that of the human body [115]. Blocking this pathway via the addition of the calcineurin-inhibitors cyclosporine and tacrolimus has been shown to eliminate the ability of *Cryptococcus* to grow at higher temperatures [116]. Indeed, these calcineurin-inhibitors have been shown to act in a synergistic manner with anti-fungal agents against *Cryptococcus* isolates obtained from clinical cases [117]. Additionally, SOT patients with a calcineurin-inhibitor as part of their immunosuppressive regimen appear to have a lower risk of mortality and possibly less CNS involvement in the setting of cryptococcosis compared to those not receiving one of those agents [76].

Another aspect of treatment that should be considered is the potential for drug–drug interactions, in particular with the azole agents. Calcineurin inhibitors require their doses to be decreased when co-administered with azoles [62]. Similarly, mTOR inhibitors also require dose decreases however in an even greater magnitude that can completely restrict their concurrent use [61]. The presence of a an opportunistic infection such as cryptococcosis generally leads to a reduction of the overall immunosuppression as allowed and these interactions require careful monitoring to ensure that goal is met safely.

The European Society for Clinical Microbiology and Infectious Diseases, the Infectious Diseases Society of America, and the American Society for Transplantation have developed recommendations to guide treatment each with specific guidance for SOT patients. These recommendations vary based on the extent of the infection [52, 94, 114].

38.2.6 Complications

One of the hallmarks of CNS cryptococcosis is elevated intracranial pressure. This problem is generally relieved by drainage of fluid via lumbar puncture. If increased pressure persists in spite of drainage, this can lead to a need for more continuous diversion of cerebrospinal fluid. In particular, ventriculoperitoneal shunting has been shown to be safe and effective in managing this issue [118, 119]. A trial to assess the potential of acetazolamide in HIV patients with CNS cryptococcosis to reduce intracranial pressure was terminated early due to serious adverse events and a lack of benefit [120]. There are no studies designed to examine a benefit to steroids for the con-

trol of increased intracranial pressure in the setting of cryptococcal meningitis. One HIV treatment trial did track high dose steroid usage and showed worse mortality and clinical response in those that received steroids compared to those that did not [121]. The Infectious Diseases Society of America guidelines for *Cryptococcus* has specifically recommend against the use of steroids in this setting [114].

With reductions in total immunosuppression in the face of an opportunistic infection, the potential exists to develop immune reconstitution inflammatory syndrome (IRIS). This has been reported in the SOT population [122, 123]. The occurrence of IRIS has been associated with an increased risk of allograft loss in renal transplant recipients [124]. A lack of inflammation in the CSF (fewer than 20 WBCs) at the time of diagnosis has been shown to be a risk factor for the development of IRIS in the HIV population [125]. In the SOT population, discontinuation of calcineurin inhibitors and CNS disease were associated with an increased risk of IRIS, however it did not appear to increase the risk of death [99]. There are no trials to assess potential benefit of steroids or other therapy for IRIS. Anecdotal evidence to support the use of steroids exists and guidelines suggest their use as a component of the treatment of severe IRIS with complications [94, 114, 122].

38.2.7 Mortality

Estimates of mortality at 90 days range from 14% to 21% amongst all SOT patients with cryptococcosis of any type [76, 88, 96]. The TRANSNET study found a 27% mortality at 1 year following infection [1]. Mortality rates appear similar when compared to HIV patients [88, 96].

38.2.8 Prophylaxis

While secondary prophylaxis following cryptococcosis can be considered, there have been no trials to assess for a benefit related to this. Relapse has been reported as rare when patients are appropriately treated [126]. There have been no trials to assess for the potential benefit of primarily prophylaxis in the SOT population.

38.3 Other Yeasts

38.3.1 Trichosporon

Trichosporon is a basidiomycetous yeast found worldwide and in the same family as *Cryptococcus* [127]. The most common species in clinical disease are *T. asahii*, *T. mucoides*, and *T. asteroides* [127]. It has generally been associated with hematologic malignancies, but is reported in a variety of forms in solid organ transplant recipients [128, 129]. Similar to other yeasts as well as bacteria, it can form biofilms on prosthetic surfaces and broadly increase its resistance to anti-fungal agents [130]. The most common forms of invasive disease are fungemia, urinary tract infections, peritonitis, and endocarditis [127]. *Trichosporon* is notable in particular for the poor treatment activity of the echinocandin class of anti-fungal agents [131]. This should be kept in mind in cases of breakthrough yeast infection while patients are being treated with an echinocandin [132]. The activity of the triazoles and amphotericin-B vary according to species, indicating a need to ensure full identification of the organism to allow for optimal treatment [133].

38.3.2 Rhodotorula

Rhodotorula is also a basidiomycetous yeast with a predominance for Asia and the regions of the Pacific [134]. The yeast produces carotenoid pigments and colonies can appear salmon to pink depending on the species isolated [135]. The most common species causing pathogenic disease in humans are *R. mucilaginosa* and *R. glutinis* [136, 137]. The most common form of invasive disease is fungemia, however reports of endocarditis, endophthalmitis, and peritonitis also exist [134, 136, 138]. Reports indicate an association with hematologic malignancies and the presence of a central venous catheter, however it has also been reported in SOT recipients [137–139]. The triazoles have generally poor in vitro activity versus *Rhodotorula* species, but amphotericin-B MICs are generally acceptable [140]. *Rhodotorula* species demonstrate in vitro resistance to the echinocandins, and these agents should be avoided to treat these organisms [138].

38.4 Other Considerations

Dimorphic fungi can appear as yeast forms in tissue specimens and blood cultures. This includes *Histoplasma*, *Blastomyces*, *Coccidioides*, and *Paracoccidioides* as the most common agents. Similarly, patients with fungemia due to one of these organisms are usually initially identified simply as "yeasts," and very often patients are begun on an echinocandin therapy based on an assumption that the organism is a *Candida* species. Echinocandins have little in vitro activity versus the endemic mycoses and *Cryptococcus* species, and should be avoided in these circumstances. Rather, in the proper clinical setting, these organisms should be suspected and thoroughly evaluated through a thoughtful diagnostic work-up and treatment adjusted appropriately. Another potential confounding organism is *Fusarium*, which in spite of being a mold may initially appear as a yeast on blood culture broth, leading to the mistaken impression of a diagnosis of candidemia [141].

Mold Infections After Hematopoietic Stem Cell Transplantation

Kieren A. Marr

39.1 Microbiology and Pathogenesis: An Overview

Pathogenic fungi are typically classified into yeasts, molds, and dimorphics, based on the cellular morphology of the organism that exists outside and inside the body. The most common pathogenic yeasts are within the Basidiomycetes phylum, and these include *Candida* species and *Cryptococcus* species. These organisms exist as unicellular forms in the host and the environment. Some pathogenic fungi switch between a multicellular hyphal and unicellular yeast form, which is a process called dimorphic switching. This switch allows the organism to adapt to different stresses in each environment, with the in vivo switch to yeast typically associated with pathogenicity. This group of phylogenetically diverse organisms within the Ascomycetes phylum includes *Talaromyces marneffei* (previously called *Penicillium marneffei*), *Blastomyces dermatitidis*, *Coccidioides* species (*C. immitis* and *C. posadasii*), *Histoplasma capsulatum*, *Paracoccidioides* species (*P. brasiliensis* and *P. lutzii*), and *Sporothrix schenckii*. They typically cause disease in both immune-competent and immune-compromised hosts, especially in people who have defects in Th1 cellular immunity, which allows latent organisms to escape host control.

This chapter focuses exclusively on infections caused by molds, which are fungi that exist as multicellular hyphal (or filamentous) organisms in both the environment and the host. The most common pathogenic molds fall within the Ascomycetes phylum, with prominent examples including *Aspergillus* species, *Fusarium* species, and *Scedosporium* species. Organisms that are classified within the Mucormycetes phylum have also become more common causes of disease in immune-compromised people; this includes organisms within the genus *Rhizopus*, *Mucor*, *Rhizomucor*, *Absidia*, and *Cunninghamella*. This chapter will focus discussion on three large groups of infections: (1) Aspergillosis, with the term encompassing infections caused by numerous *Aspergillus* species; (2) Mucormycosis, with the term encompassing infections caused by any of the organisms within Mucormycetes; and (3) Other molds, with a focus on the most common "other" infections caused by *Fusarium* and *Scedosporium* species.

This chapter is not meant to serve as microbiology reference, but some understanding of the organisms is necessary in order to have a functional grasp of their diseases, diagnosis, and treatments. Understanding the microbiology of fungi has become complex, in part because identification of these organisms has evolved as scientists have discovered new ways to identify genetic relatedness. As a result, the morphologic identification of key organisms is now known to yield only a rudimentary classification schema. Genetic and multiphasic taxonomy have identified "new" species, or "cryptic" species within many common pathogens. Following the microbiologic classification of pathogenic fungi has become quite complex. For instance, we now know that there are >100 species within the *Fusarium* genus, sometimes with quite a lot of phenotypic variability even within clustered species complexes that are common medical pathogens [1, 2]. Similarly, many of the morphologically identified species within the genus *Aspergillus* are now known to encompass numerous genetically disparate species, some of which have important differences with regard to pathogenicity, growth environments, and susceptibilities to antifungals [3–7]. Clinicians should understand how their clinical microbiology laboratory identifies and reports organisms, as methods vary from conventional morphologic descriptions to DNA sequencing. In this chapter, species names can be assumed to encompass multiple cryptic species, except where clinically relevant differences warrant more discussion.

39.2 Pathogenicity and Clinical Diseases

Aspergillus fumigatus is the most common cause of human disease, and the best studied organism. This organism grows as a mold in the environment, with asexual production of

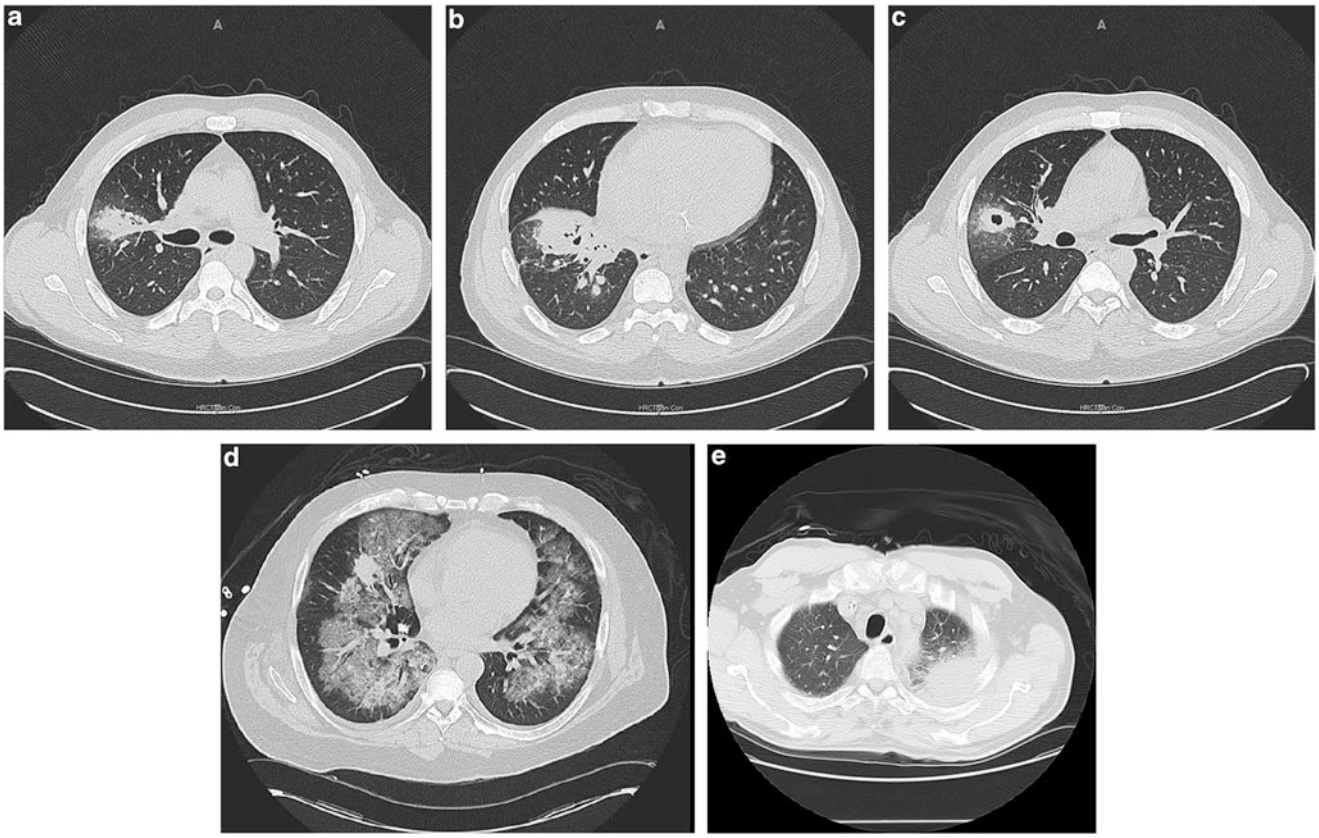

FIGURE 39-1. Radiographic presentations of pulmonary diseases caused by molds. Panels (**a**–**c**) demonstrate progression from a typical nodular infiltrate with halo sign to cavitation within a neutropenic patient during cellular recovery. Panel (**d**) shows a less typical presentation of progressive pulmonary disease in setting of aspergillosis post-engraftment in an allogeneic HSCT recipient. Panel (**e**) shows a bulky infiltrate adjacent to pleura caused by *Rhizopus* spp., which progressed with necrotic inflammation through chest wall.

tiny, hydrophobic conidia (spores) that serve as the primary infective cells into the respiratory tract. In the host, conidia are cleared from the airway, or germinate into filamentous cells, which can trigger destructive inflammatory responses, and/or invade into lung. When secondary immune defenses are deficient—as with neutropenia—these organisms can invade into the blood stream and travel to distant sites, such as skin, brain, and liver. Occasionally, these organisms cause only cutaneous disease, especially after local inoculation into necrotic tissue. More recently, increased awareness has been focused on the potential of *Aspergillus* species, like other molds (e.g., Mucormycetes) to cause local invasive disease in the gastrointestinal tract. This most frequently presents as a complication coincident with multi-organism neutropenic enterocolitis, as focal masses or lesions that cause bleeding, as a source of disseminated infection, or as hepatic abscesses after breach in gut integrity [8–12].

In general, molds are most frequently present with sinus or pulmonary disease. The classic pulmonary presentation is of pulmonary nodules that develop during neutropenia, with symptoms of fever, cough, or pleuritic pain. Radiography can show nodules with a corresponding "halo" that represents focal hemorrhage. These lesions typically increase in size during neutropenia, before ultimately becoming necrotic after neutrophil recovery, seen as a cavity on chest X-ray or CT scan. However, other presentations are more common in non-neutropenic hosts, with development of multifocal infiltrates, tree-in-bud nodules suggestive of tracheobronchial involvement, and even frank airway disease (Figure 39-1).

Other molds typically cause similar syndromes, with a propensity to cause invasive sinus or lung disease. However, there are subtle features that are characteristic of different types of molds. Mucormycetes are typically adept at living within necrotic environments, and pulmonary lesions can sometimes demonstrate a "reverse halo" sign, whereby an inner zone corresponding to tissue necrosis can appear early in the course of pulmonary disease. However, this has been noted with multiple pulmonary diseases other than mucormycoses [13–17]. In addition, these infections may present as large bulky lesions can that progress through tissue planes, boring through pleura, soft tissues, and bone (Figure 39-1).

Some of the other common molds, especially *Fusarium* and *Scedosporium* species, can replicate asexually directly from the filamentous cells in vivo. These molds more frequently

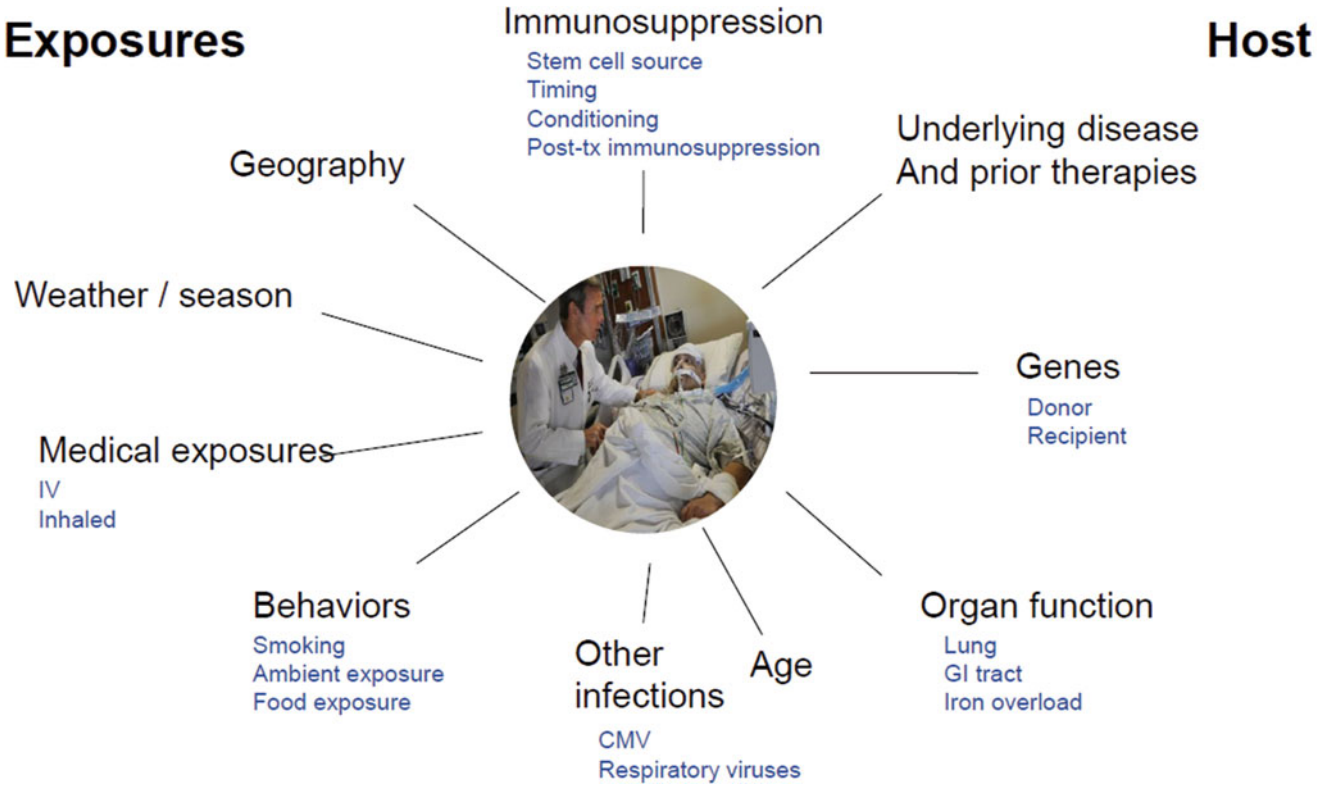

FIGURE 39-2. Schematic diagram of risks that influence probability of developing an invasive mold infection. Multiple variables influence exposure through respiratory and gastrointestinal routes, and host susceptibility to invasive infection [35, 102–108].

grow within the blood stream, and cause disease with higher fungal-burden. Clinically, they may be recognized by growth in blood cultures, and/or with disease that features multiple skin lesions, sometimes in different stages of development. As opposed to *Fusarium* and *Scedosporium*, *Aspergillus* species and Mucormycetes rarely grow from blood cultures, even with documented invasive disease.

39.3 Epidemiology of Invasive Mold Infections

Risks for invasive mold infections (IMI) are summarized schematically in Figure 39-2. Variables that affect exposure to fungi, through both respiratory and gastrointestinal routes, and host susceptibility to invasive disease shape individual susceptibility for these infections. In the sections below, epidemiology will be discussed within the hematopoietic stem cell transplant (HSCT) population specifically.

Invasive pulmonary aspergillosis (IPA) has been known to be a devastating complication of protracted neutropenia for many years. In the 1990s, attention was drawn to high rates of IPA occurring later after HSCT, with multiple single-center studies reporting incidence figures exceeding 10%, with high mortality rates (60–80%) [18, 19]. Today, changes in transplant types (e.g., stem cells and conditioning regimens), diagnostic monitoring, and prevention strategies have largely resulted in stabilization of rates of IPA, as well as improved outcomes after diagnosis [20–26]. Caution is advised in drawing conclusions from different cohort data sets, as these numbers are largely influenced by ascertainment bias given tremendous variability in diagnostic strategies and duration of follow-up across centers. However, one can estimate the incidence of IPA in the range of 5–12% in the highest risk allogeneic HSCT population, and outcomes have improved substantially over time [20–26].

As opposed to IPA, the incidence of infection caused by "other" molds, especially Mucormycetes, *Fusarium* species, and *Scedosporium* species, has increased in the last two decades [27–31]. This may be the result of numerous factors, including diagnostic or reporting bias, given an increased tendency to perform invasive procedures resulting in microbial diagnoses (bronchoscopy), and pressure exerted by use of azoles that have differential activity (e.g., voriconazole). Changes in hosts may lead to increased risks for specific types of infections. For instance, some of the underlying metabolic changes that can occur late after allogeneic HSCT with graft vs. host disease (GVHD)—such as diabetes and iron overload—may specifically predispose to infection with Mucormycetes [32, 33]. In one recent study that utilized data derived from the CIBMTR database, risks for non-*Aspergillus* mold infections (NAMI) amongst a large contemporary

cohort of allogeneic HSCT recipients were assessed [34]. Results suggested that patients with NAMI had more advanced underlying disease and poor Karnofsky performance status at HSCT, with very poor outcomes after infection. Risk factors for mucormycosis include acute GVHD, prior *Aspergillus* infection, and older age. Risks for fusariosis included receipt of cord blood, prior CMV infection, and transplant before May 2002. In this study, infections caused by non-*Aspergillus* molds were diagnosed relatively infrequently, and with similar frequencies in the contemporary antifungal era compared. Risks for infection were largely associated with the severity of illness in the host, and specific factors that predict unusual molds; for example, long-term steroid exposure (even in the HSCT context) is a strong predictor of mucormycosis, while long-term neutropenia is a strong predictor for fusariosis.

When understanding the epidemiology of mold infections, it is always important to consider these organisms as having unique, characteristic environmental growth preferences. For instance, infections caused by *Fusarium* and *Scedosporium* species are most common in the southern USA, Spain, France, and Australia. Weather characteristics can influence risks for aspergillosis and other mold infections, appearing to suggest "outbreak" conditions, but unrelated to single-sources or anthropogenic events (e.g., construction). Examples include increased rates of IPA associated with high ambient spore counts in dry summers in the northwest USA [35] and real outbreaks of specific infections associated with weather disruptions. A recent example of the latter is the development of multiple cutaneous mucormycosis cases that occurred after a destructive tornado in the USA [36]. Understanding the characteristics of these organisms and the underlying endemic natures of exposures assists in developing prevention strategies.

39.4 Diagnostics

Radiology serves as a foundation for early diagnosis of IMI in the setting of suspected disease. As mentioned above, CT scans are especially valuable in providing characteristics of pulmonary disease, and they increase sensitivity of detecting abnormalities compared to conventional chest X-rays. Nodular lesions, halo signs, cavitary lesions, tree-in-bud nodules, focal or multifocal consolidations, and wedge-shaped peripheral lesions are all common presentations of mold complications in the lung. In non-neutropenic HSCT recipients, non-classic abnormalities are more frequently recognized, including more diffuse ground-glass abnormalities and multifocal consolidations [37].

Establishing a microbial diagnosis has become more important than in prior years, as the foundation of optimal drug therapy has leaned away from polyenes, to include azole drugs that have differential activities, and with increased recognition of azole drug resistance amongst common organisms such as *A. fumigatus* [38, 39]. Studies have shown that bronchoscopy, if performed early after recognition of pulmonary abnormalities, has a good sensitivity and is safe [40, 41]. Examination of lavage with culture and augmented testing for fungal antigens (e.g., galactomannan) provide enhanced sensitivity and important information pertaining to likely cause of disease. Biopsy is not routinely employed or necessary, except for cases in which diagnosis is elusive, as risk–benefits shift in patients with different types of lesions and complication risks. In general, biopsy is warranted in patients in whom disease is progressing despite broad antifungal coverage. Yield may be increased with video assisted thoracotomy compared to transbronchial approaches.

Multiple different assays are now commercially available to enhance diagnostic testing for molds, especially *Aspergillus* species. The first, and the most widely employed, is the Platelia serum galactomannan enzyme immunoassay (GM EIA), which utilizes a rat monoclonal antibody in a double-sandwich EIA format. This antibody (EBA2) actually recognizes galactofuranose (galF) side chains of the galactomannan molecule, which is a common constituent of the polysaccharide cell wall of Ascomycetes fungi [42, 43]. The test is now performed in multiple local and regional microbiology laboratories, and although somewhat complex and costly, it provides good information as an aid to diagnose infection with serum or bronchoalveolar lavage (BAL) fluid. Predictive values of test results from BAL are particularly helpful, as in this setting the prevalence of disease is obviously higher than with screening applications on serum [44, 45]. Importantly, detection of "galactomannan" with these methods is not specific for IPA, as multiple organisms, including those that cause similar syndromes (ex. *Fusarium* spp.), express galactomannan—or more specifically—galF antigens that are recognized by the kit antibody [46–48]. Antigens that cause cross-reactivity are also found in multiple drugs, most notably beta-lactam antibiotics [49]. These tests may be falsely positive in HSCT patients, especially in the setting of mucosal breakdown, either early after conditioning or with severe GVHD [50].

More recently, diagnostics that detect other fungal antigens have been developed and cleared by regulatory agencies for use as diagnostic aides. Numerous diagnostic laboratories across the world offer tests that detect beta-D-glucan, largely by harnessing chemical reactions that occur within the limulus amebocyte assay cascade of the horseshoe crab. As this antigen is very abundant on numerous fungal pathogens, and the methods that are employed in these tests serve as a very sensitive primitive immune system of the crab, these tests are typically sensitive, but not specific. Recent studies have reported potential utility of beta-D-glucan tests when used as an aide to diagnose IPA [51, 52].

Numerous centers are now using polymerase change reaction (PCR) tests to assist diagnosis of IMI. Commercial assays and in-house assays have been described and examined in multiple studies. Recent efforts of European groups

have led to optimization of methods to draw and prepare blood products for testing, and for testing itself. These tests also have reasonable performance characteristics, although obviously may vary across tests and labs [53–55].

Finally, new tests developed for use as screening assays and as aides to diagnose IMI are being developed, with a specific focus on aspergillosis. One recent diagnostic cleared for use in the European Union is the lateral flow device that detects a protein antigen in blood or BAL, providing enhanced sensitivity over conventional diagnostics [56, 57]. Others tests in development rely on detection of antigen in unique body fluids (urine) [58] and detection of novel biomarkers, such as fungal metabolites in breath sensors [59]. The landscape of this active field changes daily, limiting over-arching conclusions regarding "best" strategies; however, most would agree that some type of non-culture based method now needs to be employed to optimize diagnostic technologies in centers caring for high-risk HSCT patients.

39.5 Prevention

Efforts to establish preventative strategies have focused on modulating variables that dictate respiratory exposure, enhancing diagnostic screening using radiography or microbial detection, and on employing early antifungal therapy, as part of "prophylactic" or "pre-emptive" strategies. High risks in allogeneic HSCT recipients warrant focus on all of these preventative measures.

Across the world, attention has been drawn to modulating environment in order to minimize airway exposure to inhaled molds. Although centers typically adhere to some standard practice, very little is known about what works best. The high costs and complexities associated with laminar airflow have largely yielded to use of high efficiency air filtration (HEPA) as a standard in housing neutropenic and high-risk transplant recipients within the hospital. Use of masks is typical and widespread, albeit with little data to suggest that it actually works. Results of one small randomized trial evaluating masks failed to show superiority in prevention of documented or suspected IPA, although the trial was small [60].

Serial monitoring of blood using the GM EIA assay and/or *Aspergillus*-specific PCR has been employed in some centers to enhance early diagnosis and to trigger "pre-emptive" therapy, and some randomized trials have evaluated their use. A recent Cochrane meta-analysis that evaluated 18 primary studies encompassing 19 cohorts and 22 data sets reported that both GM EIA and PCR-based screening has moderate diagnostic accuracy when used in high-risk patient groups. This study reported that GM EIA and PCR have good negative predictive value (NPV), useful to exclude disease, but low prevalence limits the ability to rule in a diagnosis. As these biomarkers detect different aspects of disease, some suggest that combinations are likely to be most useful [61]. We lack the large randomized trials necessary to show that we can safely reserve antifungal use in high-risk settings, such as with fever during neutropenia. However, an Australian randomized trial did show that a targeted approach that combined PCR and GM EIA worked to decrease empirical use of antifungals, without observed differences in clinical outcomes amongst 240 patients enrolled [62]. More work—and perhaps better diagnostic tests—will need to be done to fully supplant the widespread use of antifungal therapy for "empiric" indications such as fever during neutropenia, but we may be closing in on that goal.

