Preface

The success of the previous editions of *Transplant Infections*, as a reference work to bring together information directed at the management of the infectious complications occurring specifically in immunocompromised individuals undergoing transplantation, has led to the creation of this fourth edition. No other text focuses solely on exogenously immunosuppressed transplant patients, and no text combines solid organ and hematopoietic stem cell transplantation (historically referred to as bone marrow transplantation). Many texts focus on immunocompromised patients, but the field of transplant infectious diseases has evolved over the past 25 years as a field unto itself, with conferences devoted solely to this specialty, and guidelines, both national and international, being developed for the management of such patients. In addition, peer-reviewed journals now exist that publish information on this specialized area, and training programs devoted to the subspecialty of transplant infectious diseases within the field of infectious disease are being developed.

The field of transplant infectious diseases has continued to grow and expand since the third edition was published in 2009. In this edition, we have continued to highlight differences between solid organ and hematopoietic stem cell transplantation by adding additional chapters where we felt this differentiation would give added value to the readers. We have added a chapter on the new rapidly evolving topic of the microbiome. The major problem of antibacterial resistance has also been addressed more in depth by having separate chapters on gram-negative and gram-positive bacterial infections. We have also expanded some chapters on viral infections, such as the respiratory viruses, since recognition of the importance of these pathogens has grown, and new diagnostic testing is now available in real time. We have added a chapter on long-term care of the transplant recipient, given the success of transplantation and the increasing number of long-term survivors. A number of new authors have been added, and chapters have been substantially revised or completely rewritten.

This edition remains a globally inclusive product of leading authors and investigators from around the world. Perspectives from Argentina, Australia, Brazil, Chile, New Zealand, Western Europe (Italy, Spain, Sweden, Austria, Germany, France, and Switzerland), the United States, Canada, and Israel have been synthesized in this edition.

We continue to believe that much can be learned from appreciating both the similarities and the differences in the pattern of infections and the resulting morbidity and mortality in various transplant settings. Our goal with this textbook is to provide background and knowledge for all practitioners who work with transplant patients, in order to improve both the care and outcomes of transplant recipients and to provide a framework for education of physicians, transplant coordinators, and trainees in the field. As success in the field continues to grow, we hope that this text will provide a knowledge base that would advance the field and make transplantation safer for all who need this lifesaving intervention. We thank all the contributors for their effort and trust the reader will find this a valuable reference text as they care for transplant recipients.

Part I
Introduction to Transplant Infections

1 Introduction to Hematopoietic Cell Transplantation

Andrew R. Rezvani and H. Joachim Deeg

1.1 Introduction

The lymphohematopoietic system is the only organ system in mammals with the capacity for complete self-renewal. Therefore, donation of hematopoietic stem cells (HSC) does not result in a permanent loss for the donor. Reports on the therapeutic use of bone marrow to treat anemia associated with parasitic infections date back a century [1, 2], but not until the observations on irradiation effects in Hiroshima and Nagasaki and the ensuing systematic research into hematopoietic cell transplantation (HCT) in animal models were the principles of HCT established [1, 3, 4].

In 1957, the first clinical transplant attempts of the modern era were undertaken [1, 5, 6]. As predicted from animal studies, patients who underwent transplantation from allogeneic donors developed graft-vs.-host disease (GVHD) [4]. Patients transplanted from syngeneic (monozygotic twin) donors generally did not develop GVHD, but many of them died from progressive leukemia, apparently because of a lack of the allogeneic graft-vs.-leukemia (GVL) effect, which had been described by Barnes and Loutit in murine models [7]. These studies immediately established that allogeneic HCT functioned as immunotherapy.

Beginning in the late 1950s and early 1960s, Dausset et al. characterized the first histocompatibility antigens in humans [8]. Epstein et al. were the first to show the relevance of those histocompatibility antigens for the development of GVHD in an outbred species [9]. Initially, the only source of HSC used clinically was bone marrow. However, cells harvested from peripheral blood, either after recovery from chemotherapy or after the administration of hematopoietic growth factors such as granulocyte-colony stimulating factor (G-CSF), were shown to result in accelerated hematopoietic recovery after autologous transplantation. These cells, as well as cord-blood cells, are now being used with increasing frequency in allogeneic HCT [10, 11].

1.2 Rationale and Indications for Hematopoietic Cell Transplantation

Current indications for HCT are summarized in Table 1-1. The majority of HCT are performed to treat malignant diseases. Myelosuppression is the most frequent dose-limiting toxicity of cytotoxic therapy for malignancies. Infusion of HSC—autologous or allogeneic—as a "rescue" procedure allows for the dose escalation of cytotoxic therapy, until toxicity in the next most sensitive organs (intestinal tract, liver, or lungs) becomes dose limiting. This strategy, often referred to as high-dose therapy with stem cell rescue, has been used extensively in the past. However, progressive dose intensification, although possibly effective in disease eradication, has resulted in minimal, if any, improvement in survival because of increases in therapy-related toxicity and mortality. These observations, combined with an increasing appreciation of the central role of immunologic graft-vs.-tumor reactions in the success of allogeneic HCT, have led to new concepts of transplant conditioning [12].

"Replacement" therapy in patients with congenital or acquired disorders of marrow function, immunodeficiencies, or storage diseases represents a second indication for HCT. Patients with severe autoimmune diseases (e.g., rheumatoid arthritis, Crohn's disease, or systemic sclerosis) represent another group of patients who may benefit from HCT [13, 14]. In contrast to the benefit of graft-vs.-tumor alloreactivity in malignant diseases, patients with nonmalignant disorders are unlikely to derive any benefit from donor alloreactivity.

Finally, HSC (or their progeny) may be effective vehicles for gene therapy and for immunotherapy. Objectives of gene therapy include the replacement of defective or missing enzymes (e.g., adenosine deaminase, glucocerebrosidase) or of the defective gene [15, 16]. Experience with the use of allogeneic cells, often T lymphocytes, as immunologic

P. Ljungman et al. (eds.), *Transplant Infections*, DOI 10.1007/978-3-319-28797-3_1

Table 1-1. Categories of disease treated with hematopoietic cell transplantation[a]

Malignant
Hematologic malignancies
Acute leukemias
Chronic leukemias
Myelodysplastic syndromes
Myeloproliferative neoplasms
Non-Hodgkin lymphoma
Hodgkin lymphoma
Plasma cell dyscrasias (e.g., multiple myeloma)
Selected solid tumors
Germ cell tumors
Ewing sarcoma
Neuroblastoma
Nonmalignant
Acquired
Aplastic anemia and red cell aplasias
Paroxysmal nocturnal hemoglobinuria
Autoimmune disorders (e.g., multiple sclerosis, systemic sclerosis, rheumatoid arthritis, Crohn's disease)
Congenital
Immunodeficiency syndromes (e.g., SCID)
Hemoglobinopathies
Congenital anemias (e.g., Fanconi anemia)
Storage diseases (e.g., mucopolysaccharidoses)
Bone marrow failure syndromes (e.g., dyskeratosis congenita)
Osteopetrosis

[a]This list is not all encompassing; transplants have been carried out for various other disorders.

bullets is more extensive. Donor lymphocyte infusion (DLI) for reinduction of remission in patients with chronic myelogenous leukemia (CML) who had relapsed after HCT has been remarkably successful, leading to application of this approach in other diseases. A modification of this strategy is the use of genetically modified donor lymphocytes expressing a "suicide gene," which can be activated to abrogate adverse effects of DLI, particularly GVHD [17].

The principles of immunotherapy are also exploited prominently in allogeneic HCT following reduced-intensity conditioning (RIC), also referred to as non-myeloablative or "mini"-transplants (both terms, however, are misleading, as the end result is intended to be "ablation" of the disease, and a mini-transplant is still a full transplant, albeit with a lower-intensity conditioning regimen). In this approach, the intensity of the conditioning regimen is reduced to prevent early mortality, but enhanced donor anti-host reactivity is required to eliminate host cells (Figure 1-1).

1.3 Sources of Hematopoietic Stem Cells and Donor Selection

HSC can be obtained from a variety of donors and cellular compartments, including the bone marrow, peripheral blood, and cord blood. The choice of stem cell source is dependent upon several factors. Although autologous marrow or peripheral blood stem cells (PBSC) are theoretically available for every patient (feasibility has been reported even for patients with severe aplastic anemia), these would not be useful without genetic manipulation for genetically determined disorders and would be suboptimal for malignant disorders, because of the concern of contamination with malignant cells and the lack of an allogeneic antitumor effect. Autologous marrow or PBSC can be purged of contaminating malignant cells by chemical means or by antibodies which recognize tumor cells. However, slow engraftment and residual tumor cells that resist purging limit the usefulness of this approach. Currently available purging methods have generally failed to show clinical benefit and thus none are widely used [18, 19], although research continues into more effective approaches to HSC purification and tumor purging [20].

Generally, each full sibling has a 25 % chance of sharing the complete HLA genotype with another sibling. Somewhat less than 1 % of patients will have a syngeneic (identical twin) donor. The lack of an HLA-identical related donor in more than 70 % of patients has led to the development of large data banks of volunteer unrelated donors and research into alternative allograft sources such as HLA-haploidentical family members and umbilical cord blood.

Supported by the efforts of the National Marrow Donor Program in the United States, the Anthony Nolan Appeal in the United Kingdom, the DKMS in Germany, and other groups internationally, more than 20 million volunteer donors have been typed for HLA-A and HLA-B and a rapidly increasing number also for HLA-C, HLA-DR (DRB1), and HLA-DQ antigens. The probability of identifying a suitably HLA-matched unrelated donor for a Caucasian patient in North America is about 75 %. This probability is lower for other ethnic groups, in part because of lower representation in the data bank and in part because of greater polymorphism of the HLA genes. As a result, the likelihood of finding a fully HLA-matched unrelated donor for some ethnic minorities in the United States may be as low as 16 % [21].

Cord-blood cells, generally not matched for all HLA antigens of the patient, are being used with increasing frequency. Because of the immunologic naivete of umbilical cord-blood cells and the low T-cell content, these cells can be transplanted across significant (major) HLA barriers with acceptable rates of GVHD. Suitably HLA-matched umbilical cord-blood units can be found for 80–100 % of patients [21]. The second major alternative source of hematopoietic grafts is HLA-haploidentical family members. These donors are available for nearly all patients, since they include any parent, any child, and many siblings. With the use of posttransplant cyclophosphamide as GVHD prophylaxis, HLA-haploidentical allogeneic HCT can be performed with similar or perhaps even lower rates of acute and chronic GVHD compared to HLA-identical related or HLA-matched unrelated donors [22]. Currently, the optimal alternative-donor source of hematopoietic cells remains unclear. Contemporaneous single-arm studies of HLA-haploidentical

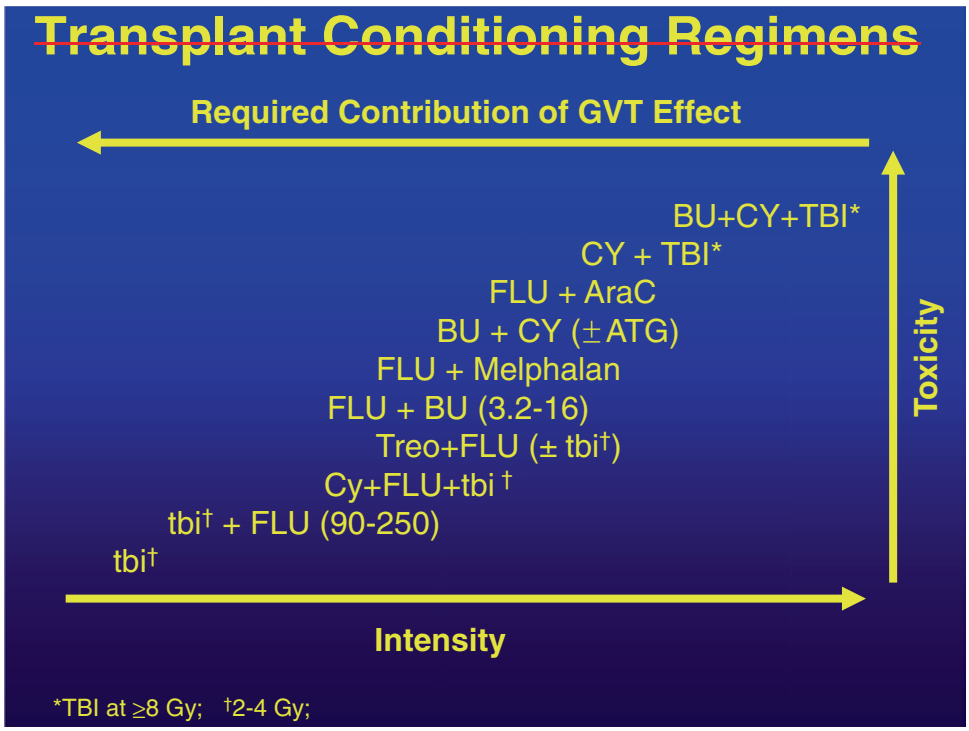

FIGURE 1-1. Selected conditioning regimens for hematopoietic cell transplantation, arranged by relative intensity, toxicity, and reliance on immunological graft-vs.-tumor effects. Abbreviations: *GVT* graft-vs.-tumor effect, *BU* busulfan, *CY* cyclophosphamide, *TBI* total body irradiation (high-dose, ≥12 Gy; low dose, 2–4.5 Gy), *FLU* fludarabine (at doses of 90–250 mg/m^2), *ATG* antithymocyte globulin, *araC* cytarabine arabinoside, *TREO* treosulfan (3×10 to 3×14 g/m^2).

vs. cord-blood transplantation suggest that overall survival is comparable, with somewhat higher rates of relapse with haploidentical donors and higher rates of transplant-related mortality with umbilical cord blood [23]. A national multicenter randomized clinical trial is currently underway in the United States, organized by the Blood and Marrow Transplant Clinical Trials Network (BMT-CTN), comparing these two sources of hematopoietic cells.

1.4 Transplant Procedure

1.4.1 Transplant Conditioning

1.4.1.1 Rationale for Conditioning

1. To ablate the patient's disease, or at least to reduce the number of malignant or abnormal cells to below detectable levels (this applies to allogeneic, syngeneic, and autologous donors). Ablation appears to allow for greater efficacy of graft-vs.-tumor reactions.
2. To suppress the patient's immunity and to prevent rejection of donor cells (this applies to allogeneic, but not to autologous, HCT). Immunosuppression is also needed in preparation for some syngeneic transplants, apparently to eliminate autoimmune reactivity which may interfere with sustained hematopoietic reconstitution.

The notion that conditioning is necessary to "generate space" in the transplant recipient has been abandoned. Donor cells, given in sufficient numbers and replete with T cells, create their own space and proceed to repopulate the recipient's marrow [24].

Exceptions to the requirement for pretransplant conditioning for allogeneic HCT exist in some children with severe combined immunodeficiency (SCID), because their underlying disease does not allow them to reject transplanted donor cells, and in patients in whom even partial donor engraftment can completely correct the genetic defect [25].

1.4.1.2 Modalities for Transplant Conditioning

Modalities used to prepare patients for HCT have been reviewed extensively elsewhere [26, 27]; a subset of commonly used regimens is shown in Figure 1-1. In principle, conditioning for HCT can include the following approaches:

1. Irradiation, in the form of total body irradiation (TBI), total lymphoid irradiation [28], or modifications thereof. Many conventional TBI regimens deliver 12–14 Gy over 3–6 days. In addition, bone-seeking isotopes (e.g., holmium) and isotopes (e.g., ^{131}I, ^{92}Y) conjugated to monoclonal antibodies (MAbs) directed at lymphoid or myeloid antigens (e.g., anti-CD20, CD45) are in use [29–31]. TBI may also be a component of RIC regimens, usually at lower doses of 2 Gy [32].
2. Chemotherapy (e.g., cyclophosphamide, 120–200 mg/kg over 2–4 days) is included in many conventional regimens. Busulfan (available in oral and intravenous formulations)

at 16 mg/kg (or lower doses), targeted to predetermined plasma levels, is often used in combination with cyclophosphamide. Other agents, including etoposide, melphalan, thiotepa, cytarabine, and, more recently, treosulfan [33, 34], may be used either alone or in combination and with or without irradiation.

3. Biologic reagents (e.g., antithymocyte globulin [ATG]) or MAbs directed at T-cell antigens or adhesion molecules suppress recipient immunity. Others are directed at antigens expressed on the recipient's malignant cells; in addition, cytokines or cytokine antagonists are being investigated. Anti-T-cell therapy predisposes the individual to viral infections, in particular CMV and the reactivation of Epstein–Barr virus (EBV) with the risk of developing EBV-related lymphoproliferative disorders (PTLD) after transplantation [35].

1.4.2 Marrow Harvest

The marrow donor receives general or regional (e.g., epidural, spinal) anesthesia, and, under sterile conditions, multiple aspirates of marrow are obtained from both posterior iliac crests. Additional potential aspiration sites are the anterior iliac crests and the sternum. Approximately 10–15 mL/kg of donor weight is collected. If no ABO incompatibility exists and if the marrow is not to be subjected to any in vitro purging procedure, the resulting cell suspension is infused intravenously without manipulation. The rate of serious or chronic complications among healthy bone marrow donors is approximately 1 % [36].

1.4.3 Alternative Stem Cell Sources

HSC circulate at low concentrations in blood [37]. Their frequency increases dramatically during the recovery phase following cytotoxic therapy and after the administration of recombinant hematopoietic growth factors such as G-CSF, which dislodge cells from the marrow. Peak blood concentrations of $CD34^+$ cells are typically reached on day 4–5 after initiating G-CSF. A single leukapheresis may be sufficient to harvest the number of HSC required for a transplant. For autologous procedures, the goal is to collect at least $2–5 \times 10^6$ $CD34^+$ cells/kg recipient weight; for allogeneic transplants, the goal is $2–11 \times 10^6$ $CD34^+$ cells/kg, although the optimum dose has not been determined and doses outside this range are sometimes used [38].

Umbilical cord blood represents a segment of the peripheral circulation of the fetus and is easily accessible after delivery. Cord-blood cells are less immunocompetent than adult cells and might therefore carry a lower risk of inducing GVHD than adult cells. The concentration of HSC in umbilical cord blood is high, but the small volume that is usually available (80–150 mL) had initially limited the use of these cells to children and smaller adults. In larger adults, approaches have included the use of two cord-blood units to ensure adequate cell dose and engraftment, as well as ex vivo expansion of hematopoietic precursors in umbilical cord-blood units for infusion together with an unmanipulated cord-blood unit [39, 40].

1.4.4 Purging

There are several reasons to purge collected donor cells or to fractionate them into subpopulations. In autologous HCT, the goal is to eliminate contaminating tumor cells, either by negative selection (removal of tumor cells with antibodies or physicochemical means) or by positive selection (purification of $CD34^+$ cells from the graft). Conversely, in allogeneic HCT, one may want to retain certain cell populations (e.g., $CD4^+$ cells) with potential for later uses such as posttransplant DLI. With the development of "tandem" HCT, combining high-dose therapy and autologous HCT to reduce the tumor burden with a subsequent allogeneic HCT to exploit the GVT effect, purging of autologous cells has lost some of its relevance.

1.4.5 Hematopoietic Stem Cell Infusion: The Actual Transplant

Donor cells are infused intravenously via an indwelling central line, often a Hickman catheter. Directed by cell surface molecules which interact with receptors on endothelial cells, HSC home to the marrow cavity. The actual infusion of stem cells is generally uneventful, though it can occasionally cause transient mild hypotension or hypersensitivity reactions, or reactions to the chemical used to cryopreserve autologous cells.

1.5 Care After Transplantation

Complications of HCT, including infections, are related to the underlying disease, the preparative regimen, and the interactions of donor cells with recipient tissue (GVHD with immunosuppression and end-organ damage). All patients experience at least transient pancytopenia, although this may be mild with RIC regimens. Patients undergoing high-dose conditioning generally develop severe pancytopenia, including neutropenia, within days after completion of conditioning. This period may last 2–4 weeks with marrow allografts, 10–14 days with mobilized PBSC grafts, or 4–6 weeks with umbilical cord-blood grafts. The period of neutropenia ends with engraftment of the donor cells, clinically defined by stable increases in the white blood cell count. Cytopenias are less pronounced after RIC, and the pattern of engraftment may be less apparent in the peripheral white blood cell count. Engraftment in these patients is generally documented by demonstrating donor chimerism by cytogenetic or molecular means in peripheral blood leukocytes and bone marrow.

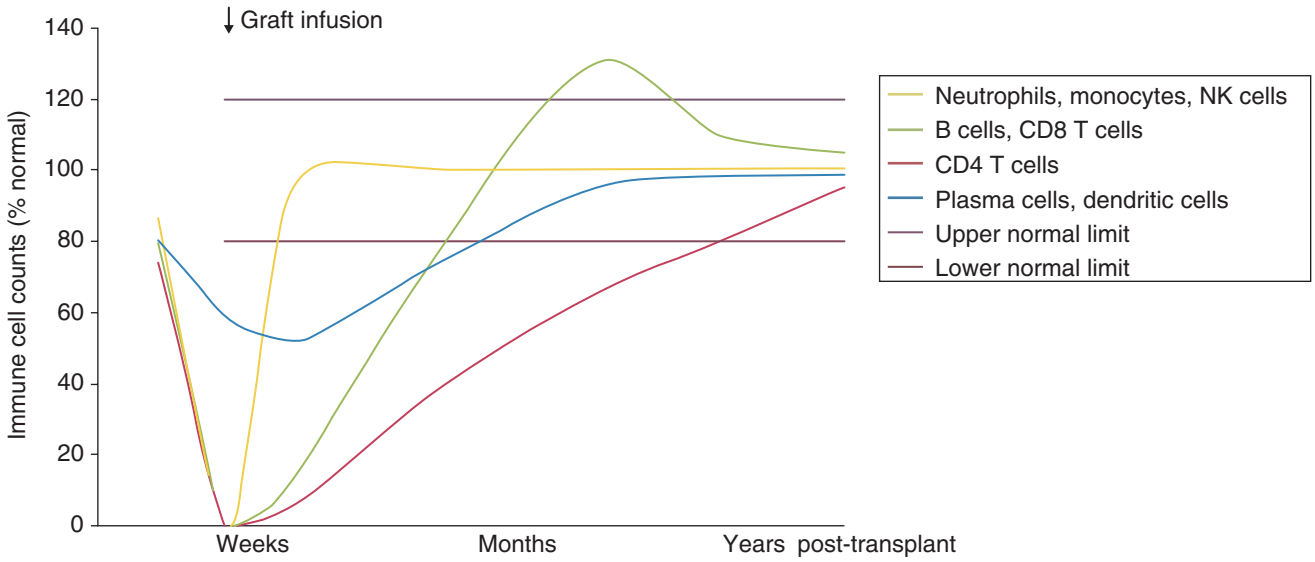

FIGURE 1-2. Approximate pattern of immune cell recovery after high-dose conditioning and hematopoietic cell transplantation. With the use of reduced-intensity conditioning, nadirs tend to be higher and to occur later. These recovery rates are influenced by clinical variables, in particular graft-vs.-host disease, stem cell source, and patient age. Storek J, Immunological reconstitution after hematopoietic cell transplantation - Its relation to the contents of the graft, Expert opinion on biological therapy, 8(5):583–97, copyright 2008, Informa Healthcare. Adapted with permission of Informa Healthcare.

Most patients prepared with high-dose regimens require transfusion support with platelets, red blood cells, or both. Transfusion requirements are substantially reduced in patients prepared with RIC regimens, because the nadir of cells often is in a range in which no transfusions are required [41]. An increasing number of transplants, both autologous and allogeneic, are being performed primarily in the outpatient clinic rather than in the hospital, due to the increased use of RIC and improvements in logistical and supportive care.

Quantitative and functional deficiencies of granulocytes and T lymphocytes for various periods after HCT are responsible for most of the infectious complications seen after HCT (Figure 1-2). While all patients receive prophylactic antimicrobials, granulocyte transfusions are not routinely given. Studies performed in the 1980s suggested that laminar air flow (LAF) rooms and gastrointestinal decontamination could reduce the frequency of infections and the duration of febrile episodes, but neither is used routinely in modern practice because of the high cost of LAF and the availability of effective broad-spectrum antibiotics [42]. It should be emphasized, however, that current research is again focused on the role of the intestinal microbiome in transplant outcomes, particularly in GVHD.

The most widely used modality of GVHD prophylaxis is the in vivo administration of immunosuppressive agents, such as methotrexate, cyclosporine (CSP), glucocorticoids, tacrolimus (FK506), mycophenolate mofetil (MMF), sirolimus, and others, either alone or in combination. At many institutions, the current standard is a combination of a calcineurin inhibitor with methotrexate or MMF, but several other combinations are used. Novel regimens have demonstrated promising results in single-arm studies, but have not yet proven superior in randomized clinical trials [43]. In one randomized trial, the addition of ATG to standard GVHD prophylaxis significantly decreased rates of acute and chronic GVHD, although it also increased the risk of fatal EBV-driven posttransplant lymphoproliferative disease and did not improve overall survival [35, 44]. Due to the non-selectivity of these agents, recipients are broadly immunosuppressed and thus susceptible to infections. In vitro T-lymphocyte depletion of donor marrow for GVHD prophylaxis may obviate the need for immunosuppressive treatment after HCT; however, the elimination of mature T cells is associated with a risk of rejection, delayed immunologic reconstitution, an increased risk of PTLD, and, for some disorders, disease recurrence. Both immunodeficiency and therapeutic immunosuppression predispose the patient to infections.

1.6 Hematologic Recovery

Patients conditioned with high-dose regimens are at risk of infections early after HCT, due to granulocytopenia until the transplanted donor cells produce new effector cells. If the donor marrow is T cell depleted, recovery of blood counts may be further delayed. If the granulocyte count at day +21 after transplantation is <200 cells/μL, patients are often given G-CSF or granulocyte-macrophage colony-stimulating factor. After PBSC transplants, engraftment (defined by >500 granulocytes/μL) occurs as early as day +9 or +10, thus

clearly shortening the length of granulocytopenia. Rather slower recovery (over several weeks) may be seen with cord-blood transplants.

One advantage of RIC regimens is the slow decline of patient cells, so that donor cells have begun to recover before patient cells have reached their nadir. Consequently, several groups have reported lower rates of early infection after RIC conditioning as compared with high-dose conditioning [45, 46].

1.7 Immunologic Recovery

All components of the innate and adaptive immune systems are deficient after HCT. Cell-mediated immunity, chemotaxis, and neutrophil function are severely impaired even after autologous transplants. The development of GVHD substantially impairs immune reconstitution, through a combination of direct graft-vs.-host toxicity to the thymus resulting in altered T-cell selection and use of immunosuppressive therapies to treat GVHD. Optimal immune reconstitution can only occur in the absence of GVHD.

1.7.1 Uncomplicated Recovery

Shortly after HCT, damaged epithelial barriers facilitate the penetration of pathogenic bacterial or fungal organisms. Mucosal surfaces begin to heal within a week or 2 of completion of high-dose conditioning, helped by the recovery of granulocytes and their scavenging function, even though phagocytosis and superoxide production may still be impaired. After the transplant, the volume and immunoglobulin content of saliva also improve with time, facilitating oropharyngeal cleansing. Even with uncomplicated recovery, T- and B-cell-mediated immune responses against viral, bacterial, fungal, and other organisms are broadly suppressed; natural killer (NK) cells recover more quickly. To some extent, the pattern of immune recovery is dependent on the immunity of the donor from whom the transplanted cells originated. The pattern of immunocompetence is also influenced by the recipient's prior antigen exposure, whether to the pathogen itself or in the form of a vaccine. Much of the literature on immune reconstitution after allogeneic HCT describes patients who were prepared with high-dose conditioning. While the use of RIC regimens has increased rapidly in recent years, there are fewer data available on immune recovery in this setting, and the impact of RIC on immune reconstitution remains somewhat unclear. Preliminary studies suggest that the tempo of immune recovery may be faster after RIC, at least by quantitative measurements [47, 48], but late immune function may be similar to that seen after high-dose conditioning [49].

1.7.2 B Cells

B-cell numbers are very low or undetectable shortly after high-dose conditioning, but may rise to supranormal levels by 1–2 years [50]. Recovery is faster with autologous than with allogeneic HCT; memory B cells lag behind naive cells. Early, but not late, recovery for both populations is faster for PBSC recipients than for marrow recipients [51]. The B-cell compartment is generally replaced completely by donor-derived cells, except in patients with T+B− SCID, in whom the recipient's B cells tend to persist [52]. Some antibodies of host origin (e.g., ABO isoagglutinins) that are derived from long-lived plasma cells may be detectable for months or even years after HCT. Persistently low B-cell counts after HCT may be associated with a high risk of infection [53]. In the era of targeted therapy, treatment with B-cell-directed MAbs such as rituximab before or after HCT may also impair and delay B-cell reconstitution [54, 55]. Some evidence suggests that poor B-cell reconstitution can lead to a dysregulated homeostatic environment with high levels of B-cell activating factor (BAFF) and other B-cell survival factors, which in turn promote the survival of alloreactive B cells and associate with an increased risk of chronic GVHD [56–58].

During recovery, fewer B cells express CD25 and CD62L; more express CD9c, CD38, IgM, and IgD; and antigen density is increased (as in neonatal B cells). $CD5^+$ cells may or may not be increased. Immunoglobulin gene usage appears to be restricted shortly after HCT and to be skewed toward the V-segments that are frequently used in neonatal B cells (e.g., VH6). Concordantly, the antibody repertoire is restricted [59]. IgG and IgA production may be abnormal for 1–2 years after HCT. Serum isotype levels after grafting recover in the same sequence as they evolve in neonates (i.e., IgM, IgG1, and IgG3 recover early, but IgG2, IgG4, and IgA may not follow until much later) [60]. Many of the early antibodies are autoantibodies, or else have irrelevant specificities. Antibodies with relevant specificities recover only if the antigen is encountered, and they recover more quickly if both patient and donor are immune. At 3 months after HCT, total IgG levels in recipients of allogeneic PBSC tend to be lower than those in marrow recipients. Antibodies to polysaccharide antigens tend to recover later than those directed at proteins. B-cell counts and IgM levels may recover more quickly after RIC as compared to high-dose conditioned patients, though IgA recovery is delayed in both groups [48]. In addition to quantitative deficits in B-cell number and immunoglobulin levels, the B-cell pool early after HCT is marked by qualitative functional impairment. Isotype switching is deficient in the absence of effective T-cell help. Additionally, B cells from transplant recipients have a decreased capacity for somatic hypermutation independent of T-cell help, suggesting an intrinsic or environmental defect. Thus, B-cell deficits after HCT are comprised of at least three factors: low B-cell numbers,

decreased T-cell help, and intrinsic defects such as impaired somatic hypermutation.

Antibody responses to vaccination are almost universally lower than those of normal controls, and repeated boosters are required. Responses are better in younger individuals and in those with T-cell-replete grafts; this may be related to CD4 recovery, which is faster in younger individuals. The policy has been to delay revaccination until 1–2 years after HCT to minimize the risk of potential side effects and to increase the probability of antibody responses.

1.7.3 T Cells

1.7.3.1 CD4⁺ Cells

The number of $CD4^+$ T cells is low for 1–3 months after high-dose conditioning and rises slowly toward normal over several years. The kinetics are similar following both autologous and allogeneic transplants. Early in the process, most cells are memory T cells; naive T cells follow gradually, particularly in older patients. These kinetics might be related to diminished thymic function, but data on thymic recovery after HCT in older patients are conflicting [61, 62]. After PBSC transplantation, both naive and memory $CD4^+$ T cells are more abundant than after marrow transplantations. Early after HCT, most $CD4^+$ T cells are derived from transplanted mature T cells and T-cell precursors; later, they are stem cell derived, at least in pediatric patients. $CD4^+$ T-cell reconstitution may occur more rapidly after RIC than after high-dose conditioning [48].

$CD4^+$ T cells generally express CD11a, CD29, CD45RO, and HLA-DR and less CD28, CD45RA, and CD62L, consistent with the prominence of memory cells. Responses to polyclonal stimuli are low. Proliferative responses to frequently encountered antigens (e.g., Candida species) tend to normalize over 1–5 years, whereas responses to unlikely antigens (e.g., tetanus) remain subnormal. Responses to neoantigens (e.g., dinitrochlorobenzene) and recall antigens (e.g., mumps) are abnormally low for 2–3 years after HCT.

1.7.3.2 CD8⁺ Cells

$CD8^+$ T cells are low for 2–3 months after HCT; subsequently, they rise quickly, resulting in an inversion of the typical CD4:CD8 ratio. These $CD8^+$ cells are largely memory cells expressing CD11a, CD11b, CD29, CD57, HLA-DR, and CD45RO but little CD28, CD45RA, and CD62L. The presence of a $CD11b^+CD57^+CD28^-$ phenotype suggests anergic or suppressor-type CD8 cells. $CD8^+$ cells appear to be derived from transplanted T cells and stem cells.

CMV-specific or EBV-specific $CD8^+$ cells can be transferred successfully from donor to recipient, and they may persist for at least 18 months in the absence of glucocorticoid treatment [63, 64]. Even established and refractory CMV infections can be treated effectively by the infusion of expanded CMV-specific $CD8^+$ donor cells; this approach has been most effective in the absence of glucocorticoid treatment for GVHD or in the setting of T-cell-depleted allotransplantation [65]. The logistical difficulty of generating CMV-specific cells for clinical use has been a barrier to the wide application of this approach. However, several groups have reported progress in developing simpler and more scalable means of producing virus-specific donor T cells for infusion [66, 67].

The role of immunoregulatory $CD4^+CD25^+$ T cells (T_{reg}) in clinical transplantation remains to be fully established. Adoptive transfer of T_{reg} has been explored as a treatment for GVHD [68], but its efficacy remains to be confirmed.

1.7.4 Antigen-Presenting Cells

Monocytes reach normal levels within 1 month after high-dose conditioning, although their function may remain impaired for a year [69]. G-CSF-mobilized PBSC contain large numbers of monocytes with altered cytokine profiles that may suppress allogeneic T-cell responses. G-CSF-mobilized monocytes settle in tissues in the early posttransplantation period.

The reconstitution of dendritic cells (DC), their maturation, and the development of DC1 and DC2 have been incompletely characterized. DC precursors in the blood recover within 6 months, and DC reconstitution appears to be a clinically important event. Low numbers of DC at 1 month after RIC and allogeneic HCT have been associated with an increased risk of mortality and disease relapse; $CD16^+$ DC counts at 3 months also had strong prognostic significance [70]. In one study, low numbers of plasmacytoid DC at 3 months after HCT were associated with higher risks of infection and death [71]. Langerhans cell levels are low in the early posttransplantation period, but return to normal by 6 months. Follicular DC are reconstituted rather slowly, which may contribute to the delayed return to function of the germinal centers and memory B cells.

1.7.5 Natural Killer Cells

NK cells recover rapidly after HCT. With the recognition of the killer inhibitory receptor, there has been renewed interest in these cells because of their possible function in engraftment and the prevention of relapse [72]. Robust NK-cell reconstitution after allogeneic HCT has been associated with reduced relapse incidence and with improved survival [73]. Recent data suggest that NK cells may also play a role in controlling CMV reactivation after allogeneic HCT. Some studies have found that CMV viremia produces a rapid expansion of adaptive NK cells, leading to protection against CMV disease [74, 75]. However, other groups have reported no correlation between the numbers of $NKG2C^+$ NK cells and protection from CMV viremia [76, 77].

1.8 Graft-vs.-Host Disease and Graft-vs.-Leukemia Effects

Acute and chronic GVHD occur in 10–50 % and 20–50 %, respectively, of patients after HLA-identical sibling HCT and in 20–60 % and 30–70 %, respectively, of patients who undergo transplantation from alternative donors. Without prophylaxis, virtually all recipients of allogeneic transplants develop GVHD. Acute GVHD may occur within days (e.g., among HLA-nonidentical recipients) or by 3–5 weeks after HLA-identical transplantation following high-dose conditioning. The main target organs are the immune system, skin, liver, and intestinal tract. Risk factors for acute GVHD include donor/recipient HLA mismatches, the use of unrelated rather than related donors, and TBI-containing conditioning regimens [78]. Importantly, after RIC, classic manifestations of acute GVHD may develop several months after HCT and may overlap considerably with those of chronic GVHD [79]. Features of chronic GVHD may be present as early as 50–60 days after HCT. Therefore, revised diagnostic criteria distinguish acute from chronic GVHD on the basis of pathology and biology, rather than time of onset [79]. Patients with late-onset or recurrent acute GVHD, and those with overlap syndromes of acute and chronic GVHD, have particularly poor prognoses. A recent analysis of data from the Center for International Blood and Marrow Transplant Research (CIBMTR) indicates that the incidence of chronic GVHD has been steadily increasing over time [80], possibly associated with the increasing use of alternative donors and G-CSF-mobilized peripheral blood rather than bone marrow allografts. On the other hand, there are data suggesting that posttransplant cyclophosphamide, given as GVHD prophylaxis, reduces the incidence of chronic GVHD.

HCT is a unique form of allotransplantation in that many recipients develop donor/host tolerance over time, to the point that maintenance immunosuppression can be completely discontinued. In patients without GVHD, all immunosuppressive medication is generally stopped by 6 months to 1 year after HCT. Even chronic GVHD is not necessarily a lifelong condition; many patients with chronic GVHD develop tolerance and resolution of GVHD over time and are able to discontinue immunosuppressive treatment. A study from the Fred Hutchinson Cancer Research Center indicated that, on average, immunosuppressive treatment was required for approximately 2 years in patients with chronic GVHD [81].

The immunopathophysiology of GVHD is complex. The initial damage to host tissue is induced by the transplant-conditioning regimen [82]. The subsequent development of acute GVHD involves antigen presentation. Shlomchik et al. showed that host DC play a pivotal role in this process [83]. Interactions of MHC antigens (with bound peptides derived from minor histocompatibility antigens) and T-cell receptors lead to activation, clonal expansion, and differentiation of donor T cells. Accessory T-cell surface molecules, such as CD4 or CD8, also contribute to the immunologic synapsis between T cells and antigen-presenting cells. The effector phase leads to host cell destruction via inflammatory signals, cytolytic effects, and programmed cell death (apoptosis). Inflammatory cytokines, which are primarily released from the gut, allow the transfer of endotoxins and lipopolysaccharides (LPS) into the circulation, triggering macrophage activation. The result is the further production of cytokines, such as tumor necrosis factor α (TNFα) and IL-1 [84], leading to target cell death and the expression of costimulatory molecules, such as CD80, CD86, and MHC class II antigens, on DC; T-cell stimulation; and the release of T helper-1 (Th1) cytokines (IL-2, interferon-a [IFN-a]).

Recent experiments also emphasize the role of other cytokines, particularly TNFα, IL-15, and IL-18 [85]. In mouse models, TNFα is a central mediator of GVHD that works predominantly in the intestinal tract. Anti-TNF antibodies prevent or ameliorate GVHD in mice [86]. In humans, anti-TNF therapy appears active in treating established acute GVHD [87], but ineffective as GVHD prophylaxis [88]. However, the actions of different cytokines and effector cells (e.g., large granular lymphocytes) and regulatory T cells (T_{reg}) are still incompletely understood. The role of T_{reg} with a $CD25^+CD4^+$ phenotype, which is functionally reminiscent of the classic "suppressor T cell," is still being defined, as is the role of Th17 cells [89–91].

Elevated serum levels of soluble Fas ligand have been observed in some patients with GVHD [92]. Fas-mediated apoptosis may also be involved in the control of alloreactive T cells [93]. Perforin-mediated cytotoxicity also plays a role in both GVHD and GVL effects [94, 95]. However, even T cells from mice doubly deficient in both FasL and perforin can cause GVHD after mismatched-donor HCT [96].

1.8.1 Stem Cell Source

The kinetics of GVHD depend upon the source of stem cells. PBSC mobilized by means of chemotherapy or G-CSF have been used extensively for allogeneic and autologous stem cell rescue, and they are associated with rapid hematopoietic reconstitution. G-CSF may polarize donor cells toward Th2 cells and promote regulatory T-cell function, favoring the development of tolerance [97]. Several clinical studies suggest that the incidence of acute GVHD is similar in marrow and PBSC recipients, whereas the incidence of chronic GVHD appears to be increased with PBSC [98]. However, the higher incidence of chronic GVHD with PBSC may not be associated with a significant increase in mortality. In fact, the results of several trials suggest that, particularly in patients with high-risk malignancies, survival is improved in PBSC recipients, perhaps due to a more vigorous GVT effect

or to more rapid immune reconstitution [99, 100]. Bone marrow allografts are often preferred in nonmalignant diseases, where GVT effects are unnecessary and minimization of GVHD is the overriding goal.

Studies directed at the mechanisms involved in the effects of PBSC show an increased production of IL-10, decreased levels of TNFα in monocytes from G-CSF-mobilized PBSC, and reduced expression of costimulatory molecules and MHC class II antigens. Thus, a tolerogenic effect related to monocytes may be present, possibly juxtaposed with a countereffect due to increased numbers of T cells.

Chronic GVHD has prominent features in common with autoimmune disorders [101], including the presence of T lymphocytes with abnormal cytokine profiles (e.g., secretion of IL-4 and IFNγ). Thymic damage, inflicted by the conditioning regimen as well as by preceding acute GVHD, leads to the failure of intrathymic selection and an escape of autoreactive cells to the periphery [102]. A similar mechanism appears to be responsible for a syndrome analogous to allogeneic GVHD which can develop after syngeneic or autologous HCT. Recently, the role of B cells in chronic GVHD has attracted renewed attention, based in part on reports indicating that the anti-CD20 MAb rituximab could treat or prevent chronic GVHD [58]. Some groups have posited that autoantibodies produced by autoreactive B-cell clones contribute directly to chronic GVHD [103]. Alternately, B cells may contribute indirectly, by influencing effector and regulatory T-cell compartments, as they do in other autoimmune diseases [104, 105].

As stated, the immune system is a major target of GVHD. Immunodeficiency is a key feature of GVHD that is amplified by the immunosuppressive therapies used to treat GVHD, thereby rendering patients highly susceptible to infections. The risk is further accentuated by damage to various barrier structures, particularly the skin and intestinal tract. All aspects of immune recovery after HCT are impaired or delayed in patients with GVHD; in patients with chronic GVHD, immunoincompetence may extend over years.

1.8.2 Prevention and Treatment of GVHD

Methods of GVHD prophylaxis are summarized in Table 1-2. Combination regimens of methotrexate (or MMF) and a calcineurin inhibitor (cyclosporine or tacrolimus) are the most widely used regimens after high-dose conditioning. The addition of prednisone to methotrexate and CSP has been shown to increase or to decrease the incidence of acute GVHD, depending on the timing of prednisone administration [106, 107]. Some trials of FK506 (tacrolimus) combined with methotrexate have shown an incidence of GVHD lower than that observed with CSP; however, disease-free survival was not improved [108]. Other trials have suggested that tacrolimus may be superior to CSP only in the unrelated-donor setting [109]. Some groups have explored the use of sirolimus in addition to or in place of methotrexate, although this approach did not prove superior to standard tacrolimus/methotrexate in a randomized clinical trial and was possibly associated with a higher risk of chronic GVHD [43]. Various prophylactic regimens have been employed after RIC HCT, including combinations of MMF with CSP, sirolimus, and T-cell depletion.

TABLE 1-2. Modalities of graft-vs.-host disease prevention

Selection of histocompatible donors
T-cell depletion
Ex vivo
Negative selection and removal of T cells
Removal of naïve T cells
Positive selection and purification of hematopoietic stem cells

Anti-T-cell monoclonal antibodies (e.g., alemtuzumab)
Posttransplant cyclophosphamide
Pharmacologic inhibition of T-cell function
Calcineurin inhibitors, antimetabolites, etc.
Cytokine blockade
Gnotobiosis

T-cell depletion of donor marrow, which is clearly effective in reducing the incidence of GVHD, has increased the probability of graft failure, posttransplant infection, and relapse of leukemia [110, 111]. Graft failure problems have been overcome in part by the in vivo administration of a Campath-1H MAb or of polyclonal ATG [35, 112, 113]. Alternatively, additional DLI may be given preemptively or therapeutically after HCT to reduce the risk of disease recurrence and graft failure. Some preliminary studies have suggested that depleting specific donor T-cell subsets from the DLI product may render this approach more effective [114, 115].

Much of the morbidity and mortality associated with acute and chronic GVHD derives from immunosuppression and the associated risk of potentially lethal infections. If GVHD develops despite prophylaxis, aggressive therapy is required. Glucocorticoids remain the first-line therapy for acute and chronic GVHD. Despite decades of investigation, there is no standard, effective second-line therapy for steroid-refractory acute or chronic GVHD [116]. Steroid-refractory GVHD poses a significant challenge from the standpoint of infectious disease, as patients are typically treated with escalating doses of various immunosuppressive agents in an effort to control alloreactivity. Patients with severe or refractory GVHD are profoundly immunosuppressed, and infection remains one of the major causes of mortality in this population. Standards of care for infection surveillance and prevention vary institutionally in patients receiving treatment for active GVHD, but in general such patients require close monitoring for opportunistic infections, both typical (e.g., CMV, respiratory viruses) and atypical.

1.9 Graft Failure

Graft failure (either primary or secondary) occurs in <5 % of patients undergoing allogeneic HCT. Major risk factors for primary graft failure after high-dose conditioning include myeloproliferative neoplasms, the use of marrow rather than PBSC as a stem cell source, HLA mismatch, ABO incompatibility, and cryopreservation of the graft before infusion [117]. Several host cell types, particularly $CD8^+$ T lymphocytes and NK cells, participate in the rejection of donor cells. Donor T cells counteract this host response, thereby facilitating engraftment and preventing rejection. As a consequence, T-cell-depleted marrow is more susceptible to rejection, as described above. Graft failure is associated with a very high risk of infections due to prolonged neutropenia. Patients with graft failure after high-dose conditioning generally will not have spontaneous complete autologous hematopoietic recovery and require salvage with a second HCT if clinically feasible [118]. In contrast, RIC regimens generally allow recovery of host hematopoiesis if the donor graft is rejected.

1.10 Delayed Complications

By 2 years after HCT, about 80 % of patients have returned to pretransplant activities. However, some patients develop delayed or chronic complications (Table 1-3). These complications are related to elements of the conditioning regimen (most importantly, irradiation or high-dose busulfan), side effects of HCT (chronic GVHD, immunodeficiency), or combinations thereof. The presence and severity of chronic GVHD are the dominant factors influencing quality of life in long-term survivors of allogeneic HCT [119]. Life-threatening complications include infections, pulmonary dysfunction, autoimmune disease, musculoskeletal problems, and new malignancies.

Table 1-3. Delayed complications of hematopoietic cell transplantation

Chronic graft-vs.-host disease
Infection
Airway and pulmonary disease (e.g., bronchiolitis obliterans)
Autoimmune dysfunction
Impaired growth and development
Endocrine dysfunction
Sterility
Cataracts
Dental problems
Osteopenia or osteoporosis
Aseptic necrosis of the bone
New malignancies
Psychosocial dysfunction

1.11 Summary

HCT offers effective and potentially curative therapy for many life-threatening malignant and nonmalignant diseases. Side effects include acute toxicity to multiple organs, the development of GVHD and immunoincompetence, and secondary effects related to immunosuppressive therapy. The result is a high susceptibility to infections, which are a major cause of morbidity and mortality after HCT. Both GVHD and its therapy are important predisposing factors; thus, reducing the incidence and severity of GVHD is an important component of efforts to reduce posttransplant infections. Transplant-conditioning regimens have undergone multiple modifications aimed at reducing early toxicity and permitting HCT in older patients and those with medical comorbidities. RIC may allow for faster immune recovery and better infection control and has expanded the availability of HCT to higher-risk patient populations. New antibiotics and methods of cellular therapy have also enhanced the ability to eradicate infections. Recent advances in laboratory techniques have facilitated a greater understanding of the role of the host microbiome in immune function. Host-microbiota interactions may be particularly important in the setting of allogeneic HCT, as the sites most heavily colonized with microbiota are also primary targets for GVHD (e.g., skin and gut). The interplay between the donor immune system and the host microbiome may play a significant role in modulating alloreactivity, tolerance, and GVHD. Early work has associated specific posttransplant changes in the gut microbiome with higher or lower risks of GVHD [120, 121], although more study is required to disentangle causation and confounding factors, such as antibiotic use, which may influence the microbiome. The emerging understanding of the role of the microbiome in transplantation has been reviewed elsewhere recently [122] and is discussed in more detail in Chap. 52.

Introduction to Solid Organ Transplantation

Nagaraju Sarabu and Donald E. Hricik

2.1 Historical Perspective

Organ transplantation has been the subject of ancient myths dating back to the twelfth century. The modern era of transplantation began in the early 1900s with the development of surgical techniques for constructing vascular anastomoses [1] leading to successful kidney transplantation in dogs in 1902 [2]. The first series of human kidney transplants were performed in the Ukraine beginning in 1933, but each of five attempted transplants failed [3, 4]. Around the same time, Kuss et al. [5], Servelle et al. [6], and Dubost et al. [7] reported technically successful transplantation of kidney allografts in humans, placing the organs heterotopically in the iliac fossa, similar to the technique used in the modern-day operation. However, all of these grafts failed over a short period of time. In 1954, Murray et al. [8, 9] performed a kidney transplant between identical twins and achieved long-term function. During the subsequent 10 years, more than 30 kidney transplants between identical twins were performed worldwide.

These early transplants between identical twins were successful because the donors and recipients were syngeneic, sharing the same immune system and thus eliminating the possibility of immunologically mediated rejection of the graft. In the 1940s, the seminal experiments of Medawar first delineated the immunologic basis for allograft rejection [10] and the need for immunosuppressive therapy to achieve successful transplantation using non-syngeneic grafts. By 1963, the first human liver transplantation was performed, using early forms of immunosuppression [11]. One year later, Barnard [12] performed the first successful human heart transplant. Shortly thereafter, techniques were developed for clinical heart–lung [13] and pancreas [14] transplantation.

Since those early days, remarkable strides have been made to increase the success of organ transplantation to prolong the lives of patients with end-stage organ disease. General advances in medical science, including improvements in surgical techniques and the development of effective antimicrobial agents, have undoubtedly played a role in this success story. However, the current success of organ transplantation has been related more directly to an improved understanding of the mechanisms of allograft rejection and the development of immunosuppressive drugs capable of preventing or treating rejection.

Although transplantation offers a survival advantage and improved quality of life for most patients with end-stage organ disease, the continued disparity between the supply of allografts from deceased donors and the growing demand for these organs represents the main limiting factor in field of transplantation today. In addition, while the mechanisms and treatments for acute forms of allograft rejection are well understood, our understanding of chronic forms of rejection remains limited, and organs continue to be lost from both immune and nonimmune causes. The remainder of this chapter will review the known mechanisms of allograft rejection, the drugs used to prevent and treat rejection, and current outcomes of organ transplant recipients.

2.2 Mechanisms of Allograft Rejection

Alloimmune reactions resulting in rejection of an allograft remain the major barrier to long-term survival of transplanted organs. Immunologic tolerance can be achieved with relative ease in small animals. However, the human immune system is complex, containing redundant pathways that make tolerance difficult to achieve. Thus, in the current era, allograft rejection remains the major threat to long-term survival of transplanted kidneys and the vast majority of transplant recipients require life-long treatment with immunosuppression drugs. Delineation of mechanisms leading to allograft rejection has been critical to the development of agents capable of preventing or treating rejection.

Mammalian immune responses evolved to protect the host from infectious pathogens and to provide discrimination of

P. Ljungman et al. (eds.), *Transplant Infections*, DOI 10.1007/978-3-319-28797-3_2

self from nonself. An efficient response requires the recognition of pathogens and subsequent activation of key cells and soluble mediators of immunity [15, 16]. Similarly, immune responses resulting in the recognition and destruction of an allograft require cells with an ability to migrate, antigen-presenting cells (APCs), soluble mediators such as cytokines and effector cells that injure the graft.

2.2.1 Allorecognition

The major histocompatibility complex (MHC) is a set of cell surface molecules encoded by genes contained on chromosome 6 [17, 18]. The primary immunologic function of MHC gene products is to present fragments of foreign proteins, forming complexes that can be recognized by T lymphocytes through their antigen-specific receptors. Antigen presentation begins when an MHC complex binds a peptide antigen. MHC molecules are composed of a highly polymorphic polypeptide alpha chain and a monomorphic beta chain, consisting of beta2-microglobulin in the case of class I MHC. Allospecificity of class I MHC molecules, expressed constitutively on all nucleated cells, resides in the alpha chain, a polypeptide with a prominent groove or pocket that is the site where foreign proteins bind for presentation to T cells. Class II MHC molecules are expressed constitutively only on APCs, including macrophages, dendritic cells, and B cells. Adjacent portions of the highly variable alpha chain and a non-variable beta chain form a peptide groove. Highly variable amino acid residues located in the groove determine the specificity of T cell antigen recognition. The same T cell receptor (TCR) can recognize either class I or class II MHC molecules, but restrictions are imposed by the engagement of the T cell surface molecule, CD4, to class II molecules and CD8 to class I molecules. Thus, CD4-positive T cells primarily engage peptides presented by class II MHC, while CD8-positive T cells engage peptides presented by class I MHC (see Figure 2-1a).

Immediately following vascularization of an allograft, donor antigens enter the systemic circulation via APCs and travel to the spleen and lymph nodes where naïve T cells are activated. At the same time, recipient cells enter the allograft. *Direct allorecognition* occurs either in the secondary lymphoid system or in the graft. In the lymphoid system, this occurs when the recipient's naïve lymphocytes are engaged with donor APCs that have traveled to the lymph nodes or spleen. In the graft, direct allorecognition occurs when donor APCs engage with recipient lymphocytes [19]. *Indirect allorecognition* occurs in the secondary lymphatic system when donor proteins or peptides are first processed by recipient APCs and presented to the TCR by the recipient's MHC on the surface of the APC (Figure 2-1b). In the graft, indirect allorecognition occurs when recipient APCs process donor peptides and engage recipient lymphocytes by presenting those processed peptides in the groove of the recipient MHC [19]. The direct pathway of allorecognition plays a dominant role in early T cell-mediated acute rejection episodes while the indirect pathway is believed to be more important in mediating chronic rejection.

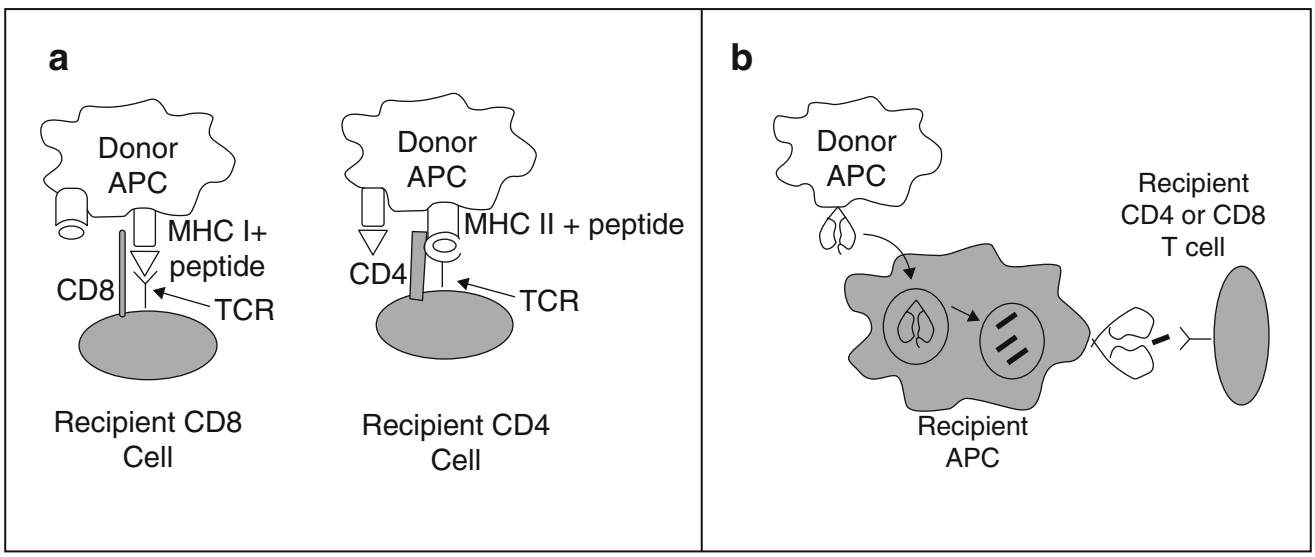

FIGURE 2-1. (**a**) Depiction of *direct allorecognition* in which a donor antigen-presenting cell (APC) presents peptide to the T cell receptor (TCR) within the context of donor major histocompatibility complex (MHC) molecule. *Left side*: presentation of a peptide within a class I MHC molecule to a CD8-positive T cell. *Right side*: presentation of a peptide within a class II MHC molecule to a CD4-positive T cell. (**b**) Depiction of *indirect allorecognition* in which an antigen is first processed by a recipient antigen-presenting cell (APC) and then presented within the context of a recipient major histocompatibility complex (MHC) molecule to either a CD4- or CD8-positive T cell. Hricik, pp. 956–66, Copyright 2015, with permission from Elsevier.

2.2.2 T Cell Activation and Differentiation

The TCR consists of two polypeptide chains, alpha and beta, that are linked to each other. The TCR is linked to another group of cell surface molecules known as CD3, a complex that consists of several covalently bound peptide chains. When the TCR binds to an MHC-presented antigen, there is a conformational change in CD3 that activates intracellular signal pathways, including tyrosine kinases located on the intracytoplasmic tails of the CD3 peptides as well as on the CD4 and CD8 accessory molecules. This antigen-driven signal, transduced by the TCR–CD3 complex to the T cell cytoplasm, has been called "signal one" (see Figure 2-2). It is essential but not sufficient alone for full activation of T cells.

A second antigen-independent signal ("signal 2"), provided through additional accessory molecules resulting in "co-stimulation" of the T cell, is necessary for full activation of the T cell [20] (see Figure 2-2). Although the family of known co-stimulatory ligands is large, the two most important are ligands between the T cell surface molecules, B28 and CD154 (CD40 ligand), and the APC surface molecules B7 and CD40, respectively. Without co-stimulation, the provision of signals through the TCR alone leads to clonal and antigen-specific anergy. The T cell does not produce cytokines and does not divide, but instead becomes unresponsive to appropriate stimulation or undergoes apoptosis.

With adequate co-stimulation, T cell activation continues, and signals are transduced to the nucleus. Phosphorylation of tyrosine residues on several proteins occurs as an immediate consequence of TCR activation. The immediate effect is the appearance of newly phosphorylated tyrosine residues on a number of proteins, leading to the generation of the second messengers such as inositol 1,4,5-triphosphate (IP3) that stimulates the release of ionized calcium from intracellular stores. Released calcium interacts with the calcium-dependent regulatory protein, calmodulin. These calcium–calmodulin complexes activate other kinases and phosphatases. One of these is calcineurin, a phosphatase that plays a key role in the activation of factors required for IL-2 gene transcription.

The transcription of IL-2 and other cytokines ultimately drive cell cycle progression ("signal 3") with help from a series of kinases, including those that act in the target-of-rapamycin (TOR) pathway (see Figure 2-2). The final results of activation are the proliferation of CD4-positive helper T cells and the maturation of CD8-positive cytotoxic T cells. Activated T cells ultimately differentiate into a number of other phenotypes including memory cells that can respond

quickly and robustly to the initially presented antigen many years after the initial presentation, and regulatory T cells that can suppress immune responses and promote tolerance.

2.2.3 Effector Mechanisms

The mammalian immune system can be divided into innate and adaptive components. *Innate immunity* is mediated by several nonpolymorphic proteins (e.g., defensins, cytokines, toll-like receptors, and complement) and cells (e.g., macrophages, dendritic cells, natural killer cells, and neutrophils) that immediately contain and eliminate infectious agents. There has been recent interest in the concept that these innate responses may interact with alloimmune mechanisms, forming a potential link between nonspecific injury (e.g., ischemia reperfusion injury or infections) and allograft rejection.

In contrast, T cells and B cells provide finely tuned specificity mediated by highly polymorphic receptors and antigen-induced clonal expansion. This *adaptive immunity* develops only days to weeks after antigen exposure. The complement system serves as an interface between innate and adaptive immunity [21]. The terminal components of complement are important effectors of graft destruction, leading to membrane injury, neutrophil infiltration, and damage to epithelial and endothelial cells. However, the complement system also is involved in T and B cell stimulation.

The Fas/Fas ligand (FasL) pathway is an important effector mechanism leading to destruction of an allograft. Fas is expressed ubiquitously on parenchymal cells, while FasL is induced upon activation of CD4-positive T cells. Cross-linking of Fas with FasL leads to activation of caspase 8 and propagation of a death signal that culminates in apoptosis.

The activation of caspase enzymes leading to irreversible cell injury with DNA fragmentation can occur independently of cell surface receptors. In addition, CD8-positive T cells express cytotoxic molecules that are lethal to cells. One of these, granzyme B, gains access to the cell by a pore structure created by perforin, another product of the CD8-positive cytotoxic T cell. Entry of granzyme B into the target cell cytoplasm ultimately leads to target cell death through apoptosis. Natural killer cells are effector cells that also produce perforin and granzyme B. In addition, they produce interferon gamma, thus promoting inflammation.

2.2.4 Role of B Cells

With the help of T cells, bone marrow-derived B cells can differentiate into plasma cells that ultimately produce antibodies specific for the original peptide antigen presented to the T cell. Several growth factors required for this differentiation have been identified recently and may ultimately serve as therapeutic targets. Mature B cells are found mainly in lymphoid follicles, in bone marrow, and in low numbers in the circulation. Differentiated plasma cells generate antibodies that can act by fixing complement or by opsonizing cells that are then killed by cell-mediated lympholysis. As noted above, B cells also serve as excellent APCs.

Recently, alloantibodies have been identified as major effectors of both acute and chronic graft injury. Alloantibodies are primarily directed against HLA antigens. However, a number of less common alloantibodies to non-HLA antigens (e.g., endothelial or epithelial antigens) have been identified and occasionally cause graft injury. Preformed antibodies to HLA antigens most commonly occur in patients who have had previous transplants, blood transfusions, or pregnancy. Less commonly, they develop cross-reactively after exposure to vaccines, viruses, or other pathogens. Preformed anti-HLA antibodies are measured by a variety of cross-matching techniques. Mixing recipient serum with the cells or HLA antigens of a specific donor performs a donor-specific cross-match. When the serum of a potential transplant recipient is "cross-matched" with cells from a large panel of potential donors, the test is referred to as a panel of reactive antibodies (PRA). Patients with high PRA (i.e., preformed anti-HLA antibodies against a large number of potential donors) are said to be "sensitized" and generally exhibit graft outcomes that are inferior to non-sensitized patients. In theory, only donor-specific antibodies (DSAs) are responsible for graft injury [22]. Transplantation is usually avoided in patients with pre-existing DSAs. However, very low titers may escape detection by even the most sensitive of cross-matching techniques. Moreover, de novo DSAs develop in as many as 15 % of kidney transplant recipients during the first posttransplant year, increase in frequency with the passage of time, and are now recognized as a major cause of late graft injury and graft loss.

2.3 Types of Allograft Rejection

Allograft rejection can be classified based on clinicopathologic criteria into hyperacute, acute, and chronic forms. However, the pathologic findings obviously vary from one organ to another. This is especially true of chronic rejection which, for example, is manifested in kidney transplant recipients as some combination of interstitial fibrosis, tubular atrophy, and/or transplant glomerulopathy, in heart transplant recipients as coronary vasculopathy, and in lung transplant recipients as bronchiolitis obliterans. Lung transplantation is unique in that chronic rejection can be defined histologically but is most often diagnosed by functional parameters such as changes in forced expiratory velocity (FEV) over time. Hyperacute rejection occurs in recipients with high titers of preformed DSAs and is a rare occurrence in the era of modern, highly sensitive cross-matching techniques.

A complete description of the pathology of acute and chronic rejection in each organ is beyond the scope of this review. Pathologic scoring systems for acute rejection have been best developed in kidney [23, 24], heart [25] transplantation. For kidney transplants, use of the Banff criteria for grading rejection has become the standard of practice [23, 24]. Most centers prefer to obtain a biopsy of the organ to facilitate treatment decisions in patients with suspected rejection, although some centers do not routinely perform pancreas transplant biopsies, mostly due to concerns about bleeding. Acute forms of rejection are usually divided into cellular and humoral types, but there are sometimes components of both cellular and antibody-mediated damage in a single tissue specimen.

Cases of acute cellular rejection that are deemed to be clinically or histologically mild are often treated initially with large "pulse" doses of corticosteroids. Patients who do not respond to pulse steroid therapy and those with clinically or histologically severe rejection are treated with antilymphocyte preparations. Algorithms for treating acute antibody-mediated rejection are less well established and vary widely from center to center. Therapeutic strategies have been best defined in kidney and heart transplantation. Traditional antilymphocyte antibodies are often employed to treat antibody-mediated rejection, based on the concern for simultaneous cellular rejection. However, treatment with plasmapheresis, anti-CD20 antibodies (i.e., rituximab), and/or IVIg is now commonly used as either primary or adjunctive therapy for humoral rejection. Chapter 3 contains a more detailed discussion of drug therapy for treatment of acute rejection.

2.4 Immunosuppressive Therapy

In this section, we will focus on the mechanisms of action of commonly used classes of immunosuppressive agents, based on our understanding of how they inhibit alloimmune responses detailed in the previous section. Chapter 3 includes a more complete discussion of clinical use of these drugs.

2.4.1 Antibodies Used for Induction Therapy

In the USA, available T cell-depleting antibodies include two polyclonal agents generated in either rabbits (rabbit antithymocyte globulin, Thymoglobulin®) or horses (ATGAM®) [26]. Rabbit ATG is currently the most popular polyclonal antibody used in the USA. However, it is technically prescribed off-label for induction therapy, being approved by the Food and Drug Administration (FDA) only for the *treatment* of acute rejection. The exact mechanisms accounting for the effectiveness of rabbit ATG (or ATGAM®) are not entirely understood. These preparations includes antibodies against numerous T cell markers including CD2, CD3, CD4, CD8, CD11a, CD18, CD25, CD44, CD45, HLA-DR, and HLA class I heavy chains. Treatment is generally associated with profound lymphopenia. The agent is effective in suppressing the cellular immune responses against a variety of antigenic stimuli, but may be less reliable in preventing antibody-mediated acute rejection. Alemtuzumab (Campath®) is an anti-CD52 humanized monoclonal antibody that binds to all T and B lymphocytes as well as most macrophages, monocytes, and natural killer cells. It is FDA approved only for the treatment of lymphoma and is used off-label for induction therapy in transplant recipients [27]. The agent causes significant leukopenia, probably via antibody-mediated lysis of lymphocytes, resulting in T cell depletion that lasts much longer than that observed with the polyclonal agents (often detectable for more than 1 year).

The only nondepleting antibody available in the USA currently is basiliximab (Simulect®) [26]. This chimeric monoclonal antibody is directed against the α chain of the interleukin-2 (IL-2) receptor (also known as CD25). Binding to this receptor inhibits the proliferative signals normally mediated by IL-2 (see Figure 2-2) without causing profound depletion of lymphocytes.

2.4.2 Maintenance Immunosuppression

Corticosteroids have multiple effects on alloimmune pathways [28–30]. These agents alter the distribution of lymphocytes, leading to their sequestration in the reticuloendothelial system. They also inhibit the proliferation and function of lymphocytes by blocking the expression of various cytokines. In addition, corticosteroids inhibit transcription factors such as activating protein-1 (AP-1) and nuclear factor-κB. As a consequence, these agents inhibit the production of IL-1 (a primary stimulus for helper T cell activation) and IL-6 (a major inducer of B cell activation), thus inhibiting both the cellular and humoral arms of the alloimmune response.

Calcineurin inhibitors include cyclosporine, a small cyclic polypeptide of fungal origin and tacrolimus, a macrolide antibiotic compound [31, 32]. Multiple formulations and generic version of these drugs are now available. Within the cytoplasm of the lymphocyte, cyclosporine binds to cyclophilin, while tacrolimus binds to FK-binding protein (FKBP). Both the cyclosporine-cyclophilin and tacrolimus-FKBP compounds bind to and inhibit calcineurin, preventing its normal function and thereby blocking T cell activation (see Figure 2-2). Thus the two agents are similarly efficacious in preventing rejection. However, they exert considerably different side effect profiles (see Chap. 3).

Antiproliferative agents include azathioprine and various derivatives of mycophenolic acid (MPA), including the original agent, mycophenolate mofetil, a prodrug that is metabolized to MPA. Azathioprine is a metabolite of 6-mercaptopurine. It is processed into purine analogs that inhibit both the de novo and salvage pathways of purine

synthesis. This inhibits the synthesis of RNA and DNA, thus blocking gene replication and cell proliferation [33]. MPA (derived either from mycophenolate mofetil or available as enteric-coated mycophenolate sodium) is a reversible inhibitor of inosine monophosphate dehydrogenase (IMPDH), a rate-limiting enzyme in the synthesis of purines [34]. Like azathioprine, it works by inhibiting nucleic acid synthesis. However, the effect is relatively selective for lymphocytes because IMPDH plays a preeminent role in the de novo pathway for purine synthesis and lymphocytes do not have an effective salvage pathway that is present in most other rapidly dividing cells.

TOR inhibitors include sirolimus and everolimus [35, 36]. These drugs bind to FKBP in the cytoplasm but have no effects on calcineurin and instead inhibit TOR, an important regulatory kinase that normally mediates cell cycle progression (see Figure 2-2). Inhibition of TOR affects both lymphocytes and mesenchymal cells. The TOR pathway also mediates angiogenic effects so that TOR inhibitors exhibit unique anti-angiogenic properties.

Belatacept is currently the only available *co-stimulation blocker.* The drug is fusion protein that blocks T cell co-stimulation ("signal 2") mediated by the B7-CD28 ligand described above. As described in Chap. 3, the agent was developed largely as a replacement for calcineurin inhibitors [37].

2.5 Current Outcomes in Solid Organ Transplantation

This section will focus on the characteristics, outcomes, and long-term morbidities of solid organ transplant recipients in the United States. Most of the data comes directly from the 2013 Annual Data Report of the Organ Procurement and Transplantation Network (OPTN)/Scientific Registry of Transplant Recipients (SRTR) [38].

2.5.1 Kidney Transplantation [39]

The most common current causes of end-stage renal disease resulting in the need for kidney transplantation are diabetes mellitus (29.3 %), hypertension (21.8 %), and glomerulonephritis (18.3 %). Since 2002, the number of candidates on the deceased donor waiting list almost doubled from approximately 50,000 to 96,000 in 2013. In 2013, 16,901 kidney transplants were performed in the USA (11,448 from deceased donors and 5433 from living donors). By comparison, 15,197 transplants were performed in 2003. Despite this modest overall growth in transplant volume, living donation rates decreased almost 40 % during the same decade. Paired and other unrelated donations have increased since 2007, but not enough to compensate for the general decline in living donation. During the past decade, the number of recipients aged 50 years or older has increased. The use of donors after cardiac death (DCD) increased from approximately 4 % of all deceased donors in 2003 to more than 15 % of deceased donors in 2013.

Table 2-1. Donor characteristics used in calculating the kidney donor profile index (KDPI)

- Age
- Height
- Weight
- Ethnicity
- History of hypertension
- History of diabetes mellitus
- Stroke as the cause of death
- Serum creatinine
- Presence or absence of hepatitis C
- Type of donor: brain dead versus donor after cardiac death

Until recently, allocation of kidneys from deceased donors was prioritized using a point system, with points awarded for several variables including time on the waiting list, prior organ donation, HLA matching, and sensitization based on calculated PRA levels of >80 % [40]. The allocation system was revised in December 2014. In the new system, deceased donors will be scored on a cumulative percentage scale of 0–100 % using a kidney donor profile index (KDPI) based on ten donor characteristics shown in Table 2-1 [41]. The best 20 % of kidneys (KDPI of 0–20 %) are now preferentially allocated to the best 20 % of candidates based on estimated posttransplant survival and thus will virtually always be offered to candidates under the age of 50 years. The influence of KDPI scores on 1- and 2-year allograft survival rates is depicted in Figure 2-3. More priority will be given to sensitized patients in the new system. In addition, for patients who started dialysis before being approved for wait listing, waiting time will start at the time that dialysis was initiated. The impact of these new changes in the allocation system will be scrutinized heavily in the next few years.

During the past decade, death-censored graft survival for both deceased and living donor kidney recipients steadily increased at 1, 5, and 10 years. Death-censored graft survival at 90 days posttransplant is now approximately 97 % for deceased donors and 99 % for living donors. For patients transplanted between 2007 and 2011, the cumulative 24-month incidence of a first acute rejection episode was approximately 14 % for deceased donor recipients and approximately 12 % for living donor recipients.

Trends in the major components of immunosuppression protocols since 2003 have been characterized by a steady increase in the use of T cell-depleting antibodies for induction therapy, use of tacrolimus as the preferred calcineurin inhibitor, and use of mycophenolate derivatives in favor of TOR inhibitors (see Figure 2-4). Approximately 35 % of patients are not taking corticosteroids 1 year after transplantations but the SRTR data suggests that the use of steroid-free regimens has not changed appreciably since 2007.

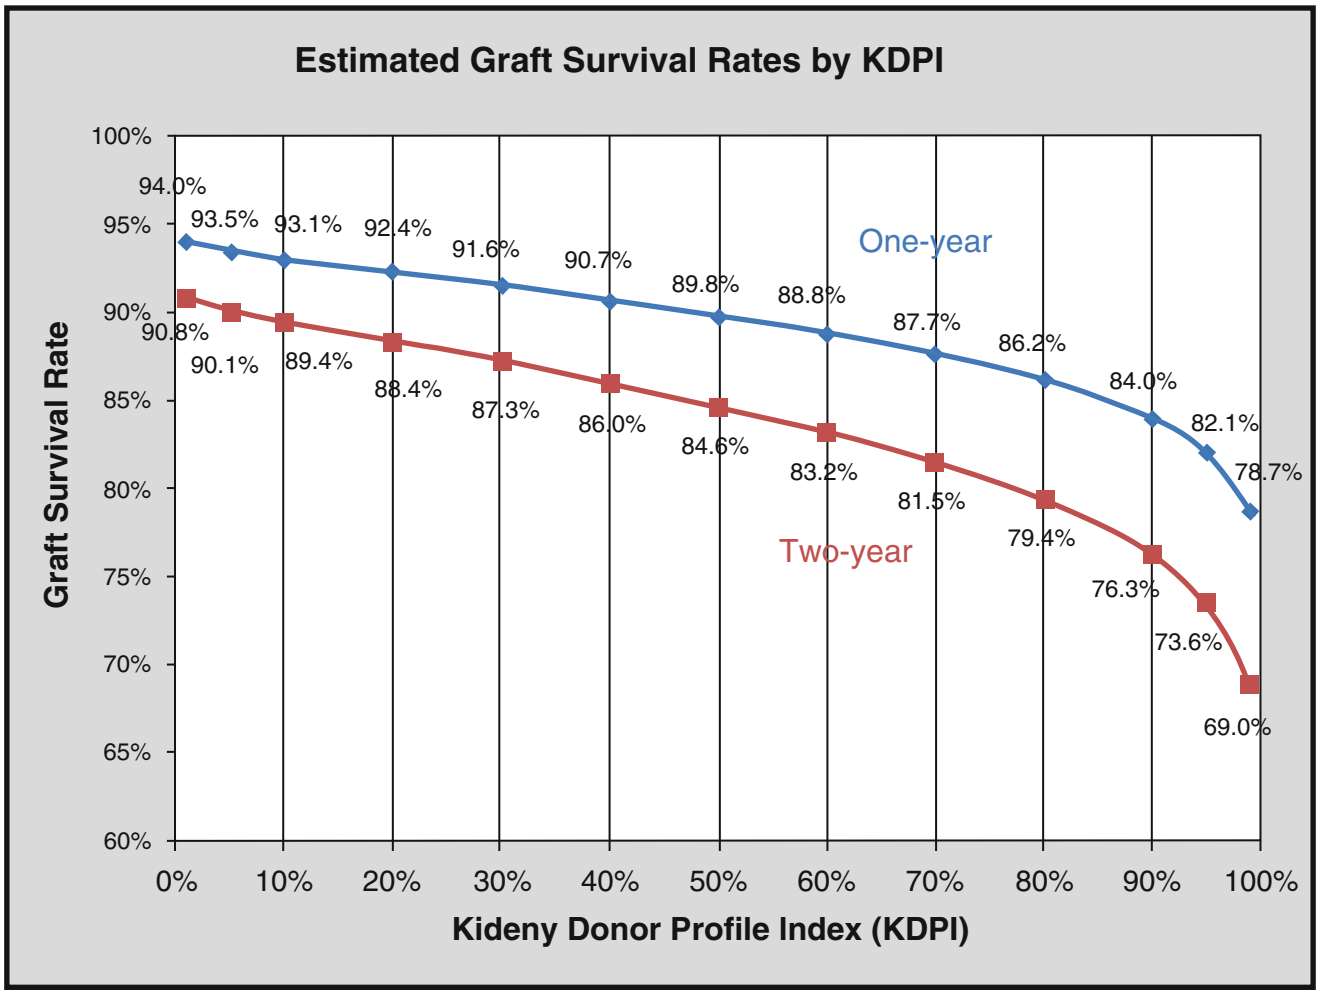

FIGURE 2-3. Influence of kidney donor profile index (KDPI) scores on 1- and 2-year graft survival rates in kidney transplant recipients. Kidney Transplantation Committee, Organ Procurement and Transplantation Network, "Proposal to Substantially Revise The National Kidney Allocation System," http://optn.transplant.hrsa.gov/PublicComment/pubcommentpropsub_311.pdf. Accessed October 30, 2015.

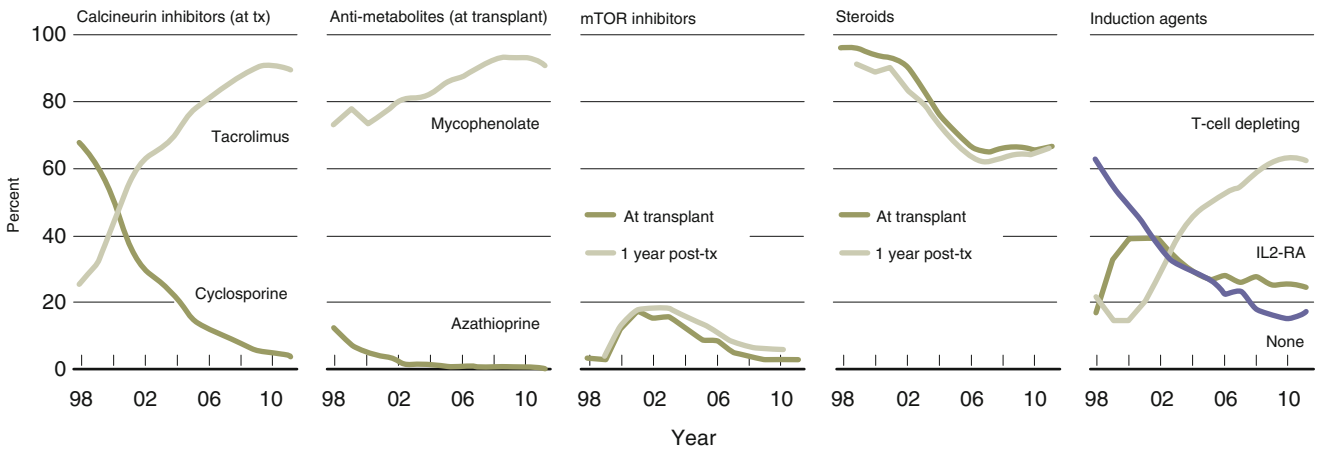

FIGURE 2-4. Trends in the use of immunosuppressant drug classes between 1998 and 2011 at the time of hospital discharge from the transplant operation (*dark lines*) and at 1 year post transplant (*light lines*). United States Renal Data System. 2014 USRDS annual data report: Epidemiology of kidney disease in the United States. National Institutes of Health, National Institute of Diabetes and Digestive and Kidney Diseases, Bethesda, MD, 2014. The data reported here have been supplied by the United States Renal Data System (USRDS). The interpretation and reporting of these data are the responsibility of the author(s) and in no way should be seen as an official policy or interpretation of the US government.

The incidence of new onset diabetes mellitus during the first year after kidney transplant has decreased from approximately 12 % in 2005 to 5 % in 2013. By 5 years posttransplant, 0.6 % of adult transplant recipients have developed posttransplant lymphoproliferative disease. Renal function at 1 year has improved steadily. Currently, almost half of patients with functioning allografts at 6 months have an estimated glomerular filtration rate of 60 mL/min/1.73 m^2 or higher.

2.5.2 Liver Transplantation [42, 43]

Currently, the most common diseases resulting in the need for liver transplantation are hepatitis C (25 %), malignancy (usually hepatocellular carcinoma, 19.4 %), and alcoholic cirrhosis (18.4 %). The recent availability of safe and highly effective antiviral drugs capable of treating and eradicating hepatitis C will likely change this pattern in the future. In 2013, 5921 adult liver transplants were performed in the USA, including 211 from living donors. At the end of that year, just over 15,000 candidates were registered on the waiting list for live transplants. Waitlist mortality and morbidity remain problematic in liver transplantation. In 2013, 1767 patients died while waiting for a transplant and another 1223 were removed from the list being deemed too ill to undergo the procedure. Allocation of livers continues to be driven by use of the model for end-stage liver disease (MELD) scores, using a system that assigns livers to candidates with the most advanced disease [43, 44]. The MELD score is currently based on measurements of serum creatinine, serum bilirubin, and the international normalized ratio (INR) (see Table 2-2).

The proportion of liver transplant patients receiving a simultaneous liver and kidney transplant rose from 6.7 % in 2010 to 8.1 % in 2013. This proportion may decrease over time as a consequence of the Share 35 policy that went into effect in the USA in 2013. That policy requires regional sharing of livers to candidates with MELD scores equal to or greater than 35. In the first several months after instituting the policy median waiting time for such patients fell dramatically from 14 months to 1.4 months [43]. The shorter waiting times may reduce the need for simultaneous kidney transplant by decreasing the frequency of prolonged hepatorenal syndrome.

By mid-2013, 59,500 US liver transplant recipients were alive with functioning grafts. Since 1991, 1-year graft survival has steadily improved from approximately 74 % to approximately 90 % in the most recent cohort. The use of antibodies for induction therapy in liver recipients has increased only slightly in the past decade. More than 70 % of liver transplant recipients receive no induction therapy at all. Tacrolimus and mycophenolate derivatives are the most commonly used maintenance agents. Steroid withdrawal is more common after liver than after kidney transplantation. Only 40 % of liver transplant patients remain on corticosteroids 1 year after transplantation. Recurrence of hepatitis C remains a problem and accounts for graft survival being poorest among the subset of liver transplant recipients with this underlying disease. Again, the recent introduction of newer antiviral agents promises to change these statistics in the next several years.

Table 2-2. Calculation of the model for end-stage liver disease (MELD) score

- MELD score = $0.957 \times \log_e$ (serum creatinine, mg/dL)[a] + $0.378 \times \log_e$ (serum bilirubin, mg/dL) + $1.120 \times \log_e$ (INR) + 0.643
- Multiply score by 10 and round to nearest whole number. Laboratory values <1.0 are set to 1.0

[a]The maximum serum creatinine allowed in the MELD equation is 4.0 mg/dL. For patients on dialysis, the serum creatinine is automatically entered as 4.0 mg/dL

2.5.3 Pancreas Transplantation [45]

Pancreas transplantation is indicated primarily for patients with type I diabetes mellitus, but also for selected type 2 diabetics who are not obese, and who have relatively low insulin requirements. Virtually all pancreas transplants are recovered from deceased donors. Most commonly, pancreas transplantation is performed together with a kidney transplant in diabetic patients with end-stage renal failure (simultaneous pancreas and kidney, SPK) and less commonly is performed alone (pancreas transplant alone, PTA) or after a previous kidney transplant (pancreas after kidney, PAK) [46]. The major indication for a PTA is hypoglycemic unawareness.

The total number of pancreas transplants performed in United States has steadily decreased in the last decade. The reasons for this decline are not clear but possibly reflect relatively high rates of technical failure, surgical complications from the procedure [47], or improved outcomes with medical therapy alone for this special population. Just under 1500 total pancreas transplants were performed in 2002, dropping to just over 1000 transplants in 2013. The decline in volume has been more pronounced for SPK and PAK transplants than for PTA transplants. Historically PTAs were performed less commonly than SPKs or PAKs. Interestingly, in 2013, transplant rates for PAK and PAT were virtually equivalent but only about 100 transplants were performed in each of those categories. The allocation of pancreas transplants has traditionally been subject to regional variances. Current efforts are UNOS are aimed at creating a national pancreas allocation system in which candidates for SPK, PAK, or PTA will combine to form a single match run list [45]. If implemented, this system would assure that SPK candidates will not have to compete against nondiabetic kidney transplant candidates.

Immunosuppressive practice for recipients of pancreas transplants has changed little in the past 5 years. T cell-depleting induction was used in approximately 80 % of all transplants in 2013. For maintenance, tacrolimus was used in

approximately 92 % and mycophenolate in 90 % of recipients. Steroids were used in 65 % initially and in 75 % of recipients at 1 year post transplant.

Due to lack of a uniform definition for pancreas transplant failure (variably defined as re-initiation of insulin, initiation of oral hypoglycemic medications, or undetectable C-peptide), the outcomes of pancreas transplant graft survival are not as standardized as those for kidney graft failure. With this limitation, graft failure rates within the first 3 months posttransplant (often described as technical losses) have decreased steadily over the past decade from 12.4 % in 2002–2003 to 7.6 % in 2012–2013. Rates were lowest among SPK recipients (2.5 % for kidney, 4.9 % for pancreas) and comparable for PTA and PAK (10.4 % and 9.9 %, respectively). Unadjusted actual 1- and 5-year pancreas graft survival for the transplants performed in 2008 were 74.3 and 50.6 % for PTA, 85.8 and 74.3 % for SPK, and 78.7 and 62.0 % for PAK. It has been postulated that better graft survival for SPK compared to PAK and PTA is due to a relatively low incidence of rejection in this group and/or earlier recognition and treatment of rejection. This may reflect the presence of the kidney transplant, which is more amenable for a percutaneous biopsy than a pancreas transplant, and can be used as a surrogate marker for rejection in the pancreas.

The incidence of first acute pancreas rejection at 1 and 2 years was 22.1 and 27.8 % for PTA, 16.0 and 20.4 % for SPK, and 17.4 and 22.5 % for PAK. Overall incidence of posttransplant lymphoproliferative disorder at 5 years was 2.6 % for PTA, 1.0 % for SPK, and 0.9 % for PAK, and the incidence was higher among recipients negative for EBV (6.4 % for PTA and 3.6 % for SPK). The number of patients living with a functioning pancreas transplant has doubled between 2002 and 2013 from approximately 7000 to 14,000.

2.5.4 Heart Transplantation [48]

About 2500 heart transplants were performed in 2013, compared to 2100 in 2002. Cardiomyopathy is the most common indication for heart transplant, followed by coronary artery disease. The number of patients waiting for heart transplant steadily increased from 2800 in 2002 to 3200 in 2013. The waiting time for heart transplant overall has not changed significantly within this time period. In 2003, 14.8 % of candidates spent 5 or more years on the waiting list, compared with only 5.4 % in 2013. Heart transplants are allocated based on a UNOS scoring system (see Table 2-3). The proportion of candidates maintained on ventricular assist devices (VADs) at the time of wait listing increased dramatically, from 7.5 % in 2003 to 27.4 % in 2013. Because of steady improvements in VAD technology, some patients are maintained on these devices for long periods of time, either as a bridge or even as an alternative to transplantation [49].

More than half of heart transplants in the USA are performed without any induction agents, and the remainder are done with either IL-2 blocking- or T cell-depleting antibodies. More than 90 % of the patients are on a combination of tacrolimus, MPA derivatives, and corticosteroids. One-, 3-, and 5-year survival rates in patients who underwent heart transplant between 2006 and 2008 were 88.1 %, 81.3 %, and 75.3 %, respectively. Survival was slightly lower for recipients with prior VADs than for those without VADs. The number of heart transplant survivors continued to increase over time with 27,120 heart transplant recipients being alive with a functioning graft in 2013.

Table 2-3. Heart transplant candidate listing status

UNOS waiting list status (in order of priority)	Patient/management description
1A	(a) Mechanical circulatory support, excepting VADs,[a] but including an artificial heart, extracorporeal membrane oxygenator, or intra-aortic balloon pump
	(b) Mechanical circulatory support within LVAD or RVAD, with complications
	(c) Continuous mechanical ventilation
	(d) Continuous infusion of high-dose intravenous inotropic agent with continuous invasive hemodynamic monitoring
1B	(a) RVAD and/or LVAD, uncomplicated
	(b) Continuous infusion of intravenous inotropic agent
2	Awaiting heart transplant but not meeting 1A or 1B criteria
7	Temporarily unsuitable to undergo transplantation (i.e., HOLD status)

[a]*VAD* ventricular assist device, *L* left, *R* right.

Rejection remains an important cause of morbidity after heart transplant with a current cumulative incidence of acute rejection at 1 year of 23.6 %. Rejection may be recognized more frequently in heart transplantation than in other organ transplants owing to the common practice of performing serial protocol biopsies, especially in the first posttransplant year. Cytomegalovirus (CMV) infection has been strongly linked to cardiac allograft vasculopathy [50]. The leading causes of death during year 1 posttransplant are infection, cardiovascular/cerebrovascular disease, and graft failure. After year 1, however, cardiovascular/cerebrovascular disease becomes the more common cause of death, followed by infection and graft failure.

2.5.5 Lung Transplantation [51]

Lung transplantation is being performed increasingly for critically ill patients with end-stage lung disease. Allocation of lungs is based on the lung allocation score (LAS), a scoring system introduced in 2005 [52]. Pulmonary diagnoses are categorized into to four groups for the calculation of LAS: group A, obstructive lung disease; group B, pulmonary

Table 2-4. Factors used in calculating the lung allocation score (LAS)

• Underlying cause of lung disease
• Age of recipient
• Body mass index
• Presence or absence of diabetes mellitus
• New York Heart Association functional status (I, II, III)
• Forced vital capacity (FEV) (percent predicted)
• Pulmonary arterial systolic pressure
• Supplemental oxygen required at rest (L/min)
• Pulmonary capillary wedge pressure
• Distance walked within 6 min
• Need for mechanical ventilation
• Serum creatinine concentration
• pCO_2

vascular disease; group C, cystic fibrosis and immunodeficiency disorders; and group D, restrictive lung disease. The LAS system was designed to estimate waitlist mortality in a fashion that allows transplantation for compromised patients while avoiding candidates whose likelihood of survival is poor. Clinical variables used to calculate the LAS score are shown in Table 2-4. A raw allocation score is calculated based on these variables and then normalized to obtain the actual LAS, which has a range of 0–100. Higher scores indicate that the patient is more likely to benefit from a lung transplant.

In 2013, 1946 lung transplants were performed, including adult and pediatric recipients, the most ever in a single year. Bilateral lung transplantation remains the preferred procedure, accounting for approximately 70 % of lung transplants performed in 2013. In 2013, 28.7 % of all US lung recipients were aged 65 years or older, compared with 7.2 % in 2003.

Short-term survival (30-day and 1-year) and long-term survival (3-year and 5-year) have plateaued since implementation of the LAS. Overall, 5-year unadjusted patient survival was 53.6 %. Survival was consistently lowest among recipients aged 65 years or older, those with LAS greater than 60, and those in diagnosis group B. Fifty percent of lung transplants currently are performed without any induction antibody therapy. Tacrolimus and mycophenolate derivatives are the preferred agents for maintenance immunosuppression and are being used in more than 90 % of lung recipients. Almost all patients are on steroids at 1 year post transplant. About 20 % and 40 % of the patients experience first acute rejection by 12 and 24 months post transplant, respectively. About 2 % of patients develop PTLD by 5 years of posttransplant with incidence up to 6 % for patients who are serologically negative for EBV at the time of transplantation.

2.5.6 Intestinal Transplantation [53]

Improvement in the medical and surgical treatment of patients with intestinal failure has resulted in a recent decrease in the number of intestinal transplantations being performed in the USA. Short-gut syndrome remains to be the most common indication. More than half the transplants are actually combined intestine-liver transplants. The number of intestine transplants decreased from 91 in 2009 to 51 in 2013. The number of intestine-liver transplants steadily decreased from a peak of 135 in 2007 to a low of 44 in 2012, but increased slightly to 58 in 2013.

Graft survival for intestine transplants has improved over the past decade. Graft failure in the first 90 days posttransplant occurred in 14.1 % of intestine recipients and in 11.2 % of intestine-liver recipients in 2013. The graft failure rate was 24.5 % at 1 year for transplants performed between 2011 and 2012, 43.6 % at 3 years for transplants performed between 2009 and 2010, 48.5 % at 5 years for those performed between 2007 and 2008, and 68.4 % at 10 years for transplants performed between 2001 and 2002.

For induction therapy in 2013, 54 % of intestine transplant recipients received T cell-depleting agents, 11 % received IL-2 receptor antagonists, and 38 % received no induction. The initial immunosuppression agents used most commonly in 2013 were tacrolimus (95.0 %), steroids (73.0 %), mycophenolate (35.0 %), and mammalian TOR inhibitors (15.0 %). Steroids were used in 70.0 % of recipients at 1 year posttransplant. Acute rejection occurred in 35–40 % of patients at 12 months and in approximately 50 % at 24 months.

For patients who underwent intestine transplantation between 2001 and 2011, 9.9 % of intestine recipients and 6.8 % of intestine-liver recipients developed PTLD within 5 years posttransplant. The incidence was highest among recipients who were negative for EBV: 12.5 % of EBV-negative intestine recipients and 8.2 of EBV-negative intestine-liver recipients.

2.6 The Future of Solid Organ Transplantation: Strategies for Achieving Tolerance

A long-standing goal in the field of solid organ transplantation is to induce immunologic tolerance to the graft such that the host's immune system can respond normally to immune stimuli without immunosuppression and with the specific absence of a detrimental immune response directed at the transplanted organ. Studies in animal models suggest that tolerance to an allograft can be achieved under a variety of conditions including elimination of the donor-reactive immune cells (deletion), induction of immunologic ignorance (the immune system fails to recognize transplant antigens), induction of anergy, or active inhibition by regulatory T cells [54]. True immunologic tolerance has been achieved in human kidney transplant recipients when a bone marrow transplant has been performed between HLA identical donors, followed by a kidney transplant using the same

donor. Based on these experiments of nature several groups have attempted to use bone marrow ablation, either marrow or stem cell transplantation, and adjunctive combinations of early immunosuppression in an effort to achieve at least "operational" tolerance [55–57].

Tregs suppress immune responses, potentially via local cytokine production and through prevention of dendritic cell activation. The recent recognition of multiple Treg phenotypes, including those that are CD25+ CD4+ Foxp3+, as well as newly developed methods for inducing Treg expansion in vitro and in vivo, has excited the transplant community [58, 59]. While only limited success has thus far been achieved toward developing human allograft tolerance in humans, multiple groups are studying whether and how Tregs can be exploited to prolong graft survival and potentially induce robust allograft tolerance.

2.7 Summary

The field of solid organ transplantation has advanced considerably in the past half century, based largely on improved understanding of the mechanisms of allograft rejection and the parallel development of effective immunosuppressive drugs. Currently available immunosuppressive drugs are not completely effective in preventing or treating allograft rejection. Moreover, long-term treatment with these agents is associated with toxicities including infection and malignancy—topics that will be covered in detail elsewhere in this book. Thus, organ transplantation remains an imperfect modality. Effective strategies for creating true immune tolerance might allow organ transplantation without the use of immunosuppressive drugs. However, a breakthrough of that kind would only partially offset the most important limitation in the field: a continued shortage of organ donors.

3 Immunosuppressive Agents

Karen L. Hardinger, Irfan A. Agha, and Daniel C. Brennan

3.1 Introduction

Over the last half century, the field of kidney transplant has experienced a significant change. From better insights into immunology, immunodiagnostics, and immunotherapeutics to refinements in the surgical processes, the course and expected outcomes for these patients have improved dramatically. The philosophy of therapeutic immunosuppression and the tools available to deliver it are steadily improving as well.

The basic profile of current immunosuppression strategy has remained fundamentally unchanged—two distinct phases can be teased out. "Induction" is the initial phase of heavy immunosuppression to avoid early acute rejection and allow for maintenance immunosuppression to become effective. The subsequent "maintenance" phase attempts at keeping the patient optimally immunosuppressed but at the same time limiting the fallout (infections, metabolic complications, malignancies, etc.) of the immunocompromised state. These two phases are periodically punctuated by a third "rescue" phase that is deployed should the patient suffer a rejection episode.

The alloimmune response is complicated and multipronged with several loops of redundancy. Over the years, many different drugs have been used in combination targeting various steps and pieces of the immune response. This sequentially arrests the immune response and has the added advantage of using lower doses of each individual drug allowing for an agreeable decrease in individual toxicities. This has led to the paradigm of combination drug regimens for the management of the kidney transplant recipient.

Despite significant gains in this respect, many problems remain. There are few reliable methods of measuring alloreactivity directly in widespread clinical use. This constrains transplant physicians to depend solely on indirect data (like blood counts and drug levels) and monitoring toxicities of the individual drugs being administered. Over-immunosuppression of a particular patient, drug-related toxicities, and side effects as well as opportunistic infections remain a daily hazard to the well-being of the transplant recipient. Indeed, increased cardiovascular mortality is one of the biggest challenges in managing the transplant patient.

3.2 Structure of Immunosuppressive Regimens

As noted, the immune response is complex and multipronged, replete with redundant loops. The purpose of immunosuppressive therapy remains avoidance of alloreactive responses and rejection of the allograft. Use of one agent alone may not protect against this alloreactivity due to the nature of the immune response or may be attended with unacceptable toxicity.

Combining drugs has been an effective strategy at targeting these complex processes at multiple points, creating synergy to achieve therapeutic effectiveness. A desired consequence is the ability to reduce exposure to each constituent drug in the regimen, decreasing individual drug toxicity as well as perhaps the overall degree of immunosuppression.

In the early days of transplantation, steroids and antiproliferative agents (azathioprine) formed the backbone of transplant immunosuppression regimens (Table 3-1). Introduction of calcineurin inhibitors (cyclosporine) revolutionized transplantation. The rates of acute rejection fell dramatically and the era of standard triple immunosuppression was ushered in—a calcineurin inhibitor anchor (cyclosporine and later tacrolimus), an adjuvant antimetabolite antiproliferative agent (azathioprine and later mycophenolic acid preparations), and steroids. This structure remains the most commonly used strategy for therapeutic immunosuppression today [1].

Identifying the critical nature of the first few months after transplantation from a rejection point of view, many centers add a layer of induction to the standard maintenance immunosuppression, especially to those thought to

P. Ljungman et al. (eds.), *Transplant Infections*, DOI 10.1007/978-3-319-28797-3_3

Table 3-1. Classification of immunosuppressive agents

Classification	Drug (generic)	Drug (trade)	Generic	Dosage form
IL-2 receptor blockers	Basiliximab	Simulect®	No	Injection
Anti-T-cell therapy	Antithymocyte globulin—horse	Atgam®	No	Injection
	Antithymocyte globulin—rabbit	Thymoglobulin®	No	Injection
CD52 antibody	Alemtuzumab	Campath®	No	Injection
Corticosteroids	Methylprednisolone	Solu-Medrol®	Yes	Injection, oral
	Prednisone	Deltasone®	Yes	Oral
Calcineurin inhibitors	Cyclosporine nonmodified, CsA	Sandimmune®	Yes	Injection, oral
	Cyclosporine modified, microemulsion	Neoral®	Yes	Injection, oral
	Tacrolimus, FK	Prograf®	Yes	Oral
	Extended-release tacrolimus	Astagraf®	No	Oral
MTOR inhibitors	Sirolimus, rapamycin	Rapamune®	No	Oral
	Everolimus	Zortress®	No	Oral
Antiproliferative	Azathioprine, AZA	Imuran®	Yes	Injection, oral
	Mycophenolate mofetil, MMF	Cellcept®	Yes	Injection, oral
	Mycophenolate sodium, EC-MPS	Myfortic®	Yes	Oral
Co-stimulation blockade	Belatacept	Nulojix®	No	Injection

be at high immunological risk. This is referred to as "quadruple immunosuppression." Polyclonal antibodies such as antithymocyte globulins or monoclonal antibodies, such as basiliximab and alemtuzumab, may be given as induction immunosuppression.