Importantly, few biomarker-based tests have been developed for non-*Aspergillus* molds, although the non-specificity of beta-D-glucan testing may suggest some utility in future screening strategies. More likely, prevention of these complications will rely on tailored application of prophylaxis, which has also become more widespread after HSCT, largely due to availability of azole drugs that have broad anti-mold coverage. Itraconazole, voriconazole, and posaconazole have all been evaluated in randomized trials for prophylaxis in neutropenic patients and in HSCT recipients, and they are variably used in different centers [63–67]. Early studies that evaluated itraconazole given for prophylaxis in HSCT recipients noted that the drug may be effective at preventing IPA, but with toxicities, mainly associated with the gastrointestinal tract [67, 68]. One large randomized trial reported that posaconazole decreases the incidence of IPA compared to fluconazole in the setting of GVHD, which was consistent with efficacy shown in patients with AML/MDS, leading to its approval for this indication in many countries [63, 69]. Voriconazole has been shown to decrease IPA relative to fluconazole in the HSCT population, although it did not improve the composite outcome of fungal free survival measured late after allogeneic HSCT [65]. This drug has also been associated with decreased mold infections in others at risk populations, including adults and children with neutropenia and steroid receipt [70–72]. Both posaconazole and voriconazole have good, selective activity against different molds, and with variable costs, tolerability, and drug interactions, have been employed at an increasing rate during vulnerable high-risk periods, such as with GVHD.

Amphotericin formulations have also been studied as prophylactic agents in both neutropenic populations and in HSCT recipients. These studies, which have been limited in non-randomized design, or have used alternative dosing regimens of lipid formulations of amphotericin B, have not generated the positive results that have been observed with mold-active azoles, largely due to toxicities [73–75]. Similarly, echinocandins have been studied, and reported to be generally safe when administered as prophylaxis, but these drugs are more effective against *Candida* species compared to invasive mold infections [76]. Finally, positive results have been reported with amphotericin formulations administered via an inhaled route [77, 78] although we don't currently have a commercial product that is easy to administer.

One relatively common situation concerns the need for "secondary prophylaxis" administered to people who have mold infections pre-HSCT. In this situation, a mold-active antifungal should be administered to prevent reactivation of existing infection, or acquisition of a secondary infection. Large observational studies have recorded risks for recurrent IPA in early and late time periods as those that associate inadequate antifungal treatment prior to conditioning, risks that extend durations of neutropenia and those that lead to severe acute GVHD [79, 80]. The best studied drug for secondary prophylaxis is voriconazole, although other products have been shown to work safely in non-randomized trials [81–84].

39.6 Treatment

Table 39-1 presents a summary of key treatment recommendations for the most common mold infections in HSCT recipients. A now "classic" paradigm-changing study showed better survival for people with IPA treated with voriconazole compared to conventional amphotericin B, positioning the mold-active azoles as "first choice" options for therapy [85]. With this in mind, voriconazole is still considered the optimal first-line therapy in multiple consensus guidelines, including those derived by transplant and infectious disease groups. However, amphotericin B formulations, most appropriately the lipid products, which are associated with fewer toxicities, are also reasonable alternatives for treatment of IPA, especially when microbial diagnosis is not confirmed, and in the setting of prohibitive drug interactions or hepatotoxicities. A new azole, isavuconazole, has become available for treatment of IPA as well as other more unusual mold infections, based on a study that suggests non-inferiority compared to voriconazole [86]. Although some early studies demonstrated potential utility of echinocandin monotherapy for mold infections [87], most experts believe that the use of these compounds should be relegated to combination therapy, but not used as a staple.

Combination antifungal therapy has become a topic of increased controversy, with early reports using animal models, case series, and observational comparisons suggesting potentially improved outcomes with different combinations compared to monotherapy. Results of a recent large randomized trial that compared voriconazole monotherapy to combination therapy with anidulafungin suggested trends to improved clinical outcomes, but not definitive superiority of the combination in primary analyses [21]. This study has been variably interpreted worldwide, and run-on studies are being designed to further our understanding of optimal treatment of aspergillosis.

No large randomized trials have been performed to determine the best options to treat the more unusual mold infections, so conclusions are drawn from case series, cohort studies, and small prospective pilot trials. Mucormycoses are typically "best" addressed with lipid formulations of amphotericin B, with aggressive surgical debridement to augment removal of organism and necrosis. These infections can also be treated with some of the newer azole drugs, such as posaconazole and isavuconazole, but no studies have compared outcomes to those of polyenes. Most experts suggest that amphotericin should remain the mainstay primary therapy until more outcomes data are available, and many suggest dose escalations from 5 mg/kg/day to 10 mg/kg/day. Posaconazole and isavuconazole are useful for long-term disease suppression and may have a role for primary therapy, although the latter is not yet well described. Other studies focusing on combination therapies with echinocandin antifungals, iron chelators, and immunomodulators suggest that we may be able to improve outcomes yet further, but more work is necessary to make clear recommendations [88, 89].

Similarly, infections caused by "other molds" that have different antifungal susceptibility profiles have not been well addressed by large treatment studies, but therapeutic regimens are based on anticipated or observed antifungal susceptibilities. Most experts suggest that invasive infections caused by *Fusarium* species be treated with voriconazole as primary therapy, with lipid formulations of amphotericin B as secondary therapy. Others suggest that the combination of both agents may lend to best results, especially in light of antifungal susceptibility differences within the species complexes, but this has not been studied enough to enable widespread promotion by guidelines committees [90, 91]. *Scedosporium* species, especially *S. prolificans*, typically display complex resistance profiles to essentially all antifungal agents, warranting consideration for an aggressive combination approach (Table 39-1).

Detailed discussion of antifungal therapies is beyond the scope of this chapter, but numerous helpful reviews and guidelines have been published [91–93]. An important reminder is that these drugs and organisms are now appreciated to have a more complex susceptibility profile than once believed. Clinical failure of antifungal therapy can represent poor drug levels, especially with mold-active azole drugs, inherent resistance amongst different types of molds, development of drug resistance within a specific organism, and immunologic failure. Not surprisingly, emergence of azole resistance has been increasingly reported, especially in centers located in environments that use azole drugs within agricultural practices [94]. It is likely that drug therapy will be increasingly directed by susceptibility testing in the future, further increasing the need for aggressive diagnostics to establish microbial diagnoses.

Augmented immunologic therapies have been increasingly explored in the HSCT population. Recent efforts have been focused on the utility of granulocyte infusions, and of fungus-specific T cells. One randomized trial that evaluated the safety and efficacy of high dose (GCSF-stimulated) granulocytes halted due to slow accrual, with preliminary reports of safety, but no difference in clinical outcomes in underpowered comparisons [95]. Another study reported that complications were very common when granulocytes were

TABLE 39-1. Summary of treatment recommendations[a]

Infection	Drug	Key recommendations and comments
Aspergillosis		
	Voriconazole	Recommended based on randomized trial results Dose with IV induction followed by oral or IV therapy Doses vary depending on weight and age (more required to maintain appropriate levels in children) Monitoring of levels and adjustment of drug dosing recommended
	Liposomal amphotericin B	Dose 3–5 mg/kg/day
	ABLC	5 mg/kg/day Not studied in randomized trials, diminishing strength of recommendation
	Combination voriconazole + echinocandin	Recommend consideration for early combination therapy in settings of severe infection and in people with severe immunosuppression
	Posaconazole	Used for maintenance in settings with uncertain diagnosis or toxicities with voriconazole
	Isavuconazole	Recommend consideration of this drug in people intolerant to voriconazole given non-inferiority in randomized trial
	Amphotericin B (conventional)	Not recommended for therapy given toxicities and documented poor outcomes compared to alternatives
Mucormycosis		
	Liposomal amphotericin B	Recommended with dose ≥5 mg/kg
	Posaconazole	Recommend consideration of this drug in people intolerant to L-AmB and as maintenance therapy based on case series (no randomized data) Oral extended release tablet preferred over solution formulation given predictability in levels and tolerability
	Isavuconazole	Recommend consideration of this drug in people intolerant to L-AmB given results of case series suggesting efficacy and safety
Fusariosis		
	Voriconazole	Recommended drug given improved outcomes in case series, dosed aggressively as described above
	L-AmB	Recommended in people not tolerant to voriconazole
	Combination therapy	Recommended consideration of combination voriconazole and L-AmB based on predicted risks of drugs and severity of infection
Scedosporium species		
	Voriconazole	Recommended first-line therapy based on case series, dosed aggressively as described above
	Posaconazole Isavuconazole	Case reports and series suggest potential utility but with limited information to date
	L-AmB	Variable activity and outcomes in case series but consideration in people intolerant to azoles
	Combination therapy	Recommended combination voriconazole and L-AmB in severe infection *S. prolificans* with resistance to all antifungals; aggressive combinations of voriconazole and terbinafine should be considered

[a]Recommendations are the author's chosen derivations from numerous guidelines, review of outcomes studies, and experience. References for comments provided in text.

used for treating aspergillosis in the lungs [96]. Some investigators have suggested that granulocyte transfusions may be particularly appropriate in people with disseminated fusariosis; a recent systematic review noted a high proportion of clinical responses after transfusion of donor-stimulated granulocytes, suggesting that this may be an appropriate strategy to "bridge" through neutropenia during active infection [97]. There continues to be great effort directed towards the potential of immunotherapies directed by adoptive transfer of T cells as an adjunct for treating multiple invasive mold infections, with preliminary reports suggesting potential utility as adjunctive therapy for pulmonary aspergillosis [98–101].

Surgery designed to resect focal areas of invasive mold infections is most important in regions where there is a build-up of necrotic tissue, and with imminent vascular compromise. An aggressive surgical approach should be considered with invasive sinus infection, pulmonary masses in approximation to vulnerable vascular structures, and with necrotic lesions associated with mechanical compromise in drug delivery. As mentioned above, surgical resection is most important with infections that are caused by Mucormycetes. Surgery should be approached cautiously with all infections in which there is not as clear a benefit, as complications that involve pleural adhesions and infected empyemas are not infrequent.

39.7 Conclusion

Invasive mold infections have been a frequent, dreaded complication of neutropenia and cellular deficiency, occurring both early and late after allogeneic HSCT. New drugs and diagnostics have resulted in major improvements over the last decades, although these ubiquitous environmental organisms remain a problem during protracted vulnerability. Efforts directed towards enhancing diagnostics and early prevention based on understandings of personal risks, use of highly sensitive screening diagnostics, and tailoring of preventative therapies, are needed to further minimize these complications in the future.

40 Mold Infections in Solid Organ Transplant Recipients

Patricia Muñoz, Maddalena Giannella, Antonio Vena, and Emilio Bouza

40.1 Epidemiology

40.1.1 The Issue from a General Perspective

Solid organ transplantation has become an important therapeutic option in many diseases. The number of patients undergoing transplantation has increased exponentially in recent years, and the advances in surgical techniques, immunosuppression, and prophylactic strategies have improved allograft and patients' survival [1, 2].

Fungal infections occur in 5–42% of solid organ transplant (SOT) recipients depending on the organ transplanted and the degree of immunosuppression [2–4]. The prevalence of invasive mycosis has declined over the past decade, due in large part to improvements in transplant surgical methods [2, 5]. During this time period, there has been a reduction of infections caused by *Candida* spp. but a rise in infection caused by *Aspergillus* spp. and other less-common mold fungi, such as Zygomycetes, *Scedosporium,* and *Fusarium* spp. [6–9]. The peculiarities encountered with the different types of transplantations deserve some discussion.

The incidence of fungal infections after **heart transplantation** has significantly decreased since the introduction of cyclosporine A (CsA). In the first Stanford series, which was conducted from 1968 to 1978, 35% of the patients had a fungal infection. However, in the past 20 years the incidence was progressively reduced to 10% [10–20] and at present, with the introduction of targeted antifungal prophylaxis, less than 5% of heart transplant recipients will develop an IFI [21–23]. Meanwhile, the incidence of fungal infections, most notably of aspergillosis, after both **lung and heart–lung** transplantation, range from 4% to 10% [1, 24, 25] and are a significant cause of morbidity and mortality.

The incidence of fungal infections in orthotopic **liver** transplant recipients has also decreased over the past 20 years, dropping from between 30 and 50% to 1–9.2% [26–35].

Kidney transplantation currently has the lowest rate of fungal infection [36, 37], with incidence ranging from 0.9% to 4% [35]. Similarly, the outcome of **pancreas** transplantation has continued to improve in recent years, and it is now an accepted treatment for selected patients with type I diabetes, mainly those who have previously undergone kidney transplantation and thus already receive immunosuppressive treatment. Reports of mold infections in these patients are extremely few. In one series on the infectious complications of pancreatic transplantation in 34 consecutive recipients, only one patient developed an infection with *Aspergillus fumigatus* [38].

40.1.2 Onset of Infection

The timing of infections after organ transplantation is quite helpful for suggesting an etiology (Table 40-1) [39–41]. In earlier studies, most cases of mold infections were reported to occur within the first 90 days after transplantation [42, 43]. However, a higher proportion of later occurring cases has been reported in recent series [9, 21, 33, 44, 45]. In the **first month** after transplantation, barrier disruptions and alterations in phagocytic function are dominant, increasing the susceptibility to infections with *Candida*, *Aspergillus,* and the Mucorales [46]. Central nervous system (CNS) infections in SOT recipients during this period are usually due to disseminated aspergillosis [47]. From **1 to 6 months** after transplantation, the type of infection changes, reflecting the shift towards infection caused by pathogens that, in the normal host, are mainly controlled by the cellular immune mechanisms. These include latent infections, such as those caused by the geographically restricted systemic fungi and other mycelial fungal infections [46, 48, 49].

From **6 months after** transplantation and on, approximately 80% of recipients are receiving stable and relatively modest levels of immunosuppressive drugs, and the incidence of fungal infections clearly decreases in these individuals [48]. The 10–20% of patients who never do well and who continue to take large amounts of immunosuppressant drugs or who develop a posttransplant neoplasia, may, however, experience aspergillosis and other opportunistic mold

P. Ljungman et al. (eds.), *Transplant Infections*, DOI 10.1007/978-3-319-28797-3_40

Table 40-1. Timing of fungal infections in SOT recipients

Early (<1 month)
Uncommon except in liver transplant recipients
Nosocomial intensive care unit *Candida* infections
Central nervous system abscess (most *Aspergillus*)
Pulmonary *Aspergillus* (aspiration/ventilation)
Intermediate (1–6 months, especially 3 months)
Candida
Aspergillus
Zygomycoses (Mucorales)
Other molds
Late pathogens
Aspergillus
Cryptococcus
Endemic fungi
Sporothrix schenkii
Dematiaceous fungi

Modified from Patterson JE. Epidemiology of fungal infections in solid organ transplant patients. *Transpl Infect Dis.* 1999;1:229–236, with permission.

infections late after transplantation [33, 46, 48, 50]. Seronegative CMV recipients who receive prolonged antiviral prophylaxis may develop CMV infection late after transplantation also increasing their susceptibility to opportunistic agents such as molds [51].

40.1.3 General Risk Factors

The basic risk factors for fungal infection are qualitatively similar in all SOT recipients [52] and the incidence varies with the following two factors: the intensity of exposure and the patient's susceptibility to infection. With regards to the latter, factors contributing to fungal infections include immune defects created by the underlying disease that led to the need for transplantation in the first place [43, 53–57], the type of organ transplanted, the occurrence of technical or surgical complications [29, 43, 53, 55, 57–61], the presence of neutropenia, thrombocytopenia, or metabolic alterations (e.g., diabetes), the intensity of immunosuppression, viral infections, the need for additional antirejection therapy, and renal failure and hemodialysis among others [29, 33, 57, 61–68].

40.1.4 Morbidity and Attributable Mortality

Fungal infections are a major cause of morbidity and mortality [3]. This is due in part to the difficulty of establishing the diagnosis early so that the infection is not disseminated at the time of diagnosis [46, 69], as well as to the limited efficacy and toxicity of some of the available antifungals [70].

The mortality associated with invasive fungal infections (IFIs) varies with the type of fungus, the organ transplanted, and the location of the disease. In heart transplant recipients, the overall mortality rate of fungal infection ranges from 29% to 36% [15, 17, 19, 21] with a marked decrease in most recent studies. In lung transplant recipients, the mortality rate of bronchial infections, which is roughly 20%, is lower than that of invasive pulmonary mycoses, which ranges from 67% to 82% [1, 71–73]. In liver transplant recipients, the mortality rate has ranged from 83% to 88% [74–76]. More recent studies have reported better outcomes with mortality ranging from 10% to 33.3% [1, 77]. Among kidney transplant recipients, patients with an IFI have a relative risk of mortality of 2.88 (95% CI = 2.22–3.74) compared with those who do not have IFI [5].

40.2 Infections Caused by *Aspergillus* spp.

40.2.1 Incidence

SOT patients constitute the third group in frequency among patients with Invasive Aspergillosis (IA), after patients with hematological malignancies and chronic pulmonary diseases [78]. As already mentioned, the incidence of IA varies according to the type of SOT from less than 2% to more than 25% [30, 42, 61, 70, 79–86].

In **heart** transplantation, *Aspergillus* is the predominant fungal isolate (70% of IFIs), accounting for 38% of all nodular lesions observed in the lungs of heart transplant recipients [29, 70, 74, 81, 82, 87–92]. The incidence of IA in this population ranges from 3.3% to 14% (average 6%) [15, 67, 92–94]. In both lung and heart–lung transplantation, colonization with *Aspergillus* occurs at some time after transplantation in 25–30% of **lung** transplant recipients [95–97]. IA occurs in 3–15% (average of 6%) of the patients [92, 95, 97–100]; 58% of these infections are tracheobronchitis or bronchial anastomotic infections, 32% are invasive pulmonary aspergillosis, and 22% are disseminated infections with extrapulmonary involvement [100]. Compared with heart, lung, or heart–lung transplantation, *Aspergillus* infection after **liver** transplantation is less common (1–8% of recipients) [43, 53, 55, 75, 83]. Although *Candida* species are the primary cause of fungal infection in these patients [31, 37, 101], *Aspergillus* can account for as many as 25% of all fungal infections in liver transplantation [35, 102]. In **kidney** transplantation, the cumulative incidence of *Aspergillus* infection is usually less than 5% (from ~0.7% to 4%) [29, 70, 90, 91], a figure which is similar to that observed in pancreas transplant recipients [86, 103].

Mortality associated with IA is nearly 100% if the disease is not treated [104]. The attributable mortality of IA varies depending on the type of infection, is still higher than 70% for disseminated disease with CNS involvement but has significantly decreased for pulmonary IA [21, 33, 77, 105, 106].

40.2.2 Microbiology of the Genus *Aspergillus*

Aspergillus is one of the most ubiquitous airborne saprophytic fungi. In both immunocompetent hosts and in SOT recipients, the species of *Aspergillus* that most commonly causes invasive disease is *A. fumigatus.* Far less common are those infections caused by *A. flavus*, *A. niger,* and *A. terreus* [20, 95, 107–109]. Notably, the first case of human infection by *Aspergillus granulosus* has been reported in a cardiac transplant patient [110]. New molecular methods have allowed the detection of less-common species (cryptic species) that frequently can be resistant to most commonly used antifungals. Resistance to voriconazole has also been described in *A. fumigatus* species, so the judicious use of antifungals is now more important than ever [111–114].

40.2.3 Onset of Infection

In earlier studies, most cases of IA were reported to occur within the first 100 days after transplantation (mean time was 17d for LT, 45 for HT, 82 for KT, and 120 for Lung T). However, in recent years a significant percentage of cases occur later. This has led to the differentiation of IA into early-onset infection, occurring <90 days after transplantation, and late-onset infection, occurring after that period. Such bimodal pattern is related to different risk factors. In fact, *Aspergillus* infection occuring in the first moths after transplantation is likely a sign of an unusually intense environmental exposure [40].

In a large retrospective study on 11,014 SOT recipients from Spain, IA occurred a mean of 234 days (range, 2–3025 days) after transplantation [33]. Early IA accounted for 57% of the episodes and 43% were late. Risk factors for early IA include a complicated postoperative course, repeated bacterial infections or CMV disease, and renal failure or need of hemodialysis. Late IA developed more commonly in older patients with an over-immunosuppressed state due to chronic graft rejection or allograft dysfunction and in patients with posttransplantation renal failure or neoplasia.

In **lung** transplant recipients, *Aspergillus* infection occurs a median of 3.2 months after transplantation, with 51% occurring in the first 3 months after transplantation and 72% within 6 months [100]. Tracheobronchitis or anastomotic infections tend to occur early, while invasive pulmonary and disseminated infections usually appear later after transplantation.

In **heart** transplant recipients, the usual time of IA onset is 36–52 days posttransplantation, with nearly 75% of the cases occurring within the first 90 days after transplantation. At one institution, the onset of IA was significantly delayed after the introduction of routine ganciclovir prophylaxis [94]. We have recently published a 24-year experience with IA in HT recipients. IA was diagnosed in 6.5% of heart transplant patients, with a significant decrease in recent years. Incidence decreased from 8.7% (24 of 277) in the period 1988 to 2000 (historical cohort) to 3.5% (7 of 202) afterward (p 0.02); four of the seven recent cases were in the context of an outbreak. In our study, IA occurring during the first 90 days after transplantation (23/31 cases, 75%) presented most commonly with lung infection, whereas episodes occurring later (8/31, 25%) showed a higher frequency of disseminated disease including CNS involvement. Related mortality was 36% with a significant reduction during recent years (46% vs 0%; p 0.04) and a trend toward lower related death in early vs late cases (26% vs 63%, p 0.09) [21].

Historically in **liver** transplant recipients IA was an early disease (16–17 days after transplantation) [59], but the onset is now delayed. A study showed that the percentage of IA occurring after 90 days of liver transplantation increased from 23% in 1990–1995 to 55% in the period 1998–2002 [44]. Improved outcome in the early postoperative period, and delayed onset of posttransplant risk factors such as CMV infection, allograft dysfunction due to recurrent hepatitis C virus hepatitis are proposed as potential explanations [44].

40.2.4 Pathogenesis and Risk Factors for Aspergillosis

This ubiquitous organism may colonize normal or immunocompromised hosts by spore inhalation. Some strains are more pathogenic than others as a study conducted in the author's hospital demonstrated; in this study, the elastase activity of the *Aspergillus* strains correlated with the invasiveness of the strain [115].

The respiratory tract is the portal of entry in as many as 95% of cases of IA [48]. Once tissue infection develops, invasion of blood vessels is the rule, accounting for the three cardinal features of IA: tissue infarction, bleeding, and dissemination with metastatic seeding [91].

The following two epidemiologic patterns are observed: a domiciliary pattern, in which the exposure occurs in the room or ward where the patient is housed, and a nondomiciliary pattern, in which the exposure occurs as the patient travels within the hospital for a diagnostic or therapeutic procedure [48]. The discovery of domiciliary outbreaks is usually relatively easy because of clustering of cases in time and space [116]. At present, this risk is attenuated largely because of better technical management of the endotracheal tube and the use of high-efficiency particulate air (HEPA) filtration [76]. Clustering is not usually present with the nondomiciliary exposure, and this type of infection usually requires a significant amount of exposure [48, 117].

Skin colonization may also occur and primary cutaneous aspergillosis has been associated with occlusive dressings [118–120]. *Aspergillus* spp. may also invade the gastrointestinal tract or, rarely, they may gain entry through an intravenous catheter [90]. The transmission of the infection via the

donor graft has also been described [121–123]. Donor-derived mold infections have been mostly described in cases in which the donor had CNS manifestations or was himself an immunosuppressed patient.

The host risk factors for aspergillosis are similar to those associated with other invasive mold infections and have been previously commented [68, 106]. Alveolar macrophages normally kill inhaled conidia, and functioning neutrophils eliminate residual mycelia. Therefore, both neutropenia and the dysfunction of macrophages and neutrophils secondary to steroid administration in SOT recipients predispose the recipient to the infection. A body of evidence now suggests that T-cell function and adaptive immunity characterized by a dysregulated production of T-helper (Th) cell cytokines play a pivotal role in the pathogenesis of IA [124–126]. Indeed, Th1 responses have been shown to confer protection against *Aspergillus*, while Th2 responses have been associated with disease progression [124, 125]. Both calcineurin-inhibitors and corticosteroids, administered to SOT recipients to prevent allograft rejection, produce a down-regulation of Th1 responses [127].

Signal transduction mediated by Toll-like receptors (TLRs) has also been shown to play a key role in immunity against aspergillosis [128, 129]. *Aspergillus* conidia stimulate both TLR2 and TLR4 to induce a Th1 cytokine response. Germination of hyphae leads to the loss of TLR4-mediated signals with an ultimately predominant Th2 response. An association between the donor TLR4 haplotype S4 and the risk of IA among recipients of hematopoietic-cell transplants from unrelated donors has been shown [129]. Recently the presence of Pentraxin 3 (PTX3) polymorphisms have been shown to increase the risk of IA in SOT recipients [130].

In SOT patients who require prolonged intubation and ventilatory support, who develop renal failure and need hemodialysis, or who present CMV infections, the risk of IA is further increased [40, 48]. Renal failure and hemodialysis have been shown to impair T-cell proliferative responses and result in an increase in activation-induced T-cell death [68, 106, 131]. A heightened susceptibility to IA among transplant recipients with CMV infection is believed to result primarily from cell-mediated immunosuppressive effects of the virus [63]. CMV may also affect the respiratory burst of macrophages.

40.2.5 Clinical Manifestations of *Aspergillus* Infection in Different Transplants

In a retrospective multicenter study of 11,014 SOT recipients conducted in Spain by the *Spanish Network for Research on Infection in Transplantation* (RESITRA), pulmonary infections accounted for 59% of the IA cases, comprising 20.5% nodular cases and 38.4% pneumonia cases. Disseminated aspergillosis was diagnosed in 41% of IA, with CNS involvement in 15.4% of cases [33].

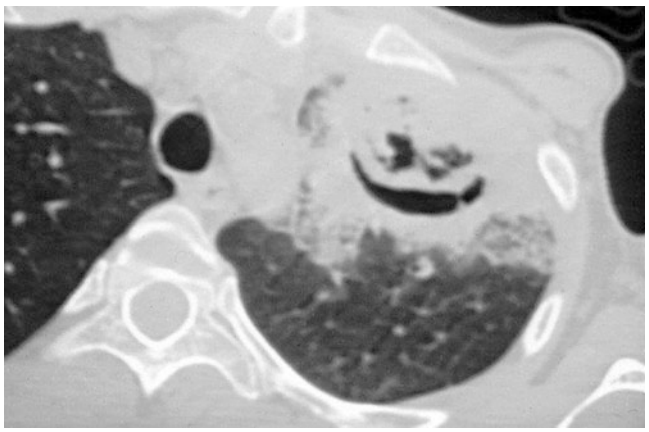

FIGURE 40-1. Pulmonary aspergillosis in a heart transplant patient.

Although pulmonary aspergillosis frequently presents with single or multiple pulmonary nodules with or without cavitation (angio-invasive aspergillosis) [12, 15, 82, 93] (Figure 40-1), a new radiological manifestation (airway-invasive aspergillosis) characterized, according to CT findings, by peribronchial consolidation or a tree in-bud pattern should also be considered. In our series of 27 heart transplant patients, 37.1% of the cases presented with this airway invasive disease. These patients had more need of hemodialysis after transplantation, more intercurrent bacterial pneumonia, and the infection was diagnosed later after symptoms onset (2.7 vs 8.5 d, p 0.09). After diagnosis, AIR-IPA patients required more mechanical ventilation (23.5% vs 90%, p 0.01) and had a higher related mortality rate (23.5% vs 70%, p 0.04) [132].

Aspergillus may disseminate from the lungs to almost any organ [133–138]. Overall, disseminated disease has been described in up to 20% of cases with higher percentage among liver recipients [106]. Disseminated infection with CNS involvement occurred in 17% of the cases studied in Spain [82]. Brain abscesses are relatively uncommon (0.6%) in SOT patients; however, 78% of those observed are caused by *Aspergillus* species [139]. Clinical manifestations of CNS aspergillosis include an alteration of mental status, diffuse CNS depression, seizures, evolving cerebrovascular accidents, and headache [76, 85, 140]. The CSF fluid is usually sterile.

Recently, Kourkoumpetis et al. reported 14 cases of CNS aspergillosis and reviewed 123 cases reported in the literature between 2000 and 2011. Solid organ transplantation was the underlying disease in 8.9% of the cases and in most patients CNS involvement resulted from dissemination from the paranasal sinuses or lungs. Of note, a significant proportion of patients had a history of previous brain pathology, which could predispose them to metastasis of infection to the CNS [141]. Of particular interest is the fact that CNS infection caused by fungi is often associated with extraneural infection with the same microorganism, which allows the sampling and evaluation of an established infection without a need to perform a brain biopsy. In a series on CNS lesions in liver transplant recipients, all of the brain abscesses found were fungal

and *Aspergillus* organisms were the most frequent isolate (75%). Furthermore, 73% of the patients had concurrent extraneural (pulmonary) infection that was caused by the same fungal pathogen [142]. Therefore, the consensus is that a diagnostic brain biopsy is not warranted in SOT recipients with CNS lesions. Occasionally, however, the colonization of extraneural sites may confuse diagnosis [46].