By effectively using these medicines, the rates of acute rejection have steadily dropped over the decades. Having achieved this goal, transplant physicians are now trying to refine these strategies to reduce the morbidity of these drugs as well as that of the immunosuppressed state. Calcineurin inhibitors have reduced acute rejection rates and have improved short-term allograft survival, but clear evidence of benefit on long-term allograft survival is not yet conclusive. These agents themselves have nephrotoxic potential and expose the recipient to harmful metabolic complications like diabetes, hypertension, and dyslipidemias, contributing to high cardiovascular morbidity and mortality. Thus, the search for alternate substitute agents led to mTOR inhibitors as well as co-stimulation blocking agents like belatacept. Calcineurin-free immunosuppression is the subject of intense current research but is not a dominant clinical trend yet.

Similarly, buoyed by the effectiveness of other agents available, many centers remove the steroid part of the standard triple immunosuppression protocols. Steroids are either completely eliminated (steroid-free regimens) or are withdrawn after a discreet but early interval posttransplant (avoidance). Monotherapy for maintenance immunosuppression is being studied but is rarely used outside of clinical trial protocols [2, 3]. Intuitively, this strategy would be reserved for patients with transplanted organs that are perceived to have less immunogenic potential and considered to be at less immunological risk.

With the many choices of drugs available, their side effect profiles (Table 3-2) as well as the ever-expanding complexity of immune risks, a one-size-fits-all strategy for therapeutic immunosuppression is no longer adequate or appropriate. Though "center protocols" still exist and with good reason, the emphasis now must be on immunosuppression individualization. A plan for each patient must be created prior to transplantation based on immunological risk and patient profile and then constantly adjusted based on the posttransplant course (Table 3-3).

3.3 Induction Immunosuppression

The first few months after transplantation are a time of heightened risk for alloimmune events. Passenger donor antigen-presenting cells cause acute rejection via the direct antigen presentation pathway. This is also the time when the recipient immune system is surveying the allograft antigens for the first time. The risk of acute rejection recedes after the first few months perhaps as the passenger antigen-presenting cells are eliminated.

To counter this early risk of rejection, a strategy to aggressively target T-cell signaling to control T-cell-mediated alloimmune responses in the early posttransplant period has become popular. Termed induction immunosuppression, this represents a period of intense immunosuppression afforded right before and immediately after kidney transplantation. Induction immunosuppression not only reduces acute rejection, but many other corollary benefits are derived as well, such as minimizing the doses necessary for other immunosuppressive agents.

Induction immunosuppression is afforded by deploying antibody-based therapy and is used in addition to usual antirejection medicines. Over the decades, use of induction immunosuppression has increased from less than 30 % of transplants in the 1980s to over 80 % in 2010 [1]. Many different types and preparations of these antibodies are available.

TABLE 3-2. Immunosuppressive medication doses and side effects

Drug	Dose	Side effects
Induction		
Basiliximab	20 mg IV × 2 doses	Hypersensitivity reactions
Antithymocyte globulin		
Rabbit	1.5 mg/kg IV × 3–7 days	Rash, fever, thrombocytopenia, leukopenia
Horse	15 mg/kg IV × 3–7 days	Rash, fever, thrombocytopenia, leukopenia
Alemtuzumab	30 mg IV × 1 dose[a]	Fever, chills, lymphopenia, neutropenia, anemia, thrombocytopenia, infection
Maintenance		
Prednisone	Maintenance: 2.5–10 mg/day Rejection: 250–1000 mg/day × 3 days IV	Mood disturbances, psychosis, cataracts, hypertension, fluid retention, peptic ulcers, osteoporosis, muscle weakness, impaired wound healing, glucose intolerance, weight gain
Cyclosporine	4–5 mg/kg po twice daily	Neurotoxicity, gingival hyperplasia, hirsutism, hypertension, hyperlipidemia, glucose intolerance, nephrotoxicity, electrolyte disturbances
Tacrolimus	0.05–0.075 mg/kg po twice daily	Neurotoxicity, alopecia, hypertension, hyperlipidemia, glucose intolerance, nephrotoxicity, electrolyte disturbances
Extended-release tacrolimus	0.1 mg/kg po twice daily	Neurotoxicity, alopecia, hypertension, hyperlipidemia, glucose intolerance, nephrotoxicity, electrolyte disturbances
Sirolimus	2–10 mg/day po daily	Hypertriglyceridemia, anemia, thrombocytopenia, mouth sores, hypercholesterolemia, gastrointestinal disturbances, bone marrow suppression, poor wound healing, edema
Everolimus	0.75 mg po twice daily	Hypertriglyceridemia, anemia, thrombocytopenia, mouth sores, hypercholesterolemia, gastrointestinal disturbances, bone marrow suppression, poor wound healing, edema
Azathioprine	1–2.5 mg/kg/day po daily	Leukopenia, thrombocytopenia, gastrointestinal disturbances, pancreatitis, hepatotoxicity
Mycophenolate mofetil	500–1500 mg po twice daily	Leukopenia, thrombocytopenia, gastrointestinal disturbances
Mycophenolate sodium	360–1080 mg po twice daily	Leukopenia, thrombocytopenia, gastrointestinal disturbances
Belatacept	10 mg/kg administered, prior to implantation, on day 5, and at the end of weeks 2, 4, 8, and 12, then 5 mg/kg every 4 weeks (plus or minus 3 days)	Edema, hypertension, diarrhea, anemia, infection, cough
Rejection		
Methylprednisolone	Rejection: 250–1000 mg/day × 3 day IV	Mood disturbances, psychosis, cataracts, hypertension, fluid retention, peptic ulcers, osteoporosis, muscle weakness, impaired wound healing, glucose intolerance, weight gain
Antithymocyte globulin		
Rabbit	1.5 mg/kg IV × 7–14 days	Rash, fever, thrombocytopenia, leukopenia
Horse	15 mg/kg IV × 7–14 days	Rash, fever, thrombocytopenia, leukopenia
Rituximab	375 mg/m^2 IV dosed to response[a]	Fever, fatigue, lymphopenia, anemia, infusion-related reactions, infection
Eculizumab	600 mg IV weekly for 6 doses[a]	Hypertension, headache, anemia, infection
Bortezumib	1.3 mg/m^2 IV days 1, 4, 8, and 12[a]	Fatigue, fever, diarrhea, nausea, gastrointestinal side effects, thrombocytopenia, neutropenia, peripheral neuropathy

PO by mouth, *IV* intravenously.
[a]Not indicated for transplantation.

3.3.1 Nondepleting Antibodies

Basiliximab is an interleukin (IL)-2 receptor antagonist and is the only Food and Drug Administration (FDA)-approved induction agent in renal transplantation. It demonstrated statistically significant reduction in the incidence of acute rejection in three landmark clinical trials, two of which used a maintenance regimen of cyclosporine and corticosteroids without an antimetabolite [4–6]. Using a more contemporary regimen, a trial comparing basiliximab to placebo (using cyclosporine, corticosteroids, and mycophenolate mofetil for maintenance) demonstrated a trend toward reduced incidence of acute rejection in the treatment group (15.3 % vs. 26.6 %), although it did not reach statistical significance [7]. None of these trials demonstrated a significant difference in patient or allograft survival. It is dosed at 20 mg intravenously intraoperatively and 4 days after transplantation. It has few adverse reactions or drug interactions.

Table 3-3. Tailoring immunosuppressive regimens on adverse events

Condition	Immunosuppressive cause	Immunosuppressive change
New-onset diabetes after transplantation	Corticosteroid, tacrolimus, cyclosporine, mTORS	Avoidance, dose reduction
Dyslipidemia	Corticosteroids, cyclosporine Sirolimus, everolimus	Avoidance, dose reduction, tacrolimus
Hypertension	Corticosteroid, cyclosporine, tacrolimus, mTORS	Avoidance, dose reduction
Osteoporosis	Corticosteroids	Avoidance, dose reduction
Bone marrow suppression	Mycophenolic acid, azathioprine, sirolimus, everolimus, tacrolimus	Dose reduction
Delayed wound healing	Sirolimus, everolimus	Avoidance
Gastrointestinal side effects	Mycophenolate mofetil, tacrolimus, sirolimus	Enteric-coated mycophenolic sodium, dose reduction, azathioprine
Proteinuria	Sirolimus, everolimus	Avoidance
Nephrotoxicity	Cyclosporine, tacrolimus, sirolimus	Avoidance, dose reduction, belatacept

3.3.2 Depleting Antibodies

The use of depleting antibodies causes a profound depletion of lymphocytes and leads to a significant reduction in acute rejection. Two depleting antibody preparations are currently available in the USA—the polyclonal antithymocyte globulin(r-ATG, Thymoglobulin® and horse-ATG, ATGAM®) and the monoclonal humanized alemtuzumab. Polyclonal antibodies have specificities for various lymphocyte surface antigens and cause a prolonged and durable depletion in lymphocytes. It may take several months for these lymphocytes to repopulate.

The optimal dose for r-ATG is unclear. Most centers use 1.5 mg/kg intravenously for 3–5 days [8–16]. However, lower doses of r-ATG (0.5, 1, and 2 mg/kg for 3 days after transplantation) have been associated with dose-dependent lymphocyte depletion (in intensity and duration) and prevention of acute rejection [17]. Conversely, nonhuman primate data suggests a more significant impact on T-cell depletion in lymph nodes (but not thymus) with higher doses [18]. Higher induction doses of 6–9 mg/kg have been used intraoperatively with subsequent sparing of maintenance immunosuppression with success [19, 20]. Rabbit antithymocyte globulin can be associated with an infusion cytokine release syndrome and premedication is suggested. Careful monitoring of blood counts is essential. Leukopenia and thrombocytopenia are commonly seen and may mandate dosage changes or interruption.

Alemtuzumab is a humanized monoclonal antibody targeting CD52 present on T lymphocytes, B lymphocytes, and monocytes. It causes profound and sustained lymphocyte depletion. Originally developed as one of the agents for conditioning in bone marrow transplantation, it was later utilized as treatment for chronic lymphocytic leukemia. In kidney transplantation, it was introduced as an agent to treat rejection in 1995 [21]. It was later tried as an induction agent followed by minimal immunosuppression in the hopes of setting up near tolerance. This strategy revealed significant rejection when alemtuzumab was used as monotherapy or with minimal maintenance immunosuppression with a single agent [22]. It became apparent that despite profound lymphocyte depletion, alemtuzumab was not effective against memory T cells in sanctuary sites [23]. It has since found increasing use in conjunction with follow-up triple immunosuppression or double therapy (minimizing or avoiding steroids). Most commonly, it is used as a single dose of 30 mg intraoperatively. It can be dosed subcutaneously, but this route is not FDA approved. A minority of centers prefer two doses, while others still use a weight-based regimen. Alemtuzumab may also be associated with an infusion syndrome and prophylaxis is recommended.

Considerable knowledge may be gained from induction trials. Rabbit antithymocyte globulin and basiliximab were compared in two multicenter induction trials in combination with cyclosporine, mycophenolate mofetil, and corticosteroids. The first trial included low-immunological-risk patients and revealed similar incidence of acute rejection with similar patient and allograft survival at 12 months post-transplantation [24]. The second trial included moderate- to high-risk patients and demonstrated an improved combined endpoint for the incidence of rejection, allograft loss, and patient death in the r-ATG arm [25, 26]. Most of the benefit in combined endpoints was attributed to the decreased incidence of acute rejection. Alemtuzumab has also shown promise in lowering acute rejection rates in low-risk patients when compared to basiliximab [27]. Among high-risk patients, alemtuzumab and r-ATG had similar efficacy. In another randomized trial, patients treated with alemtuzumab without corticosteroids and mycophenolate/tacrolimus suffered less rejection but more polyoma infections than patients treated with basiliximab, corticosteroids, and mycophenolate/tacrolimus [28]. However, in both of these trials, the reduction in acute rejection episodes did not translate to improved allograft survival or improved renal function. A recent meta-analysis supports the results concluding that alemtuzumab induction reduces the risk of rejection compared with basiliximab but not r-ATG and recommends picking induction agents based on safety and cost [29].

3.4 Summary

There is significant disagreement on the preferred induction agent and many centers adhere to their own preferences and practice. However, based on available data, some general principles may be teased out. The choice of induction immunosuppression eventually must be weighed against two major factors: the assessed immunological risk and philosophy of maintenance immunosuppression. According to the KDIGO Clinical Practice Guidelines, basiliximab may be preferred in low-risk patients, and a depleting antibody (r-ATG or alemtuzumab) may be preferred in high-risk transplant patients [30] (Table 3-4). Similarly, regimens using immunosuppression-minimizing strategies or steroid avoidance may need induction with a depleting agent. Elderly patients, those with HCV infection, and patients with other risk factors (e.g., a history of malignancy) may be considered for nondepleting antibody induction to mitigate infection or cancer risk. This remains a complicated clinical decision and must be individualized and given careful consideration.

3.5 Maintenance Immunosuppression

After a few weeks in the recipient environment, the passenger antigen-presenting cells are slowly eliminated, and the mechanism of alloimmunity switches to the more traditional indirect antigen presentation. Acute rejection may still occur but is not as common except as a consequence of noncompliance. The main concern at this stage is the development of chronic alloimmune rejection, a largely antibody-mediated rejection process. At this stage, the immune system needs to be under constant check. The emphasis remains on controlling CD4+ T-cell responses as well as immune cell recruitment and proliferation. As this is a long-term process, this has to be done suavely to avoid drug toxicity, opportunistic infection, and cancer.

TABLE 3-4. Summary of renal transplant clinical practice guidelines

Induction therapy
1. We recommend starting a combination of immunosuppressive medications before, or at the time of, kidney transplantation (1A)
2. We recommend including induction therapy with a biologic agent as part of the initial immunosuppressive regimen in KTRs (1A)
3. We recommend that an IL2-RA be the first-line induction therapy (1B)
4. We suggest using a lymphocyte-depleting agent, rather than an IL2-RA, for KTRs at high immunological risk (2B)
Initial maintenance immunosuppressive medications
1. We recommend using a combination of immunosuppressive medications as maintenance therapy including a CNI and an antiproliferative agent, with or without corticosteroids (1B)
2. We suggest that tacrolimus be the first-line CNI used (2A)
3. We suggest that tacrolimus or CsA be started before or at the time of transplantation, rather than delayed until the onset of allograft function (2D tacrolimus; 2B CsA)
4. We suggest that mycophenolate be the first-line antiproliferative agent (2B)
5. We suggest that, in patients who are at low immunological risk and who receive induction therapy, corticosteroids could be discontinued during the first week after transplantation (2B)
6. We recommend that if mTORi are used, they should not be started until allograft function is established and surgical wounds are healed (1B)
Long-term maintenance immunosuppressive medications
1. We suggest using the lowest planned doses of maintenance immunosuppressive medications by 2–4 months after transplantation, if there has been no acute rejection (2C)
2. We suggest that CNIs be continued rather than withdrawn (2B)
3. If prednisone is being used beyond the first week after transplantation, we suggest prednisone be continued rather than withdrawn (2C)
Treatment of acute rejection
1. We recommend corticosteroids for the initial treatment of acute cellular rejection (1D)
2. We suggest adding or restoring maintenance prednisone in patients not on steroids who have a rejection episode (2D)
3. We suggest using lymphocyte-depleting antibodies for acute cellular rejections that do not respond to corticosteroids and for recurrent acute cellular rejections (2C)
4. We suggest treating antibody-mediated acute rejection with one or more of the following alternatives, with or without corticosteroids (2C): plasma exchange, intravenous immunoglobulin, anti-CD20 antibody, lymphocyte-depleting antibody
5. For patients who have a rejection episode, we suggest adding mycophenolate if the patient is not receiving mycophenolate or azathioprine or switching azathioprine to mycophenolate (2D)

IL2-RA interleukin 2 receptor antagonist, *KTRs* kidney transplant recipients, *CNI* calcineurin inhibitor, *CsA* cyclosporine A, *mTORi* mammalian target of rapamycin inhibitor(s).

Adapted from KDIGO clinical practice guideline for the care of kidney transplant recipients. Am J Transplant. 2009 Nov;9 Suppl 3:S1–155.

As noted above, most centers choose to use a calcineurin inhibitor anchor (either tacrolimus or cyclosporine) along with an adjuvant agent (azathioprine or a mycophenolic acid preparation) with or without steroids. Other agents in use are mTOR inhibitors and co-stimulation blocking agents (belatacept).

3.5.1 Calcineurin Inhibitors

Calcineurin inhibitors are the first act in the modern transplantation miracle. They directly target the lymphocytes nonlethally by restricting the ability of CD4 T cells to produce IL-2, the vaunted signal three of T-cell activation limiting immune cell proliferation in response to activation of CD4 cells. This revolutionized kidney and other organ transplantation. Acute rejection rates plummeted markedly improving short-term patient and allograft survival.

Cyclosporine was the first agent in this class to be approved by the FDA in 1983. The earliest formulation of cyclosporine, cyclosporine nonmodified, is as an aquaphobic, softgel capsule. Subsequently, a microemulsion form (cyclosporine modified) was introduced. In the late 1980s, the second agent tacrolimus surfaced. It was approved by the FDA in 1994 for use in liver transplantation and has been used in all forms of transplantation since. A prolonged-release form of tacrolimus has now been introduced into clinical practice.

Early studies that compared microemulsion cyclosporine (modified) to tacrolimus using the combination of calcineurin inhibitors, azathioprine, and corticosteroids demonstrated a significant decrease in acute rejection with tacrolimus, while there was no difference in patient or allograft survival posttransplantation [31, 32]. A more recent study randomized first deceased donor recipients to one of three immunosuppressive regimens (all included corticosteroids): (1) tacrolimus with azathioprine, (2) tacrolimus with mycophenolate mofetil, and (3) microemulsion cyclosporine and mycophenolate mofetil [33]. Acute rejection rates were similar in each group, but the incidence of corticosteroid resistant rejection was lower in the tacrolimus arms. At 3 years overall renal function, patient survival, and allograft survival remained the same, but in the tacrolimus arms, improved allograft survival was seen in recipients with delayed allograft function [33]. In agreement with this data, a meta-analysis reported that for every 100 patients treated with tacrolimus rather than cyclosporine for the first year, 12 would be prevented from having acute rejection, two would be prevented from having allograft failure, but five would develop new-onset diabetes after transplantation [34]. Furthermore, the Elite-Symphony trial demonstrated that a low-dose cyclosporine regimen was not as effective as a low-dose tacrolimus regimen [35]. As a result of these trials, the KDIGO Clinical Practice Guidelines suggest that tacrolimus should be the first-line calcineurin inhibitor for renal transplant recipients [30]. Clinical trends have followed the science. Over the past two decades, tacrolimus has become overwhelmingly the more popular calcineurin inhibitor in use for kidney transplant patients

Both calcineurin inhibitors can be given intravenously or orally. They have a narrow therapeutic index and need to be monitored closely. For both cyclosporine and tacrolimus, 12-h trough levels are commonly followed. Target 12-h trough levels of 100–250 ng/mL for cyclosporine and 5–15 ng/mL for tacrolimus are typical soon after transplantation. Subsequently levels are reduced. Two-hour peak levels (C2 levels) are followed by some centers for cyclosporine but not for tacrolimus. The reference levels for these drugs given are generalizations and vary significantly between patients based on the anticipated immune risk, structure of the immunosuppression regimen (especially induction), and recipient factors like age, infection threat, and history or risk of malignancy. Calcineurin inhibitors are metabolized via the CYP3A4 pathway, predisposing them to many potentially serious drug interactions.

Despite careful therapeutic drug monitoring, many side effects may be encountered. Hirsutism, gingival hypertrophy, hypertension, and hyperlipidemia are more commonly seen with cyclosporine, whereas neurotoxicity, alopecia, and posttransplant diabetes are more commonly associated with tacrolimus.

Adherence is essential to prevent poor outcomes after transplantation. For this reason, a prolonged-release tacrolimus formulation was developed. Two pivotal trials that compared prolonged-release tacrolimus to immediate-release tacrolimus have shown comparable efficacy and safety [36, 37]. Various studies have suggested that the tacrolimus levels are slightly lower (10–20 %) with prolonged-release tacrolimus group compared to twice daily tacrolimus patients [38, 39]. There may be an increased risk of acute rejection with prolonged-release tacrolimus [36, 37] and close monitoring is warranted. A new formulation of prolonged-release tacrolimus, LCP-tacro, may become commercially available in 2016.

3.5.2 Corticosteroids

Corticosteroids were one of the earliest immunosuppressive medicines to be widely used. Almost simultaneously, the adverse effects of this use became apparent. Steroids have been implicated in increased rates of new-onset diabetes after transplantation, hypertension, and dyslipidemia. This in turn is thought to contribute to the very high cardio- and cerebrovascular mortality and morbidity in kidney transplant patients. Additionally, steroid use is thought to contribute to osteopenia and metabolic bone disease seen in these patients.

Despite this negative side effect profile, corticosteroids have proven themselves to be effective immunosuppressive agents. This is due to the myriad and multilevel effects they exert on the immune response, unlike most other agents that

target one specific pathway. Steroids, on internalization, bind to receptors and affect transcription of various genes, collectively referred to as the glucocorticoid responsive element (GRE). This genomic trans-suppression is responsible for most of the salutary anti-inflammatory effects of steroids [40]. Additional non-genomic mechanisms also contribute to reduced T-cell activation [41]. This leads to proliferation restriction and signaling changes that affect both T cells and B cells. Additionally, they impact lymphocyte trafficking by sequestering CD4 cells in the lymphatic organs.

This multilevel and multifaceted impact of steroids on the immune response made early efforts to limit or replace them tricky. In the first double-blinded, randomized, placebo-controlled, multicenter, 5-year trial comparing early steroid discontinuation (7 days posttransplant) with steroid maintenance therapy, the rate of biopsy-proven acute rejection and chronic allograft nephropathy was twice as high in the rapid corticosteroid discontinuation arm [42]. In early studies, salutary metabolic effects were deemed marginal, but a subsequent meta-analysis confirmed significant reduction in these cardiovascular risk factors in patients whom corticosteroids are avoided or withdrawn [43]. Three pooled studies of corticosteroid withdrawal have shown that despite the increased incidence of acute rejection in the withdrawal arms, short-term results demonstrate comparable patient and allograft survival [44–46].

The best candidates for steroid withdrawal are low immunologic patients conditioned with induction therapy, especially those at risk for corticosteroid adverse effects [30]. In studies of steroid withdrawal, African Americans have a much higher incidence of acute rejection [47, 48] and together with other high-immunological-risk subgroups may not be the best candidates for such withdrawal.

Timing of steroid withdrawal is critical. If withdrawal is contemplated, it should be completed in the first week after transplantation. If prednisone is being used beyond the first week after renal transplantation, it should be continued rather than withdrawn.

3.5.3 Antimetabolite Agents

Antimetabolite agents include azathioprine and mycophenolic acid. Azathioprine is a purine analog that inhibits DNA replication and suppresses B- and T-cell proliferation. Typical doses of azathioprine range from 1 to 2.5 mg/kg/day. Adverse effects of azathioprine are dose-related bone marrow suppression and gastrointestinal disturbances. Other rare, but serious, adverse events, like pancreatitis and elevations in liver function tests, paired with a potential serious drug interaction with allopurinol have limited the use of azathioprine. Mycophenolic acid causes noncompetitive reversible inhibition of inosine monophosphate dehydrogenases (IMPDH). This interferes with the de novo pathway of purine synthesis and DNA replication, producing cytostatic effects on T and B cells. Mycophenolic acid is available as mycophenolate mofetil or enteric-coated mycophenolic sodium. Mycophenolate mofetil is rapidly converted to mycophenolic acid in the liver, and enterohepatic recirculation of mycophenolic acid may occur. Typical doses of mycophenolate mofetil range from 500 to 1500 mg orally twice daily. A dose of 250 mg of mycophenolate mofetil is equivalent to 180 mg of enteric-coated mycophenolic sodium. Magnesium and zinc containing products should not be co-administered with mycophenolic acid. Common adverse effects of mycophenolate mofetil include dose-related gastrointestinal side effects, leukopenia, and thrombocytopenia.

The efficacy of mycophenolate mofetil in renal transplantation has been reported in several well-designed trials [49–53]. Mycophenolate mofetil treatment groups demonstrated a reduced incidence and severity of early rejection episodes as compared to low-dose azathioprine-treated patients with treatment regimens consisting of tacrolimus plus corticosteroid as well as cyclosporine plus corticosteroid [49]. Three-year follow-up of these studies found that the decreased incidence of early rejection in the mycophenolate mofetil arm had not translated into a significant improvement in allograft function or survival [50, 51]. As a result of the summative evidence from these trials, the KDIGO Clinical Practice Guidelines suggest that mycophenolate be the first-line antiproliferative agent in kidney transplant recipients [30].

Enteric-coated mycophenolate sodium was developed with the hopes of avoiding the upper gastrointestinal side effects of mycophenolic acid by facilitating drug release in the small intestine [54]. Two major clinical trials demonstrated that enteric-coated mycophenolate sodium is therapeutically equivalent to mycophenolic mofetil, yet they did not demonstrate a statistically significant difference in overall gastrointestinal symptoms [55, 56]. Many post-marketing studies have proven a beneficial effect of enteric-coated mycophenolate sodium, while others have not reported a difference in gastrointestinal-related adverse effects [57–69]. Gastrointestinal events are multifactorial and may be related to multiple factors including infectious etiology, gastroparesis, or concomitant medications. Enteric-coated mycophenolate sodium may offer benefit to specific populations. However, enteric coating is unlikely to influence the systemic effects of the drug including effects on enterocyte proliferation and viral infection that may be responsible for gastrointestinal side effects.

3.5.4 mTOR Inhibitors

An alternative to the calcineurin inhibitor-based regimens is a mTOR inhibitor-based regimen. Sirolimus and everolimus bind to FKBP-12 to form an immunosuppressive complex which inhibits the regulatory kinase, mTOR. This inhibition suppresses cytokine-mediated T-cell proliferation, halting

progression from the G1 to the S phase of the cell cycle. Sirolimus is dosed orally once daily (typically 2–5 mg/day) with adjustments based on target trough levels of 5–15 ng/mL. Everolimus is a sirolimus derivative with a much shorter half-life that is approved for the treatment of advanced renal cell carcinoma and renal and liver transplantation. Everolimus, initially dosed at 0.75 mg orally twice daily followed by adjustment to target serum drug concentration between 3 and 8 ng/mL, has an adverse event profile similar to sirolimus. Sirolimus is a substrate of CYP3A4 and everolimus is an inhibitor of CYP3A4. In kidney transplantation, the mTOR inhibitors, sirolimus and everolimus, have been associated with delayed allograft function; thus, the KDIGO Clinical Practice Guidelines recommend that if a mTOR inhibitor is used, it should not be started until allograft function is established and surgical wounds are healed [30]. Although sirolimus has a relatively low risk of traditional afferent arteriolar vasoconstrictive nephrotoxicity, concomitant use of angiotensin-converting enzyme inhibitors (ACEI) may cause acute renal failure [70] or anaphylaxis [71]. Sirolimus is uncommonly used early after lung transplant due to associated risk of anastomotic bronchial dehiscence [72, 73]. It has also been associated with hepatic artery thrombosis following liver transplant [74].

The de novo use of sirolimus has been proven to be comparable to a calcineurin inhibitor as seen in the ORION trial and the Spare-the-Nephron trial, while it has been associated with early posttransplant adverse events including lymphoceles, prolonged delayed allograft function, and poor wound healing [75–78]. Likewise de novo use of everolimus in combination with induction has produced acceptable rates of acute rejection, although adverse events were common [79, 80]. Based on data from the CONVERT trial, it appears that sirolimus conversion is only successful in a subgroup of patients with a baseline glomerular filtration rate more than 40 mL/min and urine protein to urine creatinine ratio less than or equal to 0.11 [81]. Likewise, the ZEUS study demonstrated the everolimus conversion is possible in low- to moderate-risk patients with normal renal function, although this may come at the expense of a higher acute rejection rate. The best evidence for calcineurin withdrawal with mTOR inhibitors is in selected patients. Close monitoring of drug concentration levels and adverse events is warranted. Whether or not calcineurin inhibitor-free/sparing regimens using mTOR inhibitor maintenance therapy is efficacious in the long term remains unknown. Therefore at this time, the KDIGO Clinical Practice Guidelines suggest that calcineurin inhibitors be continued rather than withdrawn [30].

3.5.5 Belatacept

Belatacept is a second-generation co-stimulation blocker that is administered as a well-tolerated intravenous infusion over 30 min. The recommended dosing is 10 mg/kg administered, prior to transplantation, on day 5 and at the end of weeks 2, 4, 8, and 12, then 5 mg/kg every 4 weeks (plus or minus 3 days).

Belatacept has been studied in several clinical renal transplantation trials. In a phase 2 study, more-intensive belatacept, less-intensive belatacept, and cyclosporine produced similar rates of acute rejection and allograft loss, while the glomerular filtration was statistically higher in each of the belatacept arms [82, 83]. Two phase three trials of de novo kidney transplant recipients tested the efficacy and safety of belatacept [84–86]. In both trials, patients were randomized into three groups: more-intensive belatacept, less-intensive belatacept, and cyclosporine in conjunction with basiliximab, mycophenolate, and corticosteroids. BENEFIT-EXT was designed similarly to the BENEFIT trial with the inclusion of expanded criteria donors. In the BENEFIT trial, despite the higher incidence of acute rejection in the belatacept arm, renal function was superior in the belatacept arms. In the BENEFIT-EXT trial, acute rejection rates were similar and renal function was statistically superior in the more-intensive belatacept group, but not the less-intensive group [85]. Three-year follow-up of these trials demonstrated persistent improvement in renal function (mean change +21 mL/min BENEFIT and +10 mL/min BENEFIT-EXT) [86]. Unfortunately, there was a high incidence of posttransplant lymphoproliferative disease in the belatacept-treated, Epstein–Barr virus seronegative recipient arms, and therefore, the drug is contraindicated in patients that are Epstein–Barr virus seronegative. One limitation of the BENEFIT and BENEFIT-EXT trials was that in the comparison arm, cyclosporine, a less contemporary immunosuppressant, was used at high doses and concentrations. Addressing this issue, a smaller trial used a more contemporary immunosuppressive regimen of belatacept/mycophenolate mofetil, belatacept/sirolimus, and tacrolimus/mycophenolate mofetil, in combination with r-ATG without corticosteroids [87]. Acute rejection was highest in the belatacept/mycophenolate mofetil arm, allograft loss was lowest in the tacrolimus/mycophenolate arm, and renal function was better in the belatacept arms.

A randomized, conversion trial has tested the hypothesis that belatacept-based regimens may provide a treatment option for calcineurin-based maintenance immunosuppression [88]. The relative renal benefit of belatacept was observed in patients switched from either cyclosporine (+7.7 mL/min) or tacrolimus (+6.4 mL/min). Patient survival, allograft survival, and the overall safety profile were similar between groups. Close monitoring of patients is necessary as six patients in the belatacept group had acute rejection episodes, all of them within the first six months after conversion.

Belatacept is the first immunosuppressive agent to demonstrate an improvement in glomerular filtration rate over a calcineurin inhibitor-based regimen. The chronic intravenous administration and drug cost may influence prescribing patterns and patient compliance. Further trials are needed to

explore the long-term outcomes. These trials should include more current immunosuppressive regimens.

3.5.6 Summary

In the past two decades, tacrolimus and mycophenolic acid have become the cornerstones of immunosuppressive regimens. The KDIGO Clinical Practice Guidelines recommend using a combination of immunosuppressive medications as maintenance therapy including a calcineurin inhibitor and an antiproliferative agent, with or without corticosteroids [30]. They suggest that tacrolimus be the first-line calcineurin inhibitor used and that mycophenolate be the first-line antiproliferative agent. In patients who are at low immunological risk and who receive induction therapy, corticosteroids could be discontinued during the first week after transplantation.

3.6 Treatment of Rejection

In the current era of transplantation, balancing the need for immunosuppression to prevent allograft rejection while minimizing drug toxicity, infections, and malignancy continues to be a challenging task. Potent immunosuppressive agents have significantly lowered the incidence of acute cellular rejection in the first years after transplantation. Antibody-mediated rejection continues to threaten the long-term survival of the allografts.

3.6.1 Acute Cellular Rejection

Corticosteroids are generally considered first line for treatment of cellular rejection. Methylprednisolone 0.5–1.0 g intravenously is given once daily for 3 days [89, 90], then oral corticosteroids are tapered rapidly to the pretreatment dose. If a patient was steroid-free prior to the rejection episode, many centers will continue the corticosteroids for the life of the allograft. Anti-T-cell antibodies, which remove functional T cells from the circulation, can be used when corticosteroids have failed to reverse rejection, for moderate to severe rejection, or for treatment of a recurrent rejection. Currently, there are two available antithymocyte globulins: one derived from horses and the other from rabbits. In a multicenter, double-blind, randomized trial, r-ATG demonstrated improved efficacy when compared to equine-derived antithymocyte globulin in the treatment of rejection [91]. Rabbit antithymocyte globulin, the most commonly used preparation, is dosed 1.5 mg/kg for 7–14 days and administered as an intravenous infusion delivered over a 4–6-h period preferably through a proximal central venous catheter, a peripherally inserted central catheter (PICC) line, or a high-flow vein with a 0.22 micron filter. Premedication including corticosteroids, acetaminophen, and an antihistamine is recommended to avoid infusion-related side effects and cytokine release syndrome. Other common adverse effects are leukopenia and thrombocytopenia which can be managed through dose adjustments.

Adjusting a patient's maintenance regimen may also aid in treating an acute rejection episode. If the drug levels are subtherapeutic prior to diagnosis, then the calcineurin inhibitor dose should be adjusted to reach the target range. Switching from cyclosporine to tacrolimus may also be beneficial [92]. A change to the patient's antimetabolite should also be considered. Increasing the antimetabolite dose is recommended if the patient can tolerate the higher-dose regimen.

3.6.2 Antibody-Mediated Rejection

Historically, antibody-mediated rejection has been very difficult to reverse and has not been well studied. Acute antibody-mediated rejection is less responsive to conventional antirejection therapy and has a worse prognosis than acute cellular rejection. Treatment regimens may include one or more of the following: antilymphocyte therapy, plasmapheresis, intravenous immunoglobulin (IVIG), and rituximab [93–99]. One cohort study comparing these strategies (plasmapheresis/IVIG/rituximab vs. IVIG alone) demonstrated improved allograft survival in the combination group [99]. The KDIGO Clinical Practice Guidelines suggest treating antibody-mediated acute rejection with one or more of the following alternatives with or without corticosteroids: plasma exchange, IVIG, anti-CD20 antibody, and lymphocyte-depleting antibody (grade 2C recommendation) [30]. Bortezomib and eculizumab may play a major role in antibody-mediated therapy, but more clinical data and well-designed clinical trials are needed.

3.6.3 Summary

Treatment for mild cellular rejection involves corticosteroids, whereas moderate to severe cellular rejection is typically treated with antithymocyte globulins. Humoral rejection is more difficult to treat and typically is treated with multiple therapies including IVIG, plasmapheresis, corticosteroids, and rituximab, eculizumab, or bortezomib.

3.7 Immunosuppression in Other Solid Organs

3.7.1 Pancreas Transplantation

In clinical practice, a maintenance immunosuppressive regimen containing a calcineurin inhibitor, mycophenolic acid, and corticosteroids is the preferred regimen for pancreas transplant recipients [100–102]. There is less evidence supporting the use of corticosteroid withdrawal in pancreas transplantation [103–112]. According to Scientific Registry

of Transplant Recipients (SRTR) data, 38 % of pancreas transplant recipients undergo corticosteroid withdrawal [1]. Little is known about the use of mTOR inhibitors in pancreas transplant recipients. Sirolimus appears to prevent rejection in pancreas transplant recipients, but only a few small, nonrandomized studies have been published [44, 45, 113–118].

3.7.2 Lung Transplantation

For the past two to three decades, the most commonly used regimen in lung transplant recipients has consisted of a calcineurin inhibitor plus an antimetabolite and corticosteroids [1]. There is less evidence supporting the use of tacrolimus in lung transplantation [119–122], and therefore the switch from cyclosporine to tacrolimus has been delayed when compared to other transplanted organs. Similarly, many lung transplant centers have not switched from azathioprine to mycophenolic acid [123–127]. Currently based on SRTR statistics, 86 % of new lung transplants are prescribed tacrolimus and 55 % of lung transplant recipients are given mycophenolic acid [1], perhaps because the published literature suggests an increased incidence of infection and gastrointestinal toxicity with mycophenolate mofetil [127]. Sirolimus is not commonly used or FDA approved for use in lung transplantation because it has been associated with several fatal cases of anastomotic bronchial dehiscence when used in the early posttransplantation period as well as interstitial pneumonitis. In contrast, everolimus has been studied in lung transplantation with more success [128, 129].

3.7.3 Liver Transplantation

For liver transplant recipients, the regimen that is most commonly used at the time of transplant is tacrolimus plus mycophenolic acid and corticosteroids, although corticosteroid withdrawal is becoming more common [1]. Many patients receive triple immunosuppressive therapy at the time of transplant, but agents are commonly weaned and dual or single therapy is commonplace. Lower acute rejection rates have been seen with tacrolimus (vs. cyclosporine) [130–132] and mycophenolate mofetil [133–135]. Corticosteroid withdrawal or avoidance has been attempted in liver transplant recipients in an effort to reduce adverse events and minimize the consequences of hepatitis C recurrence [136, 137]. Meta-analyses have concluded that when corticosteroids were replaced by other agents, the incidence of acute rejection was reduced and that corticosteroid-free regimens are beneficial in lowering cholesterol, cytomegalovirus infection, hypertension, and new-onset diabetes mellitus [138, 139]. Sirolimus is not approved in liver transplantation due to a higher rate of hepatic artery thrombosis when compared to cyclosporine. The use of sirolimus after 1 year after transplant as conversion therapy may be safe, although not effective as in preventing nephrotoxicity [140]. Everolimus may show more promise in patients converted for renal dysfunction, but adverse events may limit it use [141].

Heart Transplantation

Tacrolimus is the most widely used calcineurin inhibitor (75 %) in heart transplantation, mycophenolic is the predominant antimetabolite agent (88 %), and the use of sirolimus and everolimus remains low. Most patients (89 %) remain on low-dose glucocorticoids at 1-year posttransplantation. Single-center and multicenter randomized comparisons between de novo use of tacrolimus and cyclosporine after heart transplantation support the use of tacrolimus [142, 143]. The substitution of mycophenolate mofetil for azathioprine may reduce mortality and rejection in the first year after cardiac transplantation [144]. Enteric-coated mycophenolic sodium and mycophenolate mofetil appear to be similar except that significantly fewer enteric-coated mycophenolic sodium patients required dose reductions during treatment [145]. The mTOR inhibitors may be used in patients with cardiac allograft vasculopathy or renal insufficiency because of their inhibitory effects on smooth muscle proliferation and absence of intrinsic nephrotoxicity [146]. The high incidence of adverse effects, including lower-extremity edema and poor wound healing, may limit the universal use of these agents. Of the two available mTOR inhibitors, everolimus has better evidence of reducing acute rejection rates and preventing vasculopathy [147–149]. Corticosteroids are used in most heart transplant recipients at relatively high doses in the early postoperative period then tapered to low doses or discontinued altogether in the first transplant year [150, 151]. Low-risk patients may tolerate earlier (within 1–2 months posttransplantation) corticosteroid withdrawal without long-term adverse consequences [152, 153], but this may result in higher acute rejection rates and additional steroids during follow-up [154].

3.7.4 Intestinal Transplantation

Intestinal transplant recipients have the highest rejection rates and the lowest allograft survival rates due to the high immunogenicity of the bowel. Newer immunosuppressive drugs have played a significant role in the success with the procedure since the mid-1990s. Currently, most intestinal transplant recipients receive tacrolimus and corticosteroids as maintenance immunosuppression. Fewer than

200 intestine transplants are performed yearly and therefore the clinical trials of immunosuppression are few in number [155].

3.8 Conclusion

Induction, maintenance, and treatment of rejection are the three phases of immunosuppression. The choice of induction agent remains debatable and should be based on patient-specific risk factors. Basiliximab or no induction agent may be preferred in low-risk patients and r-ATG may be preferred in high-risk transplant patients. Maintenance therapy typically includes a calcineurin inhibitor and an antiproliferative agent, with or without corticosteroids. Tacrolimus and mycophenolate are the preferred maintenance agents. In patients who are at low immunological risk, corticosteroids can be avoided or withdrawn, although this practice is debatable. Treatment for mild cellular rejection involves corticosteroids, whereas moderate to severe cellular rejection is typically treated with antithymocyte globulins. Humoral rejection is treated with multiple therapies including IVIG, plasmapheresis, corticosteroids, rituximab, eculizumab, or bortezomib.

While awaiting further advances in the immunosuppressive armamentarium, we should be able to improve patient and allograft survival by tailoring available immunosuppressive agents. Maintaining the effectiveness of immunosuppressive therapy requires shifting our therapeutic approach from “one-size-fits-all” to a tailored or individualized strategy. In the current era of transplantation, immunosuppressive regimens are selected based on several factors including immunological risk of rejection, potential for excessive immunosuppression (e.g., infection and cancer), medication side effects, patient adherence, patient characteristics, cost, and presence of comorbid disease states. Balancing the need for immunosuppression to prevent allograft rejection while minimizing drug toxicity and the risk of infections and malignancy continues to be a challenging task. Given toxicities of immunosuppressive agents, different maintenance regimens are being explored to minimize adverse short- and long-term effects. Patients at risk for rejection may require more potent immunosuppressive medication, more medications, and higher doses. Patient at lower risk for rejection may need less potent medications, lower drug concentrations and dosages, or mono- or dual therapy.

Ongoing vigilant monitoring of transplant patients should be combined with a willingness to respond to rejection or infection with alterations in maintenance immunosuppressive therapy. Further study of these immunosuppressive regimens and novel agents should provide innovative strategies that extend the functional life of allografts and provide the ideal immunosuppressive regimen.

Common Drug Interactions Encountered in Treating Transplant-Related Infection

Helen W. Boucher and Shannon M. Wiehe

The treatment of patients with transplant-related infections requires close attention to the host in order to ensure adequate and safe dosing of anti-infective medications. Solid organ transplant recipients are at risk for synergistic toxicities due to drug–drug interactions between anti-infective agents and immunosuppressive medications. These toxicities relate to consequences of high exposures to the immunosuppressive and/or the anti-infective medication. While perhaps less frequent, the risk of inadequate anti-infective drug exposure and resulting treatment failure due to drug–drug interactions must also be avoided. This chapter presents a summary of the clinically significant drug–drug interactions encountered in providing anti-infective chemotherapy to solid organ transplant recipients.

Medications used for immunosuppression after organ transplantation can be split into seven categories (Table 4-1): polyclonal antibodies, monoclonal antibodies, calcineurin inhibitors, antimetabolites, mammalian target of rapamycin (mTOR) inhibitors, corticosteroids, and selective T-cell costimulation blockers. The reader is referred to Chap. 3 for more detailed information regarding the mechanism of action of these commonly used immunosuppressive agents. The risk of drug interactions is high, particularly within the calcineurin inhibitor and mTOR inhibitor drug classes.

Cyclosporine (Neoral, Sandimmune, Novartis Pharmaceuticals) and tacrolimus (Prograf, Astagraf XL, Astellas Pharmaceuticals) are calcineurin inhibitors. They suppress the immune system by blocking IL-2 signaling between immune cells. Major toxicities include electrolyte disturbances (i.e., hypophosphatemia, hypomagnesemia, hyperkalemia), hypertension, hyperlipidemia, hyperglycemia, nephrotoxicity, neurotoxicity, and others [1, 2]. Doses are adjusted to obtain target whole blood cyclosporine or tacrolimus levels and the target range is patient-specific.

Sirolimus (Rapamune, Pfizer Inc.) and everolimus (Zortress, Novartis Pharmaceuticals) are mTOR inhibitors whose actions inhibit T-cell activation and proliferation. Major toxicities include impaired wound healing, hypertriglyceridemia, hyperlipidemia, oral ulcers, proteinuria, and noninfectious pneumonitis [3–6]. Sirolimus and everolimus doses are adjusted to obtain target whole blood trough concentrations, and the target range is patient-specific. Sirolimus has a long half-life and it will take 1–2 weeks to reach steady state after initiating therapy and/or after dose changes.

Cyclosporine, tacrolimus, sirolimus, and everolimus are substrates for both cytochrome P-450 3A4 (CYP3A4) and P-glycoprotein (P-gp). Drugs and substances that induce CYP3A4 and/or P-gp may decrease cyclosporine/tacrolimus/sirolimus/everolimus concentrations, whereas inhibitors of CYP3A4 and/or P-gp may increase cyclosporine/tacrolimus/sirolimus/everolimus concentrations. Cyclosporine also inhibits CYP3A4 and P-gp and may have additional unique drug interactions not present with tacrolimus, sirolimus, and everolimus.

Azathioprine (Imuran; Prometheus Laboratories) is an antimetabolite. Major toxicities include bone marrow suppression manifesting as leukopenia, thrombocytopenia, and anemia. Standard, weight-based dosing is used for azathioprine; serum drug concentrations are not utilized [7].

Mycophenolate mofetil (MMF, CellCept; Genentech) and mycophenolic acid (MPA, Myfortic; Novartis Pharmaceuticals) are also antimetabolites, but, compared with azathioprine, their mechanism of action is more targeted to the white blood cell lines. Major toxicities include leukopenia and gastrointestinal adverse effects, most notably diarrhea [8]. Although these drugs are generally used at standard doses, therapeutic drug monitoring may be useful for MMF.

P. Ljungman et al. (eds.), *Transplant Infections*, DOI 10.1007/978-3-319-28797-3_4

MMF is a prodrug that, after absorption, is quickly hydrolyzed to MPA. Myfortic is an enteric coated formulation of MPA, which is the active moiety of both these drugs. The major metabolite of MPA, an MPA glucuronide known as MPAG, is excreted into urine and bile. Once in the GI tract, MPAG is converted back into MPA and reabsorbed, resulting in enterohepatic recirculation.

MMF and MPA are believed to have similar drug interactions. Indeed, most MPA drug interactions are derived from the MMF literature. The clinical impact may not be exactly the same, however, because each of these medications has a unique pharmacokinetic profile. In addition to the interactions listed in Table 4-2, drugs that alter the GI flora may disrupt enterohepatic recirculation of MPA. This is because natural GI flora is responsible for conversion of MPAG to MPA [75].

TABLE 4-1. Immunosuppressive agents [7]

Class	Generic name	Brand name
Calcineurin inhibitors	Cyclosporine	Neoral; Sandimmune
	Tacrolimus	Prograf; Astagraf XL
Antimetabolites	Azathioprine	Imuran
	Mycophenolate mofetil	CellCept
	Mycophenolic acid	Myfortic
Corticosteroids	Prednisone	Deltasone
mTOR inhibitors	Sirolimus	Rapamune
	Everolimus	Zortress
Polyclonal antibodies	Antithymocyte globulin, rabbit	Thymoglobulin
Monoclonal antibodies	Basiliximab (anti-CD25)	Simulect
	Alemtuzumab (anti-CD52)	Campath-1H
Selective T-cell costimulation blocker	Belatacept	Nulojix

For more information, also see Chap. 3.
Abbreviation: *mTOR* mammalian target of rapamycin.

There is scant evidence suggesting that corticosteroids may have clinically relevant drug interactions with other immunosuppressive agents [76]. Corticosteroids induce the CYP3A4 and P-gp pathways to varying degrees; cyclosporine, tacrolimus, sirolimus, and everolimus rely on these pathways for metabolism. Corticosteroids also induce uridine diphosphate glucuronosyltransferase enzymes and multidrug resistance-associated protein 2; the mycophenolate products rely on these pathways for metabolism. When possible, therapeutic drug monitoring can be used to ensure appropriate immunosuppressive exposure while initiating or tapering corticosteroids [7].

Relevant drug interactions have not been noted for the polyclonal/monoclonal antibodies or selective T-cell costimulation blockers. These drugs do, however, pose the risk of pharmacodynamic interactions and additive toxicities.

Since our last update, several new anti-infective medications have been approved for marketing. These include the antibacterial drugs tedizolid, ceftaroline, dalbavancin, oritavancin, ceftolozane–tazobactam, fidaxomicin, and ceftazidime–avibactam. New antiviral agents include antihepaciviral protease inhibitors (telaprevir, boceprevir, simeprevir), polymerase inhibitors, and NS5A inhibitors as well as antiretroviral integrase inhibitors (raltegravir, elvitegravir, dolutegravir). The new azole antifungal agent isavuconazole was also introduced and is marketed as the prodrug isavuconazonium sulfate. New immunosuppressant agents include everolimus and belatacept. The tables highlight only drugs with potential interactions in transplant recipients. Table 4-1 lists the immunosuppressive agents according to their class; Table 4-2 shows common immunosuppressant interactions; and Table 4-3 presents common interactions between anti-infective and immunosuppressant drugs.