One study revealed that *Aspergillus* organisms were a common cause of infective endocarditis (26%) that occurred within a month of solid organ transplantation [143]. Other forms of clinical presentation include mediastinitis and osteomyelitis [10, 15]. Skin and soft-tissue infections also occur [144, 145]. In heart transplant recipients, cardiac aspergillosis probably originated in the atrial suture or in the surgical site has been reported [146].

In **lung and heart–lung** transplant recipients, disease presentation can also include bronchial anastomosis dehiscence, vascular anastomosis erosion, bronchitis, tracheobronchitis, invasive lung disease, aspergilloma, empyema, disseminated disease, endobronchial stent obstruction, and mucoid bronchial impaction [52]. Kramer et al. described a distinct form of IA after lung transplantation, in which ulcerative tracheobronchitis, a semi-invasive disease involving the anastomosis site and the large airways, was encountered [147]. Bronchial stent obstruction is particularly problematic because 15% of patients will show some degree of airway narrowing, bronchomalacia, or airway stenosis [52]. The placement of an artificial stent may be then required; however, the artificial stent seems to be a trap for fungi, leading to fungal tracheobronchitis, impaction, and pneumonia. These stents have to be cleared often and mucous plugs containing *Aspergillus* are found within these stenosed airways.

In **liver** transplant recipients, aspergillosis of the wound occasionally occurs [59, 148, 149]. Other clinical manifestations are primary cutaneous infection after trauma [119], the infection of a biloma [150], gastrointestinal dissemination and systemic involvement with endocarditis [143, 151, 152] or endophthalmitis [153–155]. CNS involvement is particularly more likely to occur in liver recipients who have been retransplanted. However, disseminated and CNS infections have declined in the current era [44, 156]. It has been proposed that the in vitro anti *Aspergillus* activity of calcineurin and target-of-rapamycin inhibitor agents may have a protective effect on the risk of disseminated aspergillosis [157].

As in the other transplant groups, pulmonary aspergillosis is the most frequent clinical presentation of aspergillosis in **kidney** transplant recipients [36, 85, 108, 158–166]. Other clinical presentations include cutaneous aspergillosis [118, 167], genitourinary disease [168–174], arthritis [175, 176], isolated cerebral aspergilloma [177], epidural abscess and paraparesis [178, 179] and invasive or disseminated disease [136–138, 166, 180–187]. A potentially highly lethal form of invasive aspergillosis in kidney transplant recipients is pseudoaneurysm of the iliac artery that may be transmitted by a graft contaminated during the preservation phase [188].

40.2.6 Diagnosis of Invasive Aspergillosis

The diagnosis of IA in SOT recipients remains a significant challenge, since 25–33% of these patients may be asymptomatic initially or they may have nonspecific symptoms. Furthermore the progression of the disease is fast. The diagnosis is also crucial, mainly because the prompt recognition of these infections, combined with intensive antifungal therapy, is needed for cure [3, 74, 90, 189, 190]. The diagnosis is reached by a combination of different methods, including clinical findings, isolation of the microorganism, radiology, the serologic detection of antibodies or antigens and histopathologic evidence of invasion [191, 192].

40.2.6.1 Clinical Findings

Clinical manifestations can be subtle and may include fever and pulmonary findings, such as chronic cough or chest pain that result from angioinvasion of fungi; these may be important clues to the diagnosis of infection [90, 132, 192] and in high-risk patients may be enough to establish a presumptive diagnosis of infection and to allow institution of therapy pending a confirmation of the diagnosis [74].

40.2.6.2 Imaging Techniques

Chest radiographic findings in patients with pulmonary *Aspergillus* include nodular opacities, interstitial infiltrates, cavitary lung disease, or a pulmonary embolus pattern; however, the chest X-ray may also be normal [81, 139, 193]. In patients with infection due to angioinvasive molds, especially those with invasive pulmonary aspergillosis, computed tomography (CT) scanning is particularly valuable in diagnosing the disease when the chest radiograph remains negative or shows only minimal changes. In SOT recipients, high-resolution CT scanning of the chest is more sensitive than plain radiographs, and it may reveal disease as much as 5 days earlier [139]. In these patients, a pulmonary halo sign is less likely to correlate with IA, as it may occur with other types of pneumonia as well [132, 189]. In heart transplant recipients, the chest CT provided significant additional information in 41% of the patients with IA (mainly greater spread of the disease); and, more importantly, only the chest CT showed abnormalities (normal chest X-ray) in 18% of the cases [21].

Since mold infections in this population primarily affect the lungs and sinuses, diagnostic approaches should concentrate on these two anatomical locations, with the early and repeated, if needed, performance of CT scans. In patients with brain lesions, the use of CT scans or magnetic resonance imaging of the neuroaxis is essential for the assessment of the presence and nature of infectious processes. To date, the utility of positron emission tomography with F18-fluorodeoxyglucose (FDG-PET) to diagnose IA in SOT recipients is not determined [194]; data suggesting the utility

of FDG-PET in the diagnosis of invasive aspergillosis is mainly extrapolated from studies including hematological patients.

40.2.6.3 Etiologic Diagnosis

The currently available laboratory diagnostic methods include histopathologic evidence of invasion, isolation of the microorganism or demonstration of the DNA by molecular methods and the serologic detection of antigens or antibodies. The newer techniques remain mainly investigational at this time.

40.2.6.4 Histopathologic Evidence of Invasion

Aspergillus hyphae are 2–4 mm wide, and they frequently septate and branch at 45°. They are best-visualized with silver stains, and may be missed when the only routine hematoxylin-eosin stains are applied. In rapidly progressive infections, the hyphae are of even diameter, whereas in more chronic cases they may have bulbous, widened areas. Sporulation is rarely observed in the tissue, except for in areas containing air. In the absence of sporulation, *Aspergillus* hyphae cannot be readily distinguished from a large number of pathogenic molds, and the mycologic differential diagnosis includes *Scedosporium*, *Fusarium*, *Scopulariopsis,* and many other rarer molds.

Definitive proof of IA requires the culture of *Aspergillus* from a sterile site (e.g., brain aspirate or an abscess). Histologic evidence of hyphal invasion of the tissue with concurrent positive culture of *Aspergillus* from the same site (e.g., a transbronchial biopsy showing hyphae and a positive sputum culture for *Aspergillus*) is also definitive evidence of the disease [195]. Angiotropism and angioinvasion are important histologic characteristics of invasive mold infections. However, other fungi (e.g., *Fusarium*, *Zygomycetes)* may invade tissue and produce similar histologic images.

40.2.6.5 Isolation of the Microorganism

Pathogenic species of *Aspergillus* usually grow easily and quickly on the routine bacteriologic and mycologic media used in the clinical laboratory. The identification is relatively straightforward by microscopic criteria and the colony (conidial) color. Formal identification may require the performance of cultures on specialized media such as Czapek-Dox and malt extract. Species identification is warranted in transplant units. As mentioned, *A. fumigatus* is the most common species recovered from cases of invasive aspergillosis, followed by *A. flavus*, *A. niger*, and *A. terreus* [20, 95, 107–109]. At present molecular methods are very helpful to identify isolates at species level [196].

Increasing evidence indicates that positive cultures for *A. fumigatus* should not be overlooked in the appropriate epidemiologic and clinical setting (e.g., highly immunosuppressed transplant recipients) because this is strongly associated with the existence or risk of IA [42, 87, 197]. However, the early diagnosis of IA in SOT recipients is difficult because fungal cultures in these patients may be negative even when infection is widely disseminated [74, 90]. For instance, blood cultures are notoriously insensitive for *Aspergillus* infections, even those producing endocarditis [3]. Furthermore, the confirmation of the diagnosis may require obtaining tissue for culture using an invasive procedure [198], which may sometimes not be viable because of the increased risk involved. In HT recipients the diagnosis of IA possible only after obtaining an invasive sample (bronchoalveolar lavage or biopsy/aspiration) in 29% of the patients [21].

In IA, the sensitivity of positive respiratory samples from SOT recipients for *Aspergillus* differs depending on the type of transplant [44, 97, 199]. In a multicenter Spanish study in **heart** transplant recipients, the sensitivity of various respiratory tract cultures for the diagnosis of IA were as follows: sputum examination, 45%; bronchoalveolar lavage (BAL), 83%; bronchial washing, 100%; transbronchial biopsy, 50%; open-lung biopsy, 50%; and transthoracic needle aspiration, 50% [19]. During a 10-year study period, *Aspergillus* spp. were recovered from 10.5% of heart transplant recipients and a positive predictive value (PPV) of 60–70% for IPA [197]. When analyzed by species, the positive predictive value of recovering *A. fumigatus* was 78–91%, whereas it was 0% for other species. The positive predictive value increased from 88% to 100% when *Aspergillus* was recovered from a respiratory specimen other than sputum and decreased from 50% to 67% when it was recovered only from sputum [197]. The performance of BAL is most valuable in patients with diffuse changes on CT scans [3].

In a multicenter Italian study of IFI in **lung** transplant recipients, the use of BAL for the diagnosis of IA had a sensitivity of 100%; a specificity of 92%; and positive and negative predictive values of 16 and 100% [92]. *Aspergillus* spp. can be detected in airway samples from ~25% to 30% of lung transplant recipients [95, 100]. Although airway colonization with *Aspergillus* organisms correlates with a low positive predictive value for IA in lung transplant recipients, it is associated with a higher risk of subsequent invasive infection [37, 189, 200]. The risk of progression from colonization to IA is increased in lung transplant recipients with lower values of T-cells response (<50 ng/mL ATP with the Cylex ImmuKnow assay) [201]. Patients with positive airway cultures for *Aspergillus* within 6 months after transplantation were 11-fold more likely to develop IA [202] and should undergo a bronchoscopic examination to exclude the presence of tracheobronchitis or invasive disease. In another report, the isolation of *Aspergillus* organisms from a respiratory specimen was associated with a 22-fold greater risk for subsequent IA.

In **liver** transplant recipients with invasive pulmonary aspergillosis, *Aspergillus* species are detected in respiratory

secretions (sputum or BAL) in 50% of these individuals [56]. Colonization of the respiratory tract with *Aspergillus* organisms is uncommon in liver transplant recipients (~1.5%), but it has a high positive predictive value of subsequent development of IA, ranging from 41% to 72% [189].

The diagnosis of extrapulmonary infection is usually more difficult [3, 203]. Any suspicious lesion (e.g. skeletal or cutaneous) should be biopsied and cultured for fungi according to the recommendations found in the current guidelines [3, 195, 203].

Although the Clinical Laboratory Standards Institute has developed a standardized method for mold susceptibility, a clinical correlation of increased minimal inhibitory concentration for molds has not yet been established with regard to the susceptibility testing of fungal isolates [111, 204]. Azole resistance by *Aspergillus* species is increasingly reported in recent years [112, 113], and some patients exposed chronically to antifungal triazoles have been reported to have refractory infection caused by isolates with elevated MICs [205, 206]. The clinician must realize that some molds are going to be less susceptible to some classes of antifungal drugs (e.g., *A. terreus* is clinically resistant to amphotericin) [1]. Nevertheless, predicting the expected susceptibility pattern of a particular mold is much more difficult that it is for yeasts. Because of the emerging development of resistance, testing the susceptibility of *Aspergillus* organisms and other molds to the available antifungal drugs is warranted in these infections.

40.2.6.6 Serology

In recent years great advances have been performed in the serologic diagnosis of IA, mainly in hematological patients, allowing a rapid diagnosis. The serologic diagnosis of IA is based on the detection of circulating antigens in biologic fluids, such as serum, urine, or BAL fluid [207, 208]. Briefly, the Platelia (Sanofi Diagnostic Pasterur, Marnes la Coquette, France) sandwich-enzyme immunosorbent assay (ELISA) for the detection of galactomannan (GM) is currently one of the more used methods. A recent meta-analysis showed a greater utility of the GM test in neutropenic bone marrow transplant recipients than in SOT patients, in whom sensitivity of serum samples was 71% and specificity 89% [209]. In a retrospective study of IA in liver transplant recipients, Fortun et al. found a sensitivity of GM of 55.6% and a specificity of 93.9%, with a positive predictive value of 71.4% [210]. GM was not very useful either in heart transplant recipients [21]. In heart transplant recipients GM showed a sensitivity of 28.6% [21]. Other specimens, such as bronchoalveolar lavage (BAL), have been proven to be more advantageous in this population. At the index cutoff value of ≥1, the test yielded sensitivities and specificities ranging from 60% and 98%, respectively in lung transplant recipients and 100 and 91% in liver transplant patients [200].

Although in hematological patients GM test may enable the early diagnosis of IA [211], and monitor treatment response [212, 213], further studies are mandatory in SOT patients since these aspects have not been specifically proven in this population.

Unfortunately, false negative and positive results are not uncommon in SOT recipients. False negative results of the GM assay have been related to the previous use of antifungal agents (44% of lung transplant recipients with false negative GM) [1]. False positive GM results are common in lung (20%) and liver transplant recipients (9–13%), mainly in the early postransplantation period [24]. Potential causes are the specific underlying conditions leading to the transplantation (e.g., cystic fibrosis and chronic obstructive pulmonary disease, autoimmune liver disease and dialysis requirement), or administration of betalactams [1].

Other tests, such as the detection of cell wall markers like the galactosaminoglycan or **1-3-β-** d **-glucan**, or the polymerase chain reaction (PCR) are still not so widely used. 1-3-β-D-glucan is a cell wall component of yeasts and molds [214]. It is detectable in blood during IFI caused by the *Aspergillus*, *Fusarium,* and *Acremonium* species [214]. The test proved to be useful for the diagnosis of invasive aspergillosis in living-donor liver allograft recipients in one study [215]. Some authors have proposed that a reasonable approach to the clinical application of these assays is serial screening (weekly or biweekly) of patients with a high risk of IFI. Once a positive result is obtained and confirmed, the use of an assay with high fungal specificity (e.g., GM sandwich-ELISA for aspergillosis) could help to narrow down the specific type of fungal infection further and could aid in the choice of targeted preemptive antifungal therapy [216].

Recently, the diagnostic value for IFI of the 1-3-β-D-glucan was questioned in the transplant population because of the low positive predictive value of the test. Indeed, in a study performing 1-3-β-D-glucan on BAL and serum samples from 135 SOT patients with proven, probable, or no IFI, the sensitivity, specificity, positive and negative predictive values of the test were 79.2, 38.5, 27.6, and 86.3% in BALs and 79.2, 81.8, 69.2, and 83.1% in serum sample tested [217].

The use of **PCR** to detect invasive fungal pathogens, including *Aspergillus*, is receiving increasing attention. PCR screening for *Aspergillus* has a sensitivity, specificity, and negative predictive value of 100%, 65% and 100%, respectively [218]. Some protocols use universal fungal PCR primers that enable the detection of a broad range of fungi [219–221], and a sensitivity of 1–10 fg of fungal DNA can be achieved. In one study, the sensitivity of the PCR used on whole blood was 100% in patients with documented IFI when two or more samples were analyzed [220]. In one study in renal transplant recipients blood panfungal PCR preceded clinical signs of invasive fungal infections by 27 days [222]. Quantitative PCR can be used to monitor the fungal level to indicate the response to treatment, similar to the use of PCR monitoring in cytomegalovirus disease [223].

The results are better when the technique is performed on bronchoalveolar lavage specimens, with sensitivities and specificities of pan *Aspergillus* PCR reaching 100% (95% CI 79–100%) and 88% (95% CI 79–92%), respectively.

However, PCR-based molecular diagnostic tests for *Aspergillus* are not commercially available, remain largely unstandardized, and their precise role in the diagnosis and management of invasive aspergillosis in SOT recipients remains to be determined [224]. Finally, it should be noted that the specificity of PCR performed on lower respiratory tract samples is moderate, as a positive result only indicates the presence of *Aspergillus*, and does not allow distinguishing between colonization and infection [225].

Recently, a **lateral flow device** (LFD), detecting a glycoprotein antigen found in the serum and BAL of patients with IA [226], has been proposed as a new diagnostic approach for detecting IPA in immunocompromised populations, including SOT patients [227]. An early semiprospective multicenter study evaluating LFD device in BAL from SOT patients (26 lung transplants, 13 liver, 6 kidney, and 2 heart transplantation) showed a sensitivity, specificity, positive and negative predictive values for probable IA of 91%, 83%, 63%, 97%, respectively [228]. However, despite initial promising results, further and larger studies are warranted before safe conclusions on the performance of *Aspergillus* spp. LDF can be reached. Clinical trials evaluating the role of *Aspergillus* LFD as an alternative to GM in serum and BAL fluid are currently underway (clinicaltrial.gov identifier NCT 02058316).

Finally, different technologies detecting volatile organic compounds exhaled in the breath of patients infected with IA have been recently tested [229–231] with increasing enthusiasm by the scientific community. However, their role in SOT patients remains to be clarified.

40.2.6.7 Differential Diagnosis

The clinical presentations of fungal infections in SOT are nonspecific, and they often overlap with other infectious and noninfectious processes. Therefore, a histologic and microbiologic analysis is mandatory. In any fungal infection diagnosed in a SOT patient, a careful search should be made for metastatic infection, especially if the location at which the infection was found involves the skin, the skeletal system, and/or the CNS. The clinician must remain aware of this type of infection because, in many cases, the diagnosis is only established postmortem.

40.2.7 Treatment

Early treatment with an effective antifungal drug decreases the high fatality rate associated with these infections. The development of new antifungals and the performance of antifungal susceptibility tests have enabled longer survival in patients who contract fungal infections [232]. However, the emergence of multidrug-resistant pathogens, medication toxicity and drug–drug interactions must be carefully evaluated [233].

The drugs used in the treatment of deep fungal infections in SOT recipients do not differ significantly from those used in other types of immunocompromised hosts, although antifungal treatment in this specific population has special features [90]. The therapy is complicated by the following three factors: (a) the continuing need for immunosuppression, except for recipients of kidney and pancreas allograft recipients whose condition may be maintained with dialysis and insulin therapy if the graft fails; (b) the need for a prolonged course of therapy; and (c) the potential for all of the currently available antifungal agents to interact with essential immunosuppressive drugs, particularly CsA [46, 91, 234–241].

40.2.7.1 Antifungal Agents

Over the past decade, there has been a considerable research in antifungal drugs targeted against IA [106, 195]. To date, the antifungal agents licensed for the first-line treatment of IA include amphotericin B and its lipid formulations, itraconazole, voriconazole, posaconazole, and caspofungin [195]. Micafungin and anidulafungin, which are also candins, have in vitro, in vivo, and clinical activity against *Aspergillus* but are not yet licensed for primary therapy of IA [195]. The severity of the infection, the clinical form, renal insufficiency, the drug interactions, the availability of the drug, and its cost are some of the factors that can help in making the selection of the best drug.

Voriconazole is a triazole, for which both oral and intravenous formulations are available. It has a broad spectrum of antifungal activity that includes *Candida* species, *Aspergillus* species, *Cryptococcus neoformans*, fungi that cause the endemic mycoses, *Fusarium* species, *Paecilomyces lilacinus*, *Scedosporium apiospermum,* and dematiaceous fungi [242–246]. It is not active against Zygomycetes, however. It has good penetration of both the CSF and brain.

The largest randomized trial for primary therapy of invasive pulmonary aspergillosis demonstrated that voriconazole was superior to amphotericin B deoxycholate, followed by other licensed antifungal therapy [247]. This study included 11 SOT recipients. At week 12, successful outcomes were observed in 52.8% of the patients in the voriconazole group and in 31.6% of those in the amphotericin B group. The survival rate at 12 weeks was 70.8% in the voriconazole group and 57.9% in the amphotericin B group (hazard ratio, 0.59; 95% CI 0.40–0.88). Patients treated with voriconazole had significantly fewer adverse events that were drug-related, except for transient visual disturbances. Therefore, the authors of this study concluded that voriconazole was more beneficial for the treatment of IA than amphotericin B.

Other series studying SOT recipients, with proven or probable invasive pulmonary aspergillosis, confirmed a

favorable response rate with voriconazole [232, 248, 249]. Particularly remarkable is one study of CNS aspergillosis, including 25 SOT recipients, treated with voriconazole for a median of 93 days (range 1–1128), that showed a favorable response rate of 48% (40% for SOT) [250]. Intravitreal voriconazole has also been used in a lung transplant patient with *Aspergillus* endophtlamitis [251, 252]. Because of better survival and improved response of initial therapy with voriconazole, this agent is now considered the drug of choice for primary therapy of IA in most patients, including SOT recipients, by the recent Clinical Practice Guidelines of the Infectious Diseases Society of America (IDSA) (A-I level recommendation) [195].

Voriconazole is generally well tolerated but early recognition of side effects may be extremely important. Patients taking voriconazole can develop skin rash, prolongation of QT interval, visual disturbances, and hepatic enzyme elevation [253, 254]. Periostitis, skeletal fluorosis, and exostoses have also been reported [255, 256] mainly, but not always, in patients receiving long-term therapy. Clinical presentation includes multifocal pain in different skeletal regions with elevation of alkaline phosphatase and of plasma fluoride level [257, 258]. Bone scintigraphy reveals areas of increased radiotracer uptake and prompt discontinuation of voriconazole should result in improvement of symptoms. Early recognition of this phenomenon is important to prevent unnecessary tests and procedures. In a recent report a consistent number of patients reported nail changes and alopecia associated with prolonged voriconazole therapy [259]. Rare cases of cutaneous squamous cell carcinoma [260–265] have also been described.

One issue of paramount importance in the treatment of SOT recipients with IA is the drug interaction of antifungal agents with the immunosuppressant agents. The triazole agents are potent inhibitors of the CYP34A isoenzymes and have the potential to increase the levels of calcineurin-inhibitor agents and sirolimus [266]. Itraconazole has been shown to increase CsA or tacrolimus levels by 40–83% [267] and a 50–60% reduction in the dose of calcineurin-inhibitor agents may be necessary with the concurrent use of voriconazole [266]. The use of sirolimus is contraindicated in patients receiving voriconazole, although some authors have safely coadministered them with sirolimus dose reduction by 75–90% [268–272].

Coadministration of posaconazole increased cyclosporine exposure and necessitated dosage reductions of 14–20% for cyclosporine [273]. Posaconazole increased the maximum blood concentration and the area under the concentration-time curve for tacrolimus by 121% and 357% respectively [273].

For patients who are intolerant of or refractory to voriconazole, a **lipid formulation of amphotericin B** is regarded as an appropriate alternative. Beginning in the early 1990s and for almost a decade, lipid formulations of amphotericin B, have been the mainstay of the treatment for IA in SOT recipients, largely because of a lower potential of nephrotoxicity than conventional amphotericin, but probably also due to less efficacy. A study compared the efficacy of amphotericin B lipid complex (median dose of 5.2 mg/kg/day) and amphotericin B deoxycholate (median does of 1.1 mg/kg/day) for the treatment of IA in SOT recipients [274]. The overall and IA-related mortality rate was 33 and 25% in the amphotericin B lipid complex group, and 83 and 76% in the amphotericin B deoxycholate group [274]. In another study of 47 SOT patients with IA who were treated with lipid formulations of amphotericin B (5–7.4 mg/kg/day), the overall 90-day mortality was 49% and the IA associated mortality was 43% [275]. Based on the AmBiLoad study, in which liposomal amphotericin B at the dose of 3 mg/kg/d of per day showed similar efficacy to 10 mg/kg/d and less toxicity, doses higher than 5 mg/kg/d are not recommended [276]. Some clinicians initiate therapy with conventional amphotericin B and switch to a lipid formulation only with patients who cannot tolerate the drug or who are refractory to treatment. However, in SOT recipients, the use of conventional amphotericin B in the high dose required for the treatment of IA is associated with significant renal toxicity, mainly in patients receiving CsA or tacrolimus [57, 277]. Accordingly, if available, the authors of this chapter recommend starting therapy with one of the lipid-based formulations. If infusion related symptoms appear, such as fever, chills, headache, nausea, and vomiting, the use of preparative medication for subsequent infusions is appropriate. Aerosolized amphotericin B deoxycholate or lipid formulations of amphotericin B have been used for the treatment of tracheobronchial infection in SOT, although this approach has not been standardized and remains investigational [195].

Caspofungin is the only candin currently approved by the US FDA for the first line therapy of IA. It inhibits glucan synthesis of the fungal cell wall. At this time, this is only available in an intravenous formulation. It is highly active against *Candida* and *Aspergillus* infection, but comparative data for amphotericin or voriconazole in SOT patients are not available. In a study that employed caspofungin as primary therapy for IA in 12 SOT recipients, the response rate was 92% [278]. Although caspofungin has been used successfully as salvage therapy in IA as single agent [279] and in combination with other drugs [280], a recent study analyzing 181 hematological patients with IA reported an higher *Aspergillus*-mortality rate in patients treated with primary salvage therapy with caspofungin compared with voriconazole alone. In the same study, the combination of voriconazole and caspofungin did not result in a better outcome [281]. The pharmacokinetics of caspofungin is unaltered by coadministration of tacrolimus, but caspofungin may reduce tacrolimus concentrations by up to 20% and may increase cyclosporine A plasma concentrations by 35% [282]. Caspofungin should be used with caution in patients treated with CsA due to elevated liver function tests [87, 282, 283].

To date limited experience exists with the use of **posaconazole, micafungin, or anidulafungin** for the treatment of IA in SOT recipients [284]. Anidulafungin showed no clinically

relevant drug interactions with immunosuppressors used in SOT [285, 286] and micafungin a mild inhibitor of cyclosporine levels and increased sirolimus serum concentrations by 21% when administered concomitantly [287].

40.2.7.2 Combination Therapy and Other Considerations

The high lethality of IA justifies any attempt to improve monotherapy by combination therapy. As yet, no conclusive results are available and updated guidelines of the IDSA suggest reserving this option for salvage therapy [195]. However, several authors have shown that the combination of amphotericin B, caspofungin, and voriconazole generally has a synergistic or additive effect in vitro and in experimental models [288–300].

A prospective, multicenter study in SOT recipients compared outcome in 40 with IA patients who received primary therapy with voriconazole plus caspofungin with 47 patients, from an earlier cohort, who received a lipid formulation of amphotericin B [275]. The two groups were well matched, including the proportion with disseminated disease (10% vs. 12.8%), proven IA (55% vs. 51.1%), or *A. fumigatus* (71.1% vs. 80.9%). Overall survival at 90 days was 67.5% in the cases and 51% in the control group. Mortality was attributable to IA in 26% of the cases and in 43% of the controls ($p=0.11$). Deaths tended to occur later in cases than in the control patients (mean 49.5 vs. 36.7 days, $P<0.11$). In the multivariate Cox regression model, CMV infection and renal failure were independently predictive of mortality at 90 days. Combination therapy was associated with a trend towards lower mortality (HR 0.58, 95% CI: 0.30–1.14, $p=0.117$) when controlled for CMV infection and renal failure. When 90-day mortality was analyzed in subgroups of patients, combination therapy was independently associated with reduced mortality in patients with renal failure, and in those with *A. fumigatus* infection, even when adjusted for other factors predictive of mortality in the study population [275]. No correlation was found between in vitro antifungal interactions and outcome. None of the patients required discontinuation of antifungal therapy for intolerance or adverse effects however, patients in the combination therapy arm were more likely to develop an increase in calcineurin-inhibitor agent level, or gastrointestinal intolerance [275].

A retrospective survey of invasive pulmonary aspergillosis in lung transplant recipients (9/19 disseminated), showed a mortality rate of 86% (12/14) in patients who received Amphotericin B preparations (amphotericin B deoxycholate or a lipid formulation of amphotericin B) and 0% (0/3) in those who received voriconazole plus caspofungin [301]. Mortality rate in patients receiving voriconazole plus caspofungin was also lower compared to lipid formulations of amphotericin B (0/3 vs. 8/8, $p=0.006$).

A higher response rate and superior survival was also observed in a retrospective series of CNS aspergillosis when antifungal combination therapy was administered [250].

The most important data supporting the role of combination therapy for treatment of IA have been recently provided from a randomized, double-blind, placebo-controlled multicenter trial comparing voriconazole and anidulafungin with voriconazole monotherapy [302] The main results of this study are described in this chapter.

In many transplant programs in Europe combination therapy constitutes the standard antifungal therapy for invasive aspergillosis in SOT recipients [303, 304]. Surveys of antifungal therapeutic practices for IA in transplant recipients documented that, currently, combination therapy is used as first-line treatment in 34–47% of the transplant centers, and as salvage therapy in 58–80% of them [305, 306].

However, not all antifungal combinations are beneficial, and some may be deleterious [195]. Pending definite clinical results and considering cost, treatment with the combination of voriconazole and caspofungin or anidulafungin may be less costly than therapy with 5 mg/kg/day of liposomal amphotericin B [307].