TABLE 4-2. Common immunosuppressant drug interactions

Immunosuppressant	Interacts with	Interaction	Clinical effect	Management
Azathioprine (AZA; Imuran)	Allopurinol [9, 10]	AZA is metabolized to 6-MP (active); 6-MP is inactivated by xanthine oxidase (XO); allopurinol inhibits XO	Significant increase in 6-MP exposure; AZA toxicity (i.e., bone marrow suppression)	Reduce AZA dose; will require 66–75 % AZA dose reduction when adding allopurinol
	Aminosalicylates: mesalamine, olsalazine, sulfasalazine [11, 12]	AZA is metabolized to 6-MP (active); 6-MP is inactivated by TPMT; aminosalicylates may inhibit TPMT	Higher risk of bone marrow suppression	Monitor CBC regularly with concomitant use
	Infliximab [13]	Infliximab reduces AZA clearance	Leukopenia	Monitor CBC regularly with concomitant use
	Warfarin [14]	Unknown	Dose-dependent inhibition of warfarin effect	Titrate warfarin; will require ~2.5-fold higher warfarin when adding AZA
	*Cytochrome P-450 3A4 (CYP3A4) and P-glycoprotein drug interactions also apply			

(continued)

TABLE 4-2. (continued)

Immunosuppressant	Interacts with	Interaction	Clinical effect	Management
Cyclosporine (CSA; Neoral, Sandimmune)	Everolimus [15, 16]	Everolimus is a substrate of CYP3A4 and P-gp; CSA inhibits CYP3A4 and P-gp	Concomitant administration of cyclosporine (Neoral) increases EVR AUC and C_{max} by 168 % and 82 %, respectively	EVR dose adjustment may be needed upon initiation or discontinuation of cyclosporine Titrate EVR dose; utilize whole blood trough concentrations
	Micafungin [17]	Micafungin is a mild inhibitor of CYP3A4 in vitro; CSA is a CYP3A4 substrate	Concomitant use results in slightly increased CSA exposure	Titrate CSA; utilize whole blood CSA concentrations
	Mycophenolate mofetil [18, 19]	CSA inhibits enterohepatic recirculation of MPAG	30–50 % reduction in the MPA $AUC_{0–12\ h}$	Note the alteration in MPA exposure when changing concomitant immunosuppression; consider MMF dose adjustments
	Sirolimus [20–22]	Sirolimus is a substrate of CYP3A4 and P-gp; CSA inhibits CYP3A4 and P-gp	Simultaneous administration increases SIR C_{max} and AUC by 116 % and 230 %, respectively	Stagger administration by at least 4 h; note that staggered administration minimizes but does not ameliorate the interaction
			Administering SIR 4 h after CSA increases SIR C_{max} and AUC by 37 % and 80 %, respectively	Titrate SIR; utilize whole blood trough SIR concentrations
	HMG-CoA reductase inhibitors "statins" [23–26]: rosuvastatin, simvastatin > atorvastatin, lovastatin, fluvastatin > pravastatin	Competition for metabolism by CYP3A4; altered statin transport in the liver	Concomitant use results in increased statin exposure; appears more potent with CSA than TAC	Use lower statin doses (i.e., 50 % reduced); watch for myopathies and other statin side effects Use with simvastatin and atorvastatin not recommended
	*Cytochrome P-450 3A4 (CYP3A4) and P-glycoprotein drug interactions also apply			
Everolimus (EVR; Zortress)	Cyclosporine [15, 16]	Everolimus is a substrate of CYP3A4 and P-gp; CSA inhibits CYP3A4 and P-gp	Concomitant administration of cyclosporine (Neoral) increases EVR AUC and C_{max} by 168 % and 82 %, respectively	EVR dose adjustment may be needed upon initiation or discontinuation of cyclosporine Titrate EVR dose; utilize whole blood trough concentrations
	Octreotide [15]	Unknown	Coadministration of EVR with depot octreotide increased C_{min} by 50 %	Note altered octreotide exposure with EVR
Mycophenolate mofetil (MMF; CellCept)	Acyclovir, ganciclovir [27]	The antiviral and MPAG compete for renal tubular secretion; particularly in renal impairment	Risk for increased acyclovir, ganciclovir, and MPAG concentrations	Use combination with caution in renal insufficiency; monitor CBC
	Antacids (i.e., Mg, Al) [28]	Impaired absorption of MMF/MPA	25–33 % reduction in MPA C_{max} and 17–37 % reduction in the MPA $AUC_{0–24\ h}$	Stagger administration by 2–4 h
	Bile acid sequestrants: cholestyramine, colesevelam, colestipol [27, 29]	Drugs that bind bile acids interrupt enterohepatic recirculation	40 % reduction in the MPA $AUC_{0–24\ h}$	Avoid concomitant use
	Oral contraceptives [27]	Unknown	Mean levonorgestrel AUC was decreased by 15 %	Consider additional method of birth control

(continued)

TABLE 4-2. (continued)

Immunosuppressant	Interacts with	Interaction	Clinical effect	Management
	Cyclosporine [18, 19]	CSA inhibits enterohepatic recirculation of MPAG	30–50 % reduction in the MPA $AUC_{0-12\,h}$	Note the alteration in MPA exposure when changing concomitant immunosuppression; consider MMF dose adjustments
	Ganciclovir	See acyclovir		
	Nevirapine [30]	Competition for and/or altered enterohepatic recycling	Slight but significant reduction in nevirapine exposure; unknown effect on MPA	No recommendations have been made
	Proton pump inhibitors [27, 31]	Decreased solubility of MPA at increased gastric pH	MPA C_{max} reduced by 30–70 %, AUC reduced by 25–35 %	Clinical significance unknown Use with caution
	Rifampin [32]	Unknown	Major reduction in MPA $AUC_{0-12\,h}$	Consider MPA drug monitoring while on rifampin
	Sevelamer [33]	Impaired absorption of MMF/MPA	30 % and 25 % reduction in MPA C_{max} and AUC, respectively	Stagger administration by 2 h
Mycophenolic acid (MPA; Myfortic)	Acyclovir, ganciclovir [34]	The antiviral and MPAG compete for renal tubular secretion; particularly in renal impairment	Risk for increased acyclovir, ganciclovir, and MPAG concentrations	Use combination with caution in renal insufficiency; monitor CBC
	Antacids (i.e., Al, Mg) [34]	Antacids decrease MPA absorption	25 % and 37 % reduction in MPA C_{max} and AUC, respectively	Avoid concomitant administration
	Bile acid sequestrants: cholestyramine, colesevelam, colestipol [34]	Drugs that bind bile acids interrupt enterohepatic recirculation	Reduced MPA exposure	Avoid concomitant administration
	Oral contraceptives [34]	Unknown; this interaction is assumed from the MMF experience	Mean levonorgestrel AUC was decreased by 15 %	Consider additional method of birth control
	Cyclosporine [35]	CSA inhibits enterohepatic recirculation of MPAG	20–30 % decrease in the bioavailability and a significant reduction in MPA $AUC_{0-24\,h}$	MPA dose requirements may be higher when used with CSA
	Ganciclovir	See acyclovir		
	*Cytochrome P-450 3A4 (CYP3A4) and P-glycoprotein drug interactions also apply			
Sirolimus (SIR; Rapamune)	Cyclosporine [20–22]	Sirolimus is a substrate of CYP3A4 and P-gp; CSA inhibits CYP3A4 and P-gp	Simultaneous administration increases SIR C_{max} and AUC by 116 % and 230 %, respectively	Stagger administration by at least 4 h; note that staggered administration minimizes but does not ameliorate the interaction
			Administering SIR 4 h after CSA increases SIR C_{max} and AUC by 37 % and 80 %, respectively	Titrate SIR; utilize whole blood trough SIR concentrations
	Micafungin [36]	Unknown	SIR AUC is increased by 21 %; no effect on SIR C_{max}	Consider therapeutic alternatives or titrate SIR doses per whole blood trough SIR concentrations
	*Cytochrome P-450 3A4 and P-glycoprotein drug interactions also apply			

(continued)

TABLE 4-2. (continued)

Immunosuppressant	Interacts with	Interaction	Clinical effect	Management
Tacrolimus (TAC; Prograf, Astagraf XL)	HMG-CoA reductase inhibitors "statins": simvastatin, atorvastatin, lovastatin, fluvastatin, pravastatin, rosuvastatin [23, 26]	Competition for metabolism by CYP3A4; altered statin transport in the liver	Concomitant use results in increased statin exposure; appears more potent with CSA than TAC	Use lower statin doses (i.e., 50% reduced); watch for myopathies and other statin side effects
Cytochrome P-450 3A4 (CYP3A4) and P-glycoprotein (P-gp) drug interactions	Anticonvulsants: carbamazepine, oxcarbazepine, phenobarbital, phenytoin [15, 20, 37, 38]	Induction of CYP3A4-mediated CSA/TAC/SIR/EVR metabolism	Decrease in plasma CSA/TAC/SIR/EVR concentrations	Titrate CSA/TAC/SIR/EVR dose; utilize CSA/TAC/SIR/EVR whole blood concentrations Consider therapeutic alternatives (i.e., valproic acid, lamotrigine, gabapentin)
	Rifampin [15, 20, 39, 40]			Titrate CSA/TAC/SIR/EVR dose; utilize CSA/TAC/SIR/EVR whole blood concentrations Consider rifabutin if appropriate [41]
	St. John's wort [42, 43]		Unpredictable and varying decrease in CSA/TAC/SIR/EVR concentrations	Avoid concomitant use
	Amiodarone [44] Danazol [45] Nefazodone [46]	Inhibition of CYP3A4-mediated CSA/TAC/SIR/EVR metabolism	Increase in CSA/TAC/SIR/EVR concentrations	Titrate CSA/TAC/SIR/EVR dose; utilize CSA/TAC/SIR/EVR whole blood concentrations
	Grapefruit juice [47]		Unpredictable and varying increase in CSA/TAC/SIR/EVR concentrations	Avoid concomitant use
	Macrolide antibiotics: clarithromycin [48–50], erythromycin [51–53], telithromycin		Significant increase in CSA/TAC/SIR/EVR concentrations	Avoid concomitant use whenever possible; consider azithromycin [54] If coadministration is necessary, empirically reduce CSA/TAC/SIR/EVR doses, monitor CSA/TAC/SIR/EVR whole blood concentrations; titrate CSA/TAC/SIR/EVR dose
	Nondihydropyridine calcium channel blockers: diltiazem [55–57] > verapamil [15, 20, 57]		Increase in CSA/TAC/SIR/EVR concentrations; appears to be more potent with diltiazem versus verapamil	Titrate CSA/TAC/SIR/EVR dose; utilize CSA/TAC/SIR/EVR whole blood concentrations
	Anti-HIV protease inhibitors [58]: amprenavir, atazanavir, darunavir, fosamprenavir, indinavir, lopinavir [59, 60], nelfinavir, ritonavir [59, 60], saquinavir Anti-HCV protease inhibitors [61]: boceprevir, telaprevir		Significant increase in CSA/TAC/SIR/EVR concentrations	When initiating CSA/TAC/SIR/EVR, use low doses and utilize whole blood concentrations to determine the dosing interval; may need to utilize liquid formulations to achieve small oral doses Titrate CSA/TAC/SIR/EVR dose and/or interval; utilize CSA/TAC/SIR/EVR whole blood concentrations

(continued)

TABLE 4-2. (continued)

Immunosuppressant	Interacts with	Interaction	Clinical effect	Management
Azole antifungals: itraconazole [62, 63], posaconazole [64, 65], voriconazole [51, 66], isavuconazole [67] > fluconazole [68, 69], ketoconazole [20] > clotrimazole [70, 71]			For ketoconazole, fluconazole, and clotrimazole: titrate CSA/TAC/SIR/EVR dose and/or interval; utilize CSA/TAC/SIR/EVR whole blood concentrations For voriconazole, posaconazole, and itraconazole: empirically reduce CSA/TAC/SIR/EVR doses, monitor CSA/TAC/SIR/EVR whole blood concentrations; titrate CSA/TAC/SIR/EVR dose For voriconazole, ketoconazole, and itraconazole: note that concomitant use with EVR is not recommended [15] For voriconazole and posaconazole: note that concomitant use with SIR is contraindicated [72, 73] but safe coadministration has been reported [64, 74] if SIR doses are cut by at least 50 % before initiating voriconazole or posaconazole; titrate per SIR whole blood trough concentrations Clotrimazole troches can more than double TAC concentrations due to inhibition of intestinal CYP3A4 and P-gp	

Table 4-3. Common interactions between anti-infective agents and immunosuppressive agents

Anti-infective category	Anti-infective agent/class	Immunosuppressive agent or group of agents	Interaction	Clinical effect	Management
Antifungal	Polyene antifungal: amphotericin B formulations	CSA/TAC/SIR/EVR	Additive nephrotoxicity	Increases risk of kidney injury	Monitor CSA/TAC/SIR/EVR concentration and kidney function
Antifungal	Azole antifungals: itraconazole [62, 63], posaconazole [64, 65], voriconazole [51, 66], isavuconazole [67] > fluconazole [68, 69], ketoconazole [20] > clotrimazole [70, 71]	CSA/TAC/SIR/EVR	Inhibition of CYP3A4	Increases CSA, TAC, SIR, and EVR levels in varying amounts	For ketoconazole, fluconazole, and clotrimazole: titrate CSA/TAC/SIR/EVR dose and/or interval; utilize CSA/TAC/SIR/EVR whole blood concentrations For voriconazole, posaconazole, and itraconazole: empirically reduce CSA/TAC/SIR/EVR doses, monitor CSA/TAC/SIR/EVR whole blood concentrations; titrate CSA/TAC/SIR/EVR dose For voriconazole, ketoconazole, and itraconazole: note that concomitant use with EVR is not recommended [15] For voriconazole and posaconazole: note that concomitant use with SIR is contraindicated [72, 73] but safe coadministration has been reported [64, 74] if SIR doses are cut by at least 50 % before initiating voriconazole or posaconazole; titrate per SIR whole blood trough concentration Clotrimazole troches can more than double TAC concentrations due to inhibition of intestinal CYP3A4 and P-gp
		TAC	Additive QTc prolongation	Increases risk of torsade de pointes	Monitor electrocardiogram for QTc prolongation
Antifungal	Anidulafungin/echinocandin	CSA	No significant interaction		
Antifungal	Caspofungin/echinocandin [77–80]	CSA	increase LFTs		Likely not clinically relevant
Antifungal	Micafungin/echinocandin [17]	CSA	Micafungin is a mild inhibitor of CYP3A4 in vitro; CSA is a CYP3A4 substrate	Concomitant use results in slightly increased CSA exposure	Titrate CSA; utilize whole blood CSA concentrations
Antifungal	Micafungin/echinocandin [36]	SIR	Unknown	SIR AUC is increased by 21 %; no effect on SIR C_{max}	Titrate SIR; utilize whole blood SIR concentrations
Antibacterial	Aminoglycosides [81]	CSA/TAC/SIR/EVR	Additive nephrotoxicity	Increases risk of kidney injury	Monitor CSA/TAC/SIR/EVR concentration and kidney function

(continued)

TABLE 4-3. (continued)

Anti-infective category	Anti-infective agent/class	Immunosuppressive agent or group of agents	Interaction	Clinical effect	Management
Antibacterial	Chloramphenicol [82–85]	CSA	Potential inhibition of CYP3A4 and 2C9 (rapid onset)	Increases CSA concentration by about 50%	Monitor CSA concentration and kidney function
Antibacterial	Quinolone antibiotics [37]: ciprofloxacin, ofloxacin, levofloxacin, moxifloxacin	CSA	Inhibition of CYP3A4	Increases CSA concentration	Monitor CSA concentration
Antibacterial	Quinolone antibiotics [86]: ciprofloxacin ofloxacin levofloxacin moxifloxacin	TAC	Inhibition of CYP3A4	Increases TAC concentration	Likely not clinically relevant; monitor TAC concentration
			Additive QTc prolongation	Increases risk of torsade de pointes	Monitor electrocardiogram for QTc prolongation
Antibacterial	Quinolone antibiotics [20]: ciprofloxacin, ofloxacin, levofloxacin, moxifloxacin	SIR	Inhibition of CYP3A4	Increases SIR concentration	Uncertain clinical significance; monitor SIR concentration
Antibacterial	Linezolid, tedizolid [87]	AZA/MMF	Additive bone marrow suppression	Increased risk of thrombocytopenia, leukopenia, and anemia	Monitor CBC and use limited course or select alternatives
Antibacterial	Macrolide antibiotics: clarithromycin [48–50], erythromycin [51–53], telithromycin, azithromycin	CSA/TAC/SIR/EVR	Inhibition of CYP3A4	Significant increase in CSA/TAC/SIR concentrations	Avoid concomitant use whenever possible; consider azithromycin [54] If coadministration is necessary, empirically reduce CSA/TAC/SIR/EVR doses, monitor CSA/TAC/SIR/EVR whole blood concentrations; titrate CSA/TAC/SIR/EVR dose
		TAC	Additive QTc prolongation	Increases risk of torsade de pointes	Monitor electrocardiogram for QTc prolongation
Antibacterial	Metronidazole [37, 88]	CSA/TAC	Inhibition of CYP3A4	Increases CSA/TAC concentration	Monitor CSA/TAC concentration
Antibacterial	Nafcillin [89]	CSA	Unknown mechanism	Increases CSA concentration	Monitor CSA concentration
Antibacterial	Rifampin [32]	MMF	Unknown	Major reduction in MPA $AUC_{0-12\ h}$	Consider MPA drug monitoring while on rifampin [90]
Antibacterial	Rifampin/rifabutin	MMF	Induction of the uridine diphosphate glucuronosyl transferase in the kidney, liver, and intestines		
Antibacterial	Rifampin [15, 20, 39, 40]	CSA/TAC/SIR/EVR	Induction of CYP3A4-mediated CSA/TAC/SIR/EVR metabolism	Decrease in plasma CSA/TAC/SIR/EVR concentrations	Titrate CSA/TAC/SIR/EVR dose; utilize CSA/TAC/SIR/EVR whole blood concentrations Consider rifabutin if appropriate [41]
Antihepaciviral	Protease inhibitors [61]: boceprevir, telaprevir	CSA/TAC/SIR/EVR	CYP3A4 inhibition	Significant increase in CSA/TAC/SIR/EVR concentrations	When initiating CSA/TAC/SIR/EVR, use low doses, and utilize whole blood concentrations to determine the dosing interval; may need to utilize liquid formulations to achieve small oral doses Titrate CSA/TAC/SIR/EVR dose and/or interval; utilize CSA/TAC/SIR/EVR whole blood concentration

Antihepaciviral	Protease inhibitor [91, 92]: simeprevir	CSA	Possible intestinal CYP3A4/P-gp inhibition by simeprevir Inhibition of CYP3A4 and P-gp by CSA	Increase in both simeprevir and CSA concentrations	Monitor CSA whole blood concentration Monitor for increased side effects of simeprevir or avoid combination
		TAC	Unknown	May decrease TAC concentrations	Minimal clinical significance Monitor TAC whole blood concentration
Antiviral	Acyclovir, ganciclovir [27, 34]	MMF	The antiviral and MPAG compete for renal tubular secretion; particularly in renal impairment	Risk for increased acyclovir, ganciclovir, and MPAG concentrations (evidence of increased antiviral levels)	Use combination with caution in renal insufficiency; monitor CBC
Antiviral	Foscarnet [93]	CSA/TAC/SIR/EVR	Additive nephrotoxicity	Increases risk of kidney injury	Monitor CSA/TAC/SIR/EVR concentration and kidney function
Antiretroviral	NNRTI: efavirenz, etravirine, nevirapine [15, 58, 94, 95]	CSA/TAC/SIR/EVR	Induction of CYP3A4-mediated CSA/TAC/SIR/EVR metabolism	Decrease in plasma CSA/TAC/SIR concentrations	Titrate CSA/TAC/SIR/EVR dose; utilize CSA/TAC/SIR/EVR whole blood concentrations
Antiretroviral	Nevirapine [30]	MMF	Competition for and/or altered enterohepatic recycling	Slight but significant reduction in nevirapine exposure; unknown effect on MPA	No recommendations have been made
Antiretroviral	Anti-HIV protease inhibitors [58]: amprenavir, atazanavir, darunavir, fosamprenavir, indinavir, lopinavir [59, 60], nelfinavir, ritonavir [59, 60], saquinavir	CSA/TAC/SIR/EVR	CYP3A4 inhibition	Significant increase in CSA/TAC/SIR/EVR concentrations	When initiating CSA/TAC/SIR/EVR, use low doses, and utilize whole blood concentrations to determine the dosing interval; may need to utilize liquid formulations to achieve small oral doses Titrate CSA/TAC/SIR/EVR dose and/or interval; utilize CSA/TAC/SIR/EVR whole blood concentration

Efavirenz: induction increases (more rapid CL) TAC and CSA and prednisolone.

Abbreviations: *CSA* cyclosporine (Neoral, Sandimmune), *TAC* tacrolimus (Prograf, Astagraf XL), *SIR* sirolimus (Rapamune), *EVR* everolimus (Zortress), *MMF* mycophenolate mofetil (CellCept), *AZA* azathioprine (Imuran), *HIV* human immunodeficiency virus, *HCV* hepatitis C virus.

Diagnostic Testing: General Principles

Sarah E. Turbett and Eric S. Rosenberg

5.1 Introduction

Solid organ (SOT) and hematopoietic stem cell transplantation (HSCT) are processes that result in complex interactions between the donor and the recipient and require the use of immunosuppressive medications to induce immune tolerance. Infectious complications are an unfortunate consequence of transplantation and careful assessment before, during, and after transplantation is necessary to prevent significant morbidity and mortality. Recognition of infection is often more difficult in transplant recipients due to the necessary suppression of immune function and as a result, the use of diagnostic assays for the identification of infection is of increased importance [1]. When considering optimal diagnostic testing strategies in transplant recipients, the infectious disease history prior to transplantation in both the donor and recipient, factors related to the transplantation itself (nosocomial processes or procedure-related complications), and issues unique to the use of immunosuppression to prevent organ rejection or graft vs. host disease (GVHD) must be considered [1–3].

Having an understanding of the testing used in the diagnosis of transplant-related infectious diseases, including the strengths and pitfalls of each test, is vital in care of the transplant recipient. The goal of this chapter is to provide an overview of the use of diagnostic tests in the care of the transplant patient. More specifically, testing strategies for both before and after SOT and HSCT will be discussed with a focus on appropriate use for risk stratification and clinical decision-making in this population.

5.2 Diagnostic Testing Prior to Transplantation

Given the potential for both transmission and reactivation of infections after transplantation, pretransplantation screening of potential donors and recipients is performed prior to the procedure. This process allows for the identification of any conditions which might preclude either the donor or the recipient from taking part in the transplantation and to identify and treat any active infections prior to the initiation of immunosuppressive therapy [4]. Pretransplantation screening also allows a physician to better define the risk of infection and to develop strategies for preventing infection through diagnostic monitoring, the use of prophylaxis, or immunization prior to transplantation [4]. Diagnostic testing for both active and latent infections in the pretransplantation setting is an integral part of the pretransplantation evaluation and is often tailored to the organ or cells to be transplanted as well as the epidemiology or risk factors of the donor and recipient.

5.3 Pretransplant Testing in Solid Organ Transplantation

5.3.1 Donor Screening: Living Donors–Routine Testing

The use of organs obtained from living donors provides a unique opportunity to assess the donor for the presence of active and quiescent infectious diseases that could potentially be transmitted to the recipient via the transplanted organ. For living donors, pretransplantation diagnostic testing for the following infections is required: cytomegalovirus (CMV), Epstein-Barr Virus (EBV), human immunodeficiency virus (HIV), Hepatitis B (HBV), Hepatitis C (HCV), and syphilis [5, 6] (Table 5-1). All of these tests must be performed using FDA-licensed, -approved, or cleared tests in a CLIA-certified laboratory or one that meets equal conditions as determined by the Centers for Medicare and Medicaid [5].

5.3.1.1 Cytomegalovirus and Epstein-Barr Virus

The transmission and acquisition of CMV from donor to recipient may result in significant morbidity. Although prior infection with CMV in the donor and/or recipient is not a

Coccidioides	IgG[n]		X		X
Histoplasma	IgG[o,p]		X		

[a]ELISA antibody assay preferred given its higher specificity for detection [29, 30].
[b]If Ag/AB testis positive, HIV-1/-II differentiation assay is performed to differentiate HIV-I and HIV-II infection [14].
[c]If discrepancies between HIV-I/-II Ag/AB test and HIV-I/-II differentiation assay HIV NAT should be performed [14].
[d]HIV NAT should be performed if potential donor or recipient is identified as high risk for HIV infection [6].
[e]HBV NAT should be performed when anti-HBC alone is positive to assess for occult infection.
[f]Positive anti-HCV with a negative HCV NAT is followed with repeat anti-HCV with another FDA-approved assay [13].
[g]A positive screening test for HTLV-I/II should be confirmed with virus-specific western blot or line immunoassay [25].
[h]WNV IgM testing is not FDA-approved for screening but can be performed to increase the sensitivity of WNV detection [28].
[i]If TP-EIA is positive, RPR is then performed with a positive result confirming the diagnosis. If RPR is negative, TPPA is performed to confirm diagnosis. If TPPA is negative, FTA-ABS is performed to confirm diagnosis. If FTA-ABS is negative, TP-EIA is considered a false positive result [8, 9].
[j]A two-stage TST should be performed in living donors and recipients from endemic regions [4, 19].
[k]ELISA antibody assay preferred for *Strongyloides* given its higher sensitivity and specificity [22, 23].
[l]Stool examination for ova can be performed if antibody assay is unavailable but is not recommended due to its low sensitivity [22].
[m]Routine testing for *Toxoplasma* is only recommended in potential cardiac donors and recipients.
[n]EIA, complement fixation, and immunodiffusion assays available for *Coccidioides* screening [22, 24].
[o]Screening for *Histoplasma* with immunodiffusion or complement assay is recommended [24].
[p]Presence of H precipitin band on immunodiffusion assay of complement fixation titer ≥ 1:32 is diagnostic of active infection [24].

contraindication to transplantation, knowing the serostatus of the donor and recipient is critical in defining the recipient's risk for developing CMV disease and for optimizing risk reduction strategies either through the use of prophylaxis or preemptive monitoring. Donor screening to assess for past exposure to CMV should be performed using assays with high sensitivity and specificity for anti-CMV IgG. Tests that include detection and measurement of CMV IgM should be avoided due to poor specificity [7]. Equivocal anti-CMV IgG results in the potential donor should be interpreted as positive to ensure appropriate prophylactic and monitoring strategies of the recipient in the posttransplant setting [7].

Acquisition of EBV transmitted from donor to recipient may result in acute EBV infection in previously uninfected recipients. Active EBV replication has been associated with the development of posttransplantation lymphoproliferative disorder (PTLD). As EBV induces the production of several different EBV-specific antibodies, testing for past exposure with the viral capsid Antigen IgG (VCA IgG) is the diagnostic study of choice [4]. Nonspecific screening tests for EBV

such as heterophile antibody is not an acceptable strategy as the production of heterophile antibodies typically wane within months to 1 year after infection.

5.3.1.2 Syphilis

Syphilis screening should be performed according to the syphilis testing algorithm described by the Centers for Disease Control (CDC) and begins with an initial enzyme immunoassay treponemal test (TP-EIA) [8, 9]. If TP-EIA is positive, a non-treponemal test such as the rapid plasma regain (RPR) should then be performed with a positive result confirming the diagnosis of syphilis [8, 9]. In the event of a negative non-treponemal antibody test, a second treponemal test such as the *Treponema pallidum* particle agglutination (TPPA) should be performed [8, 9]. If the second treponemal antibody test is negative, a third treponemal antibody test, such as the fluorescent treponemal antibody (FTA-ABS), is then done [8, 9]. If either the second or third treponemal antibody test is positive, a diagnosis of syphilis is made and treatment of the donor should be considered. Negative results of the RPR, TPPA, and FTA-ABS in the setting of a positive TP-EIA indicate either a false positive result or prior resolved infection [8, 9].

5.3.1.3 Testing for Hepatitis C Virus and Human Immunodeficiency Virus

Given the potentially devastating consequences of acquiring HCV and/or HIV infection from a potential organ donor, screening for these viruses is a complex process and depends on the use of both serology and direct virus detection in the blood stream via nucleic acid testing (NAT) for accurate diagnosis. These tests are performed to improve the sensitivity of detection of virus in donors with potential recent infection when seroconversion or detection of antibody production has not yet occurred. Termed the "window period," this period of time is often marked by high levels of circulating antigen or virus prior to the development and detection of a virus-specific antibody response. Therefore, testing for antibodies directed against HCV and HIV during this time period can result in a "false negative" result and can lead to unintended transmission [10]. As positive results for HCV and HIV can have implications for donor eligibility, combining these testing modalities improves the sensitivity of detecting these infections prior to transplantation [5, 6].

5.3.1.3.1. Hepatitis C Virus

Donor screening forHCV is performed using both anti-Hepatitis C antibody (anti-HCV) and a Hepatitis C nucleic acid test (HCV NAT) and must be performed within 28 days of donation [5, 6]. HCV NAT allows for the direct detection of HCV RNA in donor plasma at RNA levels as low as 2.0–9.4 IU/mL [11, 12]. This highly sensitive assay has reduced the preseroconversion window period to approximately 4–6 days from exposure as compared to approximately 60 days with antibody testing alone, greatly increasing the diagnosis of acute HCV infection in potential donors [11]. A positive HCV NAT with or without a positive anti-HCV is indicative of active hepatitis C infection and is considered to be a contraindication to living liver donation [5]. Due to the waxing and waning nature of Hepatitis C viremia, a single negative HCV NAT cannot be used as a stand-alone test to rule out HCV infection and must be paired with anti-HCV Ab testing. A positive anti-HCV in the absence of detectable HCV RNA, however, can indicate either a resolved infection with HCV or a false positive result [11, 13]. If there is concern for a false positive anti-HCV, current CDC guidelines recommend repeat testing for anti-HCV with another Food and Drug Administration (FDA)-approved assay [13]. Although controversy exists around the use of organs other than the liver from a donor with anti-HCV Ab positivity; donation may be considered in cases where the recipient is severely ill or who have prior infection with HCV with appropriate informed consent [4].

5.3.1.3.2. Human Immunodeficiency Virus

Screening for HIV infection should be performed using a fourth-generation antigen/antibody combination immunoassay which detects both HIV-1 and HIV-2 and must be performed within 28 days of donation [5, 6, 14]. This test identifies antibody directed against HIV type 1 and HIV type 2 as well as the presence of HIV-1 p24 antigen, a protein shed into the blood stream during periods of active viral replication. Shedding of p24 antigen typically occurs at high levels shortly after initial HIV infection and may be detectable 7–10 days prior to antibody [15]. Screening with a fourth-generation antigen/antibody combination test results in a significant shortening of the window period prior to seroconversion, increasing the sensitivity of acute HIV detection [14].

If a potential donor is identified as high risk for HIV infection, HIV nucleic acid testing (HIV NAT) should also be performed to increase the sensitivity of diagnosis [6]. HIV NAT is the first detectable biomarker in acute HIV infection, preceding the appearance of p24 antigen by several days [16]. If the initial combination HIV-1/2 antigen/antigen test is positive, supplemental testing with an HIV1/2 differentiation assay should be performed to exclude the possibility of a false positive screening test and to differentiate HIV-1 from HIV-2 infection [14]. Due to the detection of p24 antigen, donors with acute HIV-1 infection may have a reactive HIV1/2 antigen/antibody screening test prior to the development of HIV-1-specific antibody. Therefore, discrepancies between

the results for the initial HIV 1/2 antigen/antibody test and the HIV 1/2 differentiation assay should be resolved with HIV NAT testing [14]. Donors who test positive for HIV are excluded from donation [5, 17].

5.3.1.4 Hepatitis B Virus Screening

For HBV, testing for both Hepatitis B surface antigen (HBsAg) and Hepatitis B core antibody to both IgM and IgG (anti-HBc) should be performed. The presence of these markers is highly sensitive for the detection of active HBV infection [4–6, 18]. Unlike HCV and HIV screening, HBV nucleic acid testing (HBV NAT) is not routinely performed in donors from countries with low endemic rates of HBV infection as the additional benefit of HBV NAT testing appears to be small [19]. In instances when anti-HBc alone is positive, further testing for HBV should be performed with a hepatitis B nucleic acid testing (HBV NAT). The detection of HBV DNA in this setting should be considered diagnostic of active HBV infection. Potential living donors who are positive for HBsAg are excluded from donation [5]. The decision to use an organ from a positive anti-HBc donor regardless of HBV DNA testing is a complex decision often made on a case-by-case basis. Testing must be performed within 28 days of donation [5].

5.3.2 Donor Screening: Deceased Donors-Routine Testing

In the United States, pretransplant diagnostic testing for deceased donors is performed by organ procurement organizations (OPO's) for all transplant programs in a given Donation Service Area (DSA) [5]. As with living donors, all laboratory testing must be completed in CLIA-certified laboratories or in one which meets the same standards as determined by the Centers for Medicare and Medicaid Services using FDA-licensed or -approved tests [5]. In general, deceased donor screening is similar to the approach described for living donors. Testing for CMV, EBV, syphilis, HIV, HBV, HCV is required and is the same as that described above for living donors [5, 6]. In addition, blood cultures and cultures from the harvested organ (i.e., Urine from donor kidney or sputum and/or bronchoalveolar lavage fluid (BAL) from the donor lung) should be performed at the time of transplantation [4, 5]. This is done to assess for active infection as well as colonizing flora which could result in invasive infection after transplantation [4]. In the case of potential deceased heart donation, antibody testing for *Toxoplasma* IgG must be performed given the potential development of this infection from seropositive donors after transplantation [4]. Donor screening for toxoplasmosis in noncardiac donors is not required [4].

5.3.3 Donor Screening: Optional Testing in Donors

Although the rationale for the routine testing detailed above identifies the most common donor-derived pathogens, there are many other less common latent infections that can be transmitted by the donor to the recipient at the time of transplantation. The presence of these latent infections is largely determined by the donor's epidemiologic exposure. A thorough history from the donor or a close family member is essential in determining these epidemiologic risk factors which can then allow for further targeted diagnostic testing. The most common of these pathogens include *Mycobacterium tuberculosis*, *Strongyloides stercoralis*, *Trypanosoma cruzi*, *Histoplasma capsulatum*, *Coccidioides immitis*, Human T lymphotrophic virus-1 (HTLV-1), and West Nile virus.

5.3.3.1 Mycobacterium tuberculosis

Current OPTN policies recommend testing for*Mycobacterium tuberculosis* (TB) in living donors if a potential donor is considered to be at increased risk for latent infection and the American Society of Transplantation recommends testing for TB in all living donors regardless of the donor's individual risk [4, 5]. Testing should be performed using either the Mantoux tuberculin skin test (TST) or an interferon-gamma release assay (IGRA) [4, 5, 20]. A two-stage TST in which a negative TST result is repeated 1–3 weeks later, can be performed in living donors from TB endemic regions [4, 20]. The TST measures a delayed hypersensitivity reaction to the presence of purified TB protein derivative in those infected with TB whereas the IGRA measures the cellular immune response to TB proteins through the release of interferon-gamma (IFN-γ) [21]. Both TST and IGRA have sensitivities ranging between 80 and 90% [21]. IGRA testing does have an increased specificity for the diagnosis of TB infection as it does not cross react with Bacillus Calmette-Guerin (BCG) vaccination as compared to the TST [21]. Neither test seems to be superior for the diagnosis of TB in immunosuppressed individuals [21]. In a living donor, a positive TST or IGRA must be followed by additional testing to assess for active TB infection [4, 21]. While TST cannot be performed in deceased donor blood [22], IGRA testing can be performed, however, the utility of these tests have not been studied in this population and therefore cannot be used solely to determine the overall TB risk [22]. Furthermore, the time constraints associated with potential deceased donation make IGRA testing impractical as results will often not be available by the time the decision for donation is made [4]. Latent TB infection in both living and deceased donors is not a contraindication to donation although active infection in a living or deceased potential donor is a cause for exclusion [4].

5.3.3.2 *Strongyloides stercoralis*

Donor-derived transmission of parasitic infections has been well documented in the posttransplant setting. *Strongyloides stercoralis* is a common parasite found in tropical climates that can live latently within an asymptomatic potential donor [23]. Although rare, donor-derived transmission of this infection can result in significant morbidity and mortality to the recipient [23]. Potential donors with epidemiologic risk factors for *Strongyloides stercoralis* should be screened for this infection prior to donation. The preferred screening method is serology with enzyme-linked immunosorbent assay (ELISA) for IgG antibody as this has a greater sensitivity and specificity for the detection of the organism as compared to other methods [23, 24]. Stool examination for *Strongyloides stercoralis* ova can also be performed but is not recommended given its significantly lower sensitivity [23]. It may be considered when antibody testing cannot be performed. A positive test for *Strongyloides stercoralis* is not a contraindication to donation in potential living donors but would require treatment prior to donation [23]. A positive test in deceased donors is also not a contraindication to donation but would require treatment in the recipient following transplantation.

5.3.3.3 *Trypanosoma cruzi*

Trypanosoma cruzi is another parasitic infection that can be transmitted from donor to recipient at the time of transplantation. Endemic in Central and South America, infected individuals develop chronic infection which is often asymptomatic [23]. Screening of all potential donors who have lived in an endemic region is recommended and is often done with serology testing [23]. There are currently several FDA-cleared tests for the identification of latent infection in potential donors. A positive test for *T. cruzi* is a contraindication to cardiac donation but not for other organ donations [4].

5.3.3.4 *Endemic Fungal Infections*

Donor-derived transmission of endemic fungi such as *Histoplasma capsulatum* and *Coccidioides immitis* is an uncommon occurrence in the posttransplant setting, however, when transmission occurs, morbidity and mortality is high [4, 23]. Due to overall low rates of transmission, routine testing for *Histoplasma* in potential candidates from endemic regions is not recommended [25]. Potential living donors from endemic areas who have a history of histoplasmosis or a pneumonia of unclear etiology within the past 2 years, however, should undergo diagnostic testing [25]. Serologic testing with the use of immunodiffusion assay or complement fixation is recommended with the identification of an H precipitin band on immunodiffusion assay or a complement fixation titer of ≥1:32 being diagnostic of active infection [23, 25]. The identification of an M precipitin band on immunodiffusion or complement fixation titers <1:32 are less specific for active infection and may indicate past infection with a low risk for transmission [23, 25]. Outside the setting of suspected active *Histoplasma* infection, serum or urine *Histoplasma* antigen testing has limited utility and should be avoided as a screening test in the asymptomatic living donor. Potential deceased donors from endemic regions with symptoms suggestive of histoplasmosis should undergo organ examination for signs of infection [25]. If present, tissue for fungal histopathology and culture as well as serum *Histoplasma* serology and antigen assay should be performed [25]. Active disseminated infection in a potential donor is a contraindication to donation, however in deceased donors, identification of this is often made after transplantation [4, 25].

The majority of patients with transmissible *Coccidioides immitis* infection are asymptomatic [23]. Therefore, potential living donors from endemic regions should be screened with serologic assays in combination with chest imaging [25, 26]. Multiple serologic assays are available including enzyme immunoassay (EIA), complement fixation (CF), and immunodiffusion (ID) [25]. Detection of IgG antibody via immunodiffusion has the highest specificity for diagnosis but has a lower sensitivity than other assays particularly early in infection [25]. Potential living donors with a positive serological test should then undergo further evaluation and testing to identify the degree of infection including cultures, imaging, and cerebrospinal fluid (CSF) studies depending on the clinical situation [25]. Active infection in a potential living donor is a contraindication to transplant until treatment has been completed [25]. Potential deceased donors from endemic areas should undergo organ examination followed by cultures, fungal histopathology, and serologic testing. Active known *Coccidioides* infection in a potential deceased donor is a contraindication to transplant, however, diagnosis is often made after transplantation [27].

5.3.3.5 *Human T-Cell Lymphocytic Virus-1*

Human T-cell lymphocytic virus-1 is endemic in parts of the Caribbean, Japan, and West Africa. Donor-derived transmission of HTLV-1 is a rare but potentially serious complication in SOT. Due to the overall low seroprevalence of this virus in the United States, routine testing of potential donors is no longer performed [4]. Optional screening of potential donors at risk for asymptomatic HTLV-I infected, however, can be performed using FDA-approved screening tests for HTLV-1/2 [26, 28]. These are combined serologic screening tests for both HTLV-I and HTLV-II [26, 28]. One limitation to testing is that the currently available assays are unable to

distinguish between HTLV-I and HTLV-II infection [26]. As HTLV-II has never been determined to cause human disease, being able to distinguish between these two entities is clinically important [26]. Therefore, a positive initial assay should always be confirmed by a virus-specific western blot or line immunoassay [26]. The presence of known HTLV-I in a potential donor results in exclusion from donation [4].

5.3.3.6 West Nile Virus

Donor-derived transmission of West Nile Virus (WNV) has been documented in SOT. Targeted testing of potential living donors in locations of WNV activity and during time periods when transmission is thought to be high can be performed [29]. WNV nucleic acid testing (WNV NAT) is the preferred diagnostic testing strategy and ideally should be performed using an FDA-approved WNV NAT, within 2 weeks of donation [28, 29]. Serologic testing for IgM to WNV is also available but is not an FDA-approved screening test as it has not been studied for this indication [29]. It can be considered as a supplemental test to WNV NAT to increase the sensitivity of WNV detection [29]. Overall, the false positive rate of WNV NAT is low, however, if a false positive is suspected, repeat WNV NAT using another NAT can be performed [29]. Potential living donors with a positive test for WNV should be excluded from donation [4]. Potential deceased donors with symptoms suggestive of WNV should also undergo NAT testing and if there is clinical suspicion of infection, they should be excluded from organ donation [4].

5.3.4 Recipient Screening: Routine Testing

For potential SOT recipients, routine pretransplant diagnostic testing for the following infections is recommended: CMV, EBV, HIV, HBV, HCV, syphilis, TB, varicella (VZV), hepatitis A (HAV), measles, mumps, and rubella (MMR) [4]. Testing strategies for CMV, EBV, HCV, syphilis, and TB are the same as those described above for potential donors. For HBV screening in the potential recipient, anti-HBs testing in addition to HBsAg and anti-HBc to assess for potential immunity is recommended. Potential recipients who are seronegative for HBV should undergo vaccination prior to transplant [4]. VZV screening should be performed using standard serological techniques for the detection of IgG antibody to determine if vaccination is needed prior to transplantation. It should be noted, however, that these assays have a low sensitivity for the detection of vaccine-induced immunity and can lead to false negative reports in those previously vaccinated [30]. ELISA-based assays are preferred given their higher specificity for the detection VZV immunity in order to prevent false positive results [30, 31]. Diagnostic testing for HAV and MMR should be performed using standard commercially available serologic assays in all potential recipients to assess for immunity [4]. Seronegative individuals should receive vaccination prior to transplantation if there are no contraindications [4]. In all individuals being considered for heart transplantation, testing for anti-*Toxoplasma IgG* must be performed given the potential development of this infection after transplantation [4]. Serologic methods as described above in deceased donor screening are recommended. Finally, screening of the potential SOT recipient for active infection and multi-drug-resistant colonizing flora through the use of standard culture techniques or NAT is often done prior to transplantation [4].

The development of CMV infection is one of the most common infectious complications of transplantation. As mentioned in the section on donor screening, testing is performed using anti-CMV IgG due to its improved specificity for detection of latent infection [7]. Assays that measure CMV IgM should not be used due to the poor specificity. Careful interpretation of anti-CMV IgG results is required as false positive results have been reported in individuals with multiple blood transfusions or in children less than 1 year of age from passive transfer of anti-CMV IgG antibodies [7, 32]. Whenever possible, a pretransfusion blood sample is best for testing [7]. If pretransfusion testing is not possible and/or equivocal results persist in the potential recipient, the result should be interpreted so as to ascribe the highest CMV risk to that individual based on the donor's CMV serostatus [7]. In children less than 1 year of age, CMV culture or NAT of numerous mucosal sites should be performed to help decipher any equivocal findings [7].

5.3.5 Recipient Screening: Optional Testing

Individuals at risk for *Strongyloides stercoralis*, *Toxoplasma gondii*, *Trypanosoma cruzi*, HTLV-1, and *Coccidioides immitis* should be screened as previously described [4]. Pretransplantation screening for *Histoplasma capsulatum*, however, is not recommended given the tests low sensitivity for the detection of latent infection in potential recipients [4]. Diagnostic testing for HTLV-I can also be performed and follows the recommendations previously described above [4].

5.4 Pretransplant Testing in Hematopoietic Stem Cell Transplant

5.4.1 Donor Screening: Routine Testing

The Food and Drug Administration (FDA) currently requires that all potential HSCT donors be screened for CMV, HIV, HBV, HCV, syphilis, HTLV-I/II, and WNV [33]. Testing for HIV, HBV, HCV, syphilis, and HTLV-I/II is also supported

TABLE 5-2. Pretransplant diagnostic testing in hematopoetic stem cell transplant donors and recipients

		Donor		Recipient	
Organism	Test	Routine	Optional	Routine	Optional
CMV	IgG	X		X	
EBV	VCA IgG	X		X	
VZV	IgG[a]			X	
HSV-I/II	IgG			X	
HIV-I/II	AB or Ag/AB	X		X	
	NAT	X		X	
HBV	sAg	X		X	
	anti-HBc (IgM and IgG)	X		X	
	anti-HBs			X	
	NAT	X			X[b]
HCV	Anti-HCV	X		X	
	NAT	X		X	
HTLV-I/-II	IgG	X		X	
WNV	NAT[c]	X		X	
Syphilis	RPR or TP-EIA	X[d]		X	
TB	TST or IGRA[e]				X
T. cruzi	IgG		X		X
Strongyloides	IgG[f,g]		X		X
Toxoplasma	IgG		X		X
Malaria	Malaria rapid antigen[h]				X
Ehrlichia	IgG[i]		X		
Anaplasma	IgG[i]		X		
Coxiella	IgG[j]		X		
Babesia	Blood smear light microscopy or PCR		X		
Rickettsia rickettsii	IgG[j]		X		

[a]ELISA antibody assay preferred given its higher specificity for detection [29, 30].
[b]If HBsAg or anti-HBc is positive, HBV NAT should performed.
[c]WNV IgM testing is not FDA-approved for screening but can be performed to increase the sensitivity of WNV detection [28].
[d]Potential donors with a positive RPR must have a TP-EIA performed to confirm the diagnosis [32].
[e]A two-stage TST can be performed in recipients from endemic regions [4, 19].
[f]ELISA antibody assay preferred for *Strongyloides* given its higher sensitivity and specificity [22, 23].
[g]Stool examination for ova can be performed if antibody assay is unavailable but is not recommended due to its low sensitivity [22].
[h]A negative malaria rapid antigen diagnostic test should be confirmed by thick and thin blood smear examination [40, 41].
[i]For *Ehrlichia* and *Anaplasma,* an immunofluorescence assay is recommended with a fourfold increase in titer being diagnostic [37].
[j]Serology for *Coxiella* and *Rickettsia* using indirect immunofluorescence antibody is preferred [37, 38].

by the American Association of Blood Banks (AABB) [34] (Table 5-2). For HIV, either a third generation test for HIV-1/2 antibody or a fourth generation antigen/antibody combination immunoassay for HIV-1/2 as well as HIV NAT is recommended [33, 34]. For CMV, HCV, and HTLV-I/II the diagnostic methods described in the section on SOT donor screening should be used [33]. For HBV, the FDA requires anti-HBc and HBsAg testing whereas the AABB also recommends HBV NAT testing to assess for HBV infection [33, 34]. Detection of HBV DNA by NAT is diagnostic for HBV infection although a single negative (undetectable) NAT result is not sufficient to rule out this infection. Potential donors who test positive for HIV or HTLV-I/II on initial screening tests are excluded from donation [33]. Potential donors who test positive for HBV (a positive HBsAg, anti-HBc or HBV NAT) and HCV are generally excluded from donation although in some situations exceptions may be made [33]. Confirmatory testing for these viruses can and should be performed in relation to the donor but will not change the outcome of donor ineligibility [33].

CMV seropositivity is not a contraindication to donation but does inform prophylaxis or monitoring strategies in the recipient following transplantation [33]. For syphilis screening, either a non-treponemal antibody test such as the RPR or a treponemal antibody test such as the TP-EIA can be performed [33]. Potential donors with a positive treponemal-specific antibody test are excluded from donation whereas due to the low specificity of non-treponemal antibody assays,

those with an initial positive non-treponemal antibody test but a negative confirmatory treponemal antibody test are not excluded [33]. Testing must be performed within 30 days of donation for stem cell and bone marrow transplantation and within 7 days for umbilical cord blood transplantation [2]. For WNV, WNV NAT as described in the section on screening of SOT donors should be performed on all potential donors [29]. Potential donors who test positive for WNV should be deferred from donation for 120 days [35]. Although not required by the FDA, screening for EBV infection with the use of VCA IgG is often performed to assess for risk of posttransplantation proliferative disorders.

5.4.2 Donor Screening: Optional Testing

As with SOT, transmission of other less common latent infections from a potential HSCT donor can have significant consequences in the recipient posttransplantation. Pretransplantation screening for these infections includes a thorough history to identify epidemiological risk factors in the potential donor. If risk factors are identified, further diagnostic testing is then performed.

Similar to SOT, *Trypanosoma cruzii* transmission has been described in HSCT donation and therefore, serologic testing using an FDA-approved assay should be performed in potential donors from endemic regions [2, 36]. Potential donors who are repeatedly seropositive on a screening assay are deferred from donation regardless of the results of confirmatory testing [36].

Potential donors with symptoms suggestive of active *Mycobacterium tuberculosis* should be evaluated fully for evidence of infection and excluded from donation if a diagnosis of active TB is made [2]. Latent TB in a potential donor, however, is not a contraindication to donation as the risk of transmission is minimal [2]. Therefore, routine screening of potential donors with risk factors for latent TB is not recommended [2].

Pretransplantation screening of potential donors for malaria is recommended in those who have resided or travelled to an endemic area [2]. Initial screening involves a careful history. Potential donors with a history of travel to an endemic area should be deferred from donation for 1 year from return and those who have resided in a malaria endemic region should be deferred from donation for a 3-year period [2]. Diagnostic testing for asymptomatic malaria infection in potential donors with potential exposure is not recommended as the likelihood of detecting parasitemia during dormant disease is exceedingly low [2, 34].

Pretransplantation screening for *Toxoplasma gondii* can be performed in potential donors with risk factors as asymptomatic transmission to recipients has been reported [2, 37]. Antibody testing as described in the screening of SOT donor section is the preferred diagnostic tool. Potential donors with acute infection should be deferred from donation, however, past or latent infection is not a contraindication to donation [2].

Although no current FDA guideline exists, testing for tick borne illnesses such as *Ehrlichia*, *Anaplasma*, *Coxiella*, *Babesia*, and *Rickettsia rickettsii* can also be considered in potential donors residing in endemic areas. The diagnosis of Babesiosis can be made either with detection of the parasite directly on thick and thin blood smear examination or through nucleic acid amplification of the *Babesia* 18s rRNA gene through polymerase chain reaction (*Babesia* PCR) [38]. Potential donors with either evidence of *Babesia* or a past history of infection should be deferred per AAAB recommendations. NAT is the most sensitive way to make the diagnosis of *Ehrlichia* and *Anaplasma*; however, serologic testing using immunofluorescence assay (IFA) remains the test of choice with a fourfold increase in IgG antibody indicating active infection [38]. For *Coxiella,* serology through indirect immunofluorescence methods is the diagnostic study of choice [38]. For *Rickettsia rickettsii* or Rocky Mountain Spotted Fever (RMSF) diagnosis is often made based on clinical features and epidemiology [39]. Serologic testing using indirect immunofluorescence antibody (IFA) can be performed and it has been shown to have a 94–100 % sensitivity for the diagnosis of RMSF after 2 weeks of onset of symptoms [39]. Sequential serologic testing looking for acute and convalescent titers is the recommended approach [39]. There is no formal recommendation from the FDA or the AABB regarding deferment of potential donors with active infection with *Coxiella*, *Ehrlichia*, *Anaplasma*, or *Rickettsia rickettsii* although most would recommend deferment until resolution of illness [40].

5.4.3 Recipient Screening: Routine Testing

Pretransplantation screening of potential HSCT recipients for CMV, EBV, Herpes Simplex Virus (HSV), VZV, HBV, HCV, HIV, and syphilis is recommended [2, 37]. Testing for WNV and HTLV-I/II is also often routinely performed by blood banks. Testing for CMV, EBV, HCV, HIV, syphilis, WNV, and HTLV-I/II should follow the testing methods outlined in the section on diagnostic methods for SOT donors. Testing for VZV should follow the methods outlined in the section of diagnostic methods for SOT recipients. For HBV screening, HBsAg, anti-HBc, and anti-HBs should be performed [2]. If a recipient tests positive for anti-HBc or HBsAg, nucleic acid testing (HBV NAT) should then be done [2]. For HSV, IgG serology for HSV should be performed using standard serologic methods; type specific anti-HSV IgG is not required [2]. Positive serologies for any of the above latent infections are not a contraindication to HSCT but do inform the physician regarding potential reactivation risk in the recipient and allow for the implementation of appropriate monitoring or prophylactic strategies.

5.4.4 Recipient Screening: Optional Testing

Similar to SOT recipients, potential HSCT recipients may also harbor other latent infections at the time of transplantation depending on their epidemiologic exposure risk. For TB, routine diagnostic testing of all potential recipients for *Mycobacterium tuberculosis* is controversial. Those with risk factors for TB, should be screened using the diagnostic methods previously described in the SOT section [2]. Transplantation of a potential recipient with active TB should be deferred until the infection is controlled whereas latent infection should not delay transplantation [2].

Reactivation of parasitic infections has been well documented in HSCT recipients. For example, reactivation of *Toxoplasma gondii*, *Strongyloides stercoralis*, and *Trypanosoma cruzii* have all been described. For *Toxoplasma*, potential recipients with risk factors for latent infection should be screened using IgG antibody testing [2, 37]. For *Strongyloides*, screening using antibody testing as described in the section on SOT is the preferred diagnostic method [2]. Stool examination for ova and parasite is not recommended due to its low sensitivity but can be performed if antibody testing is not available [2]. In that setting, at least three stool samples should be evaluated to increase the sensitivity of detection [2, 37]. Testing for *Trypanosoma* follows those diagnostic methods previously outlined in the SOT section.

Pretransplantation screening of potential recipients for malaria is recommended in those who have resided or travelled to an endemic area [2]. Initial diagnosis should be made through the use of a Malaria Rapid antigen diagnostic test which detects the presence of both a *Plasmodium falciparum*-specific antigen and a pan malaria antigen found in all malarial species in whole blood of individuals with detectable malaria parasitemia [41]. The only currently FDA-approved Malaria Rapid Antigen diagnostic test has a 96 % sensitivity for the detection of *P. falciparum* and an 84 % sensitivity for non-*P. falciparum* infections [41]. Given the potential for false negative results, especially for the detection of non-*P. falciparum* species, the CDC currently recommends that all negative Malaria Rapid antigen diagnostic tests be confirmed by thick and thin blood smear examination [42]. Potential recipients who test positive for malaria should be treated prior to transplantation.

5.5 Diagnostic Testing After Transplant

Once transplantation has occurred, recognition of infection based on clinical symptoms becomes more difficult as the immune suppression used to induce immune tolerance also suppresses the immune systems response to infection. As a result, relying on the presence of fever or localizing symptoms is not adequate for the identification and localization of infection. Furthermore, the list of potential infectious pathogens is significantly larger after transplantation and ranges from common community or hospital-acquired organisms to opportunistic pathogens. Due to the morbidity and mortality associated with many of these infections, early and aggressive diagnostic testing is needed for prompt and accurate diagnosis. Although standard microbiologic testing remains the cornerstone of the diagnostic workup following transplantation, there are several diagnostic challenges and principles that are unique to the immunocompromised host including the role of serologic testing and the use of both direct detection antigen assays and highly sensitive NAT for diagnosing infection and assessing response to treatment.

5.6 Serologic Testing After Transplantation

Although serologic testing is central to the evaluation of the donor and recipient before transplantation, the use of serology for the diagnosis of active infection after SOT and HSCT is of limited value in these populations [43–45]. The attenuation of the immune response as a result of transplantation and the use of immunosuppressive medications make development and detection of antibody responses an unreliable predictor of active infection [43, 45]. For example, studies evaluating serial serology testing for CMV (both IgM and IgG) in SOT recipients failed to predict the development of active CMV disease and did not correlate with CMV viremia [44]. In general, serologic testing should be avoided following transplantation and instead direct detection of infectious pathogens through the use of staining techniques, culture-based methods, histopathology, antigen detection, or molecular methods is recommended.

5.7 Direct Antigen Detection of Infectious Pathogens

Microbiologic staining and culture-based methods as well as histopathology are the most common techniques used for direct pathogen detection in the posttransplant setting and remain the cornerstone of the diagnostic work up in patients with infectious symptoms. Direct antigen detection assays have also been developed to aid in the diagnosis of infectious pathogens in transplant recipients. These tests detect pathogen specific antigens through the use of antigen specific antibody binding and can be performed on various media including serum, bronchoalveolar lavage, CSF, and urine. Various methods are used and can provide either qualitative or quantitative results depending on the platform.

5.8 Nucleic Acid Testing After Transplantation

NAT for the direct detection of pathogens is routinely used in the diagnosis of primary infection or reactivation of latent disease in the posttransplant setting. Depending on the assay used, NAT can be performed directly on blood, urine or other body fluids. Although NAT can be used for the detection of many potential pathogens, it is most commonly employed in the diagnosis of active viral infection.

The use of NAT enhances the ability to detect pathogens with high sensitivity, often before clinical symptoms have developed. This capability allows for a preemptive monitoring approach in which NAT can be performed at regular intervals to identify and potentially treat infections prior to the development of clinical symptoms and disease [7]. This preemptive strategy has been studied for the monitoring of CMV infection following transplantation and is considered a reasonable approach for monitoring the recipient for viral infections including CMV and EBV [7, 46]. In addition to being a reliable tool for the diagnosis of both active and asymptomatic disease, quantitative NAT can also be used to monitor response to treatment and overall treatment duration for certain pathogens [47].

Despite the many advantages of NAT there are several notable disadvantages including high cost and interlaboratory variability. Since many laboratory-developed and commercially available assays were developed prior to the availability of international reference standards, comparison of values between platforms may be difficult. For example, prior to the advent of an international reference standard for CMV developed by the World Health Organization, significant interlaboratory variability had been well documented [7, 48, 49]. As not all nucleic acid assays have reference standards, being aware of the potential variability between laboratories is important in being able to interpret the results effectively.

Another potential challenge with NAT in the posttransplantation setting is differentiating low-level asymptomatic viral replication from clinical disease. Since the most common use of NAT following transplantation is to detect reactivation of latent virus, it is sometimes difficult to determine when a positive nucleic acid test is detecting the presence of low-level background viremia of unclear significance vs. active clinical disease [7, 50, 51]. Unfortunately, established guidelines for cut-off values for NAT have not been established for most infectious pathogens and interpretation is often required based on the clinical scenario. Serial monitoring of NAT, however, can be useful in this setting as significant increases in viral load can indicate the development of clinical disease. For example, for CMV, a greater-than-threefold increase in viral load level over a period of approximately 1 week has been associated with the development of clinical disease requiring treatment [7, 51].

5.9 Diagnostic Testing for Specific Infectious Diseases After Transplant (Table 5-3)

5.9.1 Bacteria

For the majority of bacterial infections, gram stain, culture, and histopathology from the site of presumed infection remain the preferred diagnostic tests. Other viable methods for the detection of bacterial pathogens include direct antigen detection assays and NAT. One example of a direct antigen assay is the urinary *Legionella* antigen test that can be used in addition to culture for the diagnosis of *Legionella* pneumonia [52]. These assays use either ELISA or lateral flow assay (LFA) to detect antigen to *Legionella pneumophila* serogroup 1 which accounts for the majority of infections with *Legionella* [53]. Multiple urinary antigen assays have been FDA-approved for the diagnosis of *Legionella* and a recent meta-analysis revealed a pooled sensitivity and specificity for these tests of 74 and 99 % [54]. A similar urinary antigen test has also been developed for *Streptococcus pneumoniae* detection; however, this test has a more variable sensitivity and specificity as compared to the urinary legionella antigen assays and does not differentiate colonization from active infection, particularly in children [52, 53, 55].

5.9.2 Mycobacteria

The diagnosis of active *Mycobacterium tuberculosis* (MTb) infection relies on microbiologic staining for acid-fast bacilli, culture, and histopathology from the site of presumed infection [56, 57]. Samples can be obtained from many potential sites including sputum (expectorated vs. induced vs. bronchoalveolar lavage), pleural fluid, gastric aspirate, urine, CSF, bone marrow, bone, or blood [56]. If noninvasive staining and culture techniques fail to yield a diagnosis, pursing biopsy for tissue staining, culture, and histopathology is recommended when possible. When pulmonary tuberculosis is suspected and sputum or induced sputum samples are to be used for diagnosis, at least three single specimens preferably collected on three separate days should be submitted so as to increase the sensitivity of detection [56, 58]. When bronchoscopy is pursued, a sputum sample obtained after the procedure is also recommended [56].

NAT has also been developed to aid in the diagnosis of tuberculosis including multiplex assays designed to detect the presence of MTb DNA as well as genetic mutations commonly associated with the development of rifampin resistance [59]. The sensitivity of MTb NAT is significantly enhanced in AFB smear positive individuals [60]. Use of MTb NAT in AFB smear negative respiratory specimens is less sensitive and if performed should be interpreted with caution. Despite the utility of these multiplex assays in the

TABLE 5-3. Laboratory diagnostics by organism

Organism type			Preferred diagnostic procedures

	Babesia microti	Microbiologic examination
		Histopathology
		NAT

[a]Multiple different growth media used depending on the type of bacteria expected.
[b]Urinary antigen test available for *Streptococcus pneumoniae* but sensitivity only 52–78 % in patients without bacteremia [53].
[c]Considered gold standard for diagnosis of *Legionella* pneumonia but sensitivity only 25–75 % [91].
[d]Detects *Legionella pneumophila* serogroup 1 only. Sensitivity and specificity are 74 % and 99 % respectively [92].
[e]Preferred over NAT testing. IgM antibody or convalescent serologies performed 2–3 weeks later can be performed [53].
[f]For suspected pulmonary tuberculosis, at least three expectorated or induced sputum samples obtained are required [54, 56].
[g]If bronchoscopy is performed, a sputum sample after the procedure should be obtained to increase detection rate [54].
[h]Detects MTb DNA and genetic mutations associated with rifampin resistance [58].
[i]For suspected pulmonary tuberculosis, three expectorated or induced sputum samples are recommended [59].
[j]Three currently FDA-approved probes: *Mycobacterium avium complex* (MAC), *Mycobacterium kansasii*, *Mycobacterium gordonae* [59].
[k]Sensitivity of nucleic acid probes range from 85 to 100 % with a specificity of 100 % [59].
[l]Considered gold standard for diagnosis of Candidemia but sensitivity only 50 % [61].
[m]Assay has 75 % sensitivity but lacks specificity for the diagnosis of invasive Candidiasis [62].
[n]False positives reported with hemodialysis, human blood products, certain antibiotics and bacterial infections, surgical gauze [61].
[o]Does not provide information on antifungal susceptibility and should not replace traditional diagnostic methods.
[p]Considered gold standard for diagnosis of invasive aspergillosis.
[q]Sensitivity 77–80 % but lacks specificity. Cannot be used primarily for diagnosis [62, 64, 65, 69, 76].
[r]Variable sensitivity depending on test characteristics, use of antifungals, type of *Aspergillus species*, population tested [60, 64, 67, 68].
[s]False positives reported with *Histoplasma* and *Fusarium species*, piperacillin-tazobactam, amoxicillin-clavulanate, cotton or cardboard, certain blood products, and certain intravenous hydration fluids containing sodium gluconate [60, 66, 69].
[t]Can be used for monitoring of serum galactomannan antigen testing for patients with HSCT [66, 67].
[u]91 % sensitive and 88 % specificity when an EIA cut-off value of ≥1.0 used [72].
[v]Considered gold standard for diagnosis and should be performed on induced sputum or BAL samples [73].
[w]95 % sensitivity and 86 % specificity and can serve as a rule-out test when pretest probability is low [60, 69, 76].
[x]NAT with an 87 % sensitivity and 92 % specificity of [75].
[y]Current gold standard for diagnosis with culture being positive in >90 % of patients with central nervous system involvement [77].
[z]Sensitivity of 97 % and a specificity ranging from 93 to 100 % [67, 78].
[aa]Serum cryptococcal antigen assays with lower and more variable sensitivity depending on the site of infection [67, 69].
[bb]Considered gold standard for diagnosis.
[cc]Urine antigen assays for histoplasmosis and blastomycosis with sensitivities of >90 % [81, 82].
[dd]Significant cross-reactivity has been seen across endemic fungi [60].
[ee]Performed weekly as a preemptive monitoring strategy or to diagnose active infection [7].
[ff]Can be used in monitoring response to treatment and treatment duration [46].
[gg]Tests using the international reference standard by the World Health Organization (WHO) recommended [7, 47].
[hh]Slightly lower sensitivity than NAT. Cannot be used in patients with neutropenia [7, 84, 85].
[ii]Serial monitoring of high-risk HSCT and SOT recipients is recommended [2, 7, 42, 83].
[jj]DFA with 77.8 % sensitivity and 99.6 % specificity with variability in these values depending on technician experience [86].
[kk]Many FDA-approved NAT tests with sensitivities greater than 90 % [87].
[ll]Due to low sensitivity, these assays should not be used to exclude infection in the transplant population [53].
[mm]Preferred diagnostic strategy due to superior sensitivity, specificity, and rapid turn-around time [88].
[nn]Due to low sensitivity, follow up testing with either NAT or viral culture is recommended with negative test results [88].
[oo]Sensitivity and specificity dependent on technician experience [53].
[pp]Often only available in reference laboratories [53].
[qq]Low sensitivity, repeated or serial samples recommended [53].
[rr]Not commercially available, only offered through the Centers for Disease Control (CDC) [89].
[ss]Sensitivity and specificity dependent on technician experience. Three separate samples recommended if clinical suspicion [53].
[tt]A negative rapid malaria antigen should be confirmed by blood smear light microscopy [40, 41].

diagnosis of pulmonary tuberculosis, these tests are generally not approved for use on non-respiratory samples and require extensive in-house laboratory validation before routine clinical use. Furthermore, a MTb nucleic acid test does not preclude the need for culture for formal identification and susceptibility testing [59].

For nontuberculous mycobacteria, microbiologic staining for acid-fast bacilli, culture, and histopathology from the site of presumed infection are also the recommended [61]. As with MTb, for presumed respiratory infection diagnosis, three separate sputum samples obtained from either expectorated or induced sputum is required [61]. Smear and culture can also be obtained from other samples such as blood, abscess cavities, bone marrow, and biopsy tissue. Whenever tissue is obtained, the specimen should also be sent for histopathological examination. Although final identification and susceptibility testing is largely determined based on culture, nucleic acid probes for the nontuberculous mycobacteria *Mycobacterium avium complex* (MAC), *Mycobacterium kansasii*, and *Mycobacterium gordonae*, have been approved by the FDA for the diagnosis of these organisms [61]. The sensitivity of these assays range from 85 to 100 % with a specificity of 100 % [61]. However, unlike MTb NAT that can be performed directly on primary specimen, these probes require growth (amplification) in culture before they can be used [61]. Furthermore, nucleic acid hybridization probes do not provide any information on drug susceptibilities.

5.9.3 Fungi

Microbiologic staining, culture, and histopathology remain the gold standard for diagnosis of invasive fungal infections in immunocompromised patients [62]. Unfortunately, these traditional methods can suffer from a low sensitivity depending on the location and type of fungal infection present, which can lead to significant delays in diagnosis and treatment. Newer diagnostic assays such as direct antigen assays and NAT have been developed for many different types of fungi and are can be helpful in the diagnosis of fungal infection in this population.

5.9.3.1 ***Candida***

For invasive infections with *Candida species*, the gold standard in diagnosis remains microbiologic staining, culture, and histopathology from the location of presumed infection. In cases of Candida blood stream infections (Candidemia) blood cultures should be sent on all patients as commercially available automated blood culture systems will detect growth of these organisms [52, 62]. Unfortunately, blood cultures are only 50 % sensitive for the diagnosis of Candidemia, leading to significant delays in diagnosis and treatment [63].

In an effort to improve the diagnosis of both Candidemia and other forms of invasive candidiasis, other diagnostic methods have been developed. Detection of β (beta)-D Glucan antigen, a cell wall component common to many fungal species including Candida, has been widely adopted as a surrogate marker for fungal infection. Although not specific for *Candida* infections, the β (beta)-D Glucan assay has been studied extensively for the diagnosis of invasive candidiasis. A recent meta-analysis of pooled studies revealed that the β (beta)-D Glucan assay had a 75 % sensitivity for the diagnosis of invasive candidiasis [64]. Although this sensitivity is higher than that of standard blood culture, issues surrounding the β (beta)-D Glucan assay's specificity make it a less attractive diagnostic tool. Furthermore, numerous false positive results have been reported in patients receiving hemodialysis, human blood products, and certain antibiotics as well as in patients with bacterial infections or those undergoing wound care with surgical gauze [63]. Finally, the β (beta)-D Glucan assay does not provide any information on antimicrobial susceptibility. Given these limitations, although a potential adjunct to the diagnosis of invasive candidiasis, the β (beta)-D Glucan assay should not replace the traditional diagnostic methods of microbiologic staining, culture, and histopathology.

5.9.3.2 Aspergillus

For invasive infection with *Aspergillus species*, the gold standard for diagnosis remains identification of the pathogen on histopathological specimens and growth in culture [62]. Unfortunately, the sensitivity of culture for the diagnosis of aspergillus is low and specimens for histopathological examination are often more difficult to obtain, leading to a high number of missed cases and significant delays in diagnosis and treatment [65]. For example, a recent study of bronchoalveolar fluid culture in immunocompromised patients with invasive pulmonary aspergillosis found a sensitivity of only 50 % and unlike *Candida*, the yield of blood culture for *Aspergillus* is very low [65]. To improve detection, many new direct antigen assays have been developed to aid in the diagnosis of invasive aspergillosis. One such assay is the β (beta)-D Glucan assay which has a sensitivity of 77–80 % for the diagnosis of invasive aspergillosis [64–66]. Similar issues with the specificity of this assay exist as for those with *Candida* infections, however, making it an unreliable tool for the diagnosis of invasive infection.

The *Aspergillus* Galactomannan antigen assay has also been developed for the diagnosis of invasive aspergillosis. This assay is a direct enzyme immunoassay (EIA) performed on serum that detects the presence of the cell wall component galactomannan which is specific to *Aspergillus species* [62, 67]. Numerous studies have shown a variable sensitivity of this assay for the diagnosis of invasive *Aspergillus* with

sensitivity ranging from 29 to 100 % depending on the test characteristics, the previous use of antifungals, the type of *Aspergillus species* present, and the population being tested [62, 65, 68, 69]. Specificity is significantly higher although cross-reactivity has been reported with other fungal organisms such as *Histoplasma* and *Fusarium species* [62]. False positive results have also been reported with certain antibiotics such as piperacillin-tazobactam and amoxicillin-clavulanate, contamination of a specimen with cotton or cardboard, certain blood products, and certain intravenous hydration fluids containing sodium gluconate [67, 70]. Serum galactomannan antigen testing is best performed as a preemptive monitoring strategy for patients with hematological malignancies and those who have undergone hematopoietic stem cell transplant as the performance of this test has been best validated in these groups [67, 68]. Studies evaluating the sensitivity of this assay in SOT recipients have not shown a benefit and routine screening using this diagnostic method is not recommended [70, 71]. Serum galactomannan antigen testing can also be used to aid in the diagnosis of active infection in transplant recipients with symptoms suggestive of invasive aspergillosis, however, due to its variable test characteristics, it cannot solely be relied on for definitive diagnosis in this patient population [72].

The *Aspergillus* galactomannan antigen assay can also be performed on BAL with improved sensitivity and specificity for the detection of invasive pulmonary aspergillosis. In patients with hematologic malignancies, the BAL *Aspergillus* galactomannan antigen assay was noted to be 91 % sensitive and 88 % specific when an EIA cut-off value of ≥1.0 was used [73]. Similar results have also been seen in patients with SOT with the BAL *Aspergillus* galactomannan antigen assay having a sensitivity of approximately 82 % [71]. False positive results can occur in the setting of colonization of the airways with both *Aspergillus* and non-*Aspergillus* species such as *Penicillium* and careful interpretation of the results based on the clinical setting is recommended [62].

Finally, many new additional diagnostic tests for the diagnosis of invasive aspergillosis are currently being studied and validated. These include lateral flow devices (LFD's), *Aspergillus* NAT, and a breath test evaluating *Aspergillus* specific volatile organic compounds (VOC's) [62]. Although initial studies appear promising, further research needs to be performed before considering their use in the routine clinical setting.

5.9.3.3 Pneumocystis jiroveci

The gold standard for diagnosis of *Pneumocystis jiroveci* (PCP) remains direct visualization of the organism in respiratory tract secretions or histopathology [74]. The most common staining technique used is the indirect IFA which uses *P. jiroveci* specific monoclonal antibodies [75]. Whenever possible, samples from induced sputum or BAL should be performed to increase the sensitivity of detection [74]. NAT has also been developed and studied for the diagnosis of PCP. A recent study looking at NAT on sputum samples from non-HIV immunocompromised patients indicated an 87 % of sensitivity and a specificity of 92 % [76]. Limitations include false positive results in the setting of colonization of the respiratory tract and careful interpretation of the results based on the clinical setting is always recommended. Finally, the β (beta)-D Glucan assay can also be used in the diagnosis of PCP as the organism produces β (beta)-D Glucan. A meta-analysis revealed that this assay has a 95 % of sensitivity and an 86 % of specificity for the diagnosis of PCP, indicating that the likelihood of infection with a negative test result is extremely low [62, 70, 77]. Given this, it can serve as a good test of exclusion when clinical pretest probability is low.

5.9.3.4 Cryptococcus species

Direct visualization of the organism with fungal stain and culture remains the gold standard for the diagnosis of Cryptococcus. Whenever possible, calcofluor fungal staining should be performed over India ink staining due to issues with the sensitivity and specificity of India Ink staining in the presence of CSF leukocytes [78]. Culture for Cryptococcus is positive in >90 % of patients with central nervous system involvement, however, growth on culture can take up to a week which can lead to delays in diagnosis and treatment [62, 79].

Several antigen assays for *Cryptococcus* are widely used for the rapid diagnosis of invasive cryptococcal infection. These assays can be performed on both serum and CSF and detect the presence of the polysaccharide capsule unique to *Cryptococcus* species [68]. Assay techniques include latex agglutination (LA) and enzyme immunoassay (EIA). CSF cryptococcal antigen testing is more sensitive and specific than that of fungal staining and culture with a sensitivity of 97 % and a specificity ranging from 93 to 100 % [68, 80]. Cryptococcal antigen assays can also be run on serum with a slightly lower and more variable sensitivity depending on the site of infection [68, 70]. False positives are rare but have been reported with other fungal species such as *Trichosporon* and with the bacterial species *Stomatococcus* and *Capnocytophaga* [81, 82]. False positives have also been reported with nonspecific binding of serum proteins (such as rheumatoid factor) and can be avoided with the treatment of serum with pronase. In addition, false positive results have occasionally been reported when samples have contacted certain soaps, disinfectants, and starches [70]. False negative results can occur in patients with high Cryptococcal antigen titers resulting in failure of agglutination between antigen–antibody complexes (prozone effect) [83].

This can be avoided through either the addition of pronase to serum or sample dilution if equivocal results are obtained [83, 84]. Overall, however, the CSF and serum cryptococcal antigen assays remain valuable diagnostic tools for the diagnosis of invasive cryptococcal infection. The β (beta)-D Glucan assay is not considered to be an appropriate test for the diagnosis of invasive cryptococcal infection as this cell wall component is not found in this organism [62].

5.9.3.5 Dimorphic Fungi

For the endemic fungi histoplasmosis, blastomycosis and coccidioidomycosis, diagnosis is made largely based on direct examination of the organism on fungal staining, culture, or histopathology. As with Cryptococcus, growth of these organisms can be slow and can lead to delays in diagnosis and treatment [62]. Direct antigen assays for histoplasmosis and blastomycosis have been developed and have been shown to have sensitivities of >90 % for the detection of disseminated infection [85, 86]. Multiple techniques are used including enzyme immunoassay, immunodiffusion, and complement fixation and can be performed on both serum and urine [62]. Significant cross-reactivity has been seen across the three different endemic fungi, however, limiting their overall usefulness in the clinical setting [62].

5.10 Viruses

For viruses, direct antigen detection methods and NAT are the preferred diagnostic screening strategies for patients in the posttransplant setting. Although serologic methods are commonly used in the pretransplant setting, these markers are unreliable in the setting of immune suppression and should not be used for routine diagnosis [43–45]. Both viral cell culture and histopathology can also be performed to aid in the diagnosis of viral infection although utility is limited by low sensitivity, prolonged turn-around time, and the need for more invasive procedures to obtain appropriate specimens [45]. Viral cell cultures from the urine and stool should not be performed as a positive culture often represents asymptomatic shedding and is not necessarily a marker of active disease [45].

5.10.1 CMV and EBV

For CMV and EBV, diagnosis in the posttransplant setting is most commonly made by direct detection of virus using NAT as these assays exhibit high sensitivity and specificity for the diagnosis of infection [43, 45]. Serial monitoring of high-risk HSCT and SOT recipients is recommended in those not receiving chemoprophylaxis so as to identify and treat infection prior to the development of significant disease [2, 7, 43, 87]. Limitations to NAT for CMV and EBV can be found under "Nucleic Acid Testing" in Sect. 5.8.

CMV infection in transplant recipients can also be reliably diagnosed through the use of CMV pp65 antigenemia. This test utilizes monoclonal antibodies to pp65 which can be found in CMV infected white blood cells and can provide a semiquantitative assessment of infectious burden [88]. Studies comparing antigenemia with CMV NAT have shown a slightly lower sensitivity as compared with NAT [89]. Advantages to this assay include its cost and rapid turn-around time [7, 88]. Limitations include its requirement for the presence of white blood cells preventing its use in neutropenic patients, lack of standardization of results, and significant skill and labor involved in processing and microscopy [7, 88]. It can also only be performed on blood whereas NAT testing can be performed on multiple specimen types.

5.10.2 Respiratory Viruses

For the respiratory viruses both direct viral antigen assays and NAT can be used for the diagnosis of infection. For respiratory syncytial virus (RSV), both direct fluorescent antigen testing (DFA) and NAT are the most commonly used diagnostic modalities in transplant patients. DFA has been shown to have 77.8 % sensitivity and 99.6 % specificity for the diagnosis of RSV with variability in these values depending on microscopist experience [90]. There are currently several RSV nucleic acid tests that have been approved by the FDA for use with sensitivities greater than 90 % [91]. It is important to note, however, that transplant recipients can shed virus in the nasal passages for a significantly longer period of time than immunocompetent hosts, requiring clinicians to depend on clinical pretest probability to differentiate active vs. past infection. Rapid RSV direct antigen assays which are typically performed as point of care tests with results within 30 min are also available but due to low sensitivity, these assays should not solely be used to exclude infection in the transplant population [52].

For influenza, NAT is the preferred diagnostic strategy for the diagnosis of infection due to its superior sensitivity, specificity, and rapid turn-around time [92]. Nasopharyngeal samples are most commonly obtained but deeper samples from the lower respiratory tract should be pursued in cases of severe, lower tract infection, due to increased sensitivity of detection of virus [93]. Limitations of NAT include its ability to identify only certain influenza strains felt to be the most prevalent during a given influenza season, leading to potential false negative results in instances of infection with uncommon strains. Direct fluorescent antigen testing is also available and can be performed when NAT testing is not

available [92]. As with RSV, similar issues with persistent viral shedding can occur in transplant recipients making it difficult to distinguish active from resolved or resolving infection. Although rapid influenza antigen detection assays are available for the diagnosis of influenza, given their reduced sensitivity for the detection of infection, follow up testing with either NAT or viral culture is recommended with negative test results [92].

For other respiratory viruses such as Parainfluenza, Adenovirus, and Human Metapneumovirus, both direct antigen detection assays and NAT can be considered for diagnosis of infections in the transplant population. Determination of which assay to use should be individualized by each institution depending on feasibility and cost.

5.11 New and Emerging Diagnostic Tools

Over the past 50 years there have been many new advances in the field of microbiology diagnostics which have transformed our ability to identify a multitude of organisms including bacteria, mycobacteria, viruses, and fungi. Compared to the standard diagnostic techniques which rely on organism growth and subsequent phenotypic identification, many of these new methods focus on the molecular signatures of pathogens through the recognition of microbial DNA, RNA, or proteins [94]. These new techniques can reduce the time to organism identification from initial specimen collection with increased sensitivity and specificity compared to standard methods, improving a physician's ability to make rapid and accurate clinical decisions for ill patients [94]. Many of these technologies have already been incorporated into routine clinical care and should be considered, if available, in the work up of the transplant patient.

Matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS) is a molecular technique that is now FDA-approved for the routine identification of bacteria and yeasts in clinical microbiology laboratories. This technique identifies bacteria and yeast through the ionization of the unique protein structure of each particular organism and measures the mass to charge ratio of each ionized subcomponent [95]. This measurement creates a unique protein signature specific to each organism that can then be compared against an extensive database of known and validated profiles ("spectra") [94, 95]. Studies have shown that MALDI-TOF MS can reliably provide identification at the genus, species, and subspecies level for a wide variety of organisms [96–100]. Analysis is typically performed as soon as colony growth of an organism has occurred and can reduce time to organism identification by 1–1.5 days compared to standard phenotypic methods [101]. Further advantages include its automation, relative ease of use, and its ability to perform high-throughput analysis [95, 102]. Finally, although the initial monetary investment in MALDI-TOF MS is high and laboratory implementation is time consuming; numerous studies have shown that long-term utilization of this technology is cost-effective compared to standard methods [100, 101].

Limitations of the MALDI-TOF include its reliance on an organism database for identification as organisms not present in the database will often not be identified or identified incorrectly [102]. Furthermore, current commercially available libraries are not approved for the identification of most mycobacteria and fungi, however, with time, this is expected to change and may dramatically shorten the time to identification of these traditionally difficult-to-identify organisms. Another limitation of MALDI-TOF MS is that some closely related bacteria may also be misidentified in certain instances [95]. Although research is ongoing, the MALDI-TOF MS currently does not perform susceptibility testing. Finally, despite the significant reduction in time to organism identification, the MALDI-TOF still requires pure culture of an organism and is not yet able to reliably detect organism directly from primary clinical specimens [102].

Molecular diagnostic techniques have also been developed for organism identification directly from positive blood culture specimens without the need for additional subculture and colony growth. The general concept is that nucleic acid amplification occurs with microbial growth and therefore these assays take advantage of novel detection strategies. One technique which has been developed to detect common bacterial pathogens as well as common antimicrobial resistance genes is a nanoparticle microarray assay which can directly be performed on positive blood cultures [103–105]. Divided into panels, these automated assays have shown to have a >90 % concordance rate compared to standard identification and susceptibility techniques [103, 104]. Furthermore, time to result with these assays is shorter than that of standard methods, resulting in significant reductions in time to organism identification and initiation of appropriate antimicrobial therapy [106]. Despite these promising results, there are some limitations to these assays, particularly with polymicrobial infections. In addition, these assays only test for several common bacterial pathogens and resistance markers, requiring the need for further subculture, identification, and susceptibility testing to identify less common bacterial pathogens. For these reasons, these assays are only approved to provide "preliminary" results and must still be confirmed by standard microbiological identification and susceptibility methods [102].

New diagnostic methods are also available for the detection of pathogens from direct clinical samples without the need for growth in the primary specimen or subculture. As

with the above microarray techniques, these tests rely on the identification of pathogen specific DNA or RNA through multiplexed nucleic acid amplification and detection. Although single organism identification NAT's are available and commonly used, newer platforms have been developed which allow for the detection of multiple pathogens in a single sample [91, 107–109]. Multiple FDA-approved platforms are available for the detection of enteropathogens in stool samples and respiratory viruses in nasopharyngeal samples [91, 107–109]. The main advantages to these assays include their high sensitivity and specificity as well as their ability to be run directly on primary specimen, leading to a result time of only hours from specimen collection [108]. This reduced turn-around time is invaluable to clinicians as it can lead to timely management decisions for ill patients. Limitations of the multiplex assays include the high cost and labor requirements as batch testing of samples is not currently available for all assays.

Finally, a technique using magnetic resonance and nanoparticle NAT technology has recently been FDA-approved for the diagnosis of Candidemia. As with the multiplex assays, this technology has the ability to detect five common *Candida* species directly on whole blood without the need for growth in the primary specimen or subculture [110]. Studies have shown that this assay has a rapid turn-around time and a sensitivity and specificity of 91 and 99.4 % for the detection of Candidemia [110]. Although this assay is highly sensitive, routine blood cultures must still be obtained to exclude other diagnoses. Furthermore, this assay does not directly detect antifungal drug resistance. In some cases, however, susceptibility information can be inferred based on organism identification (example, identification of *C. krusei* infers azole resistance).

5.12 Summary

The diagnosis of infectious diseases in the transplant patient requires an extensive evaluation of both the donor and the recipient prior to transplantation as well as a solid understanding of the risk factors present after the procedure. By understanding these factors, a comprehensive differential diagnosis can be made and the appropriate diagnostic testing and treatment can then be initiated. Prompt diagnosis often requires the use of early and aggressive diagnostic testing from a multitude of different diagnostic modalities including microbiologic staining, culture, histopathology, direct antigen detection, and molecular-based techniques such as NAT. By understanding the utility of each of these different diagnostic strategies in different clinical situations, more rapid and accurate diagnoses can be made leading to improvement in treatment and outcomes in this patient population.

Part II
Risks and Epidemiology of Infections After Transplantation

6
Risks and Epidemiology of Infections After Hematopoietic Stem Cell Transplantation

Juan Gea-Banacloche

6.1 Introduction

Understanding the epidemiology of infections after allogeneic hematopoietic stem cell transplantation (HCT) is important to implement appropriate preventive strategies as well as to effectively diagnose and treat individual patients.

Several groups of experts and professional organizations publish guidelines that provide specific recommendations for prophylaxis and management of infections after HCT [1–8], including vaccinations [1, 9, 10]. Many of these recommendations are necessarily based on low-quality evidence and rely heavily on expert opinion. Guidelines should not be followed blindly, but understood as tools that may help to provide the best possible care.

Risk factors for infection include individual characteristics (e.g., indication for HCT, prior infections, CMV serostatus, particular genetic traits) and type of transplant (based on conditioning regimen, stem cell source, degree of HLA homology, and immunosuppression). The development of graft-versus-host disease (GVHD) is frequently the decisive contributor to infectious morbidity and mortality.

6.2 Individual Characteristics and the Risk of Infection

Different indications for HCT are associated with their own infectious risks. Primary immunodeficiencies (PID), hemoglobinopathies, and hematologic malignancies present different challenges. Even in hematologic malignancies, the risk may vary depending on the specific condition: patients with chronic myelogenous leukemia (CML), acute myeloid leukemia (AML), and chronic lymphocytic leukemia (CLL) present different risks based on both the biology of the disease and prior treatment. These factors should be considered when assessing individual patients.

Prior infections must be considered. A history of infection or colonization with a multidrug-resistant organism (MDRO) like carbapenem-resistant enterobacteria (CRE), extended-spectrum beta-lactamase (ESBL)-producing Gram-negative bacteria, vancomycin-resistant enterococcus (VRE), or methicillin-resistant *Staphylococcus aureus* (MRSA) has implications regarding optimal management of fever during neutropenia [6, 11, 12], which is a common complication of HCT. Transplant candidates are routinely screened for serologic evidence of latent infections that may reactivate (HSV, VZV, CMV, EBV, hepatitis B and C, toxoplasmosis); some of these will be discussed later in this chapter. Some transplant centers will perform screening for tuberculosis with tuberculin skin test (TST) or interferon-gamma release assay (IGRA), at least for patients who are considered at significant risk for the disease. Prior invasive fungal infections may reactivate following transplant, and secondary prophylaxis is required [13–15]. Even active fungal infection has been reported to be controllable. There are, however, cases of progression of prior aspergillosis after transplant; myeloablative conditioning, prolonged neutropenia, cytomegalovirus (CMV) disease, and graft-versus-host disease (GVHD) are risk factors [15, 16].

As the correlates of native and adaptive immunity are better understood, genetic associations are coming to light. There is evidence that some donor haplotypes of *TLR4*, the gene that encodes the toll-like receptor protein 4 (TLR4) are associated with increased risk of invasive aspergillosis after HCT [17]. Recipient's mutations in *MBL2*, the gene that encodes mannose-binding lectin (MBL), have been associated with increased risk of infection after neutrophil recovery following myeloablative transplant [18]. Other polymorphisms of *MBL2* may be important for infection through a direct influence on the risk of developing GVHD [19, 20]. Different genotypes of activated killer immunoglobulin-like receptors (aKIR) in the donor have been found to protect from CMV reactivation [21]. Many of these associations are preliminary and require more data to be confirmed, but they hold the promise of a more individualized approach to infectious prophylaxis.

P. Ljungman et al. (eds.), *Transplant Infections*, DOI 10.1007/978-3-319-28797-3_6

6.3 Time Course of Infections After Allogeneic Stem Cell Transplantation

From a practical standpoint, it is helpful to consider three distinct periods during transplant: pre-engraftment (until neutrophil recovery), early post-engraftment (from engraftment until day 100), and late post-engraftment (after day 100). This framework originated with myeloablative transplants, and is eminently pragmatic. The pre-engraftment phase may be accompanied by profound neutropenia and significant mucositis, which results in increased risk of bacterial infections from the resident gastrointestinal flora, candidiasis, aspergillosis (in cases of prolonged neutropenia) and herpes simplex virus reactivation. After engraftment, with neutropenia no longer being a factor, many infections are related to the profound defect in cellular immunity caused by the conditioning regimen and the immunosuppression administered to prevent GVHD. CMV reactivation and the development of acute GVHD and its treatment play a central role during this time. The day 100 landmark derives from the standard time at which immunosuppression (e.g., cyclosporine A or tacrolimus) is frequently tapered. Infections after this point would be primarily related to lack of immune reconstitution and, in the absence of GVHD, become progressively less common.

6.4 Types of Allogeneic Hematopoietic Stem Cell Transplantation (HCT)

Not all allogeneic stem cell transplantations are the same. Several characteristics of the transplant influence the risk of infection: the conditioning preparative regimen, the source of stem cells, the degree of HLA identity between donor and recipient, and the prophylactic strategy adopted to prevent GVHD (use of T cell depletion or immunosuppressive medications). Table 6-1 summarizes the impact of these factors on infections.

TABLE 6-1. Type of transplant and infectious disease risk

Factor	Type of transplant	Risk of infection
Conditioning regimen	Myeloablative	In general, there are less early infections (mainly bacterial) with nonmyeloablative transplants, but different regimens may have very different risks
	Reduced intensity Nonmyeloablative	Nonmyeloablative regimens do not seem to result in less late infections
HLA match	HLA-matched sibling	With higher degree of mismatch, more immunosuppression is required, immune reconstitution is delayed, and the risk of infection is higher. Haploidentical and partially matched transplants often incorporate T cell depletion
	HLA-matched unrelated (URD or MUD)	
	Haploidentical	Haploidentical transplants using posttransplant cyclophosphamide seem to have good immune reconstitution
	Partially matched	
Source of stem cells	Bone marrow	G-CSF-mobilized peripheral blood stem cells often result in shorter neutropenia, but may be associated with higher risk of chronic GVHD. Conflicting data on CMV risk
	G-CSF-mobilized peripheral blood stem cells	UCD transplants result in long-lasting neutropenia and prolonged immunodeficiency, with higher risk of infection
	Cord blood (UCD)	High risk of viral infections with cord transplants
GVHD prophylaxis (posttransplant immunosuppression)	T cell depletion (in vitro via CD34+ cell selection or in vivo with ATG or alemtuzumab)	T cell depletion results in increased risk for infections. ATG and alemtuzumab may result in prolonged lymphopenia and immunodeficiency, depending on the dose used. Viral infections, EBV-related PTLD, and toxoplasmosis seem to be more common after T cell depletion
	Immunosuppressive agents	Differences between pharmacological immunosuppressive regimens are not well defined; sirolimus may be associated with less CMV reactivation

G-CSF granulocyte-colony-stimulating factor, *GVHD* graft-versus-host disease, *CMV* cytomegalovirus, *ATG* anti-thymocyte immunoglobulin, *EBV-related PTLD* Epstein–Barr virus-related posttransplant lymphoproliferative disorder.

6.4.1 Preparative (Conditioning) Regimen

The conditioning regimen administered before the infusion of stem cells has some influence on the risk of infection through its effect on neutropenia, mucosal damage, and GVHD. The conditioning regimen has several goals: reduction of the malignancy (when there is one), creation of space in the bone marrow to provide a selective advantage to the infused stem cells, and elimination of the recipient's immune system to minimize the risk of rejection. Different conditioning regimens may be more appropriate depending on the disease and the general status of the recipient [22]. Myeloablative, reduced intensity, and nonmyeloablative are the general categories, but within each one there are substantial differences that may be relevant. In general, fully myeloablative regimens result in more prolonged neutropenia and more severe mucosal barrier damage, which may impact the infectious risk during the pre-engraftment period [23].

6.4.2 Degree of HLA Similarity Between Donor and Recipient

Data from the Center for International Blood and Marrow Transplant Research (CIBMTR) indicate that there is a direct association between the number of donor–recipient HLA mismatches and the risk for mortality [24]. The current standard aims for high-resolution matching at HLA-A, HLA-B, HLA-C, and HLA-DRB1 (i.e., an "8 out of 8" match), but only about 30% of transplant candidates will have a perfectly matched sibling or unrelated donor (MUD). If a mismatch is unavoidable, a single-locus mismatched donor can be used [24]. Other alternatives include haploidentical and umbilical cord blood (UCB) transplants.

Haploidentical transplants are one special type of mismatched transplant, where the donor shares at least one complete haplotype with the recipient. Most candidates for transplant have a potential haploidentical donor. The successful use of a regimen of posttransplant cyclophosphamide to prevent GVHD in the haploidentical setting has resulted in an increasing number of this type of transplant being performed during the last decade [25]. Interestingly, early data suggest haploidentical transplants do not result in delayed immune reconstitution or increased infections [26].

Matching for UCB transplants focuses on three loci (HLA-A, HLA-B, and HLA-DRB1). The majority of UCB transplants are mismatched by at least one locus (often two). Among transplants mismatched at two loci, mismatching at HLA-C and HLA-DRB1 was associated with the highest risk of mortality [24].

The degree of mismatch between the donor and the recipient affects the infectious risk mainly through the likelihood of GVHD. More GVHD usually results in more infections. To prevent GVHD in a mismatched transplant, more potent immunosuppression may be required, increasing the risk of infection. It is also possible that immune reconstitution proceeds more slowly (even with the same immunosuppressive regimen) after a URD HCT. These factors may result in increased risk of infections associated with T cell immunodeficiency, like CMV, *Pneumocystis jirovecii* pneumonia (PCP), and Epstein–Barr virus (EBV)-related posttransplant lymphoproliferative disorder (PTLD).

However, provided the number of stem cells administered is the usual ($>3\times10^6$ kg^{-1}), neutrophil recovery proceeds at the standard pace and there is no increased risk of neutropenia-related infections.

The problems with UCB transplants include a markedly decreased stem cell dose (often $<1\times10^5$ kg^{-1}) which results in prolonged neutropenia (up to 6 weeks), with the attendant risk of bacterial and fungal infections [27]. In addition, the cord blood does not have antigen-specific memory T cells that can expand in a thymus-independent fashion to provide protection against viruses and opportunistic pathogens. This results in high frequency of late severe infections following cord transplantation, even when the neutropenic period is shortened by coadministration of stem cells from a third-party donor [28].

6.4.3 Source of Stem Cells

Stem cells may be given using the bone marrow, G-CSF-mobilized peripheral blood stem cells (PBSCs), or UCB. Frequently bone marrow will result in more prolonged neutropenia compared with PBSC, and increased infections during neutropenia should be expected. However, a multicenter randomized trial comparing peripheral blood stem cells with the bone marrow from unrelated donors showed no difference in the relapse or infectious mortality between both groups, but confirmed that chronic GVHD is more common with mobilized PBSC [29]. The particular features of UCD transplants were discussed on the preceding paragraph.

6.4.4 Strategy to Prevent GVHD: Manipulation of the Stem Cells, Immunosuppressive Drugs, or a Combination

GVHD may be prevented by decreasing the amount donor T cells or by limiting T cell function with immunosuppressive agents. The stem cells, whether from the bone marrow or the periphery, may be administered unmanipulated (sometimes called "T cell replete") or enriched by CD34 selection (also called "T cell depleted"). If unmanipulated bone marrow or PBSCs are used, the dose of CD3+ T cells administered with the graft varies between 24×10^6 kg^{-1} when bone marrow is used and 300×10^6 kg^{-1} when PBSCs are used [30]. Reductions in the amount of T cells of 2–3 $\log_{10}$ are possible,

and in some haploidentical transplant regimens, as few as 12.5×10^3 CD3+ cells are given, which still results in detectable immune reconstitution starting 2–3 months after transplant [31]. T cell depletion may minimize or altogether prevent GVHD but may result in prolonged immunodeficiency, depending on the degree of depletion. If an unmanipulated product is used, T cell depletion may be attained in vivo by using alemtuzumab or ATG. These agents produce a profound depletion of T cells in vivo, and their long half-life makes them still be present and active in the recipient when the stem cell product is administered.

If no in vitro or in vivo T cell depletion is used, one of a variety of immunosuppressive regimens will be given to prevent GVHD (e.g., tacrolimus + methotrexate, tacrolimus plus mycophenolate mofetil, cyclosporine A, sirolimus, posttransplant cyclophosphamide). A randomized controlled trial documented more infections in patients randomized to (moderate) T cell depletion than in the group who received pharmacologic immunosuppression [32]. T cell depletion in vivo with alemtuzumab has been associated with increased risk of infection [33]. It is possible that different pharmacological regimens may result in different infectious risks, but this has not been adequately studied. Preliminary evidence suggests that a sirolimus-based regimen may result in less CMV reactivation [34] and that posttransplant cyclophosphamide result in relatively decreased risk of PTLD [35].

The above categories may combine in several ways, compounding the risk of infection. These variations should be considered both when designing a regimen of anti-infective prophylaxis and when considering an individual patient who may have an infection.

6.5 Graft-Versus-Host Disease

GVHD is the most important cause of non-relapse mortality following HCT, and it is frequently complicated by infection. GVHD is categorized as acute or chronic based on its time of onset. Acute GVHD develops before day 100 and is characterized by gastrointestinal disease (secretory diarrhea, nausea, vomiting), liver dysfunction, and skin rash. Stages of GVHD in the skin, gut, and liver combine to give a grade (I–IV) of the severity of the disease. Acute GVHD grades III–IV is associated with significant mortality. The treatment of choice is high-dose systemic corticosteroids. GVHD is associated with significant immune dysregulation [36, 37] and is frequently accompanied by CMV reactivation [38]. The combination of disruption of the GI mucosa (and sometimes skin) and high-dose corticosteroids (in addition to the immunosuppressive agents concurrently given, like tacrolimus and MMF) constitute a high-risk setting for infection. Bacterial, fungal, and viral infections are common under these circumstances.

Chronic graft-versus-host disease (cGVHD) has been traditionally defined chronologically: GVHD starting after day 100. It has been classified based on its relation to prior GVHD (progressive when acute GVHD continues after day 100, quiescent when there is a period of time during which the patient is free of GVHD, or de novo when chronic GVHD is the first manifestation of GVHD) and its extension (limited or extensive, reformulated as clinical limited, or clinical extensive). The clinical syndrome of typical chronic GVHD is quite distinct from the acute form, and a new classification focusing on the clinical characteristics of the disease as well as on the timing is being increasingly used [39]. From the standpoint of infectious diseases, the important consideration is that the presence of chronic GVHD is associated with high risk of infection [40, 41]. Multiple immune defects have been described during chronic GVHD, involving humoral and cellular immunity [42, 43] as well as functional hyposplenism [44, 45]. Besides these abnormalities, that result in delayed immune reconstitution and poor response to immunizations, the risk is of infection is increased by the treatment of extensive cGVHD [41], which typically includes systemic corticosteroids and a variety of steroid-sparing agents. Notably, cGVHD is a well-documented risk for pneumococcal infections [45, 46], fungal infections, and late CMV disease. However, all types of infections are more common during cGVHD, particularly during the first few months [47].