Therapy should continue after the resolution of disease and of the reversible, underlying conditions that originally predisposed the patient to the development of the IA. The optimal duration of therapy is unknown; it is dependent on the extent of IA, the response to therapy, and the patient's underlying disease(s) or immune status. A reasonable course would be to continue therapy for the treatment of microfoci until after the clinical and radiographic abnormalities have resolved; any cultures, if they are readily obtainable, are negative; and any predisposing factors have abated. The IDSA guidelines recommend a minimum of 6–12 weeks in normal hosts and maintenance throughout the period of immunosuppression and until lesions have resolved in immunosuppressed patients [195]. Long-term therapy of IA is facilitated by the availability of oral voriconazole in stable patients. The clinical response, rather than an arbitrary total dose, should guide the duration of therapy.

Therapeutic monitoring of invasive pulmonary aspergillosis includes serial clinical evaluation of all symptoms and signs, as well as performance of radiographic imaging, usually with CT, at regular intervals. The frequency of CT should be individualized on the basis of the rapidity of the evolution of pulmonary infiltrates and the situation of the individual patient. The use of serial serum galactomannan assays for therapeutic monitoring is promising but remains investigational in SOT [305]. Progressive increase in *Aspergillus* antigen levels over time implies a poor prognosis; however, resolution of galactomannan antigenemia to a normal level is not sufficient as a sole criterion for discontinuation of antifungal therapy [195].

A growing body of evidence suggests patient-to-patient variability in the pharmacokinetics of triazoles [308, 309].

Absorption issues (for itraconazole and posaconazole), drug–drug interactions (for all triazoles), and pharmacokinetic differences (for voriconazole) all contribute in various degrees to this variability [195]. Although the available data are still scarce, accumulating reports suggest that plasma drug levels monitoring may play an important role in optimizing the safety and efficacy of azole antifungals [309]. In a study of 12 lung transplant recipients, a few patients were identified to have nearly undetectable concentrations midway or throughout the entire dosage interval [310]. On the other hand, it has been demonstrated that patients with voriconazole levels ≥5.5 mg/L where more likely to develop neurological toxicity [309]. Accordingly, until more data are available, the authors recommend systematic monitoring of voriconazole and posaconazole levels.

40.2.7.3 Additional Treatments

Surgical excision or debridement remains an integral part of the management of mold infections as it has both diagnostic and therapeutic purposes [85, 134, 144, 203, 311]. Surgery is specifically indicated if hemoptysis, particularly a life-threatening hemoptysis, is present; if lesions are impinging on the great vessels or major airways, because of the higher likelihood of catastrophic pulmonary hemorrhage; if the infection is sinonasal infections; if a single cavitated lung lesion is present that increases despite adequate treatment; if the pericardium, bone, or subcutaneous thoracic tissue is infiltrated while the patient is receiving antifungal drugs; and when intracranial abscesses are present [195]. A pneumonectomy was successfully performed for progressive, refractory angioinvasive aspergillosis in a lung transplant recipient whose disease progressed despite the use of conventional antifungal therapy [312].

Adjunctive therapy has been used in some situations and in vitro and animal studies has shown enhanced antifungal activity and modulation of cellular immune responses when cytokine or colony stimulating factors are provided [313–315]. However, no definitive role for the use of cytokines as adjunctive treatment to antifungal drugs has been established. Granulocyte and granulocyte-macrophage colony-stimulating factors and interferon-γ (IFN-γ) all increase both phagocytosis and the damage to *Aspergillus* hyphae in vitro [316]. However, no clinical benefit has been demonstrated either in the phase I and II studies of macrophage colony-stimulating factor or in a retrospective series of cases of IA in which granulocyte-colony-stimulating factor was used [317]. Guidelines of the IDSA suggest a role for IFN-γ as adjunctive antifungal therapy for invasive aspergillosis in immunocompromised non neutropenic host [195]. The use of this cytokine in organ transplant recipients is of concern, however, given the risk of potential graft rejection.

The ultimate response of these patients to antifungal therapy is largely related to host factors, such as a decrease in the immunosuppression and the return of graft function from a transplanted organ, as well as the extent of the aspergillosis when it is diagnosed. Reducing immunosuppression by withdrawing corticosteroids and decreasing the doses of CsA and tacrolimus is an important adjuvant measure to surgical treatment. In these cases, close monitoring of CsA and tacrolimus concentrations is of paramount importance. Graft function should also be followed closely in those recipients whose graft is essential for survival.

The treatment of *Aspergillus* species infection in SOT recipients is summarized in Table 40-2.

40.2.8 Prevention of Invasive Aspergillosis

Antifungal prophylaxis for SOT recipients remains a complex and controversial issue mainly due to the scarcity of large clinical trials. Antifungal prophylaxis may be provided to the whole population (universal) or only to high-risk patients (targeted). Both strategies are effective and have not been sufficiently compared, so definite recommendations cannot be given and each center will have to choose the best strategy depending on their epidemiology, experience, and access to diagnostic and therapeutic tools. However, targeted prophylaxis is the preferred option in most transplantation programs, considering the risk of toxicity and emergence of resistant isolates and that risk factors for IA are well defined, are only present in a minority of SOT recipients and during short periods of time [68, 106].

40.2.8.1 Prophylaxis in Lung Transplant Recipients

Lung transplant recipients are at high risk of suffering different types of *Aspergillus* infections, so the need of prophylaxis should be considered in every patient. However, different indications, drugs, and length of therapy are used in different programs and no clear superiority has been demonstrated by any specific strategy [318]. Some centers still use universal prophylaxis while others only treat patients with risk factors.

Preemptive antifungal therapy may also be used in lung transplant recipients and in some liver transplant recipients when *Aspergillus* colonization is detected with the aim of treating the pathogen before it causes disease in high-risk patients [73, 106]. This strategy is mainly used when pulmonary colonization by *Aspergillus* species is found immediately before or within 6–9 months after transplantation [86, 91, 319, 320]. Not enough data exist on prophylactic strategies based on positive galactomannan in serum or bronchoalveolar lavage in lung transplant recipients.

TABLE 40-2. Treatment of infections by *Aspergillus* species

	Treatment	Duration
Invasive disease[a]	**Primary therapy** Voriconazole (6 mg/kg iv every 12 h for 2 doses, followed by 4 mg/kg iv every 12 h; oral dosage is 200 mg every 12 h) **Alternative** Liposomal amphotericin B (3–5 mg/kg/day iv) or Amphotericin B lipid complex (5 mg/kg/day iv) or Caspofungin (70 mg day 1 iv and 50 mg/day thereafter) Micafungin (iv100–150 mg/day; dose not established) or Posaconazole (200 mg QID initially, then 400 mg BID orally after stabilization of disease) Itraconazole (dosage depending upon formulation)	See text
Tracheobronchial infection	**Primary therapy** Voriconazole (6 mg/kg iv every 12 h for 2 doses, followed by 4 mg/kg every 12 h; oral dosage is 200 mg every 12 h) **Alternative** Liposomal amphotericin B (3–5 mg/kg/day iv) or Amphotericin B lipid complex (5 mg/kg/day iv) or Itraconazole (dosage depends upon formulation) with or without inhaled nebulized amphotericin B (6 mg/kg q8h) or Caspofungin (70 mg day 1 iv and 50 mg/day thereafter) or Micafungin (iv 100–150 mg/day; dose not established) or Posaconazole (200 mg QID initially, then 400 mg BID orally after stabilization of diseased)	At least 21 days or until the patient is asymptomatic and cultures are negative
Colonization	Inhaled nebulized amphotericin B 6 mg/8 h Voriconazole 200 mg/12 h orally Itraconazole (dosage depend upon formulation)	At least 15–21 days or until cultures become negative
Ulcerative tracheobronchitis[b]	Voriconazole (6 mg/kg iv every 12 h for 2 doses, followed by 4 mg/kg every 12 h; oral dosage is 200 mg every 12 h) or Liposomal amphotericin B (3–5 mg/kg/day iv) or Amphotericin B lipid complex (5 mg/kg/day iv) or Itraconazole (dosage depends upon formulation) + Inhaled nebulized amphotericin B (6 mg/kg q8h)	Clearance of fiberoptic signs and negative cultures

[a]Combination therapy (voriconazole + caspofungin) is suggested in all cases of IA as primary therapy.
[b]Surgical debridement or excision of mycelial masses is necessary.

Regarding the drug of choice nebulized amphotericin B, with or without an azole, is probably the most frequently used option. In a recent study, including 27 of 64 (45.5%) active LTx centers in the United States, antifungal prophylaxis increased from 52.3% in 2011 to 77.8% in 2013, with the most common agent being inhaled amphotericin B (61.9%), followed by oral voriconazole (51.9%). A total of 74.1% of centers treat *Aspergillus* airway colonization, with 80.0% of centers using oral voriconazole. All centers treat IA, with 92.6% using oral voriconazole.

The incidence of IA in lung transplant recipients has been shown to decrease with nebulized amphotericin B (0.2 mg/kg every 8 h) [81, 321–325]. Nebulized liposomal amphotericin B appears to be more effective than conventional amphotericin [325, 326].

In one study oral itraconazole with or without nebulized liposomal amphotericin B effectively prevented invasive disease in colonized patients [327]. However, some cases of semi-invasive tracheobronchial aspergillosis were detected that required higher serum levels (more than 1000 mg/L) are required for cure [327].

Another study compared universal prophylaxis with voriconazole to preemptive prophylaxis with itraconazole, with or without inhaled amphotericin B, for the prevention of IA in lung transplant recipients [73]. The study suggested the superiority of universal prophylaxis over the targeted strategy, since all but one patient who developed IA in the itraconazole group had not received the drug. The use of voriconazole was, however, associated with abnormal liver enzymes in a significant percentage of patients [73]. Considering the possibility of adverse events and high risk of drug–drug interactions, the role of newer triazoles as antifungal prophylaxis in lung transplant recipients remains to be fully defined. Voriconazole is, however, preferred by some authors when the reason for starting the prophylaxis is the colonization of the respiratory tract with *Aspergillus* or *Scedosporium*. Prophylaxis is not indicated when other molds are recovered due to the significantly lower risk of infection.

The duration of prophylaxis is not clearly established and varies widely across centers from 3 months to >1 year in the US. Some center adjust the duration of prophylaxis to the type of patient [326]. In uncomplicated lung transplant recipients, prophylaxis is generally administered for approximately 2 weeks after surgery. In complicated lung transplant recipients, nebulized amphotericin B is administered for 4 weeks during the period of greatest immunosuppression after IA has

been ruled out. In patients who experience a rejection episode, a course of prophylaxis may be administered during the period of greatest immunosuppression; in those with repeated episodes of rejection or chronic rejection, prophylaxis may be maintained on a continuing basis. Other authors recommend the administration of nebulized amphotericin B for several weeks after transplantation or until the bronchial anastomosis has healed [86]. Others maintain that this should be lifelong therapy (6 mg/day) [325, 326].

40.2.8.2 Prophylaxis in Other Solid Organ Transplant Recipients

At present, the prophylaxis of infections by molds is not universally recommended for SOT recipients. Routine antifungal prophylaxis should be aimed at high-risk patients.

Usually antifungal prophylaxis is not recommended in **kidney transplant** recipients.

Universal antifungal prophylaxis is not warranted **in heart transplant** recipients. However, in patients deemed to be at high risk, itraconazole (400 mg daily from day 5 after transplantation to month 3 or 6) was associated with a significantly lower incidence of invasive aspergillosis and lower overall mortality (2% versus 9.6%; $P<0.05$) [67]. In a more recent study, we analyzed the security of adapting the indication and duration of antifungal therapy to the specific risk factors present in each patient, instead of using a fixed and empirical prophylaxis [22]. We performed a prospective study in which prophylaxis was only administered to heart transplant recipients with risk factors for invasive aspergillosis (13 of 133 transplanted patients; 9.8%). The duration was personalized, starting with the risk factor and continued 15–20 days after its resolution. Antifungal prophylaxis consisted mainly on the administration of candins and was effective in all but one patient who should have received a higher dose of caspofungin due to his obesity. Despite suffering an outbreak of invasive aspergillosis (IA) in the intensive care unit due to extremely high concentration of spores in the air (three cases with no personal risk factors), there was a reduction in the incidence of IA (8.6% vs. 2.2%; $P=0.01$) and *Aspergillus*-related mortality (5.75% vs. 1.5%; $P=0.06$) [22].

This study also demonstrated that a high environmental load of *Aspergillus* spores in the intensive care unit would also indicate the need for antifungal prophylaxis in all exposed transplant recipients [116].

A meta-analysis of antifungal prophylactic trials **in liver transplant** recipients documented a beneficial effect on morbidity and attributable mortality, but an emergence of infections due to *non-albicans Candida* [328]. Since the risk factors and the period of susceptibility to invasive fungal infections is clearly definable, antifungal prophylaxis targeted towards these high-risk patients is deemed to be the most rational approach in this population. A lipid formulation of amphotericin B—at a dose of at least 3 mg/kg/day—or caspofungin have been used [248, 329–331]. High-risk patients should be targeted, and the prophylaxis should continue for a period of 4 weeks after transplantation or while the risk factors remain present [151, 248, 329–332].

Most authors recommend preemptive therapy for patients who have acute, **fulminant liver failure** before transplantation, since they are considered high-risk recipients [319]. This approach advocates initiating the therapy on admission to the intensive care unit and continuing it after transplantation for 3–4 weeks, based on the concept that *Aspergillus* infection is diagnosed early after transplantation in these patients [59].

A recent prospective, multicenter, noncomparative, open-label trial performed in Spain by GESITRA evaluated the efficacy of the preemptive administration of caspofungin in **adult liver transplant** recipients at high risk of developing Aspergillosis [283]. A total of 71 patients were enrolled in the study and received caspofungin for at least 21 days. Two patients (2.8%) developed an invasive fungal infection—a *Mucor* and a *Candida albicans* surgical wound—respectively, after caspofungin therapy was finished (41 and 19 days, respectively). Six more patients (8.4%) discontinued caspofungin because of drug-related altered liver function. Hence, successful treatment outcome was obtained in 88.7%. None of these patients developed IA. The authors conclude that caspofungin is an efficacious and well-tolerated drug as antifungal prophylaxis in high risk liver transplant recipients [283].

Anidulafungin was safe in a retrospective series of adult solid organ transplantation (SOT) recipients [333]. Sixty-two patients (72%) received anidulafungin for prophylaxis. There was no need for the modification of immunosuppressive drug doses and no patient discontinued anidulafungin because of severe adverse effects. While receiving anidulafungin, one patient developed mild liver toxicity, but the liver function normalized without the discontinuation of anidulafungin.

A recent prospective, open-label, noninferiority, multicentric study (TENPIN study) analyzed the role of preemptive antifungal therapy with micafugin in high risk liver transplant recipients (48.0% had a Model for End-Stage Liver Disease score ≥ 20). Patients were randomized to receive intravenous micafungin 100 mg or center-specific standard care posttransplant. Overall, 344 patients were included: 172 micafungin; 62 fluconazole/59 L-AmB/21 caspofungin. Both arms of prophylaxis were very effective (98.6% for micafungin and 99.3% for standard care). At end of prophylaxis there were 12 episodes of invasive fungal disease, 8 candidiasis and 4 aspergillosis (2 in the micafungin arm and 2 in the standard of care—1 fluconazole and 1 L-AMB). Tolerance was excellent in both arms, although kidney function was better with micafungin. Adverse events leading to drug discontinuation was 6.4% for micafungin and 11.6% in the standard of care. At EOP, liver function tests were similar but creatinine clearance was higher in micafungin- vs standard care–treated patients [334].

TABLE 40-3. Recommended fungal prophylaxis against mold infections for solid organ transplant recipients

Type of transplant	Fungal pathogen targeted	High-risk factors	Antifungal agents	Duration of prophylaxis
Liver	*Aspergillus*[a]	Tx for fulminant hepatic failure Retransplantation Reoperation involving thoracic or intraabdominal cavity Post-Tx hemodialysis CMV infection	Echinocandins or Lipidic formulations of amphotericin B	3–4 weeks
Heart	*Aspergillus*	Post-Tx hemodialysis CMV disease Reoperation High concentration (>25 cfu/m3) of *Aspergillus* spores in the ICU or other case of IA in the Tx program	Echinocandins or itraconazole or voriconazole	During the risk factor and 2 more weeks
Lung	*Aspergillus*	Airway sample culture positive for *Aspergillus* CMV infection Obliterative bronchiolitis Rejection Increased immunosuppression	Nebulized liposomal amphotericin B ± Echinocandins Voriconazole, or Itraconazole	4–6 months ± Prolonged or perhaps indefinite

Modified from [106] and [68].
Abbreviations: *CMV* cytomegalovirus infection; *OKT3* monoclonal anti-T-cell antibodies.
[a]Liver transplant recipients with airway sample cultures positive for *Aspergillus* should be considered for therapy for invasive aspergillosis.

Another clinical trial, also including liver transplant recipients with risk factors for IFI, compared anidulafungin and fluconazole administered during a median of 21 days after transplantation [335]. This randomized, double-blind trial showed that the incidence of IFI (5.1% anidulafungin and 8.0% fluconazole) was similar in both arms. There were two cases of IA in the fluconazole arm, but not a single patient died of IFI. The results of this study are provocative, as the risk factors for Candida and Aspergillus frequently overlap and both microorganims have to be prevented in many patients. A summary of the previously commented are summarized in Table 40-3.

40.2.8.3 Avoidance of Epidemiologic Exposures After Transplantation

a) Hospital exposures. The Centers for Disease control and Prevention (CDC) guidelines suggest that hospital policies should minimize the exposure of high-risk patients to potential sources of molds (The CDC specifically refers to *Aspergillus* pathogens in neutropenic patients). These should be put into practice, especially during situations such as hospital construction and renovation. The routine use of HEPA filters in the wards is not required, with the exception of those wards containing neutropenic patients. HEPA-filtered air-handling systems should be used when the potential for the contamination of the air supply exists [336]. In addition, SOT recipients should wear special masks when they are being transported through high-risk areas within the hospital.

   In our experience, the detection of >25 cfu/m3 in nonprotected hospital air, such as an ICU without HEPA filters, is abnormal. The efficacy of antifungal drugs in these high-risk situations (i.e., in hospitals with a high incidence of fungal infections, high concentration of spores or during an outbreak) is not well established. However, when a significant nosocomial environmental exposure is demonstrated and considering the specially high susceptibility of solid organ transplant recipients [67, 116], we recommend the administration of antifungal prophylaxis to all transplants admitted in the affected area [21, 22].

   In addition, flowers and potted plants, which may be colonized with *Aspergillus*, should not be permitted in patient rooms. This restriction must also be applied to food products (e.g., nuts, cereals, spices) that may be colonized with mold spores.

b) Community exposures. A particular association has been noted between invasive pulmonary aspergillosis and gardening; therefore this hobby should be discouraged in SOT recipients [48].

40.2.8.4 Microbiological Surveillance

Microbiologic screening for fungal infections before and after SOT can be conducted for the donor graft an in the recipient [337].

a) Donor graft

   Fiberoptic bronchoscopy with microbiological sampling should be performed routinely in the lung donor in the case of lung or heart–lung transplantation [338].

b) Recipient

In the case of single lung transplantation, the remaining native lung may harbor serious opportunistic infec-

tions. Examining the excised lung of the recipient both histopathologically and microbiologically as quickly and thoroughly as possible is therefore extremely important. If an invasive infection is discovered, the transplant physician should be alerted, because the remaining native lung may harbor the same infection [338]. The presence of an aspergilloma in a potential lung transplant recipient is often considered a contraindication for lung transplantation because of the danger of serious intraoperative bleeding. However, no sound data on this issue exist, especially given the setting of modern surgical techniques. IA of the native lung often requires pneumonectomy [339].

Surveillance cultures for *Aspergillus* are not warranted. The one exception is from lung transplant recipients, in whom the testing of samples should occur. The presence of *Aspergillus* organisms in respiratory cultures mandates inspection for *Aspergillus* tracheobronchitis, anastomotic involvement, and pneumonia. Monitoring for fungal infection after liver transplantation is based on symptoms of infection, and routine monitoring is not necessary.

40.3 Infections Caused by Other Molds

40.3.1 Incidence

In the past few years, the number of infections caused by mold pathogens other than *Aspergillus* has increased. In a multicenter prospective surveillance involving 23 academic centers in the United States, 20% of the mold infections in SOT recipients and up to 56% of IFI-related deaths were caused by molds other than *Aspergillus* species [35, 340]. These mycoses had a higher mortality rate and appeared later than those caused by *Aspergillus*. Thirty-eight percent were diagnosed 6 months after transplantation and 33% at more than 2 years later. Unfortunately, these molds may have variable patterns of susceptibility to current antifungal drugs, which may make their treatment more complex. Some of them are reviewed here.

40.3.2 Mucorales

Mucormycosis or zygomycosis are the names given to the diseases caused by fungi of the order Mucorales. The incidence of mucormycosis complicating SOT seems to be increasing [341]. Although there are no global surveys of the incidence of mucormycosis in SOT patients, its frequency varies widely, from 0.4% to 16% [9, 342, 343], and the onset occurred at a median of 60 days after transplantation [344]. Some authors report a reemergence of zygomycosis and other non-*Aspergillus* mold infections after the introduction of voriconazole and caspofungin in the management of fungal infections [9]. Cases of Zygomicosis have been described after all types of transplantation [9, 344–350]. Almyroudis et al. identified ten cases of zygomycosis in SOT recipients at one center over a 10-year period and reviewed 106 additional cases identified in the literature up to 2002 [344]. In this study, mucormycosis mainly occurred in patients with kidney transplantation ($n=73$), followed by liver ($n=19$), heart ($n=16$), lung ($n=4$), heart and lung ($n=2$) and kidney-pancreas transplantation ($n=2$) [344].

40.3.2.1 Microbiology of Mucorales

Many species have been reported to cause infection in SOT recipients, including *Rhizopus* species, *Mucor* species, *Absidia* species, *Apophysomyces elegans* [351], *Conidiobolus coronatus* [352] and *Cunninghamella bertholletiae* [353, 354]. These organisms typically grow on most media within 2–5 days. However, cycloheximide does inhibit the growth of these fungi, so media containing this compound should not be used when the presence of these fungi is suspected.

The taxonomy of the Zygomycetes was based on the morphologic analysis of the fungus. The differentiation between the genera was accomplished by microscopic examination for the presence and location of rhizoids, the presence of apophyses, and the morphology of the columellae. Other taxonomically relevant features include carbohydrate assimilation and the maximal temperature compatible with growth. The capability to identify Mucorales to the species level is desirable and now is performed by molecular methods [355]. Nowadays molecular methods are crucial for mucormycosis diagnosis because the identification of *Mucorales* species can directly affect epidemiologic studies and treatment strategies, given the differences in antifungal drug susceptibility between species [356, 357]. It may also help the clinician determine whether a fungus found in a subsequent clinical specimen is a different contaminating organism, and it will aid in elucidating the species-specific responses to the new antifungals drugs.

40.3.2.2 Risk Factors

Diabetes mellitus, metabolic acidosis, including that produced in pancreatic transplant recipients with bladder drainage of exocrine secretions; neutropenia; malnutrition; therapy with corticosteroids or deferrioxamine; and acute rejection are predisposing risk factors for this infection [91, 346, 358, 359]. The best risk assessment of zygomycosis in SOT patients has been published in a prospective, multicenter, matched case-controlled study involving consecutive SOT recipients with zygomycosis between September 2003 and July 2008 [9]. The authors describe the clinical characteristics, risk factors, and outcome of SOT recipients with zygomycosis in the era of modern immunosuppressives and newer antifungal agent. In this study, including 50 SOT recipients with invasive zygomycosis and 50 SOT recipients

without zygomycosis, the following variables were significantly associated with a higher risk of infection: renal failure (OR 3.17, $p=0.010$), diabetes mellitus (OR 8.11, $p<0.001$), and voriconazole and/or caspofungin use (OR 4.41, $p=0.033$), whereas the use of the calcineurin-inhibitor, tacrolimus (OR 0.23, $p=0.002$) was associated with a lower risk of zygomycosis [9].

Use of voriconazole, which enhances the virulence of zygomycetes, has been proposed in a number of studies, including hematological patients and SOT recipients, as a risk factor for subsequent zygomycosis [360–363]. Other authors, however, coincided with Singh's finding, in suggesting that is the previous use of any azole or caspofungin, not only voriconazole, what increases the risk of zygomycosis [364].

Remarkably, in the study of Singh et al. [9] tacrolimus was independently associated with a fourfold reduction in the risk of zygomycosis. Although used for its immunosuppressive effects, calcineurin-inhibitors exert certain antifungal role affecting both the virulence and pathogenicity of at least three major opportunistic fungi, *Candida*, *Cryptococcus*, and *Aspergillus* species [365–368]. The precise role of calcineurin inhibitors in the pathogenesis of mucormycosis is not fully elucidated. Both synergistic or additive effect with antifungal agents [368] and an increased inhibition of spore germination, compared with amphotericin B alone [369] have been reported.

40.3.2.3 Clinical Manifestations

Most clinical presentations of these fungi reflect their vascular tropism. These pathogens are notorious for endothelium invasion of blood vessels, which cause infarction in the affected organs and may lead to disseminated infection, which also has extremely high mortality and morbidity rate [370].

In the previous studies, rhinocerebral disease was the most common clinical presentation with one of the following two types: rhinoorbito-cerebral and rhinomaxillary [371, 372]. At present, pulmonary disease is the most prevalent form of zygomycosis in SOT recipients (24–56%), followed by sinus or skin-soft tissue infections (13–31%) and gastrointestinal disease (11–12%) [9, 35, 344, 373, 374]. Disseminated disease occurred in 9–26% and its incidence varied according to the type of transplant recipients: 9–13% in kidney transplantation recipients, 11–20% in heart, 11–25% in lung and 26–55% in liver transplant recipients [9, 344]. A potential explanation for the fivefold higher risk of disseminated disease after liver transplantation are the unique host defense defects or the iron overload in liver transplant recipients [344].

The rhinoorbito-cerebral type begins with fever, swelling, and facial pain [374]. CNS involvement may be precluded by headache, cranial nerve palsies, altered mental status, and seizures. Orbital invasion follows, with the development of cellulitis, ptosis, ophthalmoplegia, the invasion of the ophthalmic and internal carotid arteries, and possibly cavernous sinus thrombosis. Without the early recognition of the syndrome and the prompt initiation of treatment, its mortality is significant. The rhino-maxillary type is less invasive; it involves the sphenopalatine and greater palatine arteries, resulting in thrombosis of the turbinates and necrosis of the palate [359]. This infection can be suspected in a SOT recipient with a clinical presentation of fever, maxillary swelling and edema, and opacification of sinuses on CT scans [350].

FIGURE 40-2. Cutaneous mucormycosis at intravascular catheter exit site in a heart transplant patient.

Pulmonary disease presents as lung consolidation (22.6%), nodular (25.8%), or cavitary lesions (29%) [373]. Cutaneous and soft-tissue infections present as wound infections, nodular lesions with necrotic ulcerations, venous cannula site infections (Figure 40-2), necrotizing fascitis, and sinus tract infections (e.g., after kidney biopsy) [359, 375–379]. The gastrointestinal form is even rarer and it sometimes is accompanied by gastric or intestinal perforation [359, 380–382]. Widespread dissemination to multiple viscera including the brain may occur [347, 350, 352–354, 383–385].

40.3.2.4 Diagnosis

In patients with solid organ transplantation, early diagnosis of mucormycosis is essential, since delayed or missing diagnosis is related to significant mortality and long-term morbidity. However, diagnosis is often not considered during the initial evaluation of SOT patients as demonstrated in a multicenter study performed in France in which the median time from first symptoms to mucormycosis diagnosis was 6 weeks [386].

The hallmarks of disease caused by the Mucorales are vascular invasion and tissue necrosis; black eschars and discharges should arouse the suspicion of this disease. These manifestations occur only after the patient have been infected for some time, so attempts to make a diagnosis of mucormycosis should not await the development of necrotic areas. The diagnosis depends on demonstration of the organ-

ism in the tissue of a biopsy specimen. The microscopic examination of scotch tape touch preparations over the "hairy pus" that is sometimes present in skin areas of mucormycosis may provide an immediate diagnosis.

If mucormycosis is suspected, then a CT scan of the brain, sinus, and chest should be performed, eventually associated with a bronchoscopy if the CT scan of the chest shows abnormalities [387].

An histopathologic examination of the biopsies typically show broad (10–20 mm in diameter), nonseptate hyphae with branches that occur at right angles. Rarely, septae can be visualized. The appearance of Mucorales hyphae in tissue is different from that of *Aspergillus*, *Fusarium,* and *Pseudallescheria* species, as this latter organisms appear as thinner, more regularly shaped fungal elements with more frequent, acute-angle branching. These hyphae are also septate.

The identification of the genus and species requires culture of tissue and assessment of the morphology of the fungal growth. However, in a significant number of cases, cultures results are negative. For reasons that are not altogether clear, the agents of mucormycosis can be difficult to isolate from infected tissue, and they rarely appear in blood culture. Grinding the tissue in the microbiology laboratory is not recommended because the hyphae may be destroyed, possibly preventing the isolation of the fungus from the sample. As mentioned, at present molecular methods are used for species identification [357].