When GVHD is not controlled by corticosteroids, it is called "steroid refractory," and there is currently no universally accepted standard treatment. This situation is important from the infectious disease standpoint because patients are usually treated with a variety of highly immunosuppressive regimens (e.g., ATG, cyclophosphamide, MMF, infliximab, daclizumab, alefacept, alemtuzumab, sirolimus, visilizumab, denileukin diftitox, and others) [48] that result in a wide array of infectious complications. Reactivation of CMV is very common, as are fungal infections [49, 50], Epstein–Barr virus-related PTLD [51], as well as human herpesvirus 6 (HHV-6) [52] and adenovirus [53]. There are no controlled studies to support any particular infection prevention strategy during this period of increased immunosuppression, but some authors have emphasized that early use of prophylactic antibiotics and antifungals is an essential part of a successful approach to this problem [54]. Unfortunately, this is a condition for which controlled trials are unlikely to be performed, and different centers will have to decide on a particular approach of close monitoring versus prophylaxis based on local experience and published case series.

In the following sections, the epidemiology of bacterial, fungal, viral, and parasitic diseases will be discussed. The implications for prophylaxis and management will be mentioned. Immunizations for transplant recipients, (as well as their caregivers and immediate contacts) are discussed in Chap. 48

6.6 Risks and Epidemiology of Bacterial Infections After Allogeneic HCT

6.6.1 Early Bacterial Infections: Pre-engraftment

Approximately 20% of HCT recipients will experience at least one episode of bacteremia during the first few weeks, and a similar proportion after engraftment [55]. These infections are usually related to either neutropenia with subsequent bacterial translocation through the GI mucosa (mucosal barrier injury laboratory-confirmed bloodstream infection or MBI-LCBI) or the intravascular catheter (central line-associated bloodstream infections or CLABSIs) [56].

The relative frequency of Gram-positive and Gram-negative infections during neutropenia varies in different series and with the use of prophylactic antibiotics. In some centers, the most frequent Gram-positive isolates are *viridans* group *Streptococcus* [55]; this may be a function of the conditioning regimen or the patient population. *Enterococcus faecium*, frequently VRE, is another Gram-positive organism that tends to cause bloodstream infection relatively early, although this seems to be rather institution dependent [57]. The Gram-negative bacteria are commonly *Enterobacteriaceae*. These infections are generally related to the disruption of the GI mucosa due to the preparative regimen. The role of reduced diversity of the microbiota with subsequent bacterial domination and ultimately bacteremia is an area of intense study [58]. The risk of bacteremia during neutropenia may be decreased by the use of prophylactic antibiotics [59, 60]. This had been shown in multiple studies over the years, but the recommendation of using antibiotics did not become part of practice guidelines until recently. It is not clear whether this recommendation will continue amidst the increasing concern over the role of antibiotic-induced decreased microbiome diversity on the outcome of HCT [61]. In this regard it is of interest that fluoroquinolones seem to have less detrimental effects on biodiversity of the fecal flora than beta-lactams. Levofloxacin at a dose of 500 mg/d for patients who are going to be profoundly neutropenic for longer than 1 week is the current recommendation of the IDSA [11].

6.6.2 Early Bacterial Infections Following Engraftment

In a large study from the Sloan Kettering Cancer Center, the risk factors for post-engraftment bacteremia included acute GVHD, renal dysfunction, hepatic dysfunction, and neutropenia [55]. *Enterococcus* (VRE) and coagulase-negative *Staphylococcus* were the most common Gram-positive isolates. *Enterobacteriaceae* and non-fermentative Gram-negative bacteria (including *Pseudomonas*, *Stenotrophomonas*, and *Acinetobacter*, possibly related to the indwelling catheter) were the most common Gram-negative isolates. Bacteremia following engraftment often happens in the setting of patients with a complicated clinical course, acute GVHD, and multiple medical problems or else is catheter related.

Daily bathing with chlorhexidine-impregnated washcloths decreased the risk of acquisition of MDROs and development of hospital-acquired bloodstream infections in transplant recipients in a randomized trial [62], and this practice should be considered by every transplant program.

The advantages and disadvantages of active screening for colonization by resistant pathogens have not been adequately studied in HCT recipients. It is likely that local epidemiology determines whether screening is an efficacious and cost-effective approach to either prevent infection or improve outcomes. A retrospective study on VRE bacteremia from the Sloan Kettering Cancer Center showed that VRE carriage was predictive of subsequent VRE bacteremia, but failed to detect the pathogen in many patients [63]. Performing surveillance cultures for resistant organisms in vulnerable patient populations is part of the CDC recommendations "Management of Multidrug-Resistant Organisms in Healthcare Settings, 2006" [64], and has been vigorously advocated by some experts [65].

6.6.3 Late Infections: *Streptococcus pneumoniae* and Others

HCT recipients are at high risk for *Streptococcus pneumoniae* infections (2–8.6/1000 patients transplanted) [66, 67]. Both early and late (beyond day 100) pneumococcal disease has been reported, with late infections strongly associated with active cGVHD [46]. These have been attributed to inadequate antibody production and functional hyposplenism [44, 67]. Vaccination against *S. pneumoniae* should be given to all HCT recipients, starting 3–6 months after transplant and using the 13-valent conjugate vaccine [9] (see Chap. 48 for details). Four doses of the vaccine result in enhanced antibody response and tolerable side effects [68]. Antibiotic prophylaxis against *S. pneumoniae* prophylaxis for adults with active cGVHD has been recommended [69], although there is only weak evidence supporting its efficacy. Penicillin V-K is safe and well tolerated, but the local patterns of penicillin resistance may make other antibiotics (e.g., trimethoprim, sulfamethoxazole, azithromycin, or levofloxacin) preferable, although their long-term safety is not well established.

Late bacterial infections often involve the respiratory tract. Pneumonia is the most common cause of fatal late infection [40, 70]. Chronic GVHD is the risk factor most commonly identified. Besides *S. pneumoniae*, multiple other pathogens have been reported. Nocardia also tends to occur

late and in patients with cGVHD [71, 72]. Mycobacterial infections are uncommon and difficult to diagnose [73]. Risk factors for the development of active TB include GVHD, corticosteroid treatment, and total body irradiation (TBI) [74]. The need for universal testing for tuberculosis is controversial, given the unknown sensitivity and specificity of the tests in this population and the fact that tuberculosis is a relatively uncommon complication after HCT (albeit still approximately three times higher than in the general population) [74].

6.7 Risks and Epidemiology of Fungal Infections After Allogeneic HCT

It is necessary to separate invasive candidiasis and candidemia (often related to neutropenia or to the intravenous catheter) from invasive mold infection (of which invasive aspergillosis (IA) is by far the most frequent) [75] (Table 6-2). When deciding on a prophylaxis strategy, it is recommended to consider what kind of fungal infection one is trying to prevent.

Invasive candidiasis follows prior colonization and favorable conditions for the yeast: disruption of the GI mucosa during chemotherapy or acute GVHD, overgrowth in the presence of broad-spectrum antibiotics, and/or presence of indwelling catheters (the catheter seems to be the main risk factor in the case of *C. parapsilosis*). Early studies showed that fluconazole during the pre-engraftment period could decrease the incidence of invasive candidiasis [76, 77]. Accordingly, fluconazole is recommended as part of the standard prophylactic regimen during the pre-engraftment period. The prevalent use of fluconazole has resulted in substantial decrease in the incidence of infections caused by *C. albicans* with relative increases in the incidence of other species of Candida with decreased susceptibility to this agent (e.g., *C. glabrata*, *C. krusei*) [78].

Invasive aspergillosis occurs during specific "at risk" periods following HCT, with a first peak around the time of neutropenia pre-engraftment, a second peak between days 40 and 70 (the time of acute GVHD and its treatment), and a third peak late after transplant, usually in the midst of actively treated cGVHD [79] (Figure 6-1). A variety of risk factors for invasive aspergillosis have been identified over the years, but the most consistently found to be significant in multivariate analyses are acute GVHD, chronic extensive GVHD, and CMV disease [80–82]. Systemic corticosteroids are almost always present as part of the treatment of acute and chronic GVHD.

Non-aspergillus mold infections (e.g., fusariosis, mucormycosis, scedosporiosis), sometimes referred to as emerging mold infections, have been reported with increasing frequency [83]. The increased use of prophylaxis with activity against Aspergillus would be expected to result in a relative increase of other opportunistic mycoses like mucormycosis [84].

Considering the diversity of fungal infections after transplant and the current antifungal armamentarium, it is controversial which antifungal prophylaxis is appropriate at what point during transplant. For instance, although fluconazole is a safe and well-established intervention during the pre-engraftment period of myeloablative transplants [76, 77], it is reasonable to question how necessary it is in transplants with conditioning regimens that result in shorter neutropenia.

Table 6-2. Risk factors and epidemiology of fungal infections after HCT

Pathogen	Risk factors	Comment
Candida spp.	Neutropenia, mucositis, indwelling catheter, heavy colonization, TBI	Non-*albicans Candida* is increasing; *Candida albicans* breakthrough is usually associated with fluconazole resistance
Aspergillus spp.	Prolonged neutropenia	Aspergillus is the most common mold infection in a proportion 7:1 to 9:1 in most series. Antifungal prophylaxis with voriconazole or echinocandins increases the likelihood of non-aspergillus molds
	Type of transplant: cord blood, T cell depletion, partially matched transplant	Not all species of *Aspergillus* are equally invasive or equally susceptible to antifungal agents
	GVHD, acute GVHD and chronic extensive GVHD; systemic corticosteroids	
	CMV disease	
Other molds		
Mucormycosis (formerly zygomycosis)	Prophylaxis with voriconazole	Simultaneous disease of sinuses and the lung was identified as suggestive of mucormycosis in a case–control study
Fusarium spp.	HLA-mismatched transplant	Paronychia and positive blood cultures common
	Prolonged neutropenia	
	Smoking	
Scedosporium spp.	Neutropenia, GVHD, environmental exposure, voriconazole	*Scedosporium prolificans* more invasive and refractory to treatment than *S. apiospermum*

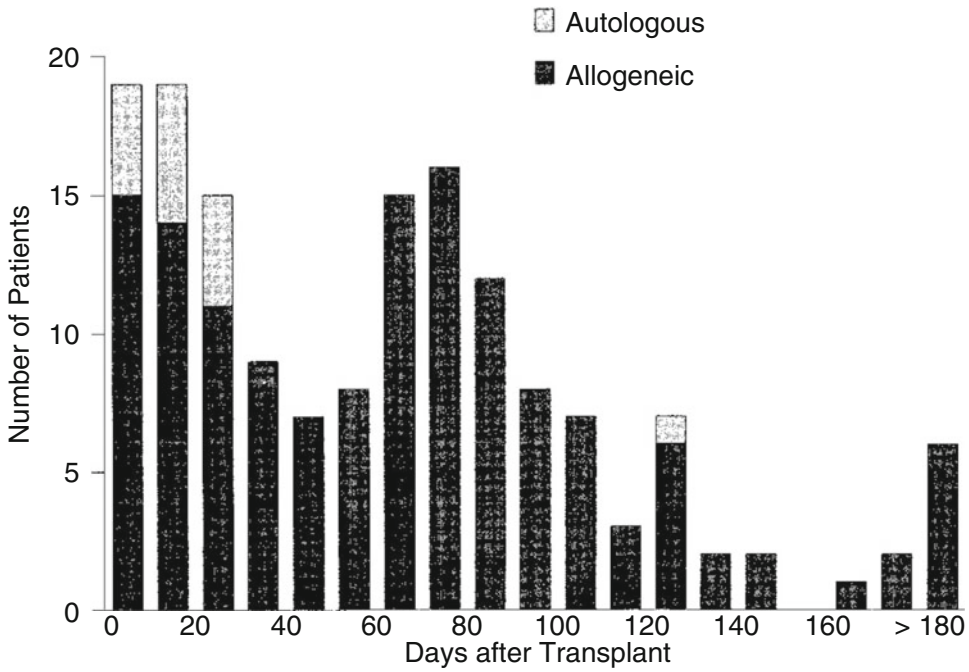

FIGURE 6-1. Time from transplant to diagnosis of aspergillosis in days (From Wald A, Leisenring W, van Burik JA, Bowden RA. Epidemiology of aspergillus infections in a large cohort of patients undergoing bone marrow transplantation. J Infect Dis 1997, Jun;175(6):1459–66, with permission).

Micafungin showed to be equivalent to fluconazole in a randomized controlled trial [85], and the same question (what kind of transplant patient would benefit most) applies.

Regarding the duration of antifungal prophylaxis, fluconazole up to day 75 posttransplant was associated with improved survival mainly due to decreased incidence of systemic candidiasis [86], but it is uncertain whether this strategy should be used for all patients or should be received for some selected subgroups considered at higher risk. Similarly, it is reasonable to question the indication for fluconazole during periods when the main fungal infection is aspergillosis. Several randomized controlled trials have compared fluconazole with another azole with activity against molds (itraconazole [87, 88], voriconazole [89], or posaconazole [90]) either as standard posttransplant prophylaxis or during periods of increased risk. The general conclusion of these trials is that the aspergillus-active drugs are, indeed, more effective than fluconazole in preventing IA, but the benefit in survival in the context of a clinical trial with careful monitoring of galactomannan antigen is hard to demonstrate [91]. The 2009 ASBMT/EBMT Guidelines recommend posaconazole or voriconazole as antifungal prophylaxis in the setting of GVHD and micafungin in the setting of prolonged neutropenia [1]. Of note, posaconazole prophylaxis was superior to fluconazole or itraconazole and improved survival in prolonged neutropenia in non-transplant patients [92]. Now, there are even more options of mold-active prophylaxis with posaconazole delayed-release tablets, intravenous posaconazole, and the new agent isavuconazole.

6.8 Risks and Epidemiology of Viral Infections After Allogeneic HCT

Viral infections remain a challenge because newer transplant modalities result in severe prolonged T cell immunodeficiency and because the current antiviral armamentarium is very limited. Multiple latent viruses may reactivate following HCT [93]. The role of monitoring by PCR is well defined mainly for CMV. Latent viral reactivation is of particular concern in recipients of cord [94] or T cell-depleted transplants. Table 6-3 presents a summary of this section.

6.8.1 Herpesviruses

Members of the herpesvirus family that have caused significant disease after transplant include HSV-1, HSV-2, VZV, EBV, CMV, and HHV-6. Posttransplant complications of HHV-7 are not well defined, although multiple associations have been described. HHV-8 infection and disease (primary effusion lymphoma and Kaposi's sarcoma) occur only infrequently after HCT.

6.8.1.1 Herpes Simplex Virus

HSV-1 and HSV-2 may reactivate following the preparative regimen and complicate chemotherapy-induced mucositis, so it is customary to administer prophylaxis with acyclovir or valacyclovir at least until engraftment. In patients with common recurrences, long-term suppression may be appropriate.

TABLE 6-3. Risk factors and epidemiology of viral infections after HCT

Pathogen	Risk factors	Comment
Respiratory virus		
Respiratory syncytial virus (RSV)	Pre-engraftment	Progression to pneumonia is associated with older age and lymphopenia
	Lymphopenia	It may be less common in nonmyeloablative or reduced intensity transplants
	Preexisting obstructive airway disease	
Parainfluenza	Unrelated donor (URD) transplant	Progression to pneumonia (less common than in RSV) is associated with corticosteroid use and lymphopenia
	CD4+ lymphopenia	
Influenza	Advanced disease	Progression to pneumonia seems less in patients who are receiving corticosteroids
	Female sex	
	Transplantation during influenza season	
Adenovirus	Lymphopenia (T cell depletion), anti-T cell antibodies, umbilical cord blood transplants, mismatched transplants (other than DRB1), haploidentical transplants	Both reactivation of latent adenovirus and new infections occur. Plasma viremia is an important predictor of disease
	Refractory GVHD	
	GVHD on corticosteroids	
Others (metapneumovirus rhinovirus, coronavirus, enterovirus, bocavirus)	Risk factors not well defined	
Herpesvirus		
HSV	HSV + serology in the recipient	
Acyclovir-resistant HSV	Low-dose prophylaxis	
	Intermittent treatment	
	HSV-seronegative donors	
Varicella zoster virus (VZV)	VZV + serology	Clinical reactivation of 25% in the first year after stopping acyclovir prophylaxis
		HCT recipients with multidermatomal zoster should be on airborne and contact precautions
CMV (early disease)	CMV + serology in recipient	Rate of CMV infection in seronegative recipients of seropositive donor (R–/D+) is very low if leucodepleted products are used
	URD transplants and mismatched transplants (in some studies)	
	T cell depletion {Holmberg, 1999 #131}	
CMV (late disease)	Chronic GVHD	
	Corticosteroids	
	CD4+ lymphopenia (<50)	
	Unrelated transplants	
	Haploidentical transplants	
	Umbilical cord blood transplants	
	T cell-depleted transplants	
Epstein–Barr virus (EBV)-related posttransplant lymphoproliferative disorder (PTLD)	Profound T cell cytopenia	
	T cell depletion	
	Anti-T cell antibodies	
	UCB transplants	
	Haploidentical transplants	
Human herpesvirus 6 (HHV-6)	UCB	Reactivation after transplant is very common; disease is rare; multiple disease associations described
	Unrelated donor transplant	
	Mismatched transplant	
	GVHD	
BK virus	Reactivation almost universal after allo-HCT	High-level viremia associated with disease

6.8.1.2 Varicella Zoster Virus

VZV predictably reactivates following transplant (approximately 25% in the first year), either as shingles, multidermatomal, disseminated, or even without a rash ("zoster sine herpete"). In patients who are at risk for VZV reactivation, the use of long-term acyclovir safely prevents the occurrence of VZV disease [95, 96], and currently it is recommended for at least 1 year following HCT.

6.8.1.3 Cytomegalovirus (CMV)

CMV remains latent in a variety of human cells. CMV-seropositive HCT recipients are at risk for CMV reactivation and disease after transplant. The term "CMV infection" is used to denote the presence of CMV in the blood detected by PCR or pp65 antigenemia [97]. Following reactivation, CMV may cause disease typically in the form of pneumonia and/or gastrointestinal disease (most commonly colitis). Other CMV diseases like retinitis or CNS involvement are rare after HCT but have been described: retinitis has been associated with high CMV viral load [98] sometimes in the context of chronic GVHD and CNS disease (encephalitis and ventriculitis), sometimes with resistant virus in the CNS [99, 100].

The risk for reactivation may be related to the presence of CMV-specific immunity in the donor. The rate of CMV infection in the donor–recipient (D/R) pairs often follows the progression $D-/R+ > D+/R+ \gg D+/R- > D-/R-$, suggesting that CMV-specific memory T cells administered with the stem cells may play a role in preventing reactivation and disease. CMV infection or disease in CMV-seronegative recipients of seronegative donors (R−/D−) is rare when leucodepleted or CMV-negative blood products are used [101].

Every transplant program must decide on a strategy to monitor CMV and prevent disease. Depending on a variety of factors, either universal prophylaxis with ganciclovir up to day 100 or a preemptive strategy of weekly monitoring and early therapy may be used. Both approaches resulted in similar overall mortality when compared in a randomized controlled trial, but universal prophylaxis was followed by more cases of late CMV disease [97, 102]. Late CMV disease has emerged as a significant problem, as it occurs when patients are not being under close monitoring by the transplant center. Risk factors include lymphopenia and chronic GVHD [103]. Preventing late CMV disease may be accomplished by either prophylaxis with valganciclovir or the preemptive approach with weekly CMV PCR monitoring [104]. The effect of CMV serostatus of donor and recipient on overall survival is complex (for a review, see [105] and Chap. 24).

6.8.1.4 Epstein–Barr Virus and Posttransplant Lymphoproliferative Disorder

PTLD is a spectrum of lymphoid proliferations that may happen after solid organ or allogeneic stem cell transplantation, usually (but not always) driven by EBV [106]. Pathologically the spectrum goes from polymorphic, polyclonal tissue infiltration of lymphocytes to monomorphic involvement with high-grade B cell lymphoma. After allogeneic HCT, the proliferating cells may be from donor (most commonly) or recipient origin. This disorder is typically related to insufficient or abnormal T cell responses against EBV [107], and accordingly it is more common in the setting of HLA-mismatched transplants, T cell depletion, or intense immunosuppression for the treatment of GVHD [108–110]. Some cases have followed the use of alemtuzumab for in vivo T cell depletion or GVHD prophylaxis [110], despite the fact that anti-CD52 also results in depletion of B cells and earlier had been reported to be associated with relatively less risk. Interestingly, the use of posttransplant cyclophosphamide to prevent GVHD seems to be associated with lower risk of PTLD [35]. Monitoring of EBV viral load by quantitative PCR is now recommended in those transplants considered at high risk. Preemptive management of increasing EBV viral load in patients at risk has been associated with good outcomes [111], although it is not clear when exactly this treatment should be given. A CT/PET may be useful to localize areas amenable to biopsy (Figure 6-2).

6.8.1.5 Human Herpesvirus 6

HHV-6 is acquired early in life, when it may cause roseola infantum and nonspecific febrile illnesses. It frequently reactivates following HCT. Using quantitative PCR, HHV-6 can often be detected in peripheral blood 2–5 weeks after transplant. Most of the time the reactivation seems to be asymptomatic [112], but a number of associations (rash, delayed engraftment, GVHD, thrombocytopenia, increased overall mortality) as well as actual clinicopathological entities (hepatitis, pneumonitis, encephalitis) have been described [113–115]. HHV-6 is possibly the most common cause of infectious encephalitis after HCT [116]. It seems to be particularly frequent after cord blood transplant. Cases of encephalitis tend to be accompanied by higher viral loads of HHV-6 in plasma [117], but the role of systematic monitoring of HHV-6 in plasma is unknown at this time, as reactivation seems much more common than disease [118] and attempts to use a preemptive strategy using foscarnet have not been successful [119]. The European Conference on Infections in Leukemia has proposed evidence-based guidelines to address the diagnostic and therapeutic uncertainties related to this infection [120].

6.8.2 Respiratory Viruses

Respiratory viruses, a heterogeneous group of virus that is responsible for most upper acute respiratory infections in normal hosts, result in significant morbidity and mortality after HCT, particularly during the first 3 months following transplant [121]. Even asymptomatic carriage of respiratory viruses at the time of transplant has been reported to result in increased risk of unfavorable outcomes [122]. Besides respiratory syncytial virus (RSV) [123], influenza, parainfluenza virus (PIV) [124], rhinovirus [125], and adenovirus, newly identified viruses including metapneumovirus [126], coronavirus [127], and bocavirus [128] have emerged as significant pathogens. These infections present significant risks both acutely and in the long term. During the acute infection, HCT recipients are at risk of developing viral pneumonia

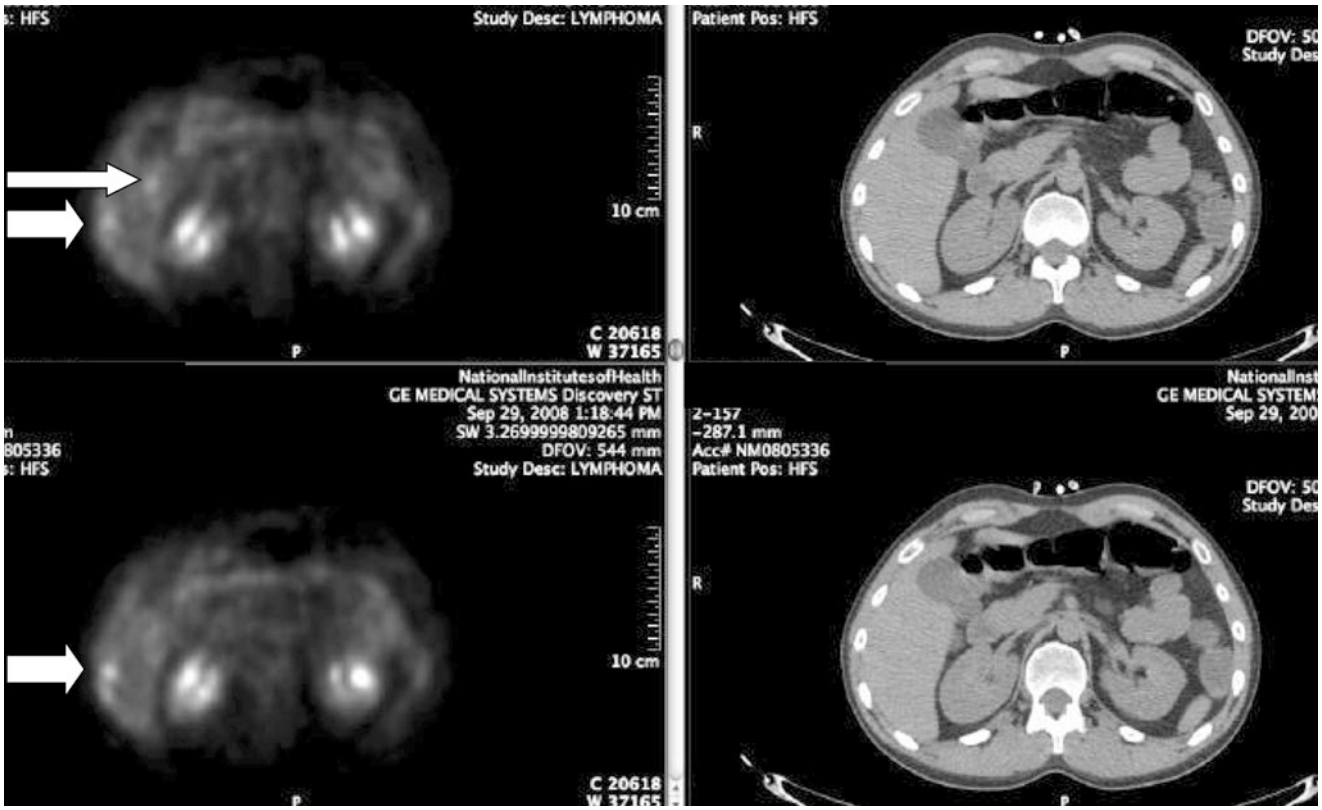

FIGURE 6-2. EBV-related lymphoproliferative disorder after a matched unrelated donor transplant. A 24-year-old man with Hodgkin lymphoma underwent a syngeneic HCT followed by MUD HCT (cyclophosphamide + fludarabine followed by alemtuzumab and cyclosporine). His day-28 CT/PET showed a mixed response: improvement in the intrathoracic lesions and cervical lymph nodes but appearance of new PET+ lesions in the liver, pharynx, and stomach. EBV viral load had been increasing slowly. Biopsies of the PET+ liver and stomach lesions showed a polyclonal EBV+ B cell infiltrate. The disease responded to rituximab and cyclosporine taper.

that sometimes progresses to respiratory insufficiency, mechanical ventilation and death, and also at risk of concomitant or secondary bacterial or fungal infections that are associated with increased mortality [124, 129, 130]. Long-term, there seems to be an association between early infection (pre-day 100) with some of these viruses (most notably PIV and RSV) and later development of chronic airflow obstruction [131]. The most significant risk factor overall for progression of these infections from the upper respiratory tract to the lungs seems to be lymphopenia [132]. Corticosteroid use seems to contribute to progression to pneumonia in RSV and parainfluenza infections but not so in influenza [129, 130] (see Table 6-3).

6.8.3 Adenovirus

Besides its role among the community-acquired respiratory virus, adenovirus may cause disease in transplant recipients following reactivation in the gastrointestinal tract followed by dissemination and end-organ damage [133]. De novo acquisition of adenovirus may also result in disseminated disease. There are more than 60 types of human adenovirus, with different tropisms and possibly varying susceptibilities to antiviral agents. They can cause a variety of diseases, including upper and lower respiratory tract infection, colitis, hemorrhagic cystitis (HC), nephropathy, and CNS disease. Systemic adenovirus disease seems to be more common in children, particularly in recipients of cord blood or T cell-depleted transplants [134–136]. Patients with GVHD on treatment with high-dose corticosteroids are also at risk (Figure 6-3). Some studies have documented that sustained high levels of adenoviremia are associated with disease [137]. It is not known yet whether a preemptive approach with cidofovir can successfully prevent disseminated disease and death [133, 138].

6.8.4 Polyomavirus: BK and JC Virus

6.8.4.1 BK Virus

BK virus infects 90% of humans by age 12. It predictably reactivates in most patients following HCT and causes hemorrhagic cystitis (HC) in a minority of them [139]. Detection of high levels of BK in the peripheral blood seems to correlate with the presence of BK-induced HC [140, 141]. In a

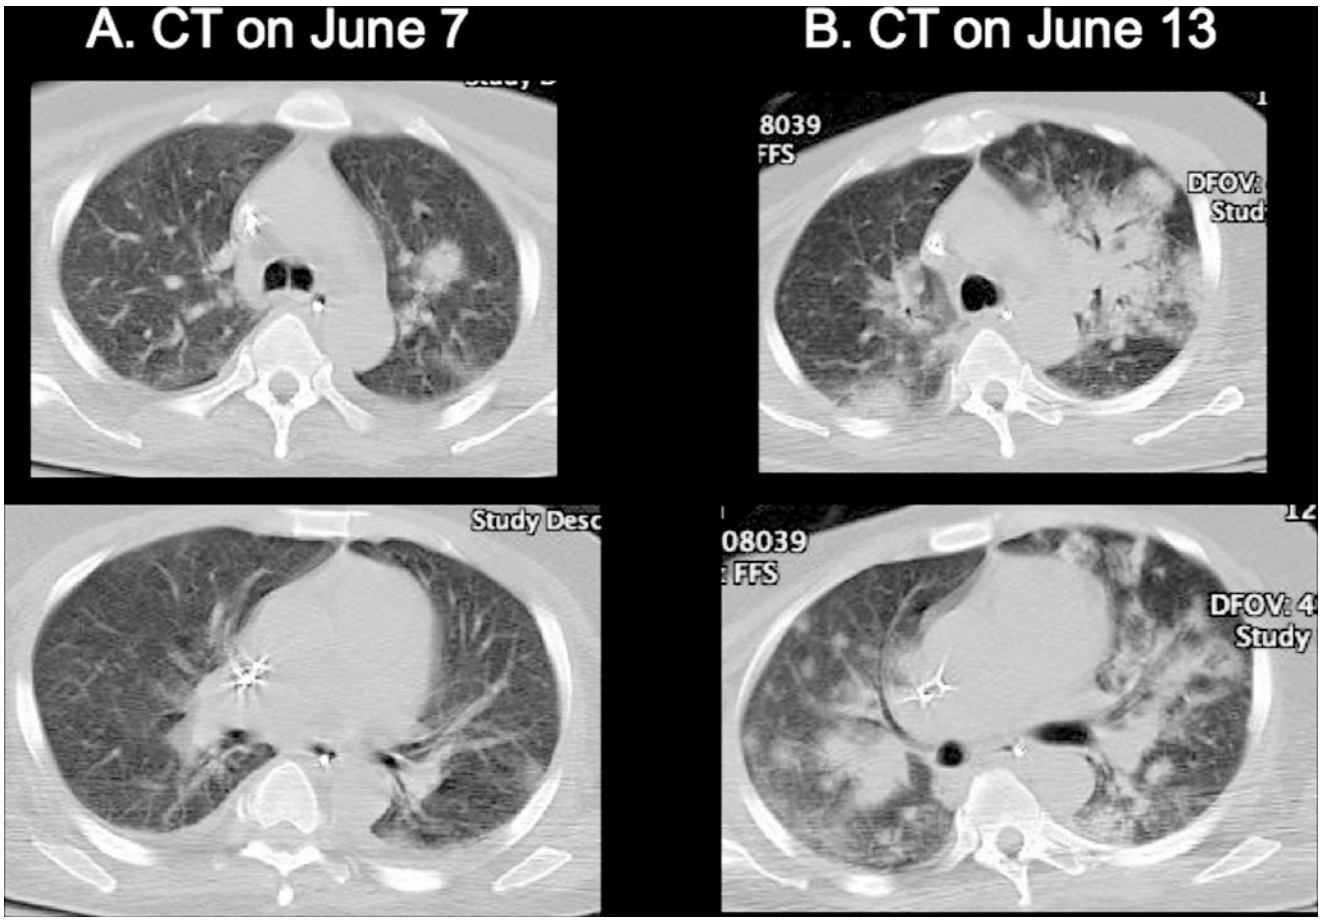

FIGURE 6-3. Adenovirus pneumonia in the setting of disseminated disease. A 48-year-old man received HLA-matched sibling donor nonmyeloablative HCT for myelodysplastic syndrome in transformation. Leukemia recurred immediately after transplant. He received several donor lymphocyte infusions/stem cell boosts and then induction treatment for AML with FLAG (fludarabine + cytarabine + G-CSF) followed by donor stem cells. Graft-versus-host disease involving the skin and gut had been documented being treated with methylprednisolone 1 mg/kg/day. After the patient recovered from neutropenia, he developed spiking fever and progressive shortness of breath. Adenovirus was isolated from tears, respiratory secretions, and urine. PCR in the blood was positive for adenovirus, and the autopsy showed only disseminated adenovirus disease.

large study from the Fred Hutchinson Cancer Research Center (FHCRC), no association was found between BK virus-associated HC and lymphopenia, corticosteroid use, and GVHD—the typical risk factors for viral infections after HCT [140]. In contrast, other smaller studies have found an association with GVHD. The pathogenesis of this disease remains unexplained. BK-induced nephropathy, a common problem after kidney transplant, remains infrequent after HCT and does seem to be related to profound immunosuppression [142]. BK pneumonitis has also been described, but it is distinctly rare [143].

6.8.4.2 JC Virus

JC virus is also acquired by most people during childhood. In immunocompromised hosts, it may cause encephalitis (JC encephalitis, previously called progressive multifocal leukoencephalopathy (PML)) with multiple areas of demyelination without edema detectable by MRI. Some studies have suggested that detectable viral load after HCT may be more common than currently thought [144]. Ascertaining risk factors for this disease is difficult because some transplant recipients may have conditions known to be associated with it and also received medications like MMF, rituximab, or brentuximab, which have been associated with PML even in the absence of allo-HCT.

6.9 Risks and Epidemiology of Pneumocystis After Allogeneic HCT

PCP is an opportunistic infection of patients with profound cellular immunodeficiency, and prophylaxis is recommended after HCT. It is now relatively uncommon: 1.3–2.4% of

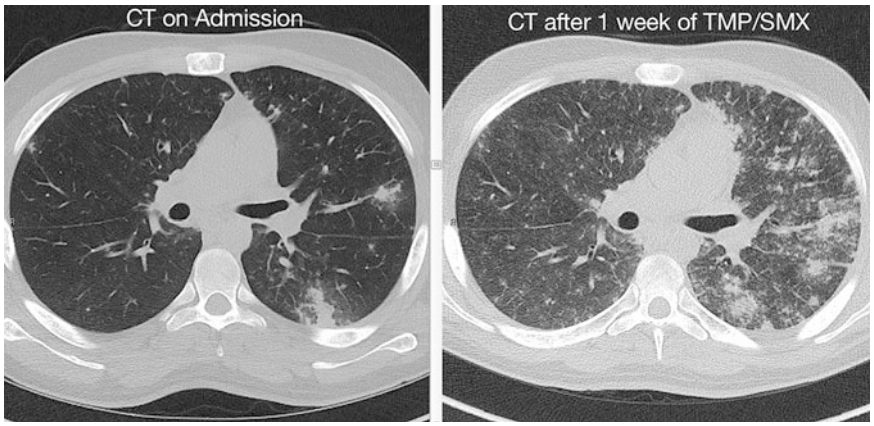

FIGURE 6-4. Pneumocystis pneumonia. A 23-year-old man with Ph+ALL s/p matched sibling allo-HCT presented for his 1-year post-transplant visit complaining of worsening fever and cough over the last 2 weeks, despite oral levofloxacin. He was in complete remission. A month earlier, abnormal liver enzymes had prompted the initiation of sirolimus for suspected chronic GVHD. He was on prophylaxis with acyclovir and atovaquone. The CT showed multifocal infiltrates. The bronchoalveolar lavage showed abundant *Pneumocystis*. After 1 week of treatment with trimethoprim/sulfamethoxazole, the radiographic pattern became characteristic of pneumocystis pneumonia. Atovaquone failures are well documented. The radiographic features of PCP after allogeneic transplant may be atypical.

patients transplanted from several series [145, 146] Most cases seem to occur relatively late, after discontinuing prophylaxis or during periods of intensive immunosuppression for the treatment of GVHD [147]. Hypoxemia is characteristic at presentation. Atypical radiological manifestations, including nodular infiltrates and pleural effusions (in contrast to typical interstitial pneumonitis), are described frequently, as is the presence of co-pathogens [148]. The preferred prophylaxis is trimethoprim/sulfamethoxazole (TMP/SMX), and several dosing regimens are effective (one single-strength tablet daily, one double-strength tablet daily, or one double-strength tablet three times/week) [149]. TMP/SMX may be poorly tolerated because of hematologic toxicity, skin rash and/or gastrointestinal toxicity [150].

It is unclear which is the prophylaxis of choice if TMP/SMX cannot be used. Aerosolized pentamidine is convenient, obviates the problem of compliance, and is less toxic than dapsone and better tolerated than atovaquone. However, it has been reportedly associated with more failures than dapsone [150]. Dapsone seemed to be effective and well tolerated in one study [151] but not in another when it was given only three times per week [152]. Dapsone should not be given to patients with G6PD deficiency. Methemoglobinemia is a well-known complication of dapsone [153] that should be considered in the presence of unexplained shortness of breath. Atovaquone suspension 1500 mg/d may be used, but published experience in HSCT recipients is limited [154, 155]. Atovaquone is expensive and poor tolerance has made compliance for some patients difficult. Absorption is better in the presence of significant amount of fat, and breakthroughs are well documented (Figure 6-4). PCP prophylaxis is recommended at least until all immunosuppression has been stopped but it is unclear how much longer to continue it [156].

6.10 Risks and Epidemiology of Toxoplasmosis After Allogeneic HCT

Most cases of toxoplasmosis after HCT represent reactivation, although rare cases of transmission with bone marrow transplant have been suspected [157]. Recipients should be tested for anti-toxoplasma IgG antibody, and if they are found to be positive, prophylaxis is recommended. Rare cases of toxoplasmosis after HCT have occurred in seronegative recipients [158, 159]. The disease tends to occur within the first 6 months after transplant, but it can happen later in the presence of persistent immunosuppression [160–162]. The risk of toxoplasmosis varies with the type of transplant and the immunosuppression: cord blood and use of ATG were found to be risk factors for disease in a prospective study [162]; most cases in another series occurred in URD or mismatched transplants [107].

TMP/SMX as given for PCP prophylaxis is considered adequate to prevent toxoplasmosis, although there have been cases on HCT recipients who were receiving it [162]. The best alternative for patients who are intolerant to TMP/SMX is unknown. Dapsone and atovaquone showed some efficacy in HIV-infected patients and there is increasing experience after HCT [163], although failures have been reported. Other

regimens include clindamycin with pyrimethamine and leucovorin, pyrimethamine with sulfadiazine, or pyrimethamine and sulfadoxine and leucovorin [107]. If a reliable quantitative PCR assay is available, frequent monitoring and preemptive treatment may be appropriate, since PCR-detected reactivation seems to precede symptoms by 4–16 days [162]. Retrospective data suggest this strategy may result in improved outcome [164].

6.11 Summary

In summary, infections following HCT are frequently related to risk factors caused by the procedure itself. Neutropenia and mucositis predispose to bacterial infections. Prolonged neutropenia increases the likelihood of invasive fungal infection. GVHD and its treatment create the most important easily identifiable risk period for a variety of infectious complications, particularly mold infections. Profound, prolonged T cell immunodeficiency, present after T cell-depleted or cord blood transplants, is the main risk factor for viral problems like disseminated adenovirus disease or EBV-related PTLD.

Besides all these "procedure-related" risk factors, there are individual characteristics that only now are starting to be investigated and understood. Future epidemiological and basic studies will likely result in truly personalized prophylactic regimens that will increase the unquestionable benefits of antimicrobial prophylaxis and reduce the cost, both direct and indirect, associated with this life-saving practice.

Risk and Epidemiology of Infections After Solid Organ Transplantation

Ingi Lee and Emily A. Blumberg

Transplant recipients are uniquely susceptible to infectious diseases due to the nature of their underlying conditions and their immunosuppressed status; consequently infections in solid organ transplantation may be associated with significant morbidity and mortality. These patients are not only vulnerable to a broad range of infectious organisms including those not normally considered to be pathogenic, but also prone to unusual presentations and more severe manifestations of infection [1]. Given the impact of infections on patient morbidity and mortality, it is critical to implement effective strategies for the prevention and early recognition of infectious complications to improve outcomes in this patient population.

This chapter is an introduction to the risks and epidemiology of infections in solid organ transplantation. It provides an overview of pre-transplantation donor and candidate screening, reviews the classic timeline for infection, and discusses methods for disease prevention including immunizations, environmental control, and post-transplantation prophylaxis.

7.1 Pre-transplantation Screening

An essential component of the pre-transplantation evaluation includes screening organ donors and transplant candidates for latent and active infections [2, 3]. This screening process is important for several reasons. Transplant care providers may identify scenarios that warrant exclusion of the organ donor or candidate from transplantation or they may diagnose active infections that require treatment prior to transplantation. The risk of post-transplantation infections that may result from reactivation of latent disease in the setting of increased immunosuppression should also be assessed and strategies individualized to minimize this risk. Lastly, planning preventive measures should be a focus during this period; this includes developing strategies for safe living and immunization, especially since vaccine response after transplantation may be suboptimal.

7.1.1 Screening the Transplant Candidate

All transplant candidates should be screened for latent and active infections using a variety of modalities. It is important to start with a careful history and physical examination. A detailed history including occupational history, places of residence, travel history, pets, and hobbies should be obtained from the transplant candidate. In some cases, this may suggest the presence of active infection and additional evaluation may be indicated to exclude diagnoses that would warrant delaying transplantation (e.g., infections with pathogens for which there are no antimicrobials such as West Nile virus [WNV] or certain respiratory viruses). Alternatively a history of prolonged residence in or birth in a location notable for unique endemic infections may prompt evaluation for subclinical infections that could reactivate after transplantation, including *Strongyloides stercoralis*, *Trypanosoma cruzi*, *Histoplasma capsulatum*, and *Coccidioides immitis* [2, 3]. All transplant candidates should be screened for infectious pathogens that have been more frequently associated with post-transplant complications by using a routine panel of testing, which is then supplemented with additional testing as indicated by history (Table 7-1). This includes serologic testing for cytomegalovirus (CMV), herpes simplex virus (HSV), varicella zoster virus (VZV), Epstein–Barr virus (EBV), human immunodeficiency virus (HIV), hepatitis B virus (HBV), hepatitis C virus (HCV), syphilis, and *Toxoplasma gondii* [2, 3]. Tuberculin testing is also important due to the increased risk of reactivation of latent infection following transplantation; both intradermal tuberculin purified protein derivative placement and interferon gamma release assays (IGRA) have been used [4, 5].

Pre-transplant screening may reveal active infections that could impact post-transplantation outcomes. Some of these may warrant excluding the transplant candidate from solid organ transplantation either temporarily or definitively. In some cases, such as WNV infection, transplantation may occur following resolution of the infection. In other cases, patients may not be eligible either due to the severe or incurable nature of the infection. Notably these criteria have

Table 7-1. Infectious diseases screening for solid organ screening for solid organ transplant candidates

Routinely administered tests	Other potential tests based on history; or clinical, laboratory, or radiologic findings
CMV antibody	Blood cultures[a]
EBV antibody (EBV VCA IgG and/or EBNA[b])	Chest imaging
HBV (hepatitis B surface antigen and antibody, and core antibody)	*Coccidioides* antibody[c]
HCV antibody and HCV RNA[d]	Cryptococcal antigen[a]
HIV 1/2 antibody	*Histoplasma* antibody[c]
HSV antibody	Respiratory virus PCR panel (including influenza A and B, parainfluenza, RSV, metapneumovirus, adenovirus)[a]
PPD or IGRA (interferon gamma release antibody)	*Schistosoma* antibody[c]
RPR (rapid plasma reagin)	*Strongyloides* antibody[c]
Toxoplasma antibody	*Trypanosoma cruzi* antibody[c]
VZV antibody	Urinalysis and urine culture
	WNV (West Nile Virus) antibody or nucleic acid testing[a,c]
	HTLV I/II antibody

[a]Recommended for individuals with symptoms consistent with these infections.
[b]*VCA* viral capsid antibody, *EBNA* Epstein–Barr nuclear antibody.
[c]Recommended for individuals from geographic regions where these infections are endemic.
[d]Recommended for candidates who are immunosuppressed prior to transplant, including those with end-stage renal disease.

evolved over time and infections that were once considered exclusions to transplantation may now be acceptable. One example of this is HIV infection, previously considered a contraindication due to concerns that immunosuppressive medications would increase the risk of opportunistic infection, HIV disease progression, and mortality [6]. The advent of highly active antiretroviral therapy (HAART) has allowed for outstanding long-term HIV control in adherent patients, and the excellent outcomes in HIV-infected individuals undergoing liver and especially kidney transplantation have encouraged increasing numbers of centers to perform renal and hepatic transplants in these patients [7–12]. Centers are also beginning to consider thoracic and pancreatic organ transplantation in HIV-positive individuals given acceptable outcomes in the initial patients undergoing these procedures [13–16]. Another exception may be infection of ventricular assist devices, as eradication of these infections typically requires device explantation and outcomes have been acceptable with transplantation [17, 18]. Many transplant candidates are hospitalized with high acuities of illness, requiring invasive procedures (e.g., central line placement, intubation, or ventricular assist device insertion) that place them at increased risk of infection. These patients require close monitoring in order to promptly identify active infections that occur while awaiting transplant; ideally these should be adequately treated prior to transplantation to minimize post-transplant complications.

Pre-transplantation screening can also identify latent infections that may reactivate after transplantation. Possible pathogens include bacteria (e.g., *Mycobacterium tuberculosis*), viruses (e.g., CMV, HBV, HCV, BK virus, EBV, HSV, and VZV), and fungal pathogens (e.g., *Histoplasma capsulatum and Coccidioides immitis*). The risk for TB is significantly increased in the transplant population with most cases representing reactivation of latent infection and screening should be performed in all transplant candidates. Options include intradermal skin testing utilizing PPD or IGRA with the latter preferred in individuals who have received BCG immunization to reduce the rates of false-positive tests [5]. When PPD testing is performed, areas of induration ≥5 mm are considered positive and patients with negative PPD results on initial testing may be considered for repeat testing after 2 weeks [5]. Both PPD and IGRA have reduced sensitivity due to common acquired immune deficiencies in candidates for transplantation; consequently it is important to take a careful history and closely review chest radiography in high-risk individuals who have negative testing. It is also important to scrutinize individuals with discordant test results. Treatment is recommended for all transplant candidates with a positive tuberculin test after active disease has been excluded. Since many transplant candidates are anergic, high-risk patients with a negative PPD or an indeterminate IGRA should also be considered for empiric treatment. These include transplant recipients with radiographic evidence of prior disease, a history of inadequately treated TB, close contact with someone who has active TB, or receipt of an organ from an inadequately treated organ donor [5, 19]. First-line treatment involves a 9-month course of isoniazid. Those who are isoniazid intolerant may benefit from a 4-month course of rifampin. However, rifampin has multiple drug interactions, including increasing the metabolism of calcineurin inhibitors, which may significantly complicate its administration post-transplantation. Consequently its use should be carefully considered in patients who may be transplanted during the course of therapy. In some cases, fluoroquinolones may be considered as alternate therapy for latent tuberculosis [20].

The optimal timing of latent TB treatment has not been defined and varies depending on the patient's risk for treatment-related hepatotoxicity. Patients without liver disease often undergo treatment prior to transplantation [5]. Because the risk of hepatotoxicity is increased in liver transplant candidates, transplant centers may choose to initiate latent TB treatment after transplantation once the patient is stable and the liver function tests have normalized [21]. Of note, treatment can be ongoing at the time of transplantation. Given that the highest risk of reactivation is within the first year following transplantation, if patients cannot be treated prior to transplantation, it is preferable to treat them as soon

as possible following transplantation [4]. Recent converters should be treated prior to transplantation if at all possible to decrease the risk of active infection either prior to or at the time of transplant.

Transplant candidate screening is an important opportunity for reevaluation of standard preventive measures. This includes an assessment of their home and work environments, pets, and hobbies in order to implement sufficient preventive measures prior to transplantation. The pre-transplant evaluation period is also an important opportunity for updating routine immunizations for vaccine-preventable illnesses, especially influenza and pneumococcal infection [22]. Patients should also undergo assessment for immunity to vaccine-preventable illnesses (e.g., varicella and hepatitis A and B) and be immunized accordingly. Further recommendations regarding immunizations will be included later in this chapter.

7.1.2 Screening the Organ Donor

The ability to fully screen organ donors will vary depending on whether the donor is living or deceased. Living donor screening has certain advantages. Notably the donor provides his or her own medical history and testing may be tailored to risks identified during the initial donor assessment. In contrast, deceased donor screening is limited to several hours where the medical history is obtained from a proxy. Family members may provide incomplete or inaccurate medical history and may be unaware of patient behaviors that place the patient at higher risk of infection. Despite these differences, the infectious pathogens tested during donor screening are similar for living and deceased donors and mirror the testing done in transplant candidates, although some testing may be performed in live donors that is currently not available or considered to be reliable in deceased donors (e.g., testing for tuberculosis). Potential donors are tested for a panel of routine serologies with additional screening guided by pertinent patient history. Further detail regarding screening the organ donor is provided in Chap. 8.

7.2 The Risk of Infection Posttransplantation

The risk of infection post-transplantation is determined by the balance between the patient's net state of immunosuppression and his or her epidemiologic exposures [1]. A patient who is more severely immunosuppressed may be susceptible to a broader range of infections, including those caused by opportunistic pathogens. Although opportunistic pathogens are more likely to cause infection in the first 6 months after transplantation, when patients are expected to be more immunosuppressed, patients in the late post-transplantation period (>6 months) on minimal immunosuppression without a significant history of rejection may be at risk of opportunistic infection, especially following a significant epidemiologic exposure.

Multiple factors contribute to a transplant recipient's net state of immunosuppression. The type, dosage, and timing of administered immunosuppressive medications remain the primary factor. Different immunosuppressive medications exert unique effects on the host immune system: (1) corticosteroids inhibit inflammatory responses and affect T-cell activation, (2) cytotoxic agents (i.e., azathioprine and mycophenolate acid) impair T-cell and B-cell proliferation and function, (3) calcineurin inhibitors (i.e., tacrolimus and cyclosporine) inhibit cytokine production, primarily interleukin-2 (IL-2), by CD4-positive T-cells, (4) target of rapamycin (mTOR) inhibitors (i.e., sirolimus) inhibit cell cycle proliferation and are associated with delayed wound healing and oral ulcers, (5) monoclonal antibodies (i.e., basiliximab and daclizumab) target the IL-2 receptor, (6) recombinant monoclonal antibodies (i.e., alemtuzumab) bind to CD52 on B and T lymphocytes, a majority of monocytes, macrophages, and NK cells, and a subpopulation of granulocytes, disrupting these cellular functions for prolonged periods, (7) polyclonal antibodies (i.e., antithymocyte globulin) induce lysis of lymphocytes with prolonged lymphocyte depletion increasing the risk of infection 3 months or longer after administration, and (8) costimulatory blockade agents (i.e., belatacept) disrupt T-cell costimulation and consequently activation. Immunomodulatory viruses (i.e., CMV, EBV, HBV, HCV, and HIV) and existing comorbidities (e.g., diabetes, renal insufficiency, and malnutrition) also contribute to the net state of immunosuppression. Transplant recipients often have more than one factor present, resulting in defects in multiple arms of the immune system. Although tests are available to assess certain immunologic defects (e.g., quantitative immunoglobulins, lymphocyte subset measurements, and gamma interferon release assays targeted against specific pathogens), there is no single test currently available that accurately assesses this net state of immunosuppression.

Epidemiologic exposure is the other main determinant of a transplant recipient's risk of infection. This exposure can be nosocomial or community acquired and may have occurred prior to transplantation. Latent infections can reactivate after transplantation in the setting of enhanced immunosuppression. Different organs also have unique epidemiologic risks due to organ-specific surgical procedures and environmental factors. For example, transplanted lungs may be at increased risk for colonization and/or infection with inhaled pathogens due to decreased mucociliary function, ischemia at the anastomosis site, and the direct exposure of the transplanted organ to the external environment. Liver and pancreas transplant recipients may be at risk of infection related to a particular surgical method (e.g., bowel anastomosis), while heart transplant candidates with pre-transplant ventricular assist devices may be at risk for device-related infections.

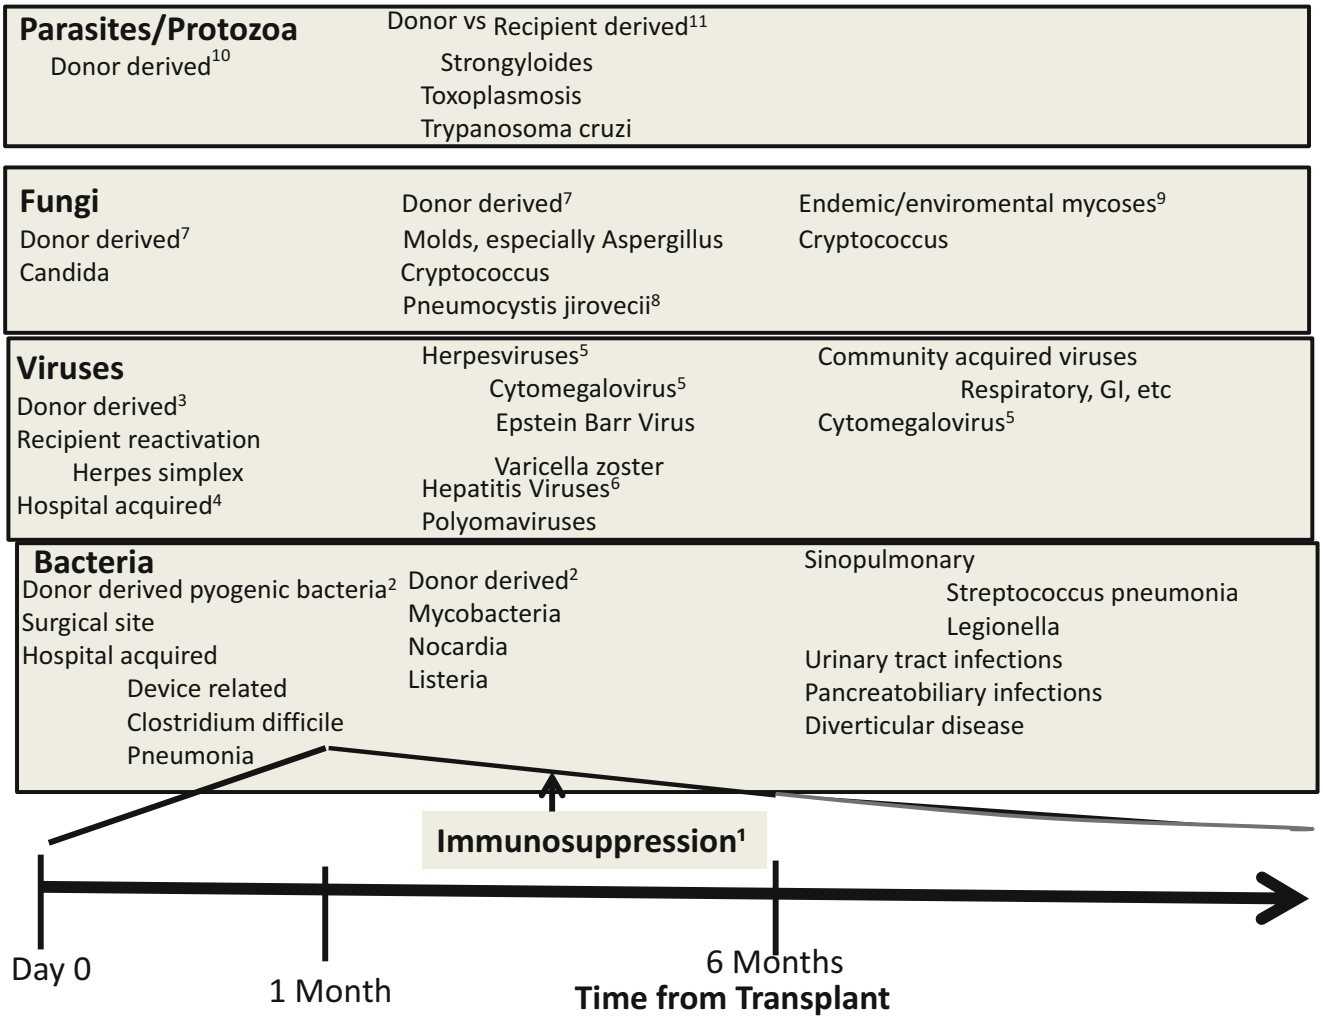

FIGURE 7-1. Epidemiology of post-transplant infection considering time from transplant. Adapted from Fishman JA, Rubin RH, Infection in organ transplant recipients, New England Journal of Medicine, 1998;338(24):1741–51, and Fishman JA, Infection in solid organ transplant recipients, New England Journal of Medicine, 2007;357(25):2601–14.

Standardized immunosuppressive therapy in solid organ transplantation has enabled the development of a useful predictive timeline for infection [1]. It includes three distinct time periods: the early post-transplantation period (0–1 month), the intermediate post-transplantation period (1–6 months), and the late post-transplantation period (>6 months) (Figure 7-1). Although changes in immunosuppressive medication regimens combined with the use of antimicrobial prophylaxis have modified this timeline, the general framework is still applicable. Transplant care providers can use this reference to develop an initial differential diagnoses for transplant recipients who present with signs of infection as well as to devise prophylactic strategies [1, 23]. However it is important to recognize that exceptions are possible; patients receiving certain more long-lasting immunosuppressive agents and those with chronic rejection or infection with immunomodulatory viruses may remain severely immunosuppressed and therefore be more vulnerable to opportunistic pathogens beyond 6 months after transplantation. Additionally it is possible that patients (especially pediatric recipients) may acquire primary infection with common opportunists (e.g., CMV and EBV) in the later post-transplant period, thus delaying the presentation of these infections.

7.2.1 Risk of Infection in the Early Posttransplantation Period (0–1 Month)

Within the first month, transplant recipients are most susceptible to nosocomial infections similar to those seen in non-immunosuppressed surgical patients, including pneumonia, urinary tract infections, catheter-related blood stream infections, and surgical site infections [3, 8, 10, 24]. Some of these may be directly related to complications of the surgical

procedure or a consequence of postoperative care; bacteria and *Candida* species are most commonly implicated [23]. Liver transplant recipients, for example, may be at increased risk of wound infections, or infections such as peritonitis or abdominal abscesses due to leaks at the biliary anastomotic site. The postoperative care may involve prolonged periods of intubation and the insertion of central venous lines or indwelling urinary catheters. These breaks in the mucocutaneous barriers place patients at increased risk for nosocomial infections including ventilator-associated pneumonias, surgical site infections, bloodstream infections, or urinary tract infections. Perioperatively, patients often receive broad spectrum antibiotics that may contribute to the emergence of antimicrobial-resistant pathogens, nosocomial fungal infections, and infection with *Clostridium difficile* colitis. Nosocomial transmission of viruses, especially respiratory viruses, may also occur [25]. Immunocompromised patients may have longer periods of viral shedding, and therefore they have opportunities to infect other organ transplant recipients by being placed in adjacent rooms on dedicated wards. Additionally, infection with *Legionella* species can occur anytime including the early post-transplantation period [26, 27]. Pneumonias are among the most commonly seen early infections; however not all pulmonary infiltrates are due to infection. The differential diagnosis is broad, and may include edema, atelectasis, rejection (in lung transplantation), and medications in addition to infection [28]; it is important to consider these diverse possibilities when evaluating patients. Transplant recipients are at increased risk for more severe pneumonias, including cavitary pneumonias; consequently early recognition of infection is critical [28–30].

Opportunistic infections are usually absent during the first month after transplantation, although there have been rare reports of infection with these pathogens. Among the most commonly reported is Aspergillus pneumonia (especially in lung recipients) [24]. It is probable that this low incidence can be attributed to the delayed impact of immunosuppressive medications introduced during this period.

Although the vast majority of early infections are nosocomial, a low incidence of donor and recipient-derived infections may also occur during this period. A Spanish study evaluating nonviral donor-derived infections reported disease transmission in 5/292 (1.71 %) of transplant recipients who received organs from infected donors [31]. All five donor-derived infections were due to bacterial pathogens. In the United States, there is mandated reporting of suspected donor-derived infections to the United Network for Organ Sharing (UNOS). Reviews of these reports by the Disease Transmission Advisory Committee of UNOS have noted that diverse pathogens have been transmitted including pyogenic bacteria, *T. cruzi*, HCV, HIV, WNV, lymphocytic choriomeningitis virus (LCMV), *Legionella* species, *H. capsulatum*, *Candida* species, *S. stercoralis*, *C. neoformans*, *Schistosoma* species, *T. gondii*, and *M. tuberculosis* [32, 33]. The timing of these infections varies; typically bacterial infections and fungal infections are most likely to present in the first month [34]. Although uncommon, these unanticipated donor-derived infections have been associated with increased morbidity and mortality, with complications including surgical site infections and mycotic aneurysms [32, 33, 35–37]. The transmission of more unusual infections in solid organ transplantation, including WNV, LCMV, or rabies, has also been documented [38–40]. Diagnosis of these infections may be confounded by the absence of recognized donor infection and the presentation of nonspecific symptoms such as fever, altered mental status, or liver enzyme elevations, followed by a rapid clinical decline oftentimes resulting in death. Recent reports have cautioned against the use of donors with neurologic processes of unclear etiology to prevent transmission of some of these infections [41].

Early infections may also occur as a continuation of an active infection in the recipient that precedes transplantation. Not all of these may be recognized prior to transplantation. Pathogens related to early recipient-derived infections may be diverse; occasionally opportunistic pathogens may occur, especially in liver transplant patients or those treated with immunosuppressive agents prior to transplantation.

7.2.2 Risk of Infection in the Intermediate Posttransplantation Period (1–6 Months)

The intermediate post-transplantation period generally refers to the time occurring 1–6 months following transplantation. During this period, most solid organ transplant recipients are at their highest net state of immunosuppression due to immunosuppressive medications exerting their full effect. Patients may also develop infections with immunomodulating viruses such as CMV, EBV, HBV, or HCV as well as experience metabolic complications including diabetes and renal insufficiency that can alter the immune system.

During this period, in the absence of prophylaxis, infections due to diverse opportunistic pathogens including bacteria (e.g., *Nocardia species*, *Listeria monocytogenes*, and Mycobacteria), fungi (e.g., *Pneumocystis jiroveci*, *Aspergillus* species, *C. neoformans*), viruses (e.g., CMV, EBV), and parasites/protozoa (e.g., *Toxoplasma gondii*) can occur. Geography can place individuals at risk for endemic mycoses including *Histoplasma capsulatum*, *Coccidioides immitis*, or *Blastomyces dermatitidis*. Lastly, donor-derived infections may present during this intermediate post-transplantation period; this is especially true of parasites (including *Strongyloides stercoralis*), protozoa, and viral infections [34]. Environmental exposures may also play a role during this period and place patients at higher risk of opportunistic infection. This includes exposure to a specific environment as well as to individuals with potentially communicable diseases. The changing nature of immunosuppressive regimens and

prophylactic strategies continues to have an impact on the infections seen during this period; both need to be considered when patients are evaluated. Specific infections seen during this high-risk period are detailed in later chapters.

7.2.3 Risk of Infection in the Late Posttransplantation Period (>6 Months)

The nature of infections in the late post-transplantation period may be a window into the transplant recipient's net state of immunosuppression. This net state of immunosuppression can be underestimated by simply reviewing the medication doses and levels as patient responses to specific regimens may vary substantially. By 6 months after transplantation, the vast majority of transplant recipients are doing well with good allograft function maintained with minimal immunosuppression. These patients typically reside in their home environments where they are most susceptible to community-acquired infections.

Transplant recipients can be at increased risk for more severe respiratory infections with community-acquired pathogens (e.g., influenza, parainfluenza, respiratory syncytial virus, adenovirus, human metapneumovirus, *Legionella* species, and pneumococcus). These patients may have longer durations of both infection and shedding, increased progression to lower respiratory tract infections, higher mortality rates, and increased risk for rejection [27, 42–47]. Transplant recipients are also at a 12.8-fold greater risk for invasive pneumococcal disease compared to the general population [46].

Other viral infections can also be seen during this period, including infections that may have been previously suppressed by prophylactic strategies. CMV infection is the most common opportunistic infection during this period. Often donor derived, CMV that may present variably as prophylaxis is discontinued [3, 48]. Transplant recipients with CMV syndrome have nonspecific symptoms including fever and fatigue that may be accompanied by laboratory abnormalities, most notably leukopenia. CMV may also present with end-organ involvement such as colitis, pneumonitis, or infected allograft. In addition to its direct effect, CMV has indirect effects on the immune system that increase the risk for allograft rejection and loss, post-transplantation lymphoproliferative disorder (PTLD), other infections, and diabetes mellitus [49–55]. Chronic viral infections, such as HBV or HCV, may also reemerge during this time. Outcomes in HBV-infected recipients have improved with the use of HBV immunoglobulin and antiviral agents [56]. Currently HCV-positive recipients fare worse, developing repeated episodes of chronic rejection, post-transplant diabetes mellitus, or chronic infection and end-stage liver disease, although the advent of more effective and better-tolerated antiviral treatment options will likely improve outcomes [56–59]. EBV may increase the risk of infections and malignancy, particularly PTLD. PTLD risk is greatest in EBV-seronegative recipients who receive organs from seropositive donors, a scenario which most often occurs in children [60]. Other risk factors have included the organ transplanted and the choice of immunosuppression agent (especially belatacept) [60–62]. Additionally, EBV viremia may provide insight into a patient's net state of immunosuppression; consequently when routine monitoring detects viremia, immunosuppressive therapy is typically reduced [60, 63].

There are documented cases of reactivation of latent infections during this period. For example, *H. capsulatum* can establish latency after primary infection and reactivate months after transplantation [64]. Posttransplantation TB rates range from 0.35 to 15 % worldwide, depending on disease prevalence with a median time to onset of 6–11 months [5, 65, 66]. The frequency of active TB varies based on the organ transplanted but is substantially higher than that of the general population (20–74 % higher), with most cases resulting from reactivation of latent recipient infection [5, 65, 66]. Donor-derived TB is estimated to account for <5 % cases [5, 67].

Lastly, transplant patients may be at risk of other infections not necessarily associated with immunosuppression. This could include health care-associated infections during periods of hospitalization. Studies suggest that transplant recipients, particularly heart, lung, and heart–lung recipients, may also be at an increased risk of pancreaticobiliary disease and diverticulitis [68, 69].

Although most recipients have stable allograft status and are infection free by 6 months after transplantation, a minority (approximately 20 %) may be chronically infected with immunomodulatory viruses or have recurrent episodes or chronic rejection requiring high-dose immunosuppressive therapy. The classic timeline for infections is not applicable to this subpopulation. These patients are more severely immunosuppressed and continue to be at risk for opportunistic infections well past 6 months post-transplantation, thus potentially making them candidates for prolonged prophylactic strategies.

7.3 Prevention of Infection

Prevention of infection is vital for improving outcomes in the solid organ transplant population. Transplant recipients need to be updated on their immunizations, preferably prior to transplantation, and they should be educated regarding behaviors that can minimize their day-to-day risk. Transplant care providers should also evaluate and identify patients who would benefit from antimicrobial prophylaxis or preemptive therapy when appropriate.

7.3.1 Immunizations

Screening of candidates prior to transplantation is an ideal opportunity to ensure that transplant recipients are updated on the following immunizations, according to age- and

condition-related guidelines: *Streptococcus pneumoniae*, *Haemophilus influenza*, influenza, diphtheria, pertussis, tetanus, hepatitis A virus, HBV, measles, mumps, rubella, poliomyelitis, and VZV [47, 48]. Although highly recommended, there is suboptimal utilization of immunizations in this population. One study reported that only 62.4 % (95 % CI 54.8–70.1 %) of lung transplant candidates received *S. pneumoniae* vaccination [70].

There are several general guidelines regarding the administration of immunizations in this population. First, it is preferable to update immunizations prior to transplantation rather than in the post-transplant period [3, 22]. Studies suggest that transplant recipients have reduced responses to diverse vaccines compared to immunocompetent individuals; this makes pre-transplantation immunization especially important [22, 71, 72]. Second, not only should immunizations be administered pre-transplantation, but they are most effective when administered earlier in the course of disease [73]. Given the suboptimal response to immunizations in certain patients with end-stage organ disease, physicians may consider confirming vaccine efficacy in patients who report prior immunization. Serologic testing for hepatitis A virus, HBV, VZV, measles, mumps, and rubella can be performed to ensure that patients maintain adequate levels of protection [74].

Even after transplantation, patients should ensure that they are current on their immunizations. Typically, immunizations are not given until at least 3–6 months post-transplantation when immunosuppression is reduced sufficiently to allow for improved immune response, although there may be exceptions to this, especially during epidemics (e.g., influenza) [22]. Transplant recipients as well as their family members and close contacts should receive yearly influenza vaccination. Strategies for pneumococcal vaccination include using conjugate pneumococcal vaccine followed by polysaccharide capsule vaccine [75]. Live attenuated vaccinations, including intranasal influenza, VZV, and MMR, are generally avoided in transplant recipients due to an increased risk for possible dissemination; however recent reports suggest that Varicella zoster vaccine may be safe in at least some pediatric recipients [22, 76].

7.3.2 Avoidance of Infectious Exposures

There are certain measures that can minimize the risk of infection among transplant recipients. In the hospital setting, patients should adhere to basic infection control measures. This includes washing hands frequently and limiting exposure to sick visitors and staff. When transplant recipients return home, these basic infection control measures need to be augmented with avoidance of potential environmental hazards. Transplant recipients should watch their diet, avoiding untreated water, undercooked meats, unwashed produce, and unpasteurized dairy products, soft cheeses, and juices. Other preventive measures include circumventing areas undergoing active construction, refraining from changing litter boxes, engaging in safe sexual practices including using latex condoms in non-monogamous sexual contacts or during periods of increased immunosuppression, and limiting hobbies such as gardening that may put them at risk for novel infectious pathogens [77, 78].

7.3.3 Prophylaxis

Prophylactic strategies following transplantation have also included the administration of anti-infective agents for more common or potentially serious pathogens during high-risk periods (Table 7-2). Prior to the initiation of prophylaxis, approximately 10–12 % patients developed PCP infection 2–6 months post-transplantation [1]. Most centers, therefore, provide PCP prophylaxis to all their transplant recipients for at least the first 6–12 months, using trimethoprim-sulfamethoxazole (TMP-SMZ) as first-line therapy. TMP-SMZ not only provides excellent protection against PCP but, when given daily, may provide protection against urinary tract infections in renal transplant recipients, *T. gondii*, *Nocardia* species, and *L. monocytogenes* [78–80]. TMP-SMZ is inexpensive and usually well tolerated.

For patients who are unable to tolerate TMP-SMZ, second-line agents include dapsone, atovaquone, inhaled pentamidine, and a combination of clindamycin and pyrimethamine [81]. These alternatives, however, may not be as effective against PCP and do not provide equivalent protection against additional pathogens like TMP-SMZ [3]. If second-line therapy with dapsone is needed, it is recommended that glucose-6-phosphate dehydrogenase (G6PD) levels should be checked prior to administration since hemolytic anemia and methemoglobinemia may occur at higher rates in transplant recipients compared to HIV patients. However, some studies suggest that these complications may occur even in the setting of normal G6PD levels [82, 83]. The duration of prophylaxis varies. Renal, heart, and liver transplant recipients on routine immunosuppression typically discontinue PCP prophylaxis at 6 months to 1-year post-transplantation, while lung transplant recipients and small bowel recipients, who are at higher risk, typically remain on lifelong prophylaxis [81]. Physicians should also consider reinitiating prophylaxis during periods of increased immunosuppression (i.e., episodes of rejection) or prolonging prophylaxis for patients with chronic rejection.

One of the most important infections in solid organ transplantation is caused by CMV. The risk for infection is predicted by donor and recipient serostatus and varies depending on the organ transplanted and the choice of immunosuppression [48]. The highest risk occurs when a seronegative recipient receives an organ from a seropositive donor (D+ R−). This not only places the transplant recipients at 60–75 % risk of primary CMV infection but also at increased

TABLE 7-2. Prophylaxis frequently administered after solid organ transplantation

Indication		Medication and dose[a]	Duration
CMV[b]		Valganciclovir 900 orally mg once daily	3–12 months[b]
		Ganciclovir 5 mg/kg intravenous administration daily	
		Valacyclovir 2 g orally 4 times daily	
Fungal[c]		Nystatin 5 mL swish and swallow four times a day	At least 1 week–3 months (all)
		Fluconazole 400 mg orally daily	Variable
		Voriconazole 400 mg orally twice daily × 2 doses, then 200 mg twice daily	
		Amphotericin 10 mg/mL inhaled daily (lung recipients)	
Pneumocystis jirovecii	Preferred	TMP/SMZ SS orally daily or DS orally three times a week	6–12 months for non-lung transplant recipients (longer if chronic rejection issues)
		TMP/SMZ SS orally daily	Lung transplant recipients remain on lifelong prophylaxis
	Sulfa allergic	Dapsone 100 mg orally daily Atovaquone	6–12 months for non-lung transplant recipients (longer if chronic rejection issues)
		1500 mg orally daily Aerosolized pentamidine	Lung transplant recipients remain on lifelong prophylaxis
		300 mg inhaled monthly	
Tuberculin test positive without active infection[d]		Isoniazid (INH) 300 mg orally daily and pyridoxine 50 mg orally daily[c]	9 months

[a]Assumes normal renal function.
[b]CMV prophylaxis varies based on the organ transplanted and donor and recipient CMV status.
[c]Guidelines for antifungal prophylaxis vary with organ, the presence or absence of specific risk factors, and the choice of immunosuppression. See Chaps. 39 and 41 for more details.
[d]Timing of treatment of latent infection with respect to transplant may vary depending on the type of organ transplant and whether the patient is a recent converter. An alternative to INH is 4 months of rifampin if given prior to transplantation. Fluoroquinolone-based regimens may be considered for patients with hepatotoxicity from INH or rifampin.

risk of infection with ganciclovir-resistant CMV and possibly recurrent CMV [84, 85]. The risk of infection is significantly lower when the recipient is CMV seropositive. In addition, CMV risk varies based on the organ transplanted. Lung, small intestine, and pancreas transplant recipients are at the highest risk of CMV infection when compared with kidney transplant recipients who are at the lowest risk [48].

Two different strategies, universal prophylaxis versus preemptive therapy, are typically used for CMV prevention [68, 86]. In universal prophylaxis, an antiviral agent is administered to all transplant recipients to prevent the development of CMV infection. In contrast, preemptive therapy involves close surveillance of CMV viral shedding (typically in the blood) in transplant recipients with therapy initiated when positive levels are detected. CMV DNA testing has supplanted antigen testing at most transplant centers. Meta-analyses suggest that compared to preemptive therapy, universal prophylaxis is associated with decreased rates of allograft rejection, opportunistic infections, and mortality [87, 88]. Randomized controlled trials in kidney transplant recipients have reported lower rates of graft loss [89] and lower rates of acute rejection among patients in the universal prophylaxis arm [90] but an increase in late CMV infection [91], higher medication costs, and increased medication-related toxicity [86].

Antiviral agents used for CMV prophylaxis include ganciclovir, valacyclovir, and valganciclovir. Valganciclovir, a prodrug of ganciclovir, administered once daily has become increasingly popular for prophylaxis in transplant recipients. The use of valganciclovir, however, may be less effective in liver transplant recipients, where there may be a higher incidence of tissue-invasive disease [92]. CMV hyperimmunoglobulin is used infrequently for CMV prophylaxis. One meta-analysis reported no differences between CMV disease, infection, or all-cause mortality in patients who received prophylaxis with an antiviral alone or in combination with CMV immunoglobulin [93]. Another meta-analysis reported that while the rates of CMV infection and rejection did not differ between groups, those that received CMV immunoglobulin had lower rates of CMV disease, overall mortality, and CMV-related mortality [94]. Duration of prophylaxis varies but is given for at least 90 days post-

transplantation, with longer durations for CMV-seronegative recipients of seropositive donor organs and for lung recipients [86]. Transplant care providers should consider reinitiating prophylaxis during episodes of rejection necessitating enhanced immunosuppressant therapy, particularly with antilymphocyte antibodies [48].

Fungal infections are associated with significant complications in the solid organ transplant population. Overall, the most common cause of invasive fungal infections is *Candida* species, followed by *Aspergillus* species [95]. Data from the Transplant Associated Infection Surveillance Network (TRANSNET) reported that the most common *Candida* species was *Candida albicans*, followed by *Candida glabrata*, which has a higher rate of fluconazole resistance [95]. Liver transplant recipients are particularly prone to invasive candidiasis, especially if they have two or more of the following classic risk factors: prolonged operation time, high transfusion requirements (>40 units of blood products), Roux-en-Y biliary anastomosis, renal insufficiency (preoperative serum creatinine > 2 mg/dL), re-transplantation or reoperation, and colonization with *Candida* species [96]. Potential risk factors that include further validation include antibiotic prophylaxis with a fluoroquinolone for spontaneous bacterial peritonitis and patients with iron overload [97]. Among all transplant recipients, lung transplant recipients appear to be at highest risk for invasive fungal infections with organisms other than with *Candida* species [95]. This population is at increased risk for infection with *Aspergillus* species, particularly at the site of anastomosis. Although voriconazole or aerosolized amphotericin B is often used, there are no large-scale, multicenter, randomized studies to direct guidelines regarding the role of antifungal prophylaxis in this population. Nevertheless many centers favor the use of antifungal prophylaxis especially for patients with risk factors including airway ischemia, *Aspergillus* colonization, CMV infection, and augmented immunosuppression [98].

Despite conclusive data to support the use of prophylactic antifungal agents, most transplant centers choose to provide antifungal prophylaxis to certain transplant recipients who are at the highest risk of invasive fungal infections (e.g., liver transplant recipients with the aforementioned risk factors and lung transplant recipients).

7.4 Summary

Infections are serious complications of solid organ transplantation that are largely determined by two factors: the transplant recipient's net state of immunosuppression and the epidemiologic exposures (including those in the pre-, peri-, and post-transplant settings). Diagnosis and management of infections in this population may be challenging. The recipient's immunosuppressed state not only makes him or her susceptible to a broad range of infectious pathogens but may also alter the presentation and affect treatment and outcomes. Given the significant morbidity and mortality associated with infections, preventive measures as well as early diagnosis and treatment are vital in improving outcomes in this patient population.

Donor-Derived Infections: Incidence, Prevention, and Management

Nicole Theodoropoulos and Michael G. Ison

8.1 Introduction

Solid organ transplantation is an ever evolving field, with significant advances in the management of recipients of solid organ transplantation, including enhanced immune suppression and antimicrobial prophylaxis for at-risk patients [1, 2]. In order to increase the number of available organs, and, in turn, save more lives of those on the transplant wait list, the donor pool must continue to expand [3]. Donors reflect the diverse US population; there are an increasing number of donors born in, who have resided in, or who have traveled to underdeveloped areas of the world or areas with geographically restricted infections [4]. As such, these donors are exposed to pathogens that can potentially be transmitted to recipients of the donor's organs. Additionally, there are newer techniques to identify many pathogens that may be transmitted from the donor to the transplant recipients [5, 6]. Finally, high-profile reports of several donor-derived infections have heightened awareness of donor-derived infections and have likely contributed to increased recognition [7–19]. In this chapter, the incidence, methods of identification and prevention, and management of unexpected donor-derived infections will be reviewed. Often, donors are expected to transmit infection (i.e., CMV donor seropositive, recipient seronegative) because of information known by the transplant team posttransplant. In most cases, such information will lead to interventions to reduce the incidence and severity of transmitted disease and is reviewed elsewhere in this text.

In the United States, the Organ Procurement and Transplantation Network (OPTN) policy sets up the framework for minimizing and tracking cases of donor-derived infection transmission. This policy includes language that defines donors at enhanced risk of disease transmission (Table 8-1); the need to obtain special informed consent before using organs from donors with known transmissible disease or risk factors for disease transmission; the need to develop local polices for screening recipients for transmitted disease posttransplant, if appropriate; and the need to report proven or potential disease transmission; policy also defines the requirements for living and deceased donor screening (http://optn.transplant.hrsa.gov/governance/policies/). The Council of Europe has also developed a similar guidance document that is updated regularly to provide similar guidance on donor screening and risk mitigation (https://www.edqm.eu/en/organ-transplantation-mission-67.html). Likewise, the European Union and national governments have established laws and directives that regulate these same functions outside the United States.

8.2 Donors at Increased Risk of Infectious Disease Transmission

Experience has demonstrated that donors with documented infections pose a risk of transmission of the infection from the donor to the recipient. While the risk of transmission varies (i.e., low risk with appropriately treated documented bacterial meningitis or *Naegleria* encephalitis, high risk with active HIV infection), the fact that there is a risk of disease transmission requires several key steps:

1. The organ procurement organization must inform the recipient center of the potentially transmissible infection.
2. The recipient center must assess if the benefit of transplantation outweighs the risk of disease transmission.
3. The recipient center must obtain special informed consent to use the organ from the donor with recognized risk of disease transmission.
4. The recipient center must develop a plan to treat the recipient, if appropriate, to prevent disease transmission and monitor the recipient for evidence of transmitted infection.

Specific details of these key steps will be discussed in greater detail later in the chapter.

Some donors do not have documented infection but instead have engaged in behaviors or have other characteristics

P. Ljungman et al. (eds.), *Transplant Infections*, DOI 10.1007/978-3-319-28797-3_8

TABLE 8-1. Known conditions that may be transmitted by the donor organ that must be communicated to the transplant center prior to transplantation

- Infections
  - Syndromes
    - Unknown infection of central nervous system (encephalitis, meningitis)
    - Multisystem organ failure due to overwhelming sepsis
  - Bacterial infections
    - Bacterial meningitis
    - Bacteremia
    - Pneumonia
    - Syphilis
    - Tuberculosis
  - Fungal infections
    - Endemic mycoses: blastomycosis, histoplasmosis, coccidioidomycosis
    - Cryptococcal infection
    - Fungal sepsis (e.g., *Candidemia*)
  - Parasitic infections
    - *Trypanosoma cruzi*
    - *Leishmania*
    - *Naegleria fowleri*
    - Strongyloides
    - Toxoplasmosis
  - Prion disease, including Creutzfeldt–Jakob disease
  - Viral infections
    - Active hepatitis A, B, or C
    - Herpes simplex encephalitis or documented viremia
    - Human immunodeficiency virus/AIDS
    - HTLV-I
    - History of JC virus infection (progressive multifocal leukoencephalopathy)
    - West Nile virus infection
    - Cryptococcal infection of any site
    - Rabies
    - SARS, MERS-CoV, influenza
    - Malignancies
  - Any known or history of malignancies
  - Melanoma, Merkel cell, and Kaposi's sarcoma
  - Hodgkin's disease and non-Hodgkin's lymphoma
  - Multiple myeloma
  - Leukemia
  - Aplastic anemia agranulocytosis
- Inborn errors of metabolism
- Drug or food allergies

TABLE 8-2. Risk factors for recent HIV, HBV, or HCV infection/increased risk donor criteria [20]

Criteria	Characteristics
Behavior and history	1. People who have had sex with a person known or suspected to have HIV, HBV, or HCV infection in the preceding 12 months
	2. Men who have had sex with men (MSM) in the preceding 12 months
	3. Women who have had sex with a man with a history of MSM behavior in the preceding 12 months
	4. People who have had sex in exchange for money or drugs in the preceding 12 months
	5. People who have had sex with a person who had sex in exchange for money or drugs in the preceding 12 months
	6. People who have had sex with a person who injected drugs by intravenous, intramuscular, or subcutaneous route for nonmedical reasons in the preceding 12 months
	7. People who have injected drugs by intravenous, intramuscular, or subcutaneous route for nonmedical reasons in the preceding 12 months
	8. People who have been in lockup, jail, prison, or a juvenile correctional facility for more than 72 consecutive hours in the preceding 12 months
	9. People who have been newly diagnosed with, or have been treated for, syphilis, gonorrhea, *Chlamydia*, or genital ulcers in the preceding 12 months
Pediatric only criteria	1. A child $\leq$ 18 months of age and born to a mother known to be infected with, or at increased risk for, HIV, HBV, or HCV infection
	2. A child who has been breastfed within the preceding 12 months and the mother is known to be infected with, or at increased risk for, HIV infection
HCV risk only	1. People who have been on hemodialysis in the preceding 12 months
Laboratory and other	1. Screening specimens are hemodiluted
	2. Donor medical/behavioral history is unavailable

that place the donor at increased risk of infection with pathogens, such as HIV, hepatitis B, and hepatitis C, that can, in turn, be transmitted to the recipient. These donors have been defined by the OPTN and US Public Health Services (PHS) as donors at increased risk of disease transmission, termed increased risk donors. The PHS updated their guidance related to increased risk donors in 2013, and this guidance has been adopted as the standard for most transplant systems globally [20]. This updated guideline refined prior guidance taking into account current knowledge of the epidemiology of HIV, HBV, and HCV in the community and the limitations of our contemporary screening practices (Table 8-2). The guideline focuses on three key core recommendations:

1. Screening:
   (a) There is no single standardized and validated tool for collecting the donor's medical and social history, although many US OPOs are utilizing the Uniform Donor Risk Assessment Interview Tool (http://www.

aatb.org/DRAI-Documents). Although living and deceased donors are considered to be equal risk in the guidelines, living donors are able to provide their own history, while histories from deceased donors are obtained from friends and relatives. These individuals may not know the fine details of the donor's social situation (e.g., the mother of a college student who does not live at home). As such, the guideline recognizes these limitations and places donors with incomplete donor histories in the increased risk category as risks may be present but unrecognized.

(b) The 2013 guidelines newly recommend that all donors be screened with serology and nucleic acid testing (NAT) for hepatitis C, regardless of risk factors, and that all increased risk donors be screened with HIV NAT in addition to routine serology. At the present time, only serology is mandated for hepatitis B screening, although this serologic assessment includes hepatitis B surface antigen (HBsAg) which allows for direct detection of the virus. The addition of NAT screening to serology will allow increased detection of acute infections as NAT decreases the length of time between initial infection and the ability of the test to detect the infection, referred to as the window period (Figure 8-1).

(c) The guideline also recognizes that living donors may continue to engage in behaviors that place them at increased risk of disease transmission between screening and donation. As such, the guidelines recommend that living donors are screened as close to the donation procedure as possible, not to exceed 28 days. The feasibility of this recommendation has been demonstrated clinically [21].

2. Consenting: Any patient who is to receive an organ from a patient with risk factors should understand the risk and agree to receive the organ based on that risk assessment. A specialized informed consent for increased risk donor organ use is mandated by policy.

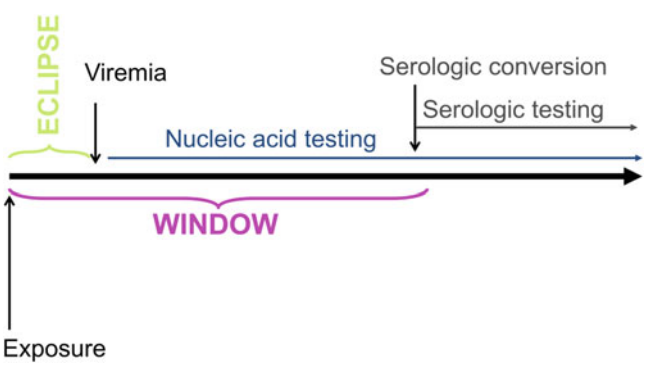

FIGURE 8-1. Interval between infection, detection of virus, and detection of antibody response to infections.

3. Follow-up testing: Perhaps one of the most important recommendations of the PHS guidelines is the need to do posttransplant testing of recipients that received increased risk donor organs to ensure that a disease transmission has not occurred. Early testing may affect outcomes if a transmission is identified, as available effective therapy can be introduced sooner after transmission. Recommendations include HIV NAT (or combined antibody–antigen assay), HCV NAT, HBV NAT, and HBsAg at 1–3 months posttransplant and HBV serology at 12 months posttransplant (including hepatitis B surface antibody, hepatitis B core antibody, and either HBV NAT or HBsAg) [20]. However, data as of 2011 show that posttransplant testing is not reliably performed [22]. Using assays that directly detect the virus in the posttransplant period is critical, and serology may not be reliable because recipients frequently fail to seroconvert due to transmitted infections. In all cases of HCV transmission identified in the United States, for example, all recipients have been seronegative but NAT positive even when tested nearly 1 year posttransplant [23, 24].

These guidelines are helpful in defining donors at increased risk of disease transmission by identifying donors with higher likelihood of HIV, HBV, and HCV infections. Review of existing data clearly demonstrates that the risk of HIV and HCV infection varies significantly by risk behavior (Table 8-3). Given the enhanced risk, it is important to realize that patients may acquire infection in the NAT window, the period of time between infection and when NAT can detect infection (see below). As such, while NAT decreases the risk of disease transmission, residual risk remains and has clearly been demonstrated by three recent transmissions of HCV from donors engaged in nonmedical drug use prior to death with negative donor NAT testing [23].

8.3 Incidence of Unexpected Donor-Derived Infections

To date, there are limited prospectively collected data on the incidence of donor-derived infections. Prior to the establishment of the OPTN/United Network for Organ Sharing (UNOS) Ad Hoc Disease Transmission Advisory Committee (DTAC) in 2005, there were no systems in place to prospectively collect data to estimate the incidence of donor-derived infections; data was only available from published case reports. Underreporting to DTAC was common initially, but recent data show a substantial increase in the numbers of reports (Table 8-4 and Figure 8-2) [24, 25]. In the era of current screening, the following unexpected transmissions have been reported: numerous bacterial species (including gram-positive cocci and gram-negative rods), *Ehrlichia chaffeensis*, legionella, syphilis, *M. tuberculosis, Candida* spp.,

Table 8-3. Residual risk of undiagnosed human immunodeficiency virus (HIV) and hepatitis C virus (HCV) infection per 10,000 donors at increased risk of infection [60, 61]

	HIV		HCV	
Risk factor	Serology alone	Serology + NAT	Serology alone	Serology + NAT
Men who have sex with men	8.3	3.4	36.0	3.8
Nonmedical intravenous, intramuscular, or subcutaneous drug use	12.9	5.3	350.0	37.8
Hemophilia	0.05	0.02	0.46	0.05
Persons who have had sex in exchange for money or drugs	2.9	1.2	107.8	11.5
Partners with any of the above risk factors	2.7	1.1	126.2	13.5
Individuals who have been exposed to blood or blood products from someone with HIV or HCV	1.3	0.5	22.0	2.3
Incarceration	1.5	0.6	68.6	7.3

Residual risk is the rate of undetected infection depending on risk factor and testing strategy.

Table 8-4. Summary of reported cases to the OPTN/UNOS Ad Hoc Diseases Transmission Advisory Committee, 2005–2014

Disease type	# of donor reports	# of recipients with confirmed transmission	# of donor-derived disease-attributed recipient deaths
Malignancies	374	79	28
Viruses	366	80	18
Bacteria	313	55	13
Mycobacteria	95	11	3
Fungi	165	45	15
Parasites	62	41	14
Other diseases	73	6	1
Total	1448	317	92

histoplasmosis, zygomycosis, *Aspergillus* spp., scedosporiosis, coccidioidomycosis, cytomegalovirus, HIV, HBV, HCV, adenovirus, coxsackievirus, human T-lymphotropic virus, lymphocytic choriomeningitis virus and a related arenavirus, West Nile virus (WNV), rabies, schistosomiasis, strongyloides, *Trypanosoma cruzi*, microsporidiosis, and *Balamuthia* spp. [7–9, 11–13, 15–19, 23–38]. From the available data from the US and French systems, donor-derived disease is transmitted in less than 1% of transplants, with approximately 0.03% of recipients dying from the transmitted disease [24, 25].

There are several key points that can be learned from the data collected to date. While confirmed bacterial transmissions are not the most commonly reported transmission, they likely represent the most common form of disease transmission. Most of the confirmed cases of bacteria transmissions involve highly resistant gram-positive and gram-negative infections. From a series of historical studies, 5–9% of abdominal organs and up to 63% of thoracic organs appear to be contaminated with bacterial pathogens at the time of procurement [25, 39–42]. Use of perioperative antibiotics reduces the risk of disease transmission, although under-recognition and underreporting of bacterial transmissions are likely. Given the high rate of contamination and the increasing prevalence of highly resistant bacteria in hospitals globally, bacterial transmissions will increase over time [25, 39–42]. As such, diligence is important among transplant teams.

Although there have been attempts to estimate the risk of donor-derived infections, none can be considered accurate as there is no formal screening process to identify potential transmissions, and the issues of under-recognition and underreporting of transmissions remain. It is critical, and required by current UNOS Policy, that everyone caring for transplant recipients considers the potential of donor origin in all infections, particularly early posttransplant, and has a plan in place to report this concern to the local OPO and to UNOS [43]. Organ vigilance systems, similar to the OPTN/UNOS Patient Safety System, contribute to more rapid communication. Efficient and timely communication is associated with a lower rate of recipient adverse events, including death [44]. As such, regions without organ vigilance systems should establish formal systems, as has recently been required by the EU directive, to improve patient outcomes and potentially improve the safety of the transplant system.

8.4 Prevention of Infectious Transmissions

The mainstay of infection prevention in organ transplantation is the use of donor and recipient screening. Despite best efforts to screen for potential infections and in a timely manner, the transplanting physicians and organ recipients must understand there always remains a risk for infectious transmission. The goals of screening donors and recipients prior to transplant are to identify conditions that disqualify the donor or recipient from the transplant, to identify and treat active infections pre-transplant, and to allow for risk mitigation strategies to minimize posttransplant infections. Screening occurs in many forms including acquisition of a careful history, detailed physical examination, detection of latent or unknown active infections by laboratory testing, examination

TABLE 8-6. Infectious disease screening tests recommended for all organ recipients

Recommended recipient screening tests for all donors	HIV 1/2 serology[a]
	Anti-cytomegalovirus antibody
	Hepatitis B surface antigen (HBsAg)
	Hepatitis B surface antibody (HBsAb)
	Hepatitis B core antibody (HBcAb)
	Hepatitis C antibody
	VDRL or RPR
	EBV serology
	Varicella-zoster virus antibody
	Toxoplasmosis antibody (for heart recipients)
	TB screening (PPD or interferon-γ release assay)
Recommended recipient screening tests for selected donors	HSV 1/2 IgG antibody
	Trypanosoma cruzi serology
	Strongyloides serology
	Coccidioidomycosis serology

and pathologic evaluation of the organ at the time of procurement and implantation, and posttransplant monitoring of recipients. There are policies that have been developed by the OPTN that mandate which screening tests must be done in all donors and recipients (see Tables 8-5 and 8-6). A number of guidelines and consensus conferences have further refined the screening of donors and recipients [20, 45–55].

8.4.1 Donor Screening Methods

While donors undergo a range of screening, including review of the donors' medical and social history and physical examination of the donor and their organs, most attention is paid to tests that are performed on the donors blood to risk stratify the donor. Mandated screening of blood has traditionally focused on detection of antibodies or antigens present in donors, typically using enzyme-linked immunosorbent assays (ELISA) for most infectious disease screening. As of 2011, molecular screening methods using NAT for HIV, HBV, and HCV screening had been implemented by most US organ procurement organizations [56]. In 2014, OPTN policy was updated to mandate HCV NAT for all deceased donor screening and HIV NAT for screening of increased risk organ donors [20, 57].

The indirect ELISA is used to detect antibodies (i.e., HBcAb) while the sandwich ELISA is used to detect antigens (i.e., HBsAg). In the indirect ELISA (http://www.paho.org/hq/index.php?option=com_topics&view=article&id=10&Itemid=40743), a known antigen is fixed to the bottom of a plastic surface, usually a multi-well plate. Serum is then added and if antibodies that react to the antigen are present, they bind to the antigen. The plates are then washed and a detection antibody (usually an anti-IgG or anti-IgM antibody) that is conjugated to a substrate-specific enzyme is applied to each well. After washing, a substrate is then applied and is converted by the enzyme conjugated to the detector antibody, typically resulting in a colorimetric change. The intensity of this change provides a semiquantitative measurement of the presence of the antigen-specific antibody. To detect an antigen, a sandwich ELISA is used in which a capture antibody (one which is specific for the antigen of interest) is bound to the plates. The patient's serum is applied and if antigen is present, it is bound by the capture assay. The plates are then washed and antigen-specific antibodies are applied—creating an antibody–antigen–antibody sandwich. Detection antibodies and substrate are added as above and the resultant colorimetric change is read. Both of these methods have relatively rapid turnaround times, are not subject to a significant risk of contamination, and can usually be done by either an automatic machine or with minimal technical skills.

As discussed below, there are clear challenges to these serological assays. To detect infection earlier, before antibodies have been created, NAT is used for screening of certain infections. NAT refers to a wide range of polymerase change reaction (PCR), transcription amplification testing (TMA), and branched DNA tests. PCR is the most widely used test in which primers that code for complimentary regions of a pathogen-specific gene of interest are selected. For RNA viruses, the RNA is first reverse transcribed to create a complementary DNA (cDNA) based on the RNA template. At this point, PCR for both RNA and DNA viruses are the same. The source nucleic acids are then mixed with the selected primers, DNA polymerase, deoxynucleoside triphosphates, and buffer materials. An initialization step activates the polymerase, and then a denaturation step melts the DNA into two single strands so that the primers may anneal. Extension or elongation then occurs and repeated cycles proceed to amplify the presence of the gene of interest. The presence of DNA can be detected in one of several ways. In real-time PCR, fluorescent dyes are used to intercalate into the double-stranded DNA to quantitatively detect the target DNA. NAT is challenged by longer turnaround time than serologic tests, greater technical expertise to perform the test, and risk of contamination that may result in false-positive test results, especially in low-volume laboratories.

8.4.2 Challenges to Current Screening Techniques

Once an individual is infected with a viral infection, there is typically local replication of the virus with subsequent viremia (see Figure 8-1) [58]. The period of time between initial infection and detectable viremia is referred to as the eclipse period. Once viremia is present, the immune system can recognize the virus and produce neutralizing antibodies to components of the virus [58]. The period between initial infection and the first detection of these antibodies is referred to as the window period [59]. Transmission of both HIV and HCV from donor to recipient has been reported to UNOS during both the eclipse and serologic window periods [17, 23, 24]. The window period differs for each virus and has been shortened over time with improved serologic tests that are able to detect antibodies earlier after initial infection (Table 8-7) [60, 61].

Unfortunately, even once antibodies are formed, it may be challenging to detect these antibodies. First, some donors require transfusion of blood and blood products or receive large volumes of fluids to replete their intravascular compartments. This may dilute the concentration of the antibodies, antigens, or viral particles to below the limit of detection; this process is referred to as hemodilution [62]. There are a number of ways in which hemodilution can be assessed, and no one method is currently considered the gold standard; a simple guideline is that testing may be less reliable if the donor has received greater than 2 L of blood or crystalloid within 48 h of blood sampling or greater than 1 L of crystalloid within 1 h of sampling in adults; recommendations are more strict for pediatric donors [62, 63]. Second, some donors may lose their serologic response to certain infections over time, particularly if they are immunosuppressed. Thirdly, in infant donors, serologic testing may detect the presence of maternal antibodies without active infection of the child [64].