Finally, although not enough clinical data are available, the negativity of β-glucan in a SOT patient with a suspicion of invasive fungal infection can support the diagnosis of mucormycosis [387]. However, because of the high prevalence of mixed fungal infection, clinicians should keep in mind that a positivity of β-glucan or galactomannan do not exclude the diagnosis of mucormicosis [388].

40.3.2.5 Treatment

Neither the classical azoles, ketoconazole, itraconazole, and fluconazole, nor voriconazole have a potential role in the treatment of mucormycosis. The standard therapy for invasive mucormycosis is amphotericin B [389]. Outcome appears to be better with lipid formulations of amphotericin B than with amphotericin B deoxycholate. Singh et al. [9] reported a fourfold higher success rate in patients receiving liposomal amphotericin B, even when controlled for other variables influencing outcomes such as renal failure, disseminated disease, and surgical resection. For primary treatment, liposomal amphotericin B with a usual dose of 5 mg/kg/day is recommended for most patients. However, some experts recommend the administration of higher than usual doses (i.e., as high as 10/mg/kg/day), if needed, in order to control the infection [350].

Posaconazole should be considered as maintenance therapy in persistently immunocompromised patients or as salvage therapy in patients who have disease refractory to or who are intolerant of standard antifungal therapy [387]. Its efficacy as salvage therapy for zygomycosis has been reported in different hosts, including patients with SOT [390–392] and in Singh series 60% of the patients receiving posaconazole as primary therapy had a successful outcome [9]. Of note, posaconazole has important drug–drug interactions with immunosuppressive agents commonly used for SOT and serum levels concentrations should be monitored in order to optimize its variable pharmacokinetic [345].

Although echinocandins have typically demonstrated little activity against zygomycetes and breakthrough infections have been reported in patients receiving these agents, there is a considerable interest in the use of echinocandins as part of combination antifungal therapy for zygomycetes [393, 394]. We evaluated the in vitro effect of combining posaconazole and caspofungin against 12 clinical zygomycetes showing that, although the caspofungin MICs were all above serum drug levels, the combination proved to be synergistic in all strains [395].

The success of treatment is dependent on an early diagnosis, the suppression of predisposing factors, the extension of the disease and the possibility of surgical treatment [9, 345, 350, 373, 396]. Appropriate surgical treatment was reported to be an independent predictor of successful outcome in SOT patients with rhino-orbital-cerebral [374] and pulmonary zygomycosis [373]. It consists of the early extensive debridement of necrotic tissue, ideally until the surgical margins are free of the infection [350]. A pulmonary wedge resection may be sufficient, however, at times, a lobectomy is required to eradicate a confined lung mucor infection, which is associated with a mortality rate of 65% [350, 396]. A surgical approach is recommended even if complete resection is not feasible.

40.3.3 Dematiaceous Fungi

40.3.3.1 Microbiology

Dematiaceous is the term that is applied to septate molds with dark walls in culture, an appearance that the walls do not necessarily have in tissue. More than 100 species that belong to at least 57 genera are known to be agents of infection. *Alternaria*, *Bipolaris*, *Curvularia,* and *Exserohilum* are the most frequently isolated genera, while others (*Chaetomium*, *Cladophialophora*, *Cladosporium*) have been reported only anecdotally. These saprophytic fungi are widely distributed in the environment. One large prospective study on dematiaceous infections in SOT recipients analyzing clinical characteristics, site of infection, and outcome has been recently published [397].

40.3.3.2 Incidence

Data from the USA was offered in the multicenter register TRANSNET, in which 2.5% of invasive fungal infections among SOT recipients were caused by phaeohyphomycosis

[397]. One American institution reported an overall incidence of infection due to dematiaceous fungi of 0.7% with a higher rate of infection among kidney/pancreas transplant patients (3.6%) [398]. In these studies, the time from transplantation to onset of infection varied widely, ranging from 19 days to 11 years [397, 398].

40.3.3.3 Clinical Manifestations

The infections caused by these fungi include chromoblastomycosis, phaeohyphomycosis, and mycetoma, although the latter could be caused by other molds or by *Actinomyces* species. Mycetoma and chromoblastomycosis are infections that are localized in the skin and subcutaneous tissue; phaeohyphomycosis comprise a heterogeneous group of infections that range from superficial, cutaneous, or subcutaneous infections to disseminated invasive disease. Some of the infections caused by these fungi are summarized in Table 40-4.

Clinically, the most common manifestations are cutaneous and subcutaneous disease, followed by pulmonary and invasive sinus infection [397]. Disseminated disease, involving more than one noncontiguous site of infection, is present in more than half of the patients, whereas bloodstream or central nervous system infection are uncommon among SOT patients [397]. The survival rate among patients with soft-tissue infections is more than 90% [397], whereas that for patients with invasive infections is lower, at approximately 50% [50, 399]. The only patient with CNS infection died [397].

40.3.3.4 Diagnosis

Melanin in the hyphal wall can be stained with the Masson-Fontana dye, allowing differentiation from other nonmelanin containing fungi. With hematoxylin and eosin staining of tissue, the fungus has a golden brown hyphal wall. The hyphae are irregular in diameter and are septate. Chains of yeast-like cells may be seen with the presence of some species. The irregular diameter and bulbous swellings of these hyphae may help distinguish them from *Aspergillus,* but culture is essential for diagnosis. Molecular methods are very helpful for the correct identification at species level [400].

40.3.3.5 Treatment

Surgical excision or debridement is recommended whenever possible, and represents a mainstay of therapy [401]. For both soft-tissue lesions and single brain abscesses, the necessity of achieving disease-free resection margins to prevent the recurrence of infection should be emphasized [402].

The recognition of infection due to dematiaceous fungi is important because these infections, unlike IA, may be more accessible to therapy. These fungi are generally susceptible to itraconazole, which is the preferred treatment option, given the wide clinical experience with this drug. However, because of varied resistance pattern among species [398, 403], antifungal susceptibility data should be obtained for all specimens, if feasible. Recently, the European Society of Clinical Microbiology and Infectious Diseases published guidelines for treatment of infection caused by dematiaceous fungi and recommended as first line options voriconazole, posaconazole, itraconazole, and amphotericin B [105, 401]. Voriconazole and amphotericin B should be preferred for the treatment of central nervous system infections because of their consistent ability to achieve good cerebrospinal fluid concentrations [105, 397].

After a recurrence, long-term itraconazole therapy may be used following repeated surgical drainage to help prevent a new recurrence. Combination therapy such as amphotericin B with 5-FC (when the fungus is susceptible to the drug) [404] has been advocated for CNS lesions, particularly for lesions that are poorly resectable or are unresectable. Posaconazole has been employed successfully as salvage therapy in hematological patients with refractory invasive mold infections, including *Alternaria* spp. [405].

In vitro susceptibility to echinocandins has been described for the *Curvularia*, *Exophiala,* and *Fonseca* species, although their role for the treatment of these infections remains to be clarified.

40.3.4 Hyalohyphomycosis

40.3.4.1 Microbiology

The term hyalohyphomycosis has been proposed for the opportunistic mycotic infections that are caused by fungi whose tissue form consists of hyaline hyphal elements. Fusariosis accounts for approximately ~1% of fungal infections in SOT recipients, being lung transplant recipients the most commonly affected [340].

Infections in SOT recipients caused by various fungi of this type in SOT recipients are summarized in Table 40-5.

40.3.4.2 Clinical Manifestations

Fusarium Species

Unlike fusarial infection in patients with hematologic malignancies or bone marrow transplantation, fusarial infection in SOT recipients tends to be localized [406, 407], it occurs later in the posttransplantation period, and it has a better outcome [408]. The skin lesions usually appear as cellulitis, ulcers, papules, or as deeply set, painful nodules. They may initially be flat (macular) with a central pallor, but they later become raised, erythematous, and necrotic. Reports on fusariosis in kidney ($n=6$), lung ($n=2$), combined heart–liver

($n=1$) and liver ($n=3$) transplantation recipients have been published. Presentation forms include seven cases of localized skin infections, three disseminated infections (one endocarditis and one with liver abscesses), one peritonitis, and 1 lung abscess [406–417].

Paecilomyces Species

Paecilomyces infection has been described in ten SOT recipients [244, 418–426]. The skin and soft tissues were affected in nine cases, and, in one pediatric lung transplant recipient, the fungus was isolated from the respiratory tract.

Scedosporium Species

Human infection with *Pseudallescheria boydii* (the anamorph state of *S. apiospermum)* or with *S. prolificans* can produce the following two distinct diseases: mycetoma and pseudoallescheriasis. Mycetoma is a chronic subcutaneous infection that is characterized by the production of grains. Pseudallescheriasis includes all other infections caused by *Scedosporium* species [427–432].

Scedosporium species now account for ~25% of all non-*Aspergillus* mold infections in SOT recipients [8]. In a recent article, Husain et al. [45] published a series of 80 transplant recipients with *Scedosporium* infections (57 SOT and 23 HSCT recipients). Among SOT recipients, 83% of the infections were due to *S. apiospermum* and 19% to *S. prolificans.* Dissemination occurred in 46% of the patients, CNS involvement in 29%, lung infection in 43% and cutaneous disease in 31%. Fungemia was significantly more common with *S. prolificans* than with *S. apiospermum* infections (57% vs 8%, $p<0.001$). The death rate ranged from 54% to 73%, a figure that was nearly 100% in patients with disseminated disease, CNS involvement, fungemia, and renal failure [45].

More recently, Johnson et al. [433] reported a series of 11 SOT patients infected by *S. apiospermium* (55%) or *S. prolificans* (45%). Overall, 55% (6/11) scedosporiasis occurred

FIGURE 40-3. Invasive lung infection caused by *Scedosporium prolificans* in a young liver transplant recipient with cystic fibrosis. The patient died despite therapy with liposomal amphotericin B and voriconazole.

in lung transplant patients, whereas 18% (2/11) were diagnosed in multivisceral transplants. Interestingly, 36% of the patients were previously colonized by the same species and developed disease despite receiving preemptive voriconazole therapy either alone or combined with other antifungal agents. Scedosporiasis occurred earlier among patients who were colonized in the pretransplantation period compared with those who were not (15 vs 217 days). Clinical manifestations include pneumonia, mediastinitis, and fungemia/disseminated disease. Patients who died (6/11, 55%) had an earlier diagnosis of scedosporiasis after transplantation and were more likely to have clinical manifestations other than pneumonia.

In recent years, *Scedosporium* infections have been observed to occur later after transplantation (4–6 months) than before [45, 434]. It is argued that the more frequent use of antifungal prophylaxis after transplantation could have delayed the onset of these infections and exerts a selective pressure favoring the emergence of these resistant pathogens [433, 435–437]. The radiological and histopathologic appearance of scedosporidiosis is indistinguishable from infections caused by other molds (Figure 40-3), with the exception of a higher tendency to involve the CNS. Definite diagnosis depends therefore on fungal culture. New molecular diagnostic methods have been also employed to distinguish *S. apiospermum* from *S. prolificans* [438, 439].

The early diagnosis of this infection is essential because S. *apiospermum* is resistant to amphotericin B, and *S. prolificans* is also resistant to most currently available antifungal agents [431, 432, 440]. Based on previous experiences [45, 433, 441], current treatment of scedosporiasis comprise voriconazole and prompt surgical debridement, if the latter is feasible [45]. A synergistic effect between voriconazole and terbinafine has been shown in vitro and this combination should be considered in case of a disease due to *S. prolificans.*

Scedosporium can colonize the sinuses and airways of patients with underlying pulmonary diseases and is the second most frequent filamentous fungus, after *A. fumigatus*, isolated from the sputum in cystic fibrosis patients with a prevalence of >8% [442]. Pretransplant colonization should be considered as an indication for double-lung transplantation in candidates for lung transplantation. In all SOT recipients, colonization by *Scedosporidium* should not be ignored and prophylaxis or suppressive therapy with voriconazole should be considered in these patients [442].

Scopulariopsis Species

Scopulariopsis infection is also extremely rare in the SOT population. Eight cases have been described [443–450], three in liver transplant recipients, three in lung transplant recipients, one in a heart and one in a lung-heart transplant recipient. Three patients presented with skin or subcutaneous tissue involvement, which was cured. Of two patients presenting with respiratory tract infections, one survived receiving combination antifungal therapy with posaconazole and terbinafine, whereas the other died. One patient, who presented with a CNS abscess, died despite treatment with amphotericin B and miconazole, and in the other fatal case *Scopulariopsis Acremonium* was identified in the pericardial biopsy after the patient died. Finally, a heart–lung transplant patient developed disseminated disease due to *Microascus cirrosus* and died 4 weeks after transplantation despite antifungal combination therapy with voriconazole and caspofungin.

40.3.4.3 Diagnosis

The diagnosis is most commonly made by culturing the organism from infected sites. In contrast to aspergillosis, in which the blood cultures are nearly always negative, fungemia due to *Fusarium* or *Scedosporium* species is not rare. These fungi are indistinguishable from *Aspergillus* in histopathologic studies (i.e., they all present with dichotomously branching septate hyaline hyphae). Therefore, it is necessary to isolate them from a culture for their identification to proceed. The identification is based chiefly on the morphologic characteristics of the asexual structures produced by the molds in culture.

40.3.4.4 Treatment

Treatment of infections caused by mold pathogens other than *Aspergillus* can be very challenging. Because randomized controlled trials have not been published yet, data regarding the optimal management of such infections are limited. As with any opportunistic infection, the first step in the therapeutic strategy should be to correct the underlying risk factors. The doses of immunosuppressive drugs, including steroids, should be decreased, if possible. The recovery of the immune status of the patient is vital since treatment with conventional antifungal drugs (e.g., amphotericin B, the

azoles) are less efficacious, either because these species are more resistant to drugs or because they have a more aggressive clinical evolution.

The optimal treatment regimen for fusarial infections is unknown. This fungus is uniformly resistant to 5-fluorocytosine, and it is usually resistant to itraconazole as well. Surgical resection, when this is possible, and prolonged treatment with a lipid formulation of amphotericin B at a dose of 5 mg/kg has been the standard of care [408]. The clinician must remember that susceptibility to amphotericin B varies. Therefore, some strains have been refractory to this treatment; in these cases the newer compound should be tried. At present, voriconazole is, in many experts' opinions, the drug of choice for *Fusarium* infections, although more data in SOT are required and susceptibility studies should be performed in each case. Salvage therapy with posaconazole was found to be effective and safe in two SOT patients with invasive fusariosis intolerant of or failing other antifungal therapies [392].

The susceptibility of *Paecilomyces* species to the currently available antifungal agents is highly variable among the different species. Therefore, precise fungal identification and in vitro susceptibility testing are mandatory. When immediate antifungal therapy is required, amphotericin B and 5-fluorocytosine should be considered for infections caused by *Paecilomyces variotti*, whereas the imidazoles might have more efficacy in treating *P. lilacinus* and *Paecilomyces marquandii* [424]. In one heart transplant recipient with leg nodules caused by *P. lilacinus*, the infection was successfully treated with terbinafine [420]. Another heart transplant patients who presented with mixed cutaneous infection due to *M. chelonae* and *Paecilomyces* species was successfully treated with sequential itraconazole and terbinafine [426]. Treatment with traditional antifungal drugs often fails. Voriconazole has demonstrated good activity in both cutaneous and ocular infections in the few cases in which this drug has been used. The new triazoles ravuconazole and posaconazole show good in-vitro activity against *P. lilacinus* and could be promising therapeutic alternatives [451].

Response to therapy in patients with scedosporiasis is strictly dependent on the site of infection, extent of dissemination, and immune status of the host. Generally, outcome is more favorable in patients who have localized infection and receive a prompt surgical debridement [401]. Antifungal therapy of infections by *P. boydii* (the anamortph of *S. apiospermum*) has not been established. Reports indicate that it has in vitro and clinical resistance to amphotericin B [245], 5-flucytosine and terbinafine. Success with itraconazole and voriconazole has been reported [45, 452]. Surgical debridement is an important adjunct in the treatment of pseudallescheriasis of the soft tissue, bone, joint and pleural, and paranasal sinuses, although it is not curative in and of itself. Voriconazole seems to be a good therapeutic option for improving surgical results, an in vitro susceptibility to caspofungin has also been described [453].

Infections caused by *Scedosporium prolificans* are quite difficult to treat because this fungus appears to be intrinsically resistant to most of the currently available antifungal agents [436]. These infections may respond to azole antifungal agents [454] or to the combination of terbinafine with the azoles voriconazole, miconazole, and itraconazole [455].

40.3.5 Other Fungi: Dermatomycoses

40.3.5.1 Microbiology

Superficial fungal infections (dermatomycoses) include some common conditions such as ringworm or dermatophytosis; pityriasis versicolor, which is caused by yeasts, such as *Malassezia* species; and some rare disorders, such us tinea nigra, a superficial form of phaeohyphomycosis caused by *Hortaea (Exophiala) werneckii*.

The dermatophytes are molds that can invade the stratum corneum of the skin or other keratinized tissues derived from epidermis, such as the hair and nails. They may cause infection at most skin sites, although the feet, groin, scalp, and nails are most commonly affected. Nail fungal invasion is termed onychomycosis. The three genera of pathogenic dermatophyte fungi are as follows: *Trichophyton*, *Microsporum,* and *Epidermophyton*.

Infections caused by *Microsporum* and *Trichophyton* have been described in the following SOT recipients: heart [456, 457]; heart–lung [458], liver [459] and kidney [460–467]. Pityriasis versicolor is the most frequent dermatomycoses in SOT population, and it has a higher prevalence than that encountered in the normal population (Figure 40-4). The prevalence of onychomycosis is similar to that observed in the immunocompetent population. The probability of dis-

FIGURE 40-4. Pytiriasis versicolor in a heart transplant patient.

ease appears to increase with the length of time after transplantation, as does the incidence of mixed or simultaneous fungal infections in the same patient [462].

40.3.5.2 Risk Factors

As in all other mold infections, the chronic immunosuppressive state of SOT recipients makes their skin more liable to fungal infections [457, 462].

40.3.5.3 Clinical Manifestations

The typical tinea lesion is an annular scaling patch with a raised margin that has a variable degree of inflammation, in which the center is usually less inflamed than the edge. The clinical appearance of the infection sometimes varies with the site, the fungal species involved, and the host's immune response. At times, the lesions are inflammatory, and. in some cases, large pustular lesions may develop. Lesions may become chronic.

The clinical appearance is altered in immunocompromised individuals. In these patients, the fungi may invade subcutaneous tissues via the lymphatics, usually causing clusters of granulomas, lymphedema, and draining sinuses. Deep dermatophyte infections may extend further, involving draining lymph nodes or other sites, including the liver and brain; these may be fatal. In SOT recipients, specifically extensive dermal disease (Majocchi's granuloma) [457, 468–470] and primary invasive cutaneous disease have been reported [459, 464].

As in nonimmunosuppressed hosts, the most common clinical pattern of onychomycosis in SOT recipients is distal and subungual onychomycosis, in which the nail plate is invaded from the distal and lateral borders. Associated thickening of the nail, which becomes white, yellow, or brown, is usually observed.

40.3.5.4 Diagnosis

The laboratory diagnosis of dermatophytosis depends on the examination and culture of scrapings or clippings from lesions. Sampling the edge of skin lesions and infected nails is important. The material should be allowed to soften in 10–20% potassium hydroxide before it is examined under the microscope. Fungal hyphae can be seen as chains of arthrospores in cleared scales or clippings.

Scrapings or nail clippings may also be cultured. The primary isolation is carried out at room temperature, usually on Sabouraud's agar containing antibiotics and cycloheximide, an antifungal agent that suppresses the growth of environmental contaminant fungi. In the case of nail disease, media without cycloheximide should be used, because certain fungi, such as *Scytalidium*, that may infect nails are sensitive to the latter. Most dermatophytes can be identified within 2 weeks. The identification mostly depends on the gross colonial and microscopic morphology.

40.3.5.5 Treatment

Itraconazole, ketoconazole, terbinafine, and griseofulvin are used as oral therapy for cutaneous and subcutaneous dermatomycoses. CsA levels should be monitored during ketoconazole therapy because they usually increase and may cause nephrotoxicity.

The oral agent terbinafine, an allylamine structurally related to naftifine, is effective in the treatment of ringworm, including onychomycosis; its efficacy is comparable to that of the azoles derivatives [457]. It is 99% protein bound. Terbinafine is metabolized in the liver and it has an initial half-life of 12 h. The drug accumulates in skin, nails, and fat. Probably because of its accumulation in fat and subsequent release, terbinafine persists in plasma for 4–8 weeks after dosing, and it has a terminal half-life of 200 to 400 h. This clearance is slowed in the presence of liver or renal impairment. Rifampin markedly increases terbinafine clearance, while cimetidine modestly decreases it. Terbinafine induces CsA metabolic degradation, which, however, is of little clinical significance. The CsA levels, however, should be controlled during treatment with this drug [471]. Side effects, principally gastrointestinal and taste complaints, rarely limit therapy. Hepatitis is an uncommon side effect. Other approaches, such as topical agents and excisional procedures, may also be used as complement of systemic antifungal drugs.

Endemic Mycoses After Hematopoietic Stem Cell or Solid Organ Transplantation

Carol A. Kauffman and Marisa H. Miceli

41.1 Introduction

The three major endemic mycoses that cause infections in transplant recipients are histoplasmosis, coccidioidomycosis, and blastomycosis. When compared with opportunistic fungi, the endemic mycoses are responsible for many fewer infections among transplant recipients [1–3]. The endemic mycoses exhibit temperature and tissue dimorphism. In the environment and at temperatures below 35 °C in the laboratory, these organisms are molds; at body temperature, they exist as yeasts (*Histoplasma capsulatum* and *Blastomyces dermatitidis*) or spherules (*Coccidioides immitis* and *Coccidioides posadasii*).

H. capsulatum, Coccidioides species, and *B. dermatitidis* occur naturally in the environment only in specific geographic areas. Thus, an infection will occur only if the patient has been in that specific area at some time in his or her life. Many patients who are markedly immunosuppressed do not feel well enough to participate in outdoor activities, and thus their exposure to the endemic mycoses is limited. However, the conidia of *Coccidioides* species are easily aerosolized, and coccidioidomycosis can be acquired simply by living in or merely passing through the endemic area [4, 5].

The exposure to one of the endemic mycoses may have occurred years, even decades earlier. These organisms have the ability to remain dormant in the body after the initial infection. Years later, when immunosuppression occurs for a variety of different reasons, the organisms reactivate and proliferate, causing disease. The prototype organism that has been documented most clearly as a cause of reactivation infection is *H. capsulatum* [6]. *Coccidioides* reactivation has been postulated to cause infection early in the post-transplantation period [7], and reactivation of *B. dermatitidis* also has been thought to account for some infections in the post-transplant period [8]. Because these infections are unusual outside the endemic area, the diagnosis can be easily missed and appropriate treatment not given in patients currently living in an area in which these organisms are not endemic. A careful history of travel and residence should be confirmed before any transplantation procedure so that the clinician is aware of all possible post-transplantation infectious complications.

Both *H. capsulatum* and *Coccidioides* species, but not *B. dermatitidis,* have been noted to have been transmitted with the donor organ, reflecting their ability to remain latent in many different tissues and to reactivate with immunosuppression [3, 9–17]. In several of these cases, the donor had spent time in the endemic area but the recipient had never even traveled to those areas.

These fungi are true pathogens in that they cause disease in healthy people, as well as immunosuppressed hosts. The severity of infection depends on the extent of the exposure (the number of conidia inhaled) and on the immune state of the host. Following inhalation, hematogenous dissemination occurs frequently, even in the normal host, but it is almost always a silent event, with no evident disease. However, immunosuppressed patients are more likely to develop severe symptomatic disseminated infection at the time of initial infection [18–20].

The agents of choice for treatment of the endemic mycoses are a lipid formulation of amphotericin B for those with severe infection and itraconazole or another azole after the patient has responded to amphotericin B. Primary therapy with an azole is used occasionally in a transplant recipient who has only localized infection, and azoles are used for prophylaxis to prevent primary infection and suppressive therapy to prevent relapse.

41.2 Histoplasmosis

41.2.1 Epidemiology

The endemic area for *H. capsulatum* encompasses the Mississippi and Ohio River valleys and focal areas along the eastern coast of the USA, many areas throughout Central and South America, and focal areas in Africa and Southeastern Asia. The organism grows best in soil that contains high concentrations of nitrogen, which is found commonly under roosts for birds and bats. Point-source outbreaks most often

P. Ljungman et al. (eds.), *Transplant Infections*, DOI 10.1007/978-3-319-28797-3_41

involve healthy individuals who have participated in a variety of activities, including cleaning attics and barns, demolishing old buildings, landscaping, and spelunking, but can also occur in an urban setting, as happened in Indianapolis several decades ago, in which more than 120,000 residents were infected [21, 22].

Histoplasmosis is the most common endemic mycosis reported in solid organ transplant recipients [1, 3, 10, 16, 17, 23–32]. The 12-month cumulative incidence rate for histoplasmosis among solid organ transplant recipients was reported to be 0.1% in the 5-year, multi-center, transplant-associated surveillance network (TransNet) study [3]. Fewer cases of histoplasmosis have been reported to occur after hematopoietic stem cell transplantation [2, 3, 20, 33–35]. It is likely that histoplasmosis is the most frequently reported endemic mycosis in transplant recipients because of the wide geographic distribution of this organism and the high attack rate among inhabitants residing in the endemic area.

41.2.2 Pathogenesis

Infection follows aerosolization of the microconidia of *H. capsulatum* into the lungs where they are phagocytized by alveolar macrophages and then convert to the yeast phase inside the cell. The organism routinely disseminates hematogenously to the organs of the reticuloendothelial system before cell-mediated immunity arms the host's macrophages to kill the intracellular yeasts [36]. The primary host defense against *H. capsulatum* is cell-mediated immunity with little contribution from the humoral or neutrophil defense mechanisms; thus, patients with cell-mediated immunodeficiencies, such as transplant recipients, are at the highest risk of severe infection.

The occurrence of histoplasmosis is bimodal, with some cases occurring within the first 6 months (40% of cases in the TransNet study) and others occurring as long as 18–20 years after transplantation [3, 16]. As most solid organ transplant recipients continue on some type of immunosuppression, the period at risk for an endemic mycosis persists long after the immediate post-transplant period.

H. capsulatum has the propensity to persist in a latent state for years and then to reactivate when immunosuppression intervenes. Reactivation infection has been noted in some transplant recipients, but differentiating reactivation from new infection in patients who live in the endemic area is difficult. Infection could as easily be due to a new infection as to reactivation.

Transmission of *H. capsulatum* from the donor organ has been documented in a small number of patients and suspected in others because of early onset of disease after transplantation [3, 10, 16, 17, 37–39]. In a few patients, *H. capsulatum* was found in the donor organ, and the recipients were pre-emptively treated with antifungal agents [3, 17].

41.2.3 Clinical Manifestations

Transplant recipients can have primarily pulmonary manifestations [3, 17, 23, 24, 29, 30] or more commonly, disseminated infection [3, 10, 17, 24, 27, 28, 30–34, 37–39]. Pulmonary infection presents with fever, chills, cough, and shortness of breath and frequently progresses to marked dyspnea and hypoxemia. Chest radiographs most often show diffuse bilateral infiltrates (Figure 41-1). Mediastinal or hilar lymphadenopathy, common seen in acute pulmonary histoplasmosis in healthy hosts, is rarely seen in immunosuppressed patients.

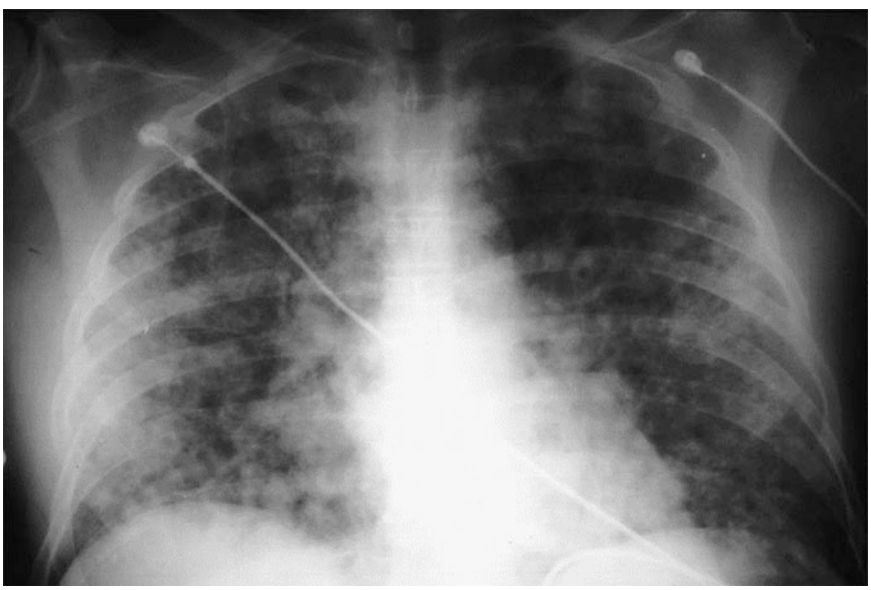

FIGURE 41-1. Bilateral pulmonary infiltrates in a patient who had received a kidney transplant 2 years before. *H. capsulatum* grew in bronchoalveolar lavage fluid and in blood cultures.

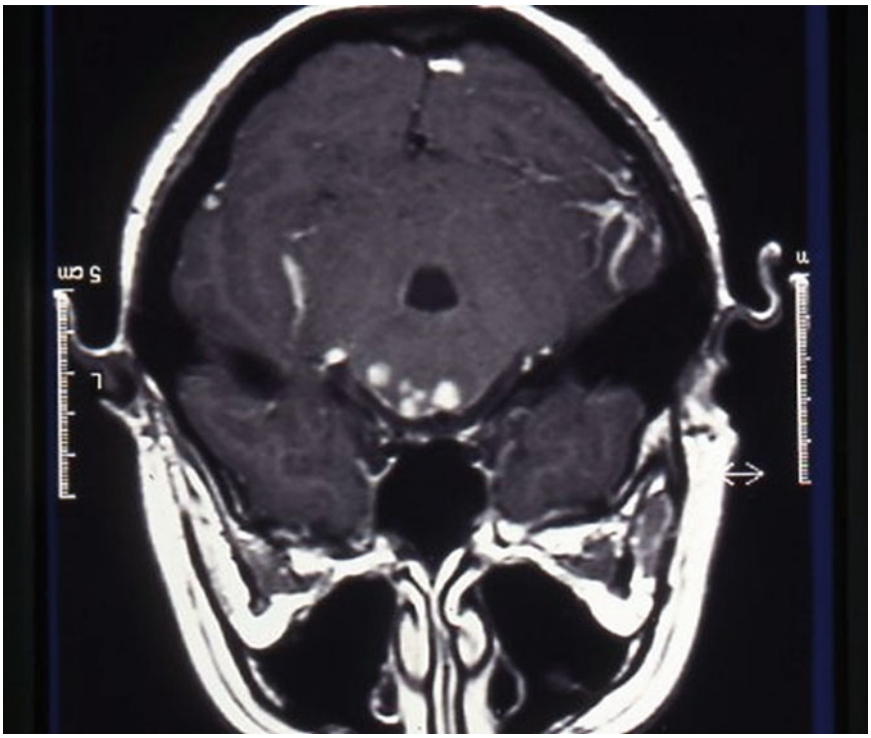

FIGURE 41-2. Enhancing brain lesions in a patient who had meningoencephalitis due to *H. capsulatum.*

The manifestations of disseminated histoplasmosis are protean, but most patients present with fever, chills, fatigue, anorexia, and weight loss. Hepatosplenomegaly, mouth ulcers, and skin lesions should be sought. The mucous membrane lesions are usually painful and nonhealing ulcers; the cutaneous manifestations include papules, pustules, plaques, ulcers, abscesses, and cellulitis. Abnormal liver enzyme values, especially elevated alkaline phosphatase, and pancytopenia are common. Gastrointestinal involvement is manifested by diarrhea and abdominal pain; ulcerations have been noted diffusely throughout the small bowel and colon. Severe disseminated histoplasmosis can be associated with DIC and life-threatening hemophagocytic syndrome [31]. Central nervous system involvement is not common, but probably occurs more often in immunosuppressed patients; it usually is characterized by lethargy, headache, and confusion. Intracranial mass lesions that are best visualized on magnetic resonance imaging can occur with or without meningitis (Figure 41-2).

The mortality of histoplasmosis in transplant recipients is reported to be 9–15% in recent series [3, 16, 24]. In cases in which the diagnosis is delayed, the mortality is high [3, 33, 34, 38]. Not surprisingly, this is especially true of patients who present outside the endemic area for histoplasmosis. When the diagnosis is made early and appropriate therapy is initiated, the mortality is less than 10%. *H. capsulatum* is very susceptible to amphotericin B, and most patients respond quickly to appropriate therapy.

41.2.4 Diagnosis

The definitive diagnosis of histoplasmosis is made by growing *H. capsulatum* from sputum, blood, other body fluids, or biopsy tissue [6]. *H. capsulatum* grows very slowly, a decided drawback in an immunosuppressed patient. The yield from blood cultures is enhanced by using the lysis-centrifugation system (Isolator tube system, Wampole Laboratories); automated blood culture systems, such as BacT/Alert and Bactec, have a lower yield and take a longer time to show growth of *H. capsulatum* [40]. Although growth in culture provides proof of the cause of the illness and is extremely important, it often merely confirms the correct diagnosis in a patient for whom treatment has already been initiated.

Serological assays (complement fixation and immunodiffusion) are useful tests for the diagnosis of histoplasmosis in normal hosts. The development of complement fixation antibody or the appearance of specific bands on the immunodiffusion assay, especially when baseline results are negative, can be quite helpful. However, these tests are often not positive in immunosuppressed patients who cannot mount an effective antibody response [41].

The detection of *H. capsulatum* capsular polysaccharide by enzyme immunoassay (EIA) on urine and serum is an extremely useful test in patients who have disseminated histoplasmosis [42, 43]. This assay has assumed an increasingly important role in the diagnosis of histoplasmosis in transplant recipients. False positive assays occur primarily with blastomycosis and less commonly with coccidioidomycosis.

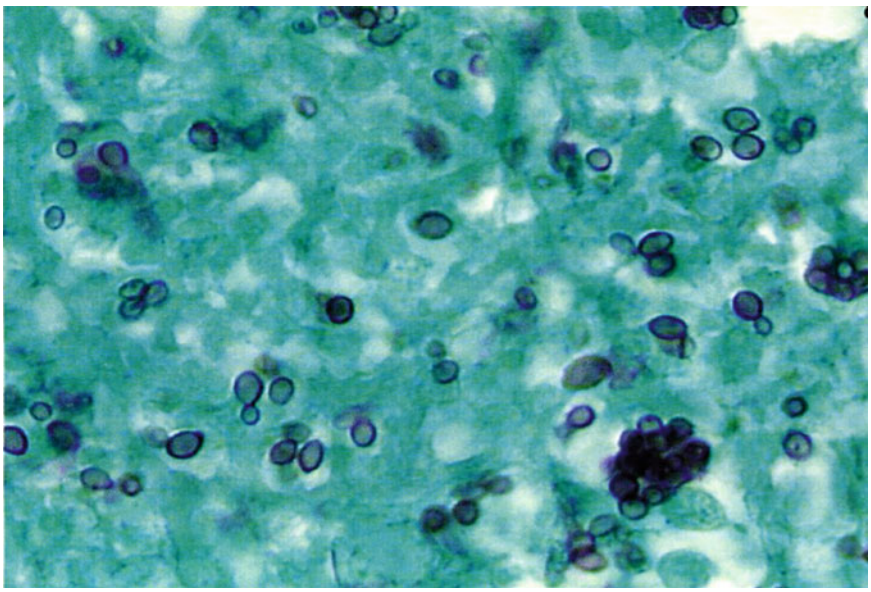

FIGURE 41-3. Liver biopsy in a transplant recipient who had fever, fatigue, elevated alkaline phosphatase, and pancytopenia. Gomori methenamine silver stain shows 2–4 µm oval budding yeasts typical of *H. capsulatum*.

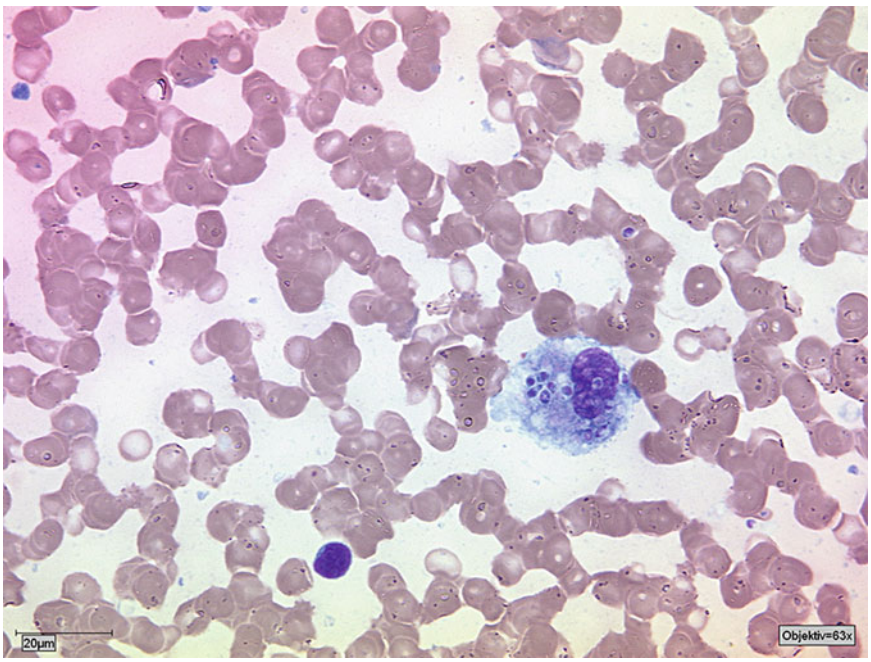

FIGURE 41-4. Peripheral smear showing *H. capsulatum* yeast forms inside a monocyte. The patient was acutely ill with high fevers, pancytopenia, and dyspnea.

False positive reactions with the Platelia *Aspergillus* galactomannan assay have been reported in immunosuppressed patients who have disseminated histoplasmosis, most likely because of the huge burden of circulating *Histoplasma* antigen in these patients [32, 44]. The converse is not the case: false positive *Histoplasma* antigen tests have not been reported in patients with invasive aspergillosis.

In a transplant recipient who has severe disease, biopsy of tissue to identify *H. capsulatum* is an important rapid diagnostic tool. Routine hematoxylin and eosin staining often will not reveal the small yeasts; either periodic acid–Schiff (PAS) stain or methenamine silver stain should be used (Figure 41-3). Appropriate tissues for sampling include the lung, mucocutaneous lesions, bone marrow, and liver. The organisms appear as small, 2–4-µm, oval, and budding intracellular yeasts. The organisms can sometimes be seen within neutrophils or monocytes on a peripheral blood smear (Figure 41-4).

41.2.5 Treatment

The Infectious Diseases Society of America guidelines for the treatment of histoplasmosis recommend antifungal treatment for all immunosuppressed hosts with histoplasmosis [45]. For patients who have moderate to severe pulmonary

histoplasmosis or who have disseminated histoplasmosis, liposomal amphotericin B, 3–5 mg/kg daily, is preferred. This formulation has been shown to have increased efficacy and decreased toxicity when compared with amphotericin B deoxycholate in patients with disseminated histoplasmosis [46]. After the patient shows clinical improvement, therapy can be changed to an azole to continue the course of therapy (Table 41-1).

The preferred azole for the treatment of histoplasmosis is itraconazole [45]. This is used for step-down therapy after

TABLE 41-1. Treatment of endemic mycoses in solid organ transplant recipients

	First line therapy	Alternative therapy	Comment
Histoplasmosis			
Mild localized acute pulmonary infection	ITRA loading dose as below[a], then 200 mg twice daily for at least 12 weeks	FLU 400–800 mg daily is a less preferred alternative	
Moderate to severe pulmonary infection	Liposomal AmB 3–5 mg/kg daily for 1–2 weeks until clinical improvement, followed by ITRA loading dose as below[a], then 200 mg twice daily for a total of 12 months	Alternatives for step-down therapy include VORI loading dose as below[b], then 200 mg twice daily, **OR** POSA loading dose as below[c], then 300 mg daily, **OR** FLU 400–800 mg daily, all for a total of 12 months	High-dose methylprednisolone should be considered for patients with severe hypoxemia or acute respiratory distress syndrome. Few patients have been treated with the alternative drugs Suppressive therapy with azoles should be considered in patients with persistent marked immunosuppression
Disseminated infection	Liposomal AmB 3–5 mg/kg daily for 1–2 weeks until clinical improvement, followed by ITRA loading dose as below[a], then 200 mg twice daily for a total of 12 months	Alternatives for step-down therapy include VORI loading dose as below[b], then 200 mg twice daily, **OR** POSA loading dose as below[c], then 300 mg daily, **OR** FLU 400–800 mg daily, all for a total of 12 months	Few patients have been treated with the alternative drugs Suppressive therapy with azoles should be considered in patients with persistent marked immunosuppression
Central nervous system infection	Liposomal AmB 5.0 mg/kg daily for 4–6 weeks, followed by ITRA loading dose as below[a], then 200 mg two or three times daily for a total of 12 months	Alternatives for step-down therapy include VORI loading dose as below[b], then 200 mg twice daily, **OR** POSA loading dose as below[c], then 300 mg daily, **OR** FLU 400–800 mg daily, all for a total of 12 months	Very few patients have been treated with the alternative drugs Suppressive therapy with azoles should be considered in patients with persistent marked immunosuppression
Blastomycosis			
Pulmonary infection	Liposomal AmB 3–5 mg/kg daily or ABLC 5 mg/kg daily for 1–2 weeks until clinical improvement noted, followed by ITRA loading dose as below[a], then 200 mg twice daily for a total of 12 months	Alternative for step-down therapy is VORI loading dose as below[b], then 200 mg twice daily for a total of 12 months. Less preferred alternatives are POSA, loading dose as below[c], then 300 mg daily, **OR** FLU 400–800 mg daily for a total of 12 months	Initial therapy with oral azoles is not recommended Suppressive therapy with azoles should be considered in patients with persistent marked immunosuppression
Disseminated infection	Liposomal AmB 3–5 mg/kg daily or ABLC 5 mg/kg daily for 1–2 weeks until clinical improvement noted, followed by ITRA loading dose as below[a], then 200 mg twice daily for a total of 12 months	Alternative for step-down therapy is VORI loading dose as below[b], then 200 mg twice daily for a total of 12 months. Less preferred alternatives are POSA, loading dose as below[c], then 300 mg daily, **OR** FLU 400–800 mg daily for a total of 12 months	Initial therapy with oral azoles is not recommended Suppressive therapy with azoles should be considered in patients with persistent marked immunosuppression
Central nervous system infection	Liposomal AmB 5 mg/kg daily for 4–6 weeks, followed by ITRA loading dose as below[a], then 200 mg twice daily for a total of 12 months	Alternatives for step-down therapy include VORI loading dose as below[b], then 200 mg twice daily **OR** FLU 400–800 mg daily for a total of 12 months. Less preferred is POSA loading dose as below[c], then 300 mg daily for a total of 12 months	Lifelong suppressive therapy with azoles should be considered

	First line therapy	Alternative therapy	Comment
Coccidioidomycosis			
Mild localized acute pulmonary infection	FLU 200–400 mg/day **OR** ITRA loading dose as below[a], then 200 mg twice daily for 3–6 months		Monitoring at 1–3 months intervals is recommend for 1 year to determine resolution or relapse
Moderate to severe pulmonary infection	Liposomal AmB 3–5 mg/kg daily or ABLC 5 mg/kg daily for 1–2 weeks until clinical improvement noted, followed by ITRA loading dose as below[a], then 200 mg twice daily, **OR** FLU 400 mg once daily for a total of 12 months	Alternatives for step-down therapy include VORI loading dose as below[b], then 200 mg twice daily, **OR** POSA loading dose as below[c], then 300 mg daily for a total of 12 months	Lifelong suppressive therapy with azoles should be considered
Disseminated, non-meningeal infection	Liposomal AmB 3–5 mg/kg daily or ABLC 5 mg/kg daily for 1–2 weeks until clinical improvement noted, followed by ITRA loading dose as below[a], then 200 mg twice daily **OR** FLU 400 mg once daily for a total of 12 months	Alternatives for step-down therapy include VORI loading dose as below[b], then 200 mg twice daily, **OR** POSA loading dose as below[c], then 300 mg daily for a total of 12 months	Lifelong suppressive therapy with azoles should be considered
Central nervous system infection	FLU 800 mg daily given as lifelong therapy	VORI loading dose as below[b], then 200 mg twice daily **OR** ITRA loading dose as below[a], then 200 mg twice daily, **OR** possibly POSA loading dose as below[c], then 300 mg daily all given as lifelong therapy	If concomitant disseminated infection and central nervous system infection are present, intravenous liposomal AmB or ABLC should be given for systemic infection, as well as FLU for central nervous system infection

AmB amphotericin B, *ABLC* amphotericin B lipid complex, *FLU* fluconazole, *ITRA* itraconazole, *POSA* posaconazole, *VORI* voriconazole.

[a]Oral itraconazole loading dose is 200 mg three times daily for 3 days. Because of problems with absorption and drug–drug interactions with itraconazole, therapeutic drug monitoring is strongly recommended. Itraconazole serum levels should be determined after ~2 weeks of treatment. Random itraconazole serum concentrations of at least 1.0 μg/mL are suggested, but we prefer to have levels closer to 2 μg/mL.

[b]Oral voriconazole loading dose is 400 mg twice daily for the first day. Because of problems with absorption and drug–drug interactions with voriconazole, therapeutic drug monitoring is strongly recommended. Voriconazole serum trough levels should be determined after ~1 week of treatment. Target voriconazole serum trough levels should range between 1.0 and 5.5 μg/mL.

[c]Oral posaconazole delayed release tablets loading dose is 300 mg twice daily for the first day. Because of problems with absorption and drug–drug interactions with posaconazole, therapeutic drug monitoring is strongly recommended. Posaconazole serum levels should be obtained after 5–7 days of treatment, with a goal of >1.0 μg/mL.

amphotericin B and for initial therapy for the uncommon presentation of mild localized pulmonary histoplasmosis in a transplant recipient. The loading dose is 200 mg three times daily for 3 days, followed by 200 mg twice daily. Better absorption is seen with the oral solution than the capsules. The oral solution should be given on an empty stomach; the capsules are given with food, and medications that inhibit gastric acid secretion must be avoided. The total length of therapy should be 12 months for most transplant recipients. Because of issues with absorption and many drug–drug interactions, it is imperative to measure serum concentrations of itraconazole to be sure that adequate levels are attained (Table 41-1).

Fluconazole should be considered a second-line agent for histoplasmosis; the response to primary therapy is less and the relapse rates are higher when it is compared with itraconazole, especially in an immunosuppressed population [45]. If a patient cannot tolerate itraconazole because of side effects or poor absorption, fluconazole, 800 mg daily, could be used, but the newer azoles, voriconazole and posaconazole, are increasingly used in this circumstance.

There are no clinical trials studying voriconazole or posaconazole for treatment of histoplasmosis. However, both agents are active against *H. capsulatum* in vitro. Increasingly, patients are reported who have been treated successfully with voriconazole, usually as step-down therapy after amphotericin B [16, 17, 24, 47]. Posaconazole has been reported as showing efficacy in patients with histoplasmosis, but none of these patients were transplant recipients [48, 49]. Isavuconazole, the newest azole agent, appears to have in vitro activity against *H. capsulatum*. However, only seven patients with histoplasmosis were treated in a salvage trial using isavuconazole. Although success was noted, there were too few patients to suggest that isavuconazole should be used to treat histoplasmosis. Echinocandins are not active and should not be used for the treatment of histoplasmosis.

Whether transplant recipients should be maintained on long-term suppressive therapy to prevent relapse of histoplasmosis has not been established. Reports of relapses after amphotericin B or azole treatment was stopped have been published [16, 17]. It seems prudent to continue therapy with itraconazole at dosages of 200–400 mg daily as long as the

patient is markedly immunosuppressed, but there are no clinical trials, as there are with AIDS patients, on which to base this practice. The decision about the use of long-term azole therapy should be based on the clinician's appraisal of the extent of immunosuppression and the possibility of recovery of cell-mediated immunity.

41.3 Blastomycosis

41.3.1 Epidemiology

The endemic area for *B. dermatitidis* includes the southeastern, south central, and north central United States, the Canadian provinces of Ontario, Manitoba, and Saskatchewan, and focal geographic areas in Africa and Europe. The primary habitat of the organism is likely soil and decaying vegetation, especially in close proximity to waterways [50, 51]. Infection occurs predominantly in middle-aged men, many of whom have outdoor occupations and hobbies. Blastomycosis is the least commonly reported endemic mycosis in the USA. Although small outbreaks have occurred, large epidemics, as have occurred with histoplasmosis and coccidioidomycosis, have not been reported.

This relatively uncommon mycosis has been reported rarely in transplant recipients. Cases have occurred more often in solid organ transplant recipients than in hematopoietic stem cell transplant recipients [3, 8, 18, 24, 35, 52–56]. Patients who have received a stem cell transplant are often not well enough while they are on immunosuppressive agents to indulge in activities that might expose them to *B. dermatitidis*. Blastomycosis has been reported in solid organ transplant recipients years after transplantation when they are back at work and doing outdoor activities, but still on immunosuppressive therapy [8]. Most stem cell transplant recipients, unless they develop graft-versus-host disease, are off immunosuppressive therapy by this time and perhaps no longer in a high-risk category.

41.3.2 Pathogenesis

Blastomycosis is primarily a pulmonary infection; infection is initiated when the conidia are inhaled from the environment. Rare cases of inoculation blastomycosis, one of which occurred in a renal transplant recipient, have been described [55]. Dissemination to the skin, osteoarticular structures, and genitourinary tract is common. A common presentation in healthy hosts is the development of single or multiple skin lesions at a time when the pulmonary focus has already resolved. Reactivation occurring years after the initial exposure has been documented, but this appears to occur less often than with histoplasmosis [53, 57]. No cases of blastomycosis transmitted by a donor organ have been documented.

Neutrophils and macrophages, as well as T lymphocytes, appear to be important components of the host response to infection with *B. dermatitidis* [50]. This dual response may be another reason that blastomycosis, when compared with histoplasmosis, is not common among transplant recipients.

41.3.3 Clinical Manifestations

Transplant recipients appear more likely than healthy hosts to develop severe pulmonary or disseminated blastomycosis [3, 8, 18, 24]. However, even when symptomatic dissemination occurs, it mimics the situation in healthy hosts in that the major target organ is the skin rather than the viscera. Among transplant recipients, the cutaneous lesions tend to be pustular (Figure 41-5a) and ulcerative and less often the typical verrucous lesions usually seen with blastomycosis (Figure 41-5a). The types of pulmonary lesions in transplant recipients are similar to those seen in healthy hosts, and they include lobar pneumonia, cavitary pulmonary lesions, and diffuse infiltrates [8, 18, 24]. Adult respiratory distress syndrome may be more common in immunosuppressed patients, including transplant recipients, and is associated with a high mortality rate [58] (Figure 41-6). Central nervous system

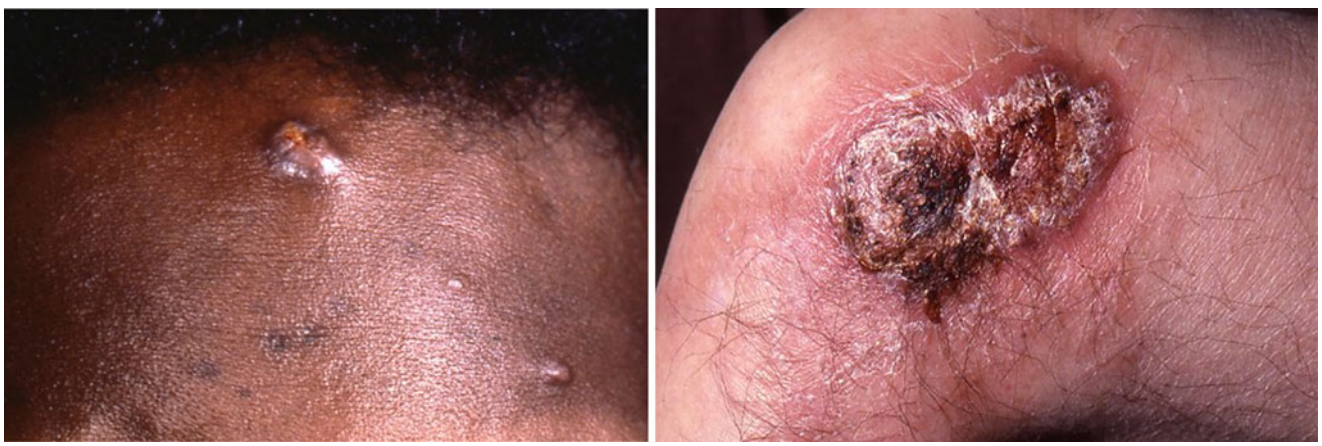

FIGURE 41-5. (**a**) Pustular skin lesions that appeared over a few days in an immunosuppressed patient and that yielded *B. dermatitidis* in culture. (**b**) More typical verrucous skin lesion of blastomycosis in an older man.

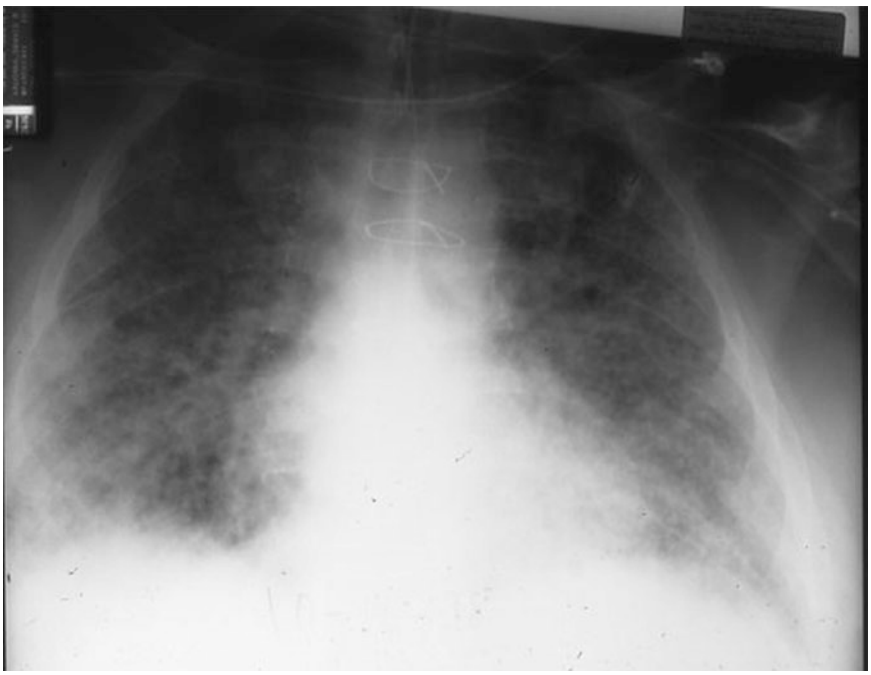

FIGURE 41-6. Chest radiograph from a patient who had acute respiratory distress syndrome (ARDS) due to *B. dermatitidis.*

infection with either meningitis or intracerebral mass lesions is a rare manifestation of blastomycosis that can occur in transplant recipients [3, 18].

41.3.4 Diagnosis

The diagnosis of blastomycosis is best made by culture of the organism from sputum, bronchoalveolar lavage fluid, urine, skin, or visceral lesions. However, histopathologic examination of a skin lesion and cytological examination of sputum or bronchoalveolar lavage fluid are reasonably sensitive and specific and are much quicker than culture methods that can take as long as several weeks to reveal growth of the mycelial form of *B. dermatitidis* [50, 54, 59]. When pustular skin lesions are present, a simple potassium hydroxide smear of purulent material aspirated from the lesion can quickly reveal the organism. Lung or other tissue biopsy specimens show the yeasts when periodic acid–Schiff or methenamine silver stains are performed. In tissues, *B. dermatitidis* appear as distinctive large (5–20 μm), thick-walled yeasts that retain a broad-based connection to the budding daughter cell (Figure 41-7).

The standard serological assays (complement fixation and immunodiffusion) for blastomycosis are neither sensitive nor specific. An enzyme immunoassay that detects the galactomannan cell wall antigen of *B. dermatitidis* is increasingly used and appears to be a useful diagnostic tool [24, 54, 60, 61]. The assay is performed on urine and serum. The major drawback is that is not specific for *B. dermatitidis*, and cross reactivity is almost routinely noted with *H. capsulatum*.

41.3.5 Treatment

The Infectious Diseases Society of America guidelines for the treatment of blastomycosis recommend that transplant recipients and other immunosuppressed patients who acquire blastomycosis should be treated initially with an amphotericin B formulation [62]. Relapses and failures have been documented in those transplant recipients who were treated with an azole as initial therapy [18, 24]. Lipid formulations of amphotericin B should be used in transplant recipients, who are often on other nephrotoxic drugs. The dosage is 3–5 mg/kg daily of liposomal amphotericin B or 5 mg/kg daily of amphotericin B lipid complex. After the patient shows a good clinical response, therapy can be changed to oral itraconazole, for a total of 12 months of antifungal therapy. The loading dose of itraconazole is 200 mg three times daily for 3 days, followed by 200 mg twice daily. Better absorption is seen with the oral solution than the capsules. The oral solution should be given on an empty stomach, the capsules are given with food, and medications that inhibit gastric acid secretion must be avoided (Table 41-1).

If the patient cannot tolerate itraconazole, voriconazole is the second-line choice. Experience is limited in the transplant population [3, 8, 47, 63]. Voriconazole has been reported to successfully cure CNS blastomycosis in individual case reports and small series of cases [47, 63–66]. A multi-center review of 22 cases of CNS blastomycosis noted success in 9 of 10 patients who had been treated with voriconazole, and recommended voriconazole as the step-down agent of choice for this uncommon complication of blastomycosis [63]. Fluconazole is not as effective as itraconazole

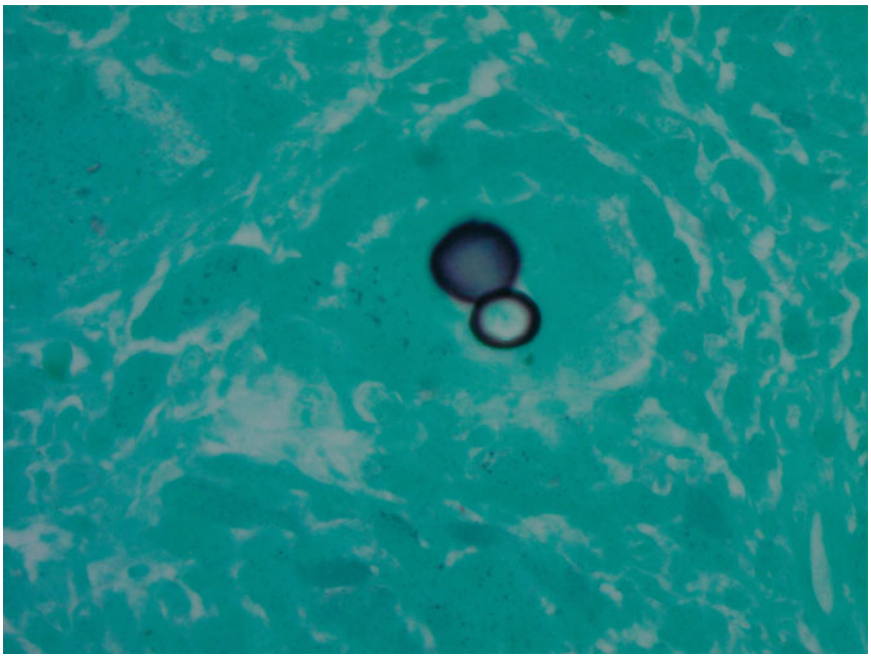

FIGURE 41-7. Lung biopsy sample showing a large, thick-walled, yeast showing broad-based budding, which is typical of *B. dermatitidis.*

for blastomycosis, and there is little experience treating blastomycosis with posaconazole [3, 67]. Echinocandins are not active and should not be used for the treatment of blastomycosis. Long-term suppressive therapy with itraconazole, 200–400 mg daily, may be prudent in transplant recipients who remain on immunosuppressive agents. The need will depend on the clinician's appraisal of the patient's immune status.

41.4 Coccidioidomycosis

41.4.1 Epidemiology

There are now two recognized species of *Coccidioides*, *C. immitis*, which is endemic in southern California, and *C. posadasii,* which is endemic in Arizona, parts of New Mexico and western Texas, and Central and South America. The clinical picture is identical and most laboratories cannot differentiate the two. *Coccidioides* species are restricted mostly to the arid conditions typifying the Lower Sonoran Life Zone, but in times of exuberant growth, the conidia can be swept into more distant areas. Recent reports describe endemic foci of *Coccidioides* species in arid areas of Washington and Utah [68, 69]. Infection is very common because of the propensity of the mycelial form of the organism to be easily dispersed [4, 70]. Most of the population in the endemic area becomes infected before adulthood. For reasons still unknown, dark-skinned persons, especially African Americans, are less likely to contain the organism during primary infection and more likely to develop disseminated coccidioidomycosis [5].

In transplant recipients, coccidioidomycosis is more prevalent than blastomycosis but less common than histoplasmosis [1–3]. Most transplant recipients reported to have developed coccidioidomycosis had received a solid organ transplant [7, 11–15, 19, 71–74]. Fewer patients have been reported who developed coccidioidomycosis after receiving a hematopoietic stem cell transplant [3, 35, 75–77].

41.4.2 Pathogenesis

The arthroconidia produced by *Coccidioides* species are easily dispersed by desert winds. After inhalation into the lungs, the conidia undergo a morphologic change, becoming large (80–100 μm), thick-walled spherules that become stuffed with enormous numbers of endospores. When the spherule is filled, it ruptures, releasing the endospores; each endospore has the potential to form a new spherule, thus perpetuating the infection. Most persons who develop coccidioidomycosis likely have asymptomatic dissemination to multiple organs, but the host with an intact immune system may experience only symptoms of a mild respiratory illness.

The primary host defense against *Coccidioides* species appears to be cell-mediated immunity. Although neutrophils are present in most coccidioidal lesions, they are unable to eradicate spherules [5]. Solid organ transplant recipients who remain on immunosuppressive agents for an extended period remain at risk of developing coccidioidomycosis [19].

In addition to infection that is related to a new exposure to *Coccidioides* species, reactivation coccidioidomycosis has been described in transplant recipients [19, 73, 77]. Reactivation is most likely to occur when a decrease in

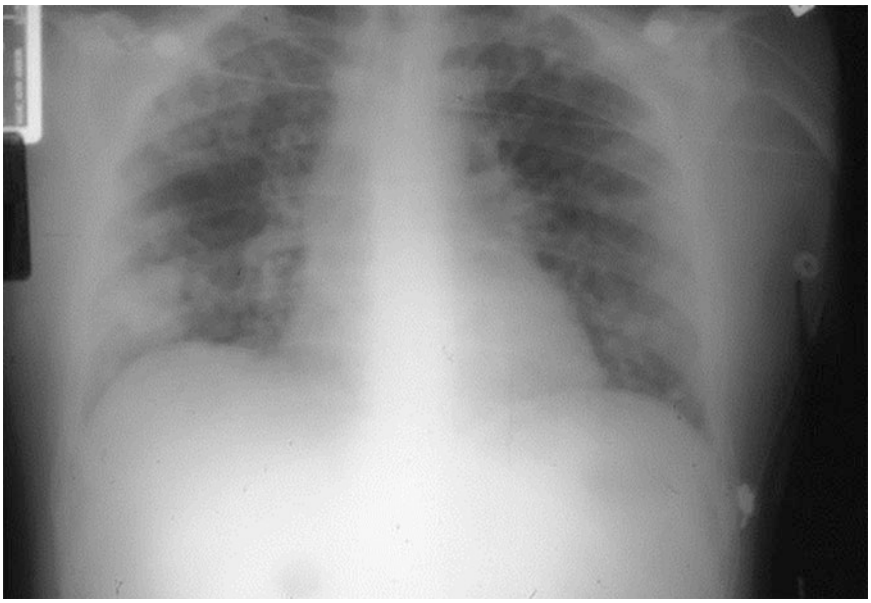

FIGURE 41-8. Chest radiograph of an immunosuppressed patient who ran a landscaping company in Tucson, Arizona.

cell-mediated immunity happens, such as occurs at the time of transplantation. Differentiating new infection from reactivation is difficult among patients living in the endemic area. Approximately half of all cases of coccidioidomycosis are estimated to occur within the first 3 months after solid organ transplantation, and these are likely due to reactivation [19]. Not unexpectedly for an organism that can survive in a latent state for years, *Coccidioides* species have been transmitted with the donor organ [3, 11–13]. The few instances in which this occurred were marked by rapid onset of infection post-transplantation and death due to overwhelming coccidioidomycosis.

The outcome of coccidioidomycosis in transplant recipients appears to be improving, but mortality still remains high. Early mortality rates in kidney transplant recipients were reported to be as high as 63% [81], but recently the mortality has been reported to be approximately 25% [19, 82]. Mortality rates among liver transplant recipients have been reported to be higher than those noted in kidney transplant recipients [71, 73], and heart transplant recipients appear to have the lowest mortality rates from coccidioidomycosis [74], but the number of cases in these latter groups is small. In the largest reported series of coccidioidomycosis in allogeneic stem cell transplant recipients, the mortality was 45% [77].

41.4.3 Clinical Manifestations

Acute pulmonary coccidioidomycosis in the healthy host is generally a self-limited infection. In hosts who are immunosuppressed, severe pneumonia with high fever, hypoxemia, and diffuse infiltrates is more likely to occur (Figure 41-8). However, a wide spectrum of pulmonary manifestations that includes nodular lesions, diffuse interstitial infiltrates, alveolar infiltrates, and cavitary lesions has been described [19, 77, 78].

In transplant recipients, *Coccidioides* is likely to disseminate widely. The sites most often involved are the skin, bones, subcutaneous tissues, and meninges. Fungemia has been documented in individual patients and appears to be more common among transplant recipients [12, 72, 73, 79, 80]. The skin lesions are typically papular, pustular, or nodular, and they often ulcerate. The symptoms of meningeal involvement include headache, cranial nerve palsies, and signs of increased intracranial pressure. In the transplant recipient, meningeal involvement is usually associated with widespread disseminated infection.

41.4.4 Diagnosis

The definitive diagnostic test for coccidioidomycosis is growth of the organism. *Coccidioides* species are the most easily grown of the endemic mycoses. Appropriate material for culture includes tissue biopsies, aspirated material from subcutaneous lesions, synovial fluid, sputum, bronchoalveolar lavage fluid, cerebrospinal fluid, and blood. In the laboratory, *Coccidioides* grows as a mold on most routine laboratory media within 3–7 days. Because the mycelial phase is highly contagious, laboratory workers should always be notified that coccidioidomycosis is a diagnostic consideration so that they can take the necessary precautions to protect themselves from exposure. Because *Coccidioides* species are considered to be bioterrorism agents, a laboratory suspecting that a culture contains *Coccidioides* species is required by law in the USA to seal the culture and send it immediately to a reference laboratory for identification.

The identification of *Coccidioides* in tissues and body fluids can be carried out while awaiting culture results. This is

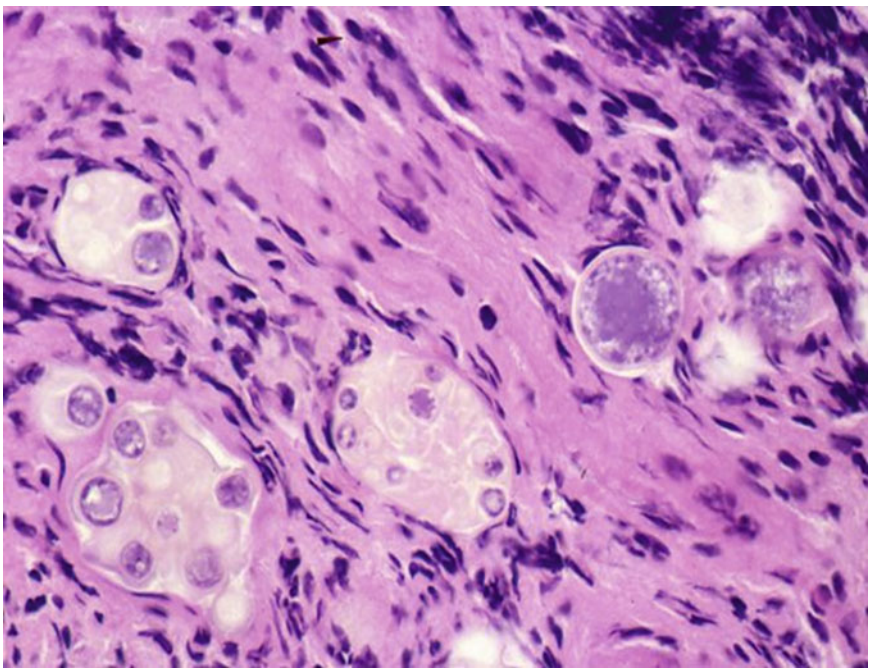

FIGURE 41-9. Lung biopsy from the patient whose chest radiograph is shown in Figure 41-8, showing several large spherules of *C. posadasii.*

especially important in a patient who is immunosuppressed and who is extremely ill with pulmonary or disseminated coccidioidomycosis. Spherules can be visualized in potassium hydroxide or calcofluor preparations of sputum or material aspirated from a lesion and also in cytological preparations from body fluids or bronchoalveolar lavage fluid. In tissue biopsies, the spherules are large enough (80–100 μm) to be seen with routine hematoxylin and eosin stains, and they also can be sought using silver methenamine staining. The spherules are quite distinctive and are easily identifiable (Figure 41-9).

For immunocompetent patients with coccidioidomycosis, serology is a useful diagnostic tool. However, in immunosuppressed patients who have disseminated infection, the serologic assays can be negative [83]. For patients with suspected coccidioidomycosis, serologic testing should be performed at a reference laboratory that has expertise in assays for *Coccidioides.* An assay for *Coccidioides* antigen has become available, but it is unclear whether this will prove useful for transplant recipients who have coccidioidomycosis [84].

41.4.5 Treatment

All transplant recipients with coccidioidomycosis should be treated with an antifungal agent [85]. For all but the most benign pulmonary infections, a lipid formulation of amphotericin B, 3–5 mg/kg daily, is recommended. After the patient shows a clinical response, treatment can be changed to an oral azole, either itraconazole, 200 mg three times daily for 3 days then 200 mg twice daily, or fluconazole, 800 mg for one dose then 400 mg once daily [86] (Table 41-1). Treatment usually is given for at least 12 months, and for transplant patients who remain immunosuppressed, lifelong therapy may be needed [19], as relapse after the cessation of therapy has been described [72, 74, 81]. It seems prudent to use suppressive azole therapy, either fluconazole or itraconazole, especially in those patients who have had disseminated infection and in those at higher risk for severe coccidioidomycosis, such as African Americans.

Several small series have reported on the use of posaconazole for the treatment of coccidioidomycosis [87–90]. To date, the experience in the transplant population remains limited. Voriconazole also has activity against *Coccidioides* species, and has been shown to be efficacious in individual patients, including those who have meningitis [91, 92]. Kim et al retrospectively compared their experience with voriconazole and posaconazole in 37 patients with coccidioidomycosis, 5 of whom were transplant recipients. Success rates were similar between the two agents; with voriconazole, 67% showed improvement, and with posaconazole, 75% were improved [90]. Isavuconazole has been used in a small number of patients with coccidioidomycosis with some success, but the numbers are too small to recommend this agent as an alternative therapy at this time. Echinocandins should not be used for the treatment of coccidioidomycosis.

Fluconazole is the agent of choice for coccidioidal meningitis [85]. In the transplant recipient who has meningitis as one manifestation of widespread dissemination, lipid amphotericin B should be used to treat the systemic infection, in addition to fluconazole for treatment of meningitis. The recommended daily dose of fluconazole for treating

meningitis is 800 mg. The intrathecal administration of amphotericin B deoxycholate has been a standard treatment for coccidioidal meningitis for many years, but because of the difficulty of administration and the high incidence of severe side effects, is used only when azole therapy has failed. All patients with coccidioidal meningitis require lifelong suppressive therapy, usually with fluconazole, to prevent relapse.

Several transplant centers within the endemic area use serology to routinely screen prospective transplant recipients and donors for evidence of prior infection with *Coccidioides* species [19, 77, 93]. Solid organ transplant recipients who have antibodies or a prior history of coccidioidomycosis within the preceding 1–2 years are routinely given prophylaxis with fluconazole, 400 mg daily for the first year post-transplantation, and 200–400 mg thereafter [93]. If active coccidioidomycosis or antibodies are found in the donor, the recipient is given fluconazole prophylaxis for life [93]. It has been recommended that patients undergoing allogeneic stem cell transplantation who have had a history of coccidioidomycosis or who have antibodies to *Coccidioides* on serological testing should be given fluconazole prophylaxis until full recovery of T cell function can be documented [77] (Table 41-1).

Toxoplasmosis After Hematopoietic Stem Cell Transplantation

Rodrigo Martino

Toxoplasma gondii is a protozoan that commonly infects animals and birds. Although *T. gondii* infection in humans is usually asymptomatic, clinical disease occurs in the immune suppressed patient. Infection may be acute (recently acquired) or chronic (latent). *T. gondii* exists in three forms during its life cycle: the tachyzoite, which is the asexual invasive form; the tissue cyst (containing bradyzoites), which persists in the tissues of the infected host during the chronic phase of the infection; and the oocyst (containing sporozoites), which is produced during the sexual cycle in the intestine of the definitive host—the cat. Transmission to humans occurs by ingesting tissue cysts or oocysts, or by blood product transfusion or organ transplantation. Following infection by oral ingestion, tachyzoites disseminate from the gastrointestinal tract and can invade virtually any cell or tissue where they proliferate and produce necrotic foci surrounded by inflammation. In immune suppressed patients, acute infection may result in severe damage to multiple organs. Even in individuals with a normal immune response, tissue cysts form in multiple organs (latent infection), and can subsequently give rise to a severe localized reactivation producing, for example, toxoplasma encephalitis or chorioretinitis.

Toxoplasmosis appears to be a relatively rare opportunistic infection following hematopoietic stem cell transplantation (HSCT). Up to the late 1990s, only 55 cases had been reported after HSCT [1–3], which contrasted with the high frequency of this complication in other patient populations with severe cellular immunodeficiencies, mainly advanced acquired immunodeficiency syndrome (AIDS). Table 42-1 summarizes the case series of toxoplasmosis in HSCT published until mid-2015, and all other cases have been described as case reports. As of mid-2015, around 300 cases of toxoplasmosis have now been reported in HSCT in peer-reviewed manuscripts, a figure that still seems small when compared with other relevant infectious complications in these patients.

The seroprevalence for *T. gondii* varies greatly between and even within countries, ranging from <15% in some North American and Japanese studies [4] and in pediatric wards, to 50–80% of adult HSCT recipients in countries with high endemicity such as France or Turkey [1, 5, 16]. This varying seroprevalence is probably the main reason for the great variability in the frequency of diagnosed cases of toxoplasmosis after HSCT, which has been estimated to average 0.8% [17], with <0.4% in areas of low endemicity to 2–3% in those with high antibody prevalence. The disease, however, is underdiagnosed, since more than half of the cases reported in the literature were diagnosed at autopsy (see Table 42-1).

Toxoplasmosis occurs mainly in allogeneic transplant recipients, although cases after autologous transplants have been published [2, 7, 18], and some are included in Table 42-1. Around 90% of patients are seropositive before HSCT, indicating that reactivation of latent tissue cysts in previously infected individuals is the usual mechanism implicated, as has been demonstrated in AIDS patients. It is, thus, important to determine the patients' serostatus prior to transplant. However, the disease may also develop in seronegative recipients from seronegative donors, suggesting that primary infection after transplant may also occur, and primary infections may be more severe than reactivations [46]. The disease usually begins early after transplant with 95% of the cases occurring within the first 6 months after the procedure, although late cases may occur, usually in patients with chronic graft-versus host disease (GVHD) requiring immunosuppressive treatment [7, 19]. Acute GVHD has been suggested as a possible predisposing factor for Toxoplasma disease, and in a study by the European Group for Blood and Marrow Transplantation (EBMT) [7] 77% of cases occurred in patients with moderate-to-severe acute GVHD or chronic GVHD. The central nervous system (CNS) is the main site of disease, but pneumonitis and myocarditis are also frequent findings, particularly when the diagnosis is made at autopsy. In fact, myocarditis, nephritis, and involvement of other deep organs are rarely made clinically but are frequent findings at autopsy [4, 7, 20].

Several recent patient series have added further insight into the importance of not overlooking this infection in this patient population (Table 42-1). A study from the Memorial Sloan-Kettering Cancer Center in New York described ten cases of disseminated toxoplasmosis among 463 patients

[a]4 definite and 16 possible cases of toxoplasmosis.

who received T-cell-depleted allogeneic bone marrow transplantation (2.2% frequency) [10]. When compared with other studies this frequency appears to be high, especially when considering that the pretransplant seroprevalence was only 23% and that these patients had a very low incidence of moderate-to-severe GVHD. This experience suggests that T-cell depletion may be an independent risk factor for this infection, although a case-control study would be needed to confirm this suspicion. Two other studies have been recently published by the EBMT Infectious Diseases Working Party [7, 21]. The first study summarized the results of a survey among European transplant centers, which showed that this infection occurs almost exclusively after an allogeneic HSCT, with 41 cases diagnosed after 4391 allogeneic HSCT (frequency 0.93%) and none after 7097 autologous HSCT [21]. However, as previously stated, cases have been described after autologous HSCT. Additionally, we have recently seen a case of pulmonary toxoplasmosis 10 months after a CD34+-cell selected autologous HSCT, suggesting that T-cell depletion may also increase the risk after autologous transplants.

Toxoplasma encephalitis typically presents with focal neurologic abnormalities of subacute onset, frequently accompanied by nonfocal signs and symptoms such as headache, altered mental status, and fever. The most common focal neurologic sign is motor weakness, but patients may also present with cranial nerve abnormalities, speech disturbances, visual field defects, sensory disturbances, cerebellar signs, focal seizures, and movement disorders. Meningeal signs are very rare. The cerebral spinal fluid may show slight mononuclear pleocytosis, increased protein, and normal glucose levels. Computed tomography (CT) brain scans often show multiple bilateral cerebral lesions that tend to be located at the corticomedullary junction and the basal ganglia. These lesions are generally hypodense and show ring enhancement after intravenous contrast injection. Magnetic resonance imaging (MRI) scans show lesions as high signal abnormalities on T2-weighted imaging, although other nonspecific space-occupying lesions may be seen [6, 7]. MRI is more sensitive than CT in the early diagnosis of this infection [6].

Toxoplasma pneumonitis may develop in the absence of extrapulmonary disease. Its clinical and radiologic features are nonspecific and may mimic interstitial pneumonitis due to other causes [22–24].

Toxoplasma chorioretinitis appears surprisingly rare compared to the incidence noted in the AIDS population, particularly since many transplant programs utilize eye examination routinely pre- and posttransplant because of the incidence of chronic ocular GVHD posttransplant [25]. Interestingly, two cases of reactivation of toxoplasma chorioretinitis were reported in recipients of autologous transplants [26].

Since toxoplasmosis is so difficult to diagnose histologically in these patients, noninvasive diagnostic tests would be of utmost importance. Isolation of the parasite from blood or body fluids using rodents or cell culture techniques is time-consuming, expensive, and is available only in few routine microbiology laboratories. In the HSCT recipient, the utility of serology is mainly to identify those at risk for developing toxoplasmosis posttransplant, since serologic studies posttransplant are seldom of use. Polymerase chain reaction (PCR) techniques were developed for diagnosis of neonatal infections and for the noninvasive diagnosis of cerebral toxoplasmosis in patients with AIDS [27]. These techniques are applicable in blood, cerebrospinal fluid (CSF), and bronchoalveolar lavage (BAL); the usual samples that are available in HSCT recipients with this infection. However, PCR techniques are not standardized, and thus the results of published studies are difficult to interpret. In AIDS, patients with brain lesions PCR in blood and CSF have a sensitivity of 50–65% and a specificity of 95–100% for toxoplasmosis [28]. Currently, however, the predictive values of any PCR technique for infectious agents in AIDS, HSCT recipients, and other patient populations depend mainly on the type of PCR and laboratory protocols used. However, many centers have developed and use a quantitative PCR with a level of detection as low as 20 parasites/mL, with parasite loads of >600/mL reported in most patients with toxoplasmosis [29]. In the EBMT study 46% of the patients with *Toxoplasma* disease and all six with infection had at least one positive PCR result, thus confirming the widespread use of this diagnostic technology in clinical practice [7]. Particularly interesting are the patients with positive PCR tests from blood samples without evidence of disease [30]. These patients may represent a transitional state between the local reactivation of tissue cysts into tachyzoites and the establishment of localized or disseminated tissue destruction by replicating tachyzoites favored by the intense cellular immunosuppression after transplant or during GVHD. This observation would be somehow similar to the early detection of cytomegalovirus (CMV) infection by PCR or the pp65 antigenemia test. Unlike the latter, however, the clinical significance of detecting *T. gondii* DNAemia is currently unknown. On the other hand, several cases of well-documented disseminated toxoplasmosis with negative serum PCR results have been described [20], and our patient with pulmonary toxoplasmosis described earlier had a negative PCR in blood samples but positive cytology and PCR in BAL samples. The earlier onset of *Toxoplasma* infection (median day 35, range 13–51) than disease (median day 64, range 4–516) in the EBMT study suggests that infection may indeed precede disease in many cases [7]. Thus, research efforts to establish the role of PCR in this setting are clearly warranted. Unfortunately, as with other PCR-based diagnostic tests for infectious diseases, the technique is not standardized, making comparisons between centers difficult unless a quality control is established [29]. Table 42-2 summarizes the published studies that analyze the potential role of screening peripheral blood (PB) samples for the early diagnosis and/or preemptive therapy of toxoplasmosis as of mid-2015. These studies emphasize the

TABLE 42-2. Results of published studies that analyze the role of monitoring PB samples with a PCR for *Toxoplasma gondii* after HSCT

Author (references)	Number of patients	Percentage of seropositivity pretransplant (%)	Number of (percentage) toxoplasma infections in seropositive patients (PCR+)	Number (percentage) toxoplasma disease	Comments
Bretagne et al. [30]	32	75	3 (13)	0	7 samples studied in the first 150 days posttransplant
Janitschke et al. [12]	75	71	7 (13)	3 (5)	Serology was found to be useless in the diagnosis of infection and prediction of disease
Martino et al. [31]	106	100	16 (16)	6 (6)	Cord blood transplantation and noncompliance to cotrimoxazole prophylaxis were risk factors for infection and disease
Edvinsson et al. [32]	12 AlloHSCT/21 AutoHSCT	30	2 (17)	1 (8)	
Fricker-Hidalgo et al. [33]	70 AlloHSCT (none received prophylaxis)	57	9 (13) (PCR+ and IgM−)	4 (5.7)	1 seronegative patient developed disease In the 4 patients with disease, 2 had negative PCR but positive IgM serology, and 1 had positive serology before PCR Confirms that serology can be helpful in the appropriate setting
Daval et al. [43]	40 AlloHSCT	100	1 (4)	0	0/25 in pts on cotrimoxazole vs. 1/15 (7%) in pts not on prophylaxis In this study, french expert parasitologists validated a quantitative PCR with a validated competitive internal control
Meers et al. [44]	208 AlloHSCT (none received prophylaxis)	100	12 (6)	6 (3)	Risk factors for infection were myeloablative conditioning, especially with irradiation, and having a seronegative donor Risk factor for disease was having a high parasitic load in PB

[45]	12 AutoHSCT 18 AlloHSCT	100	3 AutoHSCT (25) 4 AlloHSCT (22)	4 (10)	By two PCR methods, this study analyzed a sample of buffy coat from the infused stem cells, as well as posttransplantation monitoring The 4 patients who developed disease had a positive PCR in the donor "buffy coat" samples analyzed; will require confirmation in further studies

usefulness of this approach, provided a sensitive and specific quantitative PCR technique is readily available.

Since histologically proven toxoplasmosis is a very difficult-to-obtain diagnosis, various levels of diagnostic certainty have been proposed, which will aid in the interpretation of further studies in this area [7]. Histologically defined cases are considered as definite cases of toxoplasma disease, PCR-defined cases as probable, and CNS imaging-defined cases as possible cases. Table 42-3 summarizes the modified proposed EBMT definitions.

In HSCT recipients, initial therapy for toxoplasmosis should be administered for at least 3 weeks and the total

TABLE 42-3. EBMT-IDWP definitions for toxoplasmosis after hematopoietic stem cell transplantation (modified from [7])

Toxoplasmosis disease definite toxoplasmosis	Histologic or cytologic demonstration of tachyzoites in tissue samples obtained either by biopsy, bronchoalveolar lavage (BAL), or at autopsy. Isolation of the parasite by culture in these samples would be evidence of disease
Probable toxoplasmosis (PCR-documented) (rarely, positive IgM serology)	Clinical and radiologic evidence suggestive of organ involvement plus at least one positive PCR test from blood, CSF, and/or BAL, but no histologic confirmation and absence of another pathogen, which may explain the findings In patients capable of mounting a humoral immune response, positivity of *T. gondii* IgM (irrespective of IgG results) with negative PCR in a compatible clinical scenario also represents probable disease [33]
Possible toxoplasmosis (imaging-documented)	CT or MRI highly suggestive of CNS toxoplasmosis (as considered by each hospital's neuroradiologists) and response to antitoxoplasma therapy, but no laboratory evidence of toxoplasmosis and absence of another pathogen which may explain the findings
Toxoplasmosis infection	Positive PCR in blood in a patient without any evidence of organ involvement or seroconversion (positive IgM serology) for *Toxoplasma gondii* after transplant in a previously seronegative patient (with or without fever)

Abbreviations: *CT* computerized tomography scan, *MRI* magnetic resonance imaging, *CNS* central nervous system, *PCR* polymerase chain reaction for *Toxoplasma gondii.*

TABLE 42-4. Suggested treatment and prophylaxis for toxoplasmosis in HSCT recipients

Treatment	Dose
Pyrimethamine (*plus* folinic acid)	Oral, 200 mg loading dose, then 50–75 mg q.d. (folinic acid, oral, or IV 10 to mg q.d.)
	Plus one of the following
Sulfadiazine	Oral, 1–1.5 g q 6-8 h
	Or
Clindamycin	Oral or IV, 600 mg q6h

Prophylaxis	Dose
Trimethoprim *plus* sulfamethoxazole[a]	2 double-strength tablets (160/800 mg) per day, 3 days per week or 1 double-strength tablet (160/800 mg) per day, 4–5 days per week or 1 standard-dose tablet (80/400 mg) daily
	Or
Pyrimethamine and sulfadoxine (Fansidar)[a]	2–3 tables per week
Dapsone[a]	100 mg daily
Atovaquone[a]	1500 mg daily
If the above cannot be given, there is in vitro and anecdotal clinical evidence for the following alternatives [34]	
Spiramycin	Daily 25–50 mg/kg/day, maximum 2–3 g/day
Azithromycin	250–500 mg 3 days per week

[a]Also effective for *Pneumocystis jirovecci* pneumonia prophylaxis, and possibly listeriosis, nocardiosis and, in some geographic areas, partly effective in preventing gram positive cocci and gram negative bacillary (enterobacterial and non-glucose fermenting) infections [47]. The dose can be reduced in patients with mild renal insufficiency.

therapy duration should be continued until 4–6 weeks after all clinical evidences of toxoplasmosis resolves. The dosage of the medications utilized may need to be reduced or the regimen changed if side effects occur (primarily rash, diarrhea, or drug interactions). Extended therapy is with pyrimethamine and sulfadiazine or pyrimethamine and clindamycin (Table 42-4). Most patients respond to one or another of these regimens and neurologic improvement of toxoplasma brain involvement usually occurs within 7 days. Because pyrimethamine is a folic acid antagonist the most common side effect is dose-related bone marrow suppression, and patients receiving pyrimethamine should be placed on daily oral dose of 10–15 mg of folinic acid (not folic acid), and have a complete blood count performed twice weekly. Other side effects of sulfonamides include fever, rash, and hepatitis.

Data from AIDS patients suggest that prophylactic cotrimoxazole is useful in minimizing the risk of reactivation of toxoplasmosis, although there are well-reported cases of toxoplasmosis breaking through cotrimoxazole prophylaxis in marrow transplant recipients [4, 5]. Suboptimal dosing may have contributed to some of these "breakthrough"

infections. In a recent review of 47 patients with breakthrough toxoplasmosis, 37 of whom were on cotrimoxazole prophylaxis, indirect observations suggested a significantly lower efficacy of prophylaxis in regimens that use the drug less than three times a week. Thus, using either 1 standard-dose tablet (80/400 mg) daily or double-strength tablets (160/800 mg) 3 or more days per week is the recommended dosing [47], as shown in Table 42-4.

One study in marrow transplant recipients of pyrimethamine and sulfadoxine (Fansidar) described no proven cases of toxoplasmosis in 69 patients receiving this regimen; additionally, no cases of *Pneumocystis jirovecci* pneumonia were reported [16]. Other less well-studied alternatives include dapsone, atovaquone, and azithromycin. Table 42-4 describes the recommended prophylaxis in seropositive patients.

The prognosis of this infection has been considered to be very poor based on the limited published data, with nearly 90% of patients dying from toxoplasmosis (see Table 42-1). This contrasts with the 70–80% response rates observed in patients with AIDS. However, the results from the New York and the EBMT studies suggest that, if appropriately treated, up to 60% of patients may show clinical–radiologic improvement or even a complete response. This highlights the importance for a high index of suspicion for toxoplasmosis in immunocompromised patients for the appropriate diagnostic tests and for starting therapy as soon as possible. Of utmost importance is knowing the patients' serology pretransplant, since the risk of toxoplasmosis in seronegative recipients appears to be very low. However, seronegative patients may also develop toxoplasmosis, either through infection from the donor or primary infection after transplant [12].

43
Toxoplasmosis After Solid Organ Transplantation

Jose G. Montoya and Carlos A. Gomez

43.1 Introduction

The intracellular parasite *Toxoplasma gondii* infects over one billion humans worldwide and causes disease that can result in significant morbidity and mortality [1]. The term "toxoplasmosis" should be reserved for the symptomatic patient who is ill due to a recently acquired infection (primary infection) or reactivation of a previously acquired infection (chronic or latent infection). Some investigators also refer "toxoplasmosis" as toxoplasma disease [2]. In contrast, the term "*Toxoplasma* infection" is best used for the chronically infected, asymptomatic patient. Over the past 15 years, the epidemiology and our understanding of the parasite have changed considerably. Most notably, untreated water and raw shellfish are now recognized as potential vehicles of *T. gondii* transmission [3, 4] and certain strains of the parasite appear to be associated with more severe forms of illness [5]. Early in the transplantation era, toxoplasmosis was recognized as a life-threading opportunistic infection in SOT recipients [6, 7]. Recently, new studies have contributed to a better understanding of risk factors for toxoplasmosis in SOT especially in non-cardiac recipients [8, 9].

As a result of their significant immune compromise, patients with organ transplants are at a greater risk of developing the most severe forms of toxoplasmosis and, if untreated or diagnosed late, they may die as a result of the disease. SOT-recipients may develop toxoplasmosis by primary infection (primarily acquired orally or via the transplanted organ) or reactivation of *T. gondii* acquired prior to transplantation. In seronegative SOT-recipients, transplant programs should provide patients with educational material regarding preventive measures to decrease the risk of primary toxoplasma infection.

The presence of traditional epidemiologic risk factors for acute infection (e.g., ingestion of undercooked meat, ownership of cats) or even history of an illness suggestive of toxoplasmosis are not sensitive tools to determine whether a patient should be tested for *Toxoplasma* infection or toxoplasmosis [10]. More than 50% of individuals infected with *T. gondii* do not recall experiencing a syndrome consistent with toxoplasmosis, and a similar percentage have never been exposed to the risk factors traditionally associated with acute infection. Thus, to establish whether toxoplasmosis should be included in the differential diagnosis of SOT-patients, *T. gondii* serologic screening should be performed in each transplant candidate and organ donor, in the pre-transplant period, regardless of risk assessed by a careful medical history.

43.2 Etiologic Agent

Three primary forms of the parasite can be easily identified in nature: the tachyzoite, the tissue cyst (containing bradyzoites), and the oocyst (containing sporozoites) (Figure 43-1). The tachyzoite is oval to crescent-shaped, measures 2–3 μm wide and 5–7 μm long, and is responsible for the clinical manifestations observed in patients with toxoplasma disease. The tissue cyst measures up to 100 μm in diameter and is responsible for chronic infection. It is transmitted to humans via consumption of undercooked meat or transplantation of an organ. In humans, this dormant phase can be found in different organs (e.g., heart, liver, kidney, skeletal muscle, eye, and brain) and does not cause symptoms to occur unless it is reactivated by a significant impairment in T-cell and/or B-cell-mediated immunity. To produce symptoms, the bradyzoites contained inside the tissue cyst must undergo a series of metabolic and structural changes, driven by the failing immune system, to transform into tachyzoites. In immunocompetent individuals, tissue cysts can rupture spontaneously and release bradyzoites that are rapidly cleared by specific anti-*Toxoplasma* immunity and therefore almost never lead to clinical symptoms [11, 12]. In organs from donors with chronic *T. gondii* infection, tissue cysts can be transmitted within the transplanted organs. In seronegative SOT-recipients, tissue cysts embedded in the transplanted organ from seropositive donors have the potential for rupture leading to uncontrolled infection. The latter is aggravated in the context of high-degree immunosuppression that follows organ transplantation.

P. Ljungman et al. (eds.), *Transplant Infections*, DOI 10.1007/978-3-319-28797-3_43

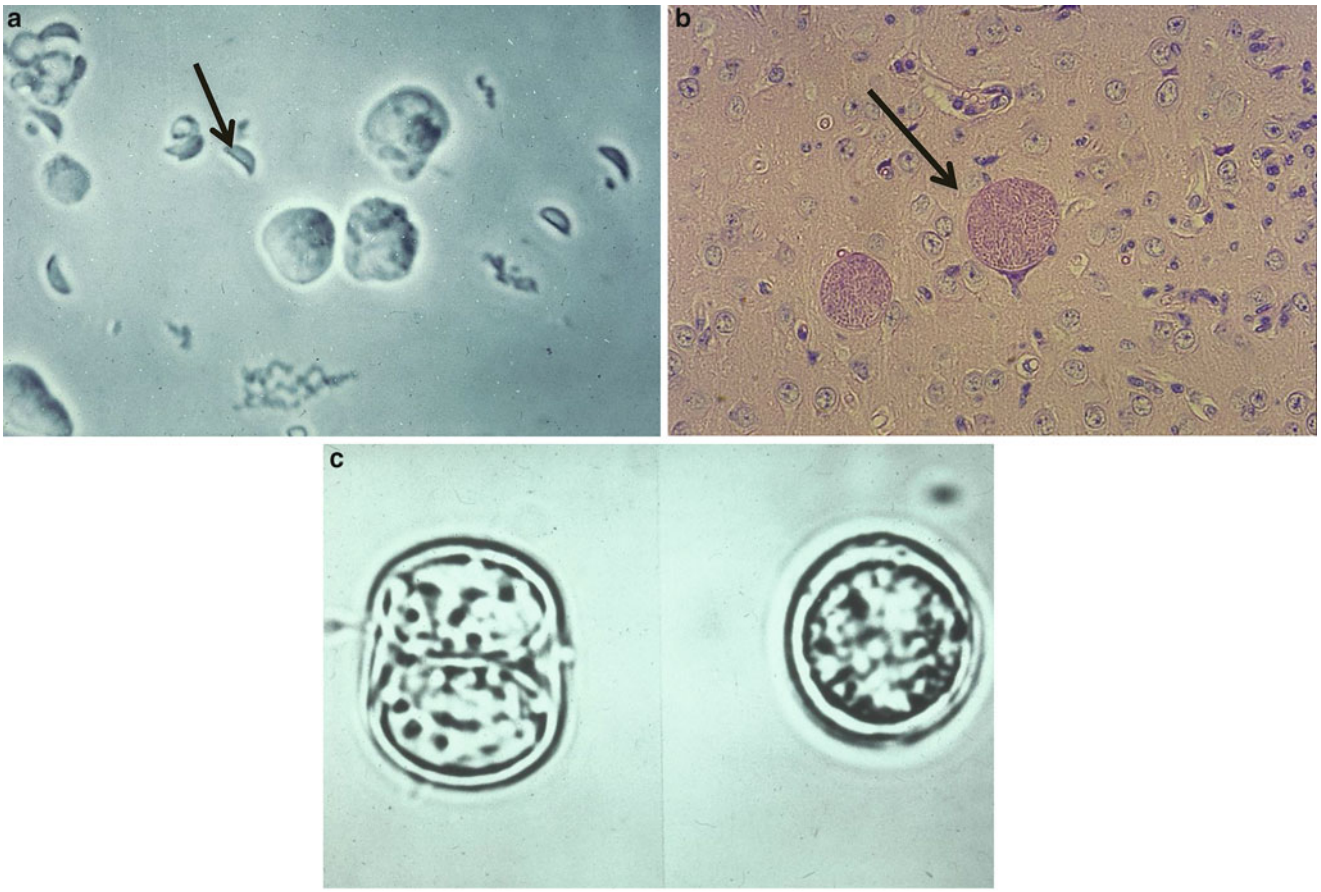

FIGURE 43-1. Main forms of *T. gondii* as found in nature (*arrows*). Tachyzoites (**a**), tissue cysts (**b**) containing bradyzoites and oocysts (**c**) in their sporulated and nonsporulated forms.

Oocysts are shed by all members of the feline family, measure 10–12 µm in diameter in the unsporulated form, and are responsible for the transmission via infected feline feces, vegetables, water, gardening, and contaminated soil. An infected feline may shed as many as ten million oocysts in a single day. Sporulation is required for oocysts to become infectious and occurs outside the cat within 1–5 days depending on temperature and oxygen availability. Sporulation is more rapid at warm temperatures (2–3 days at 24 °C compared to 14–21 days at 11 °C). Oocysts may remain viable for as long as 18 months in moist soil, resulting in an environmental reservoir from which incidental hosts may be infected (Figure 43-1).

Although one major determinant for the severity of toxoplasmosis is the integrity of the cell-mediated immune system, genetic differences among strains may explain the wide range of clinical manifestations observed between different locales [13–21]. In South America, for example, a more aggressive and lethal form of toxoplasmosis has been associated with unique strains (type I, III, and atypical strains). These virulent strains are rarely found in Europe (where type II strains are predominantly found) [5, 16, 22–25]. Disseminated disease, pneumonia, and even death have been observed in immunocompetent individuals infected with this *T. gondii* strain in South America. These emerging and more virulent strains have potentially serious implications for transplant patients who travel to or receive organs from individuals from those areas.

43.3 Life Cycle

Domestic and feral cats, small and large, are the definitive hosts of *T. gondii*. They can be infected with any of the primary forms of the parasite (tachyzoites, tissue cysts, or oocysts). Once in their small intestine, the parasite undergoes asexual or sexual (gametogony) reproduction. Oocysts are subsequently excreted via the feces in the order of millions per day. Humans and other animals (e.g., mammals, chickens, etc.) are incidental hosts and can be infected by ingesting meat (containing tissue cysts) or other food, soil, or water (containing oocysts). An epidemiologic study in the USA revealed that an elevated risk for recent *T. gondii* infection was associated with the following factors: eating raw ground beef; eating rare lamb; eating locally produced cured, dried, or smoked meat; eating raw oysters, clams, or mussels; working with meat; drinking unpasteurized goat milk; and having three or more kittens [4]. Oysters, clams, and

mussels have been shown to carry *T. gondii* under experimental conditions and act as filter feeders that concentrate on the parasite [26, 27]. Moreover, *T. gondii* oocysts remain viable in various species of shellfish under natural conditions [28, 29]. The US study was unable to explain the risk in 48% of the infections and was consistent with data from another multicenter study performed in Europe [30]. Patients may be unaware of their exposures or may have difficulty recalling specific risk behaviors.

Drinking untreated or unfiltered water has emerged as an important risk factor for *T. gondii* acquisition in humans and other animals (e.g., sea otters) in several countries including Canada, Brazil, Turkey, and Colombia [31–33]. In the aforementioned US study, there was a trend toward drinking untreated water being a risk factor associated with acute *Toxoplasma* infection. Some people in the USA are probably infected by ingesting water contaminated with oocysts.

43.4 Epidemiology

The seroprevalence for *T. gondii* infection increases with age and varies considerably by locale and socioeconomic strata [34]. The overall age-adjusted seroprevalence in the USA is around 10% but can be as high as 30% in the Northeast region and higher in certain ethnic groups [35]. Similarly, in the HIV population, the seroprevalence of latent toxoplasma infection ranges from 10% to 45% in the USA. [36]. In the recent decade, a decline in the U.S.-prevalence of *T. gondii* infection has been reported among US born persons amongst 12–49 years of age. In this group, the age-adjusted seroprevalence decreased from 14.1% in 1988–1994, to 9.0% in 1999–2004, to 6.7% in 2009–2010 [37, 38]. Nonetheless, *T. gondii* seroprevalence has substantial geographical variation with higher prevalence (>50%) in Western Europe and South American countries [34, 39–41]. As a more significant participation in the donor-pool is expected in the next decades for foreign-born organs donors, these *T. gondii* seroprevalence disparities may become relevant for transplant programs.

Solid organs from infected donors (D+) can carry and transmit the parasite to their recipients. *Toxoplasma* seronegative recipients (R−) are at greater risk of developing toxoplasmosis when they receive these organs but not receive prophylaxis against the parasite. As the heart is a recognized site of encystation for *T. gondii*, the risk of toxoplasmosis following SOT is higher in heart transplant—especially in mismatched (D+/R−) compared with other SOT-recipients. In a historical cohort, at Stanford University Medical Center, 25% of D+R− patients developed or died from toxoplasmosis because none of them received prophylaxis. The risk of toxoplasmosis in a given transplant program will vary considerably according to the seropositivity of their recipients and donors as well as the degree of exposure that seronegative patients have to *T. gondii*.

We advocate for global screening for *Toxoplasma* antibodies in patients considered for SOT, although this practice varies across different countries due to differences on the incidence rate of toxoplasmosis. For instance, serologic screening for toxoplasmosis is mandatory in France and 11 European countries whereas this practice varies across transplants centers in the USA [42]. Adequate planning for effective chemoprophylaxis against toxoplasmosis relies in the recognition, at the time of transplantation, of cases of D+R− mismatches, particularly for heart transplant recipients. Indeed, rapid availability of *toxoplasma* pre-transplant serologies is desirable in cases where the transplant clinician face severely ill SOT-recipients in whom toxoplasmosis is being considered in the differential diagnosis. Hence, for solid organ transplants, the D+R− high-risk patients should be identified prior to transplantation. Pre-transplant seropositive SOT-patients (R+) are also at risk for toxoplasmosis (by reactivation) following transplantation.

Serologic testing after transplantation to establish risk of disease or to determine if the patient has developed toxoplasmosis is potentially misleading; as post-transplant patients may see their serologies rise or change without necessarily indicating that they have toxoplasmosis disease. In addition, their serologies may not change, become negative, or remain negative in the setting of toxoplasmosis [43] (Table 43-1).

43.5 Heart Transplantation

In a recent multicenter, matched-case control study conducted between 2000 and 2009, the overall incidence of toxoplasmosis following SOT was 0.14%. Heart transplant recipients had a higher incidence of post-transplant toxoplasmosis (0.61%) compared with lower rates in kidney (0.08%) and liver transplant recipients (0.08%) [8]. In this study, a negative *T. gondii*-serostatus prior to transplantation was the only independent risk factor associated with toxoplasmosis. However, the incidence of toxoplasmosis in the group of seronegative heart transplant recipients can range from 25% to 75% in the absence of effective toxoplasma prophylaxis [44–46]. For instance, at Stanford University Medical Center results of serologic testing for toxoplasma were available prior to transplant for 575 D/R pairs; of these, 454 (79%) were D−R−, 84 (14.6%) D−R+, 32 (5.6%) D+R−, and 5 (0.8%) D+R+. Of the 32 D+R− heart transplant recipients, 16 received TMP-SMX and/or pyrimethamine and none developed toxoplasmosis. In contrast, 4 (25%) of the 16 D+R− patients who were not taking either TMP-SMX or pyrimethamine developed toxoplasmosis, and all died of the infection. Of note, none of the 98 who were seropositive patients for *T. gondii* prior to transplantation developed clinical evidence of toxoplasma reactivation [46]. In a landmark study performed at Papworth Hospital in England, Wreghitt et al. implemented a protocol of prophylactic pyrimethamine for all heart transplant recipients with *T. gondii* mismatches

(D+R−). Before the study, out of the first 65 heart transplant cases in the program, 7 were *T. gondii* mismatches (D+/R−), 4 (57%) developed toxoplasmosis, and 2 patients died. After the institution of the protocol, 5 of 37 (14%) patients whom were given prophylactic pyrimethamine developed toxoplasmosis disease; only one was symptomatic, and none died [47]. Later, many studies corroborated the efficacy of trimethoprim/sulfamethoxazole (TMP-SMX) regimens used for prevention of *Pneumocystis* pneumonia (PCP), in the prevention of toxoplasmosis in mismatched heart transplant recipients [45, 48–51]. However, the optimal length and dosing regimen of TMP-SMX prophylaxis for prevention of toxoplasmosis in high-risk heart transplant recipients (D+R−) remain unclear (Table 43-1). Toxoplasmosis in the heart transplant recipient usually occurs in the first 3 months following transplantation and consists of fever, pneumonitis, encephalitis, and myocarditis. Overwhelming *T. gondii* myocardial reactivation can simulate organ rejection and has been diagnosed through endomyocardial biopsy [52].

43.6 Kidney Transplantation

Awareness about the risk of toxoplasmosis disease in renal transplant recipients was raised since the first reported case in 1966 [53], to which was followed by sporadic cases within the early era of transplantation [54, 55]. Nonetheless, toxoplasmosis following renal transplantation remains uncommon, with incidence of 0.08% in one recent multicenter case-control study from Spain [8]. Renoult et al. reported six cases of toxoplasmosis in 373 consecutive kidney transplant recipients in France, from 1989 to 1995 (incidence of 1.6%) [56]. In the first 390 consecutive kidney transplant cases performed at that program, 68.1% were seropositive for *T. gondii* prior to transplantation (R+). Only two of 124 *toxoplasma*-seronegative recipients acquired toxoplasmosis in the post-transplant period; in both cases, the infection was disseminated. An additional review of 31 cases reported in the literature, revealed that the vast majority of cases developed signs of toxoplasmosis within the first 3 months post-transplantation, with only two cases occurring >1 year after transplantation. The most common clinical presentation was fever, pneumonitis, and generalized neurologic signs (headache, confusion, lethargy, and coma). Unfortunately, in 15 cases the diagnosis was performed post-mortem and the mortality rate was 64.5%. Acquisition of the infection through a *T. gondii*-infected-organ was the most common source of transmission [56]. Indeed, toxoplasmosis in kidney transplant recipients occurs mainly by allograft transmission from a seropositive donor, although reactivation of latent infection or primary *T. gondii* infection from environmental sources is also possible [57, 58]. In a series of 34 cases of kidney transplant recipients with toxoplasmosis, the allograft was the source of infection in 12 patients (35%) [9]. Moreover, cases of fatal toxoplasmosis in seronegative renal recipients transmitted by allografts derived from a single-donor with IgG/IgM profile indicative of recent *T. gondii* infection have been reported [56, 59]. Although rare, toxoplasmosis disease can occur upon discontinuation of TMP-SMX (used for *Pneumocystis jirovecii* prophylaxis*)* 6 months following SOT [60] (Table 43-1). Septic shock and chorioretinitis have been reported as the presenting manifestations of toxoplasmosis in kidney transplant recipients [61–63].

Table 43-1. Toxoplasmosis in the setting of solid organ transplantation (SOT)

Type of organ	Most common sources of toxoplasma infection[a]	Risk of toxoplasmosis	Recommended prophylaxis	Recommended duration of primary *Toxoplasma* prophylaxis
Heart/heart–lung	Primary infection via the transplanted organ (D+R−)	Higher in mismatched D+R−	TMP-SMX *or* Pyrimethamine *or* Atovaquone	1 year[b]
Kidney, liver, and multivisceral[c]	– Reactivation of latent infection in seropositive recipients (D−R+ *or* D+R+) – Primary infection with *T. gondii* from environmental sources	– Higher in R(+) with high degree of immunosuppression – Lower in mismatched D+R−	TMP-SMX *or* Atovaquone	1 year[b]

Adapted from [9, 42, 103].

TMP-SMX: trimethoprim/sulfamethoxazole.

[a]The sources of toxoplasmosis in SOT patients are: (1) Reactivation from latent toxoplasmosis infection in a previously infected recipient (R+). (2) Primary infection via the allograft in a previously uninfected recipient (D+R−). (3) Primary infection in a previously uninfected recipient (R−) acquired in the post-transplant period.

[b]Consider prolonging prophylaxis in SOT-recipients who receive antilymphocyte therapies, have concomitant CMV disease, who develop PCP or have undergone treatment for acute allograft rejection.

[c]Includes pancreas and small-bowel transplantation.

43.7 Liver, Pancreas, and Multivisceral Transplantation

Toxoplasmosis has been extensively reported in liver transplant recipients in the context of both primary infection—mainly transmitted through infected allografts harboring *T. gondii*—and reactivation from latent *toxoplasma* infection [9, 64–78]. Nonetheless, toxoplasmosis remains an uncommon complication following liver transplantation. In a cohort of 4872 liver transplant recipients who were followed by 9 years (2000–2009), only 4 (0.08%) developed toxoplasmosis [8]. Similar to kidney transplant recipients, the most common manifestations of toxoplasmosis in liver recipients are fever, pneumonitis, and multisystem organ failure; although cases of chorioretinitis and fatal sepsis have been reported [9, 63, 73, 74, 77]. Most patients developed toxoplasmosis within the first 30 days post-transplantation. The mortality rate remains disproportionally high (9 out of 15 patients, 60%) in a recent case-series, and it is intrinsically associated with timely diagnosis [9] (Table 43-1). Toxoplasmosis in recipients of pancreatic allografts has been reported alone [79] or in the context of multivisceral transplantation [76, 80]. A case of fatal-disseminated toxoplasmosis in a highly immunosuppressed small-bowel transplant recipient demonstrated high-burden disease in both the allograft (jejunum and ileum) and native GI tract (esophagus, duodenum, and colon) [9].

43.8 Immune Response of the Host

The combination of innate, humoral, and cellular immune responses is responsible for controlling both primary and latent infections as well as preventing reactivation. As *T. gondii* is capable of invading any nucleated cell, it provokes an intense pro-inflammatory response that evokes a fine regulation of multiple immune effectors and their signaling pathways [81]. Macrophages, enterocytes, dendritic cells, natural killer cells, T cells, TH1 cytokines (e.g., IFN-γ and IL-12), tumor necrosis factor-α (TNF-α), costimulatory molecules (e.g., CD28 and CD40 ligand), immunoglobulins, and key component of the innate immune system—reactive oxygen species (ROS) and nitric oxide species (NOS)—are crucial for the effective clearance of tachyzoites from peripheral blood, their conversion to bradyzoites, control of the parasite burden, and subsequent formation of cysts in different tissues [81]. Moreover, *Toxoplasma* exhibits inhibitory properties over the apoptotic signaling in infected cells and interferes with the NF-κβ pathways [82, 83]. Immunity in the immunocompetent host has been found to be indefinite probably due to the occasional rupture of individual tissue cysts that provoke a continuous stimulation of the immune system [84].

The greater the defect in T cell-mediated immunity in a transplant patient, the higher the risk for reactivation of latent *T. gondii* infection (i.e., D+/R− heart transplant recipient with enhanced immunosuppression due to acute rejection is at higher risk than a kidney transplant patient).

43.9 Genetic Susceptibility

Certain human leukocyte antigen (HLA) types have been associated with a greater susceptibility to develop central nervous system toxoplasmosis. The major histocompatibility complex (MHC) class II gene DQ3 (HLA-DQ3) has been significantly associated with the development of toxoplasmic encephalitis (TE) in North American Caucasian AIDS patients [85] and with the development of hydrocephalus in children with congenital toxoplasmosis [86]. The HLA-DQB*0402 and DRB1*08 alleles were associated with a high risk of developing TE in South American Caucasian AIDS patients [86].

These studies addressing host genetic susceptibility have not been performed in transplant patients, but they may explain why only 25% of high-risk (D+R−) heart transplant patients [46], and 38% of HSCT patients with previous exposure to *Toxoplasma* [87], develop toxoplasmosis when they do not receive prophylaxis.

43.10 Clinical Manifestations

Toxoplasmosis can result from symptomatic primary infection or reactivation of a previously acquired latent infection. Ninety percent of primary *T. gondii* infections are asymptomatic. Therefore, transplant donors and recipients may have been infected without their knowledge (and, as previously stated, without conventional risk factors for acute infection).

43.10.1 Acute Toxoplasmosis

Symptomatic primary infection may manifest as a painless, nonsuppurative lymphadenopathy. Fever, malaise, and visual symptoms (with retinal involvement) may also be present alone or in combination. Ocular toxoplasmosis causes retinochoroiditis and can result in blurred vision, eye pain, decreased visual acuity, floaters, scotoma, photophobia, or epiphora. Other less common, but well-documented, syndromes have been associated with acute infection including hepatitis, myositis, and myocarditis. More aggressive disease including pneumonia, brain abscesses, and death has been observed in immunocompetent patients in South America. These geographical peculiarities in clinical manifestations may be relevant for the transplant patient who becomes ill after traveling to those areas.

Acute toxoplasmosis in immunocompromised patients is rare but has been described in heart, liver, and kidney trans-

plants when seropositive donors transmit the parasite to seronegative recipients via the infected organ [8, 9, 42]. In this setting, syndromes such as fever, sepsis, pneumonia, brain abscesses, and chorioretinitis have been reported.

43.10.2 Reactivation of Latent Infection

In most individuals, primary infection is followed by a chronic phase during which the parasite appears to be dormant. Clinically meaningful reactivation is not observed in immunocompetent individuals. However, in patients with significantly impaired cell-mediated immunity, *T. gondii* can reactivate and cause encephalitis, chorioretinitis, fever of unknown origin, pneumonia, myocarditis, hepatosplenomegaly, lymphadenopathy, and rash. Although multiple brain abscesses are commonly described in patients with toxoplasma encephalitis (TE) (Figure 43-2), diffuse encephalitis without space-occupying lesions by MRI has been reported with a very high case fatality rate. Fever with pneumonia can be the sole manifestation of toxoplasmosis in immunocompromised patients including SOT and HSCT. Toxoplasmic pneumonitis can present with cough, dyspnea, hypoxia, and diffuse bilateral or localized infiltrates.