8.4.3 Donor Types

The type of donor affects testing as well. In general, there are two types of donors: living and deceased donors. The major differences between these donor types are the potential quality of the donor history and the time frame during which

Table 8-7. Interval between initial infection and detection of infection by current molecular and serologic testing methods [136, 137]

Pathogen	First detection by NAT (days)	First detection by serology (days)
HIV	7	22
HBV	20	59
HCV	7	70

donor screening may take place. In the case of living donation, the actual donor is interviewed, which may allow for collection of a more accurate medical and behavioral history. The quality of the medical and behavioral history is more challenging in deceased donation in which the histories are obtained from friends and family members who may not know all of the medical or behavioral details—especially if there was limited contact between the donor and the historian. Often, the clinical circumstances leading to the death of the deceased donor may contribute to this limitation—often donors are found down and accurate history about the preceding events may be limited [13, 15]. Likewise, donors may have undergone extensive resuscitation and/or a prolonged hospitalization that will affect donor screening and infectious risk—secondary to hemodilution as discussed above or by introduction of infection at the time of transfusion [7, 11]. There may be a significant time frame between initial screening and organ donation in the case of a living donor. As such, consideration of repeat testing closer to the time of the transplantation should be considered, and current policy recommends that HIV, HBV, and HCV screening of all living donors be performed within 28 days of the transplant [65]. When time allows, donors may be treated for potentially transmissible infections, such as latent TB, prior to the transplant, decreasing the transmission risk. Lastly, the period of time between initial evaluation and transplantation allows one to screen living donors with risk factors for contracting blood-borne viral infections, such as HIV, HBV, and HCV. In increased risk living donors, as defined by the 2013 Public Health Services Guidelines [20], counseling to abstain from the increased risk behaviors and repeat NAT and serologic testing over a period of time similar to the window period for the virus of interest should be considered to minimize the risk of an occult transmission [20].

8.4.4 Universal Donor Screening

As previously stated, screening of the potential organ donor is critical to identify pathogens that can be transmitted to a recipient. Current OPTN policy requires that screening be done for certain pathogens (see Table 8-5) and that enhanced cultures be obtained in the setting of hospitalization of ≥72 h [66]. Current policy requires only sputum gram stain and description of sputum for lung donors and does not require collection of BAL specimens for cultures (although only bacterial cultures are frequently done by some OPOs, viral, fungal, and mycobacterial cultures are typically not obtained) [66]. As of December 2014, NAT is required for HCV screening of all donors and for HIV screening of increased risk donors only. Positive NAT results suggest active viremia; as such appropriate measures need to be in place for appropriate consent and prophylaxis of and follow-up of recipients for transmission events if viremic donor organs are to be used. Negative NAT does not rule out infection, although it may suggest a lower risk of transmission.

8.4.5 Donor Screening for Endemic Infections

Over time, new pathogens have become significantly prevalent and recognized as having transmission potential via organ transplantation. Screening for these types of pathogens should be considered based on local prevalence of the disease. Endemic pathogens that have increasingly been recognized to result in disease transmission and likely should be screened for in donors from endemic regions include: Chagas disease (*Trypanosoma cruzi*), coccidioidomycosis, strongyloides, and WNV.

8.4.5.1 Chagas Disease (Trypanosoma cruzi)

Chagas disease is caused by the parasite *Trypanosoma cruzi* and is endemic to regions of Central and South America [67, 68]. Since testing for Chagas is required for all blood donors, seroprevalence in the United States is known, and significant geographic variability is recognized [53]. Available US guidelines recommend targeted *T. cruzi* screening of potential donors born in Mexico, Central America, and South America. Given the high rate of false-positive results, donors with initially reactive results should have confirmation with a second test. These guidelines suggest that programs can consider transplantation of kidneys and livers from *T. cruzi*-infected donors with informed consent from recipients but do not recommend the use of heart transplantation from infected donors [53]. Recipients of *T. cruzi*-infected donors should be monitored posttransplant with PCR-based screening with institution of antitrypanosomal treatment if recipient infection is detected [53].

8.4.5.2 Coccidioidomycosis

While there is a low but true risk of disease transmission with all endemic fungal infections, the risk appears highest for coccidioidomycosis. This is likely because of the risk of donor transmission as well as recipient reactivation of disease. Coccidioidomycosis is endemic to the Sonoran desert in the Southwest of the United States and Northwest of Mexico in addition to Central and South America. Donors and recipients from endemic regions should be screened for seropositivity by enzyme immunoassay (EIA), complement fixation (CF), or immunodiffusion (ID). If the donor or recipient is seropositive, prophylaxis with fluconazole, typically 400 mg initially (3–12 months) followed by 200 mg daily, is recommended [69].

8.4.5.3 Strongyloides

There have been an increasing number of donor-derived strongyloides transmissions in the United States, likely secondary to a large pool of potential donors with latent infection and increasing use of steroids for donor maintenance

[27]. Strongyloides is endemic in tropical or subtropical regions of the world, where seropositivity may exceed 80% in some locations. Historically, high rates of strongyloides (~3.8%) have been documented in Appalachia and the southeastern United States. Current guidelines recommend routine screening of donors from endemic regions for strongyloides IgG. Living donors should be treated with ivermectin 200 μg/kg daily on two separate days prior to donation, whereas recipients of deceased donors with positive strongyloides antibodies should receive ivermectin posttransplant [54, 70].

8.4.5.4 West Nile Virus

All US blood donors are screened for WNV. The presence of antibodies to WNV does not predict risk of infection, as they are present in those with prior WNV infection or related flaviviruses. As such, detection of virus in the blood by molecular testing predicts increased risk of transmission, although there have transmissions with negative NAT [7, 11, 71]. A 2008 survey revealed that 11/58 OPOs were currently testing donors for WNV by PCR, typically performing testing in seasons when virus would be predicted in the donor service area [72]. Universal testing may be associated with loss of organs and net loss of life in transplant candidates [73]. A more effective screen is to avoid the use of donors with unexplained encephalitis or unexplained mental status change, but unfortunately donors may be completely asymptomatic and carry the infection [7, 11, 68]. Since transmission of other neuropathogens and malignancies has been associated with patients with unexplained encephalitis, avoidance of these donors is prudent in general [13, 15, 16, 31, 74, 75]. If donor testing is utilized, it should be restricted to NAT of the donor blood during periods of time when there are WNV cases in the region from which the donor resided [54]. Use of donor WNV serology or testing of urine for WNV is not recommended at this time.

8.4.6 Recipient Screening

Just as donor screening is critical to minimize the risk of posttransplant infectious complications, recipient screening may contribute to prevention of donor-derived disease transmission (Table 8-6). This is particularly important for CMV and, in the case of potential heart recipients, toxoplasmosis, where the risk of disease and prophylactic plans are frequently determined by donor and recipient serostatus. In addition, all potential recipients should be screened for tuberculosis using medical history (to assess for potential exposure, prior testing, and prior treatment), radiologic examination (baseline chest radiograph), and testing for latent tuberculosis using either the PPD, with a 5 mm cutoff for positivity, or a TB-specific interferon-γ release assay (such as QuantiFERON-TB Gold, Cellestis Inc., Victoria, Australia) [51, 76, 77]. All potential recipients should also be screened either clinically or serologically for a history of exposure to varicella-zoster virus to allow pre-transplant vaccination of unexposed candidates [51, 78].

Recipients may have been exposed to pathogens with regional endemicity. Careful travel and residence history should be obtained from all potential recipients to determine if specialized testing is indicated. Chagas disease can reactivate in asymptomatic, latently affected recipients [67]. Since Chagas is endemic throughout much of Mexico and Central and South America, consideration of screening potential candidates from affected countries should be considered. Since the approved serologic tests lack specificity, confirmatory testing is recommended; patients with confirmed positive serologic screening should be evaluated by an expert in Chagas disease before proceeding for transplantation [53, 67]. Strongyloides is a parasitic infection that is endemic to tropical and subtropical regions of the world. Infection may remain latent after initial infection with risk of potentially lethal hyperinfection in immunosuppressed patients, particularly those who receive steroids [79]. Reactivation with associated mortality has been well described in the setting of solid organ transplantation [79, 80]. As a result, serology for strongyloides and/or testing of stool for ova and parasites should be considered in all at-risk transplant candidates [80]. Lastly, some centers test patients who have lived in areas with high endemicity for *Coccidioides immitis* for serologic exposure to the fungus [81]. There is no role in testing recipients by serology for histoplasmosis or blastomycosis [82].

Certain transplant candidates may have underlying organ diseases that predispose to pathogens that warrant special screening—this is especially true among lung transplant candidates. Patients with a history of cystic fibrosis may be colonized with pathogens that are highly resistant to usual antibiotics; as such, regular screening cultures from BAL and nasal washes may allow the tailoring of specific perioperative antibiotic regimens to minimize the risk of posttransplant infections with these resistant pathogens [83, 84].

8.5 Management

8.5.1 Vaccination

Recipient serology should be a strong driver of pre-transplant vaccination. Detailed recommendations about transplant candidate and recipient vaccination are made elsewhere (see Chap. 48). Patients who do not have evidence of hepatitis B immunity should receive three doses of HBV vaccine unless contraindicated. Although the traditional regimen of vaccination at months 0, 1, and 6 is used by most centers, there is evidence that an accelerated regimen using double doses of vaccine (at days 0, 7, and 21 or weeks 0, 2, 4, and 6 or months 0, 1, and 2) may provide similar efficacy in a shorter period of time [85–87]. Serologic evidence of protection, as

demonstrated by HBs antibody seropositivity, would potentially allow the use of a core-positive alone or HBV-infected organ in a protected recipient. Likewise, patients without prior exposure to varicella-zoster virus are at increased risk of severe infection if exposed posttransplant. Nonimmune transplant candidates should be vaccinated against varicella unless they have a contraindication to vaccination. Lastly, although there are not a lot of data regarding measles and mumps posttransplant, given recent outbreaks of these diseases in the United States and abroad, measles and mumps immunity should be ensured prior to transplantation, especially in candidates born after the vaccine era (after 1963).

8.5.2 Recipients of Organs from Increased Risk Donors

As of 2015, 19.5% of all organ donors in the United States are at increased risk of having undetected HIV, HBV, and/or HCV (increased risk donors) [88]. The 2013 PHS guidelines suggest that "even though attempts should be made to ensure the highest level of safety, organ donor and recipient selection practices and policies should not be restrictive, considering the clinical need… informed decision-making is an important part of this process for transplant clinicians and their patients" [20]. Data suggest that there may be net benefit to using increased risk donor organs, especially in patients on hemodialysis who have a risk for acquiring these infections already, particularly when further screened using NAT [89]. Per current OPTN policy, "if additional donor disease or malignancy transmission risk is identified pre-transplant, the transplant program must … explain the risks and obtain informed consent from the potential transplant recipient … before transplant, document this consent in the potential recipient's medical record and follow any recipient of the deceased or living donor organs for the development of potential donor-derived disease after transplantation" [43]. Policy also states that "if a donor is found to have an increased risk for transmitting blood borne pathogens, the transplant program must offer recipients of the donor organs…., additional post-transplant testing for HIV, hepatitis C, and hepatitis B as appropriate … [and] every transplant hospital must develop and implement a written protocol for post-transplant testing … [as well as] treatment of or prophylaxis for the transmissible disease, when available" [43]. Policy also requires that the host OPO maintain "blood specimens appropriate for serologic and … NAT, as available, for each deceased donor for at least 10 years after the date of organ transplant, and ensuring these samples are available for retrospective testing" [66]. The 2013 PHS guidelines outline how recipients of increased risk donor organs should be followed and recommend that baseline serology be drawn immediately pre-transplant and the following tests at 1–3 months posttransplant: HIV NAT (or combined antibody–antigen assay), HBV NAT and HBsAg, and HCV NAT [20]. Additionally, the following tests are recommended at 12 months posttransplant: HBsAb, HBcAb, and either HBV NAT or HBsAg [20].

Transmission without seroconversion, especially in the case of HCV, has occurred in the majority of the donor-derived transmissions to date, and therefore, posttransplant testing of recipients of increased risk donor organs must use both serologic and molecular methods [17, 20, 23]. Any documented disease transmission must be reported to the local OPO and to UNOS and should warrant further evaluation as well as referral for management of the transmitted infection [43].

8.5.3 Recognition and Management of Potential Donor-Derived Infection Transmissions

There are currently a number of limitations to the recognition of potential donor-derived transmission events. Often, a single donor provides organs to recipients at multiple different centers or recipients that are cared for by different management teams at the same center. As a result, multiple recipients may present with similar clinical illnesses, but the clustering of this illness goes unrecognized [16]. Likewise, pathogens that are commonly recognized as causing nosocomial infections may not be recognized as a potential donor-derived infection [41, 42]. Finally, onset of disease may be of variable severity in individuals and may present with variable onset posttransplant, further challenging the recognition of donor-derived transmission [11, 15, 90]. To overcome these challenges, it is critical that all transplant centers:

1. Maintain a high level of suspicion for donor-derived infection in all early infections or unexplained clinical illnesses. Any early infection or unexplained clinical illness should lead to an inquiry as to the clinical status of other recipients. This is most easily done through contact with the local OPO. This is especially true for patients with unexplained neurological or severe illness within the first 30–60 days posttransplant.
2. Develop a plan for reporting concern for a potential donor-derived infection transmission. This plan should include a local contact at the transplant center and at the OPO when there is concern for a potential donor-derived infection transmission. Likewise, it is important to consider the transplant center's risk management policies to determine if others within your institution need to be alerted. This plan should also include whom the OPO should contact at your center if there are questions about the status of recipients based on queries generated from other centers. Some have found appointing a specific surgeon and transplant infectious disease consultant as the early points of contact facilitate the clear transmission of data.

3. Provide timely feedback about your patients when information is requested by the OPO.
4. Seek outside expertise, through your local health department, UNOS's Disease Transmission Advisory Committee, and the Center for Disease Control's Office of Blood, Organ, and other Tissue Safety. These groups can advise on optimal testing, help collect appropriate specimens, and may provide insight into similar cases that allow the local center to make more informed treatment decisions.

8.5.4 Management of Recipients of Organs from Infected Donors

As previously discussed, all organ donors are currently screened with serology for HIV 1/2, CMV, EBV, HBV, and HCV and also with HCV NAT as currently required by OPTN policy [66]. Although the recent passing of the HIV Organ Policy Equity Act allows for research to be performed in using organs from donors that are HIV-1/2 infected, the use of these organs for transplant is not yet allowed outside of a research protocol in the United States [66, 91].

Donors seropositive for CMV and EBV are universally used, although donor and recipient serologic status may determine monitoring and prophylaxis plans. The risk of developing CMV viremia and diseases is greatest in seronegative recipients of seropositive organs as described later in this text [92, 93]. Universal prophylaxis and preemptive therapy can reduce the risk of viremia and disease in at-risk patients [92, 93]. Development of posttransplant lymphoproliferative disorder (PTLD) has been described, particularly in young EBV seronegative recipients of EBV seropositive donors [94–96]. Careful monitoring and intervention, as described later in this text, may reduce the risk of PTLD in this setting [94–96].

Current mandated donor screening for hepatitis B includes detection of HBV surface antigen (HBsAg) and core antibody (HBcAb). HBsAg is a marker of active viremia while HBcAb is a marker of exposure to hepatitis B virus. Since HBV vaccine only contains hepatitis B surface antigen, vaccinated donors should only have HBV surface antibody (HBsAb), but not HBcAb. If HBsAg is measured early after vaccination, it can be detected in the blood [97, 98]. The risk of transmission of HBV to a nonimmune recipient is high in HBsAg-positive donors [99]; use of these organs is discussed further in the chapter on Hepatitis B. Although HBsAg-positive donors may have been deferred in the past, advances in the use of hepatitis B immune globulin and anti-HBV antivirals now allow the selective use of these organs [99]. Donors that have isolated HBcAb positivity may represent latently infected individuals or a false-positive result. The risk of transmission of HBV in liver transplant recipients is higher than in non-liver recipients [100]. The risk of transmission of HBV from a donor with and isolated HBcAb is estimated to be less than 5% for non-liver recipients [55, 101, 102]. Additional testing of these donors with HBcore IgM and HBV DNA NAT would further stratify the risk of transmission, with the highest risk in the IgM+ and NAT+ donor [55]. Some centers use these organs, particularly in patients who have been vaccinated against hepatitis B [55]. When used in nonimmune patients, posttransplant vaccination is often combined with the use of either anti-HBV antiviral prophylaxis or hepatitis B immune globulin infusions [55]. All recipients, especially liver recipients, of HBsAg+ or HBcAb+ donors should be monitored closely for the presence of active viral replication with expansion of therapy based on these results [55, 103, 104].

Detection of HCV antibodies suggests prior infection with hepatitis C, but about 15–20% of those infected with HCV will clear the virus, and the HCV serology test has a relatively high known false-positive rate [105, 106]. Therefore, the use of HCV NAT in donor screening allows for differentiation between prior HCV infection and active infection with viremia. Use of HCV-positive donors for HCV-negative recipients is currently considered only in life-threatening situations; however, HCV-positive donor organs should be considered in HCV-infected recipients [106–109]. Small, likely clinically insignificant, decreases have been found in transplant graft and patient survival when HCV+ organs are used for HCV-infected recipients, but these are offset by the concomitant decrease in transplant waiting list time [108]. Mortality appears to be higher among heart recipients, so the use of HCV seropositive donors is less frequently considered [110–112]. One concern relates to infecting a recipient with an additional HCV genotype that may be less responsive to antiviral therapy, since genotype results are typically not known at the time of transplant. With the advent of new and evolving data regarding direct-acting antivirals and interferon-free HCV regimens, the options to treat HCV before and after transplant are continuously changing.

It should be noted that the only required bacterial screening in organ donors is blood and urine cultures of donors and screening for syphilis. OPOs are required to determine if additional culture-based testing has been conducted on the donors prior to procurement. Unfortunately, there are current challenges to this—once the donor is declared deceased, they are often "discharged" from the hospital and then readmitted under a new account under the care of the OPO until procurement. When cultures come up positive, the laboratory may not realize that the deceased patient has become a donor and that they have to inform the OPOs of the donor result. Some hospitals may stop working up cultures on "deceased" patients so that no further results are obtained. Lastly, follow-up cultures of bacteremic donors may not be available at the time of procurement.

In general, donors with positive blood cultures may be used if they have received an appropriate antimicrobial and have had a clinical response to therapy; often a complete course of therapy is given to the recipient posttransplant.

Transmission of particularly virulent organisms, such as *Staphylococcus aureus* and *Pseudomonas aeruginosa*, has been described [37, 40, 113]. Donor bacteremia or candidemia mandates treatment of all recipients with a minimum of 14 days of appropriate, active systemic therapy, and experts recommend 4 weeks of recipient therapy when receiving organs from donors bacteremic with *Staphylococcus aureus* [114]. Non-bacteremic localized infections from other sites only require treatment if transmission in the transmitted organ is plausible (i.e., positive urinary cultures require therapy in kidney recipients; sputum cultures require therapy for lung recipients but not other recipients unless bacteremic; etc.).

In patients with proven bacterial meningitis, even with bacteremia, organs can be safely used as long as the patient has received at least 24 h of appropriate antibiotics and antibiotics are continued in the recipient [115–118]. Donor bacterial colonization of lung donors is common. Donor lung sample, including donor bronchoscopy at the time of lung transplantation, may allow for directed antimicrobial therapy.

All donors are tested for latent infection with syphilis per OPTN policy. A recent survey of OPOs revealed that 87% used RPR for testing and 81% of OPOs confirmed positive initial tests with a confirmatory test; a high rate (41%) of positive RPR results was negative on confirmatory testing [119]. Transmission of syphilis by organ transplantation has been rare and is not a contraindication to organ donation [120–122]. Recipients are typically treated as latent syphilis of unknown duration with 3 weekly 2.4 million unit doses of benzathine penicillin G [51, 122].

Lastly, sometimes perfusate or transport media may become contaminated with bacteria or fungi. As with other infections, this is a risk factor for systemic infection and formation of mycotic aneurysms at the site of vascular anastamoses. A full 14-day course of active antibiotic is recommended for recipients to minimize the risk of transmission [123–125].

In general, screening for *Mycobacteria tuberculosis* is not done in deceased donors, but should be performed in all living donors [51, 54, 126, 127]. Active tuberculosis in any donor is a contraindication to donation; if a deceased donor is thought to possibly have tuberculosis, their organs should not be used unless active TB infection can be definitively ruled out [126, 128–131]. Donor-transmitted TB accounts for 4% of all posttransplant cases of tuberculosis [132]. Testing for TB can be done by the PPD placed using the Mantoux method or via a TB-specific interferon-γ release assay (such as QuantiFERON-TB Gold, Cellestis Inc., Victoria, Australia) [133]. Positive testing by either method should result in careful assessment for active disease, including chest imaging and, if appropriate, sputum and/or urinary AFB cultures. Some centers will provide latent TB treatment to the recipient of organs from these donors; this decision can be individualized as transmission if not universal [77, 129, 132]. If the recipient does not receive treatment for latent TB, a note about the donor's testing should be prominent in the recipient chart to trigger aggressive evaluation with the appropriate clinical presentations (i.e., sterile pyuria, pneumonia).

Toxoplasmosis is a parasite that remains dormant predominantly in muscle tissue. As such, the risk of transmission is greatest in heart donation [68]. Routine screening of all donors for toxoplasmosis is not done at many OPOs, but policy requires that serum is procured at the time of explanting the heart to perform toxoplasmosis serology at the recipient center [66, 134]. Positive serology is not a contraindication for transplantation. In the setting of heart transplantation, donor and recipient toxoplasma serostatus may affect prophylactic and monitoring strategies [134, 135]; generally, prophylaxis is not modified in non-heart recipients of toxoplasmosis seropositive donors [135].

8.6 Conclusion

Donor-derived infections are increasingly recognized as causes of morbidity and mortality that typically present in the early posttransplant period. Careful screening of donors through history, physical examination, and serologic and molecular testing may minimize the risk of infection transmission. It is impossible to screen for all potential pathogens, and our current screening practices have clear limitations. As a result, the possibility of donor origin should be considered for all early infections and patients with atypical clinical courses. Reporting of proven or suspected donor-derived infections is currently mandated as part of OPTN policy.

9 Transplant Infections in Developing Countries

Clarisse M. Machado

9.1 Introduction

A significant number of developing countries are located in the tropical or subtropical regions thereby having epidemiological characteristics different from developed countries with temperate climates. Along with the social and economic challenges, these countries are characterized by the occurrence of endemic infections and diseases that are absent or rare in developed countries.

The rising success rate of solid organ (SOT) and hematopoietic stem cell transplantation (HSCT) together with modern immunosuppression make transplants the first therapeutic option for many diseases affecting a considerable number of people worldwide. Thus, populous developing countries have faced a growing need of transplant procedures and struggled to develop public financing programs for SOT and HSCT to assure universal accessibility and avoid any kind of commerce [1].

Some developing countries are among the top ten countries performing the highest absolute number of kidney and liver transplants worldwide. In 2013, 5433 kidney and 1723 liver transplants were performed in Brazil, behind only the United States. Mexico and South Korea were also among the ten countries performing the highest absolute number of kidney transplants worldwide. Argentina, China, India, and South Africa, have also shown a sustained economic growth and the amplification of transplant programs is now a reality [2].

In recent years, developing countries had to adjust international transplant guidelines to their epidemiological characteristics, including the local policies and management of tropical diseases.

Table 9-1 shows the most prevalent tropical infectious diseases in developing countries. Although highly prevalent in general population in these countries, some of them have not been described in transplant recipients or do not seem to confer an increased risk in this population. Others, such as Chikungunya and Zika virus, have been recently recognized as potential threats to be confirmed in the next years.

This chapter reviews the epidemiology of viral, bacterial, and protozoan tropical diseases with greatest disease burden that have affected transplant recipients in developing countries or may represent a threat to transplant recipients living in other regions. Endemic mycosis and soil and water-associated tropical infections are reviewed in the other chapters of this book.

9.2 Viral Infections

9.2.1 Dengue

Dengue is the most rapidly spreading mosquito-borne viral disease in the world and occurs both as an endemic or epidemic disease. In the last 50 years, incidence has increased 30-fold with increasing geographic expansion to new countries and, more recently, from urban to rural areas. An estimated 50 million dengue infections occur annually and approximately 2.5 billion people live in areas where dengue viruses can be transmitted [3].

Dengue virus (DEN) is a small single-stranded RNA virus comprising four distinct serotypes (DEN1, DEN2, DEN3 and DEN4). These closely related serotypes of the dengue virus belong to the genus Flavivirus, family Flaviviridae, which are transmitted by mosquitoes of the genus Aedes, such as *Aedes aegytpi* and *Aedes albopictus*.

Infection by one serotype provides lifelong immunity against that serotype but only partial and transient protection against subsequent infection by the other three. In the immunocompetent population, there is good evidence that secondary infection increases the risk of more serious disease resulting in dengue hemorrhagic fever (DHF) or dengue shock syndrome (DSS). Patients with severe dengue have elevated circulating levels of T-cell activation markers, such as IL-8, IL-10, TGF-β, and interferon-γ [4]. Therefore, a robust immunologic response is a prerequisite for the development of DHF or DSS.

P. Ljungman et al. (eds.), *Transplant Infections*, DOI 10.1007/978-3-319-28797-3_9

Table 9-1. Distribution of tropical infectious diseases according to region[a]

Region	Viruses	Bacteria	Parasites
North Africa	Hepatitis A, rabies	Plague, tuberculosis, typhoid, and paratyphoid fever	Leishmaniasis
Sub-Saharan Africa	Dengue, zika virus, yellow fever, chikungunya, rabies, hepatitis A, hepatitis B, poliomyelitis, other viral hemorrhagic fevers	Diphtheria, tuberculosis, plague, leprosy	Leishmaniasis, malaria, schistosomiasis, trypanosomiasis
Mexico, Central America	Dengue, hepatitis A	Leptospirosis, typhoid, and paratyphoid fever	Leishmaniasis
Latin America	Dengue, zika virus, chikungunya, yellow fever, rabies, hepatitis A, hepatitis B, measles, hantavirus, other viral hemorrhagic fevers	Tuberculosis, leprosy, leptospirosis, plague	Leishmaniasis, malaria, schistosomiasis, trypanosomiasis
South-East Asia	Dengue, Zika virus, hepatitis A, hepatitis B	Leptospirosis, plague, Tuberculosis	Filariasis, malaria, schistosomiasis
South Asia	Chikungunya, hepatitis A, hepatitis B, rabies	Leptospirosis, plague, tuberculosis	Filariasis, leishmaniasis, malaria
East Asia	Hantavirus, hepatitis A, hepatitis B	Leptospirosis, plague, tuberculosis	
Northern Asia	Hantavirus, hepatitis A, hepatitis B, rabies	Diphtheria, tuberculosis	
Middle East	Hepatitis A, hepatitis B	Tuberculosis	Leishmaniasis

[a](*) Include only diseases with widespread transmission, epidemic activity or high risk for infection in some areas.

Dengue has a wide clinical spectrum varying from asymptomatic to severe and non-severe clinical manifestations. It is recognized that the number of asymptomatic carriers is at least three times that of dengue fever (DF) cases. After the incubation period, the illness begins abruptly as a flu-like illness. Symptomatic dengue virus infections are grouped into three categories: undifferentiated fever, dengue fever (DF), and DHF. DSS is the most severe forms of DHF (severity grades III and IV). Warning signs for dengue complications are abdominal pain or tenderness, persistent vomiting, clinical fluid accumulation, mucosal bleeding, lethargy, liver enlargement >2 cm, and increase in hematocrit concurrent with rapid decrease in platelet count. However, it is important to highlight that dengue may have several clinical presentations, often with unpredictable clinical evolution and outcome. The absence of warning signs does not preclude the possibility of severe disease and lethal outcome [3].

9.2.1.1 Geographic Distribution

More than 70% of the population at risk for dengue worldwide lives in the South-East Asia Region and Western Pacific Region. In the region of the Americas, an interruption of dengue transmission was temporarily reached during the 1960s and early 1970s, as a result of the *Ae. aegypti* eradication campaign. However, vector surveillance and control measures were not sustained and there were subsequent re-infestations of the mosquito, followed by outbreaks in the Caribbean, and in Central and South America. In the last 13 years, dengue outbreaks were reported in Brazil, Honduras, El Salvador, Equator, India, Indonesia, Southwest Indian Ocean, Cape Verde, Crimean-Congo, Pakistan, and Madeira Island. Only in Brazil, three outbreaks occurred during this period, in 2002, 2008, and 2015 [5].

In the region of the Americas, 871,150 cases of dengue/severe dengue and 272 deaths were reported up to May 8th 2015 (epidemiological week 16), with a case-fatality rate of 0.03. More than 85% of those cases occurred in Brazil [6].

9.2.1.2 Transmission in Transplant Recipients

Several countries in the aforementioned regions have active transplant programs. In the last 5 years, an increasing number of dengue cases have been described in transplant recipients, as a consequence of the growing incidence of dengue in several countries [3]. So far, more than 150 dengue cases have been reported [7–18]. The numbers may be even higher since most of the cases are mild and presenting as a flu-like syndrome. Thus, many cases have certainly been underdiagnosed in transplant population from endemic areas. Dengue can be transmitted by mosquito bite, blood transfusion, or by the graft.

Mosquito bite. The most frequent mode of dengue transmission in transplant recipients is through mosquito bite. According to the published cases, more than 95% of the transplant recipients were living in or have traveled to an endemic area and acquired dengue by vector transmission [8–19].

Graft transmission. Graft transmission is more rare and has been well documented in two cases of HSCT [7, 20]. In 2001, Rigau-Pérez et al. described a case of dengue in a HSCT recipient during the 1994–1995 dengue epidemics in

Puerto Rico. The patient, a 6-year-old child, died 11 days after transplantation and DEN4 was detected in blood, ascitic fluid and tissue samples. The donor developed fever 2 days after marrow harvesting and dengue was diagnosed by the presence of specific IgM antibodies. DEN4 serotype was confirmed in donor samples [7]. The other case of graft transmission was recently reported in a HSCT recipient from Germany whose unrelated donor had returned from Sri Lanka 3 days before donation. Despite the predictable risk, the recipient was in urgent need of the transplant and the transplant was consented through a Declaration of Urgent Medical Need [20]. Graft transmission was also reported but less well documented in a renal transplant recipient from Singapore whose living donor had acquired dengue 6 months before donation. As Singapore is an endemic area and dengue virus does not persist in the host for so long time after infection resolution, dengue was more likely to have been transmitted by mosquito bite [11].

Blood transmission: Dengue transmission by blood has been increasingly demonstrated as a consequence of the expanding areas of dengue transmission and more frequent outbreaks. The majority of dengue cases are well known to be asymptomatic. These individuals may offer to donate blood, and consequently viremic donors have been observed during outbreaks in all investigated areas [21–23]. The transmission of dengue to naïve blood recipients have also been detected during outbreaks. Recently, one case of blood-transmitted dengue was documented in a patient with severe aplastic anemia after platelet transfusion from a regular platelet donor who was asymptomatic at the time of donation, but seroconverted (both IgG and IgM) in the following month. The other recipient of the same platelet donation did not develop dengue [24].

9.2.1.3 Pretransplant Management

Dengue control is based on vector control and community-based programs to keep the environment free of potential breeding sources, mainly artificial water containers such as discarded tires, uncovered water storage barrels, flower vases, etc. The mosquitoes breed in limpid water. In endemic regions, transplant patients should receive information about dengue transmission and *Aedes* habits to avoid exposure. The incidence, morbidity and mortality of dengue fever and its complications are difficult to estimate, as no prospective seroepidemiological study has been performed in transplant recipients from endemic areas. Seropositive patients have a theoretical risk of developing severe dengue in case of reinfection during outbreaks. Pretransplant screening for dengue is currently not recommended, but prospective studies are necessary to evaluate the cost effectiveness of serological assessment before transplantation.

9.2.1.4 Posttransplant Management

Clinical findings: In general, case reports are more prone to describe severe cases of dengue in detriment of mild ones. Thus, among nine publications of dengue cases, six reported severe clinical presentations, DHF, or DSS [7–9, 11, 13, 18, 20]. On the other hand, in published case-series of dengue from Brazil (27 cases) and Singapore (6 cases), both in renal transplant recipients, a benign course was generally observed and death probably due to DSS was registered in 1 of the 27 patients (3.7%) from the Brazilian series [10, 12]. More recent case-series publications confirm that mild cases are more frequent than severe cases in solid organ and stem cell transplant recipients. In 2013, 102 cases of dengue in renal transplant recipients from Pakistan were retrospectively reviewed. Forty-four patients (43%) had primary and 58 (56.8%) had secondary dengue infection. Thrombocytopenia was seen in 95% of the cases, with a mean duration of 11 ± 9 days. Most of the patients presented fever (80%), which was less frequently seen in patients receiving high-dose steroids (>7.5 mg). DF occurred in 90 (88%), and DHF/DSS occurred in 12 (11.7%). High dose of steroid use had a negative impact in those with primary but not in secondary infection. Graft dysfunction occurred in 68 (66.7%) of the patients. Interestingly, patients on a CSA-containing regimen had significantly less severe disease [17]. Studies have shown that CSA can be a potential drug for the treatment of flavivirus infections [25].

Dengue mortality rates vary from 0.026% in classic dengue fever up to 5% in DHF in the immunocompetent population. In addition, the paucity of reports of DHF or DSS in transplant recipients may reflect the T-cell immunosuppression induced in this population and the consequent low inflammatory response.

Diagnosis: Before day 5 of illness, virus isolation, nucleic acid or antigen detection can be used to diagnose dengue. NS1 antigen detection kits can be used in laboratories with limited equipment and yield results within a few hours. At the end of the acute phase of infection, serology is the method of choice for diagnosis. IgM antibodies are the first immunoglobulin isotype to appear and are detectable in 50% of patients by days 3–5 after onset of illness, increasing to 80% by day 5 and 99% by day 10. IgM levels peak about 2 weeks after the onset of symptoms and then decline generally to undetectable levels over 2–3 months. Anti-dengue serum IgG is generally detectable at low titers at the end of the first week of illness, increasing slowly thereafter, with serum IgG still detectable after several months, and probably even for life [3].

Treatment: There is no specific antiviral drug and management of dengue should follow a stepwise approach including overall assessment (history, symptoms, physical examina-

tion, mental assessment, and laboratory tests), diagnosis, and assessment of disease severity. On the basis of evaluations of the history, physical examination and/or full blood count and hematocrit, clinicians are able to determine whether the disease is dengue, which phase it is in (febrile, critical or recovery), whether there are warning signs, the hydration and hemodynamic status of the patient, and if the patient requires admission. Hydration is the mainstay of dengue treatment. According to some case series, immunosuppression did not seem to affect the outcome and there is no evidence to recommend decreasing immunosuppression.

In conclusion, there should be a high index of suspicion for dengue illness in transplant recipients presenting with thrombocytopenia in endemic areas, even if afebrile. Prolonged thrombocytopenia (more than 10 days) is expected and has been observed in transplant recipients with dengue in comparison to general population (around 3 days). During epidemics, the cost benefit of screening organ donors and blood products in hyperendemic regions needs to be assessed, since studies conducted during epidemics have detected DEN viremia by PCR in 0.04–0.3% of in asymptomatic blood donors [21, 22].

9.2.2 Yellow Fever

Yellow fever (YF) is a vector-borne disease caused by yellow fever virus, a RNA virus belonging to the family *Flaviviridae*, genus *Flavivirus*, transmitted to humans by the bite of infected mosquitoes. YF virus infects humans and monkeys in three types of transmission cycle: sylvatic (jungle), savannah, and urban.

In the jungle cycle of South America, monkeys infected by sylvatic mosquitoes *Haemagogus* pass the virus to other mosquitoes that fed on them. Humans are sporadically exposed when enter the transmission cycle of the agent. In the savannah cycle, the virus is transmitted by semidomestic mosquitoes *Aedes* (mainly *Ae. africanus*) that infect both monkeys and humans and produce small-scale epidemics in African rural areas. In the urban cycle, monkeys are not involved and infection is transmitted among humans by the mosquito *Aedes aegypti*, generally causing explosive epidemics in populous areas [26, 27].

After an incubation period of 3–6 days, immunocompetent patients develop fever, muscle pain, headache, shivers, loss of appetite, nausea and vomiting, characterizing the acute phase of yellow fever. Most patients improve and symptoms disappear in few days. Around 90% of the cases are mild or asymptomatic. However, between 15 and 20% go into a severe toxic phase with reappearance of fever and the development of jaundice and sometimes bleeding. About 50% of patients in toxic phase die within 10–14 days [27].

9.2.2.1 Geographic Distribution

Over 900 million people are at the risk of being infected in the tropical areas of Africa and South America. Thirty three countries in Africa that are located between 15 latitude north and 10 latitude south of the equator, are at risk of yellow fever. Sudan is the only country in Eastern Mediterranean Region in the yellow fever zone. Large epidemics have been reported in Sudan in 1940, 1959, 2003, 2005, 2012, and 2013 [28]. In the Americas, from 1985 to 2012, 95% of all yellow fever cases were reported by four countries: Peru (54% of all cases), Bolivia (18%), Brazil (16%), and Colombia (7%). The other countries with conditions for yellow fever transmission are Argentina, Ecuador, French Guiana, Guyana, Panama, Paraguay, Suriname, Trinidad and Tobago and Venezuela. From 2000 to 2013, more than 1100 laboratory-confirmed cases were reported in the Americas, with the largest numbers reported from Brazil and Peru [29].

The annual estimated cases per year in at risk areas are 200,000, causing 30,000 deaths. Fatal cases of yellow fever have been reported among unvaccinated tourists from the United States and Europe who visited endemic areas of yellow fever [30, 31].

9.2.2.2 Transmission in Transplant Patients

No case of yellow fever has been reported in solid organ or stem cell transplant recipients. However, the occurrence of the disease in the transplant population in developing countries can be just a matter of time, in the case of urban yellow fever resurgence. The control of yellow fever is based on mosquito eradication and vaccination of people living in or traveling to risk areas.

9.2.2.3 Pretransplant Management

Since live-attenuated vaccines are contraindicated after transplant, SOT candidates from endemic regions are recommended to receive yellow fever vaccine (YFV) before transplant. This practice should be encouraged as pretransplant immunization elicits prolonged YF immunity in SOT patients, as recently demonstrated. A prospective study conducted in 53 SOT recipients (29 kidney, 18 liver, 1 heart, 2 kidney–liver, 2 pancreas–kidney, and 1 heart–liver) showed that protective YF antibody level was detectable in 98% of the recipients vaccinated before transplantation. The median time from vaccination to assessment of YF immunity was 13 years, varying from 3 to 32 years [32].

9.2.2.4 Posttransplant Management

The live-attenuated YFV is contraindicated in transplant recipients due to the potential risk of severe adverse events,

mainly encephalitis [30, 33]. Extremely rare cases of viscerotropic disease following YFV have been reported in general population [34].

Although contraindicated, some transplant patients may inadvertently receive the vaccine. Recently, an increase in the number of reported human YF cases occurred in Brazil, from 2 cases in 2006 to 46 in 2008. This increase prompted health authorities to expand the area of vaccine recommendation. These facts were widely reported by the media and caused a rush to health services to receive the vaccine, including some individuals for whom YFV is contraindicated. The safety of YFV in SOT recipients inadvertently vaccinated against YF was evaluated through a questionnaire sent to physicians affiliated to the Brazilian Society of Organ Transplantation. Nineteen SOT (14 kidneys, 3 hearts, and 2 liver) received YFV by mistake and only 1 patient had a slight reaction at the site of YFV injection. No one had systemic reactions or required hospitalization [35]. However, no recommendation for YFV safety can be made based on this data due to the small number of patients studied. SOT recipients should, if possible, not travel to endemic areas, and, if exposure is likely, the benefits of YF immunization should be evaluated and a decision should be taken carefully on a case-to-case basis [36].

A slightly different scenario is observed in HSCT recipients as immunosuppression is progressively decreased over time and live-attenuated vaccines may be used after 2 years of HSCT, if the patient is not receiving immunosuppressive drugs. Thus, YFV may be considered for HSCT recipients under those circumstances and living in areas of great risk of YF. In other situations vaccination is contraindicated and should be avoided [37].

More than 20 cases of YF vaccination have been reported in HSCT recipients without side effects [16, 38, 39]. In 2008, when an expanded area for YFV recommendation was determined in Brazil, a seroepidemiological survey was conducted in 27 HSCT recipients living in the expanded areas to identify those susceptible to YF. Information about previous vaccination was available for 24 of them. These patients underwent HSCT at a median of 406 days, ranging from 21 to 2334 days. Sixteen had received YFV before HSCT and persistent YF immunity was detected in 14 of them (87.5%). Seven patients (29.1%) were susceptible to YF despite the pretransplant vaccination in two of them. Three were within the first 2 years of HSCT, and consequently were not eligible to YF vaccination. The remaining four HSCT recipients received YFV without adverse events [16]. Interestingly, among the eight HSCT recipients who did not receive YFV before transplantation, three (37.5%) were immune. The presence of YF antibodies after HSCT may reflect passive immunity from the donor or recipient exposure to YF virus. Asymptomatic or mild cases of YF are common in immunocompetent hosts and may possibly also occur in HSCT recipients [16].

It is important to stress that vaccine strain viremia frequently occurs in healthy persons during the first week of primary YF vaccination. In booster doses, vaccine strain viremia is unlikely [30, 40]. In the case of donor vaccination, it is prudent to wait at least 1 week to stem cell or marrow harvesting or organ donation.

Transplant recipients from developed countries traveling to endemic regions of YF should be advised of the risks posed by such travel, instructed in methods for avoiding vector mosquitoes, and supplied with vaccination waiver letters by their physicians [30].

9.2.3 Measles

Measles virus belongs to the *Paramyxoviridae* family, which infects primate species, but can only be maintained in human populations. Measles is an acute illness and one of the most contagious diseases as almost all susceptible persons acquire the disease once exposed to the virus. The virus spreads from person to person within aerosol droplets generated during coughing. Measles tends to result in epidemics that cause many deaths, especially among young malnourished children. Characteristic symptoms such as fever, dry cough, coryza, rash, conjunctivitis and photophobia initiated 10 days after infection [41].

More than 20 million people are affected by measles each year. Poverty impacts lethality rates. While global measles deaths have decreased by 75% worldwide in recent years, from 544,000 deaths in 2000 to 146,000 in 2013, more than 95% of measles deaths occur in countries with low per capita incomes and weak health infrastructures [42].

Vaccination is the best way to control measles and has a major impact on measles deaths. A safe and effective live-attenuated virus vaccine is available for the past 40 years.

9.2.3.1 Geographic Distribution

Measles has not been eliminated from most countries and is the first disease to reappear when vaccine coverage falls. As a result of decreased measles vaccination coverage, developed countries have also registered epidemics of measles in recent years: Ireland and the Netherlands in 2000, Korea in 2001, Italy in 2002, Switzerland in 2006, Japan in 2007, Austria and United States in 2008. During 2011, 115 measles outbreaks were reported in 36 of the 53 member states in the European Region. More than 26,000 measles cases had been reported as of October 26th 2011. France reported the largest number of cases (>14,000); these occurred predominantly among older children and young adults who had not been vaccinated or whose vaccination history was unknown. The primary reason for the increased transmission and outbreaks of measles in Europe is failure to vaccinate [43]. Although measles elimination has been declared in the US in 2000, a

total of 159 cases were reported from January 4th to April 2nd, 2015 [44]. In 2014, more than 96,000 cases of laboratory-confirmed measles were reported in all WHO regions.

9.2.3.2 Transmission in Transplant Patients

Measles has been diagnosed in transplant patients as a result of community outbreaks or recent travel to endemic or epidemic regions. As measles epidemics resurge, susceptible transplant recipients from developed and developing countries become an easy target for measles and its complications. Previous and/or donor-transferred immunity wanes over time and measles antibodies titers are expected to fall below the protective level during follow-up. Up to 55% of HSCT and 22% of SOT recipients lose measles immunity by 24 and 6 months after transplant, respectively [45, 46].

Protection against measles in transplant recipients strongly relies on herd immunity, since live-attenuated vaccines have restricted use in this population. In SOT recipients, measles vaccination is recommended before the transplant, and in the setting of HSCT, measles vaccine can be safely used after 24 months of transplantation in patients not receiving immunosuppressive drugs [47].

The largest series of measles cases in transplant population was described in HSCT recipients during an outbreak in Brazil. In view of the limitations to the use of live-attenuated vaccines in these patients, a serological survey was performed and identified 54 susceptible to measles, 8 of which acquired measles in the first 3 months of the outbreak (attack rate 14.8%). One patient developed measles pneumonia. No patient developed CNS complications during follow-up or died of measles [45]. To interrupt measles transmission among susceptible patients, a protocol of early measles vaccination (1 year after HSCT) was successfully instituted and no more cases were seen up to the end of the outbreak which lasted 2 years [48]. During the 2000–2001 measles epidemics in Korea, one fatal case of measles pneumonia was reported in a 39-year-old HSCT recipient with chronic GVHD [49].

In the setting of SOT, five cases of measles-associated encephalitis have been reported in renal transplant recipients, at a median of 5 years after transplantation (range 3–11 years) [50–53]. Preceding measles infection was reported in three of the five patients, 6 weeks to 4 months before the appearance of neurological symptoms. In the remaining two patients, measles diagnosis was retrospectively performed by serology in one case and by necropsy in the other case. Three patients had received one dose of measles vaccine in infancy, one had not been vaccinated and in the remaining one, vaccination status was not informed. Three patients (60%) died as a consequence of CNS complications and the other two patients survived with sequelae [53]. More recently, a case of measles was diagnosed in a 31-year-old liver transplant recipient during an outbreak in public schools in Salzburg, Austria. Liver biopsy revealed portal inflammation and endothelialitis as well as alteration of the cholangium suggestive of mild acute transplant rejection triggered by measles infection [54].

9.2.3.3 Pretransplant Management

Measles is difficult to eradicate as sustained elimination requires the maintenance of more than 90% one-dose coverage among preschool children and more than 95% two-dose coverage among school-aged children [55]. Due to decreased coverage rates of measles vaccination, the disease has reappeared in developed countries.

Facing this scenario, vaccination status for measles should be checked and updated in patients awaiting SOT. The recent Infectious Diseases Society of America (IDSA) guideline states that live-attenuated vaccines can be administered to SOT candidates at 6–11 months of age if they are not immunosuppressed and if the transplantation is not anticipated in the ensuing 4 weeks [56]. However, the presence of maternal antibodies may interfere in the antibody response. A recent study in liver transplant candidates vaccinated prior to transplantation, showed a 12.5% rate of sustained immunity after transplant in children who received measles vaccine before 12 months of age and 63.6% in those older than 12 months [57].

9.2.3.4 Posttransplant Management

In addition to the pretransplant assessment of immunity and vaccination update, clinicians should have in mind that antibody levels decline rapidly in the first 12 months following transplantation. Despite the restricted use of measles vaccine in transplant populations, there is growing evidence of its safety in situations where the risk of measles complications outweighs the risk of adverse events of vaccination. Taking into account the current epidemiological situation of measles worldwide, regular monitoring of posttransplant antibody levels to measles should be considered in transplant recipients, and if loss of protective antibody level is detected, reimmunization might be an option. Several groups have reported that post-transplant measles vaccination could be efficacious and safe [58–60].

Measles vaccine administered after the 12th month of transplant was safe and effective during the 1997–1999 measles epidemics in Brazil. Around 53% of the patients were receiving immunosuppressive drugs. No moderate or severe adverse events were observed and vaccination was the strategy used to interrupt measles transmission among susceptible HSCT recipients [48].

The safety of measles vaccine beyond its recommended use has also been evaluated after solid organ transplantation. In two studies recently reviewed [61], 31 patients received

measles vaccination between 1.5 and 65 months after transplantation. No adverse event was noted among 29 children. In the remaining two children (6.4%), signs of organ rejection were observed 3 weeks after first vaccination, but the possible association of vaccination and rejection remains elusive. Seroconversion rates were higher in patients who had received measles vaccine before transplant (85%) as compared to children immunized only after transplantation (41%). Similarly, sustained immunity was observed in 64% of the patients previously vaccinated in comparison to 29% of the patients who were vaccinated only after transplantation [61–63]. In another study, overall responses rates of 73% were observed in 26 children receiving primary measles vaccination after liver transplantation. However, 18 patients required multiple doses [58].

Thus, although transplant guidelines do not recommend live-attenuated vaccines after solid organ transplantation, some groups have indicated measles, rubella, mumps and varicella vaccines in patients fulfilling the following criteria: (1) at least 1 year of transplant and stable general condition; (2) no use of systemic steroids to treat acute rejection within the last 6 months; (3) exclusive use of tacrolimus as an immunosuppressive drug, and serum through concentration of tacrolimus <5 ng/mL (indicating that rejection reaction was under control); (4) no severe immunosuppression according to blood examinations; and (5) provision of written informed consent from all patients or guardians [64].

In conclusion, compliance to vaccination guidelines is strongly recommended in both SOT and HSCT recipients. Periodical evaluation of measles immunity identifies susceptible patients eligible to revaccination. During epidemics, clinicians should have a high index of suspicion for measles in transplant recipients with respiratory symptoms, as rash may be absent or atypical. In epidemic situation when the risk of measles complications may overweigh the risk of adverse events, measles vaccination may be considered in individuals receiving immunosuppressive drugs.

9.2.4 Rabies

Rabies is a zoonotic viral disease which infects domestic and wild animals. Rabies virus causes acute and progressive encephalitis. It is transmitted to humans through close contacts with saliva from infected animals, usually a dog, cat, raccoon, skunk, mongoose, or bat. Domestic dogs cause over 99% of all human deaths from rabies. Bites are the most common mode of contamination, even though the contact of infected saliva with scratches, licks on broken skin and mucous membranes may also cause rabies [65, 66]. After the virus is inoculated into humans, it is taken up through peripheral nerves and infects the central nervous system causing encephalitis. This process may take weeks or months. The first symptoms of rabies are usually nonspecific and suggest involvement of the respiratory, gastrointestinal and/or central nervous systems.

An average of 60,000 people die from rabies annually, and more than 15 million people receive postexposure prophylaxis every year. Bat rabies variants of genotype 1 have different tissue tropisms and patients with bat lyssavirus variants may show clinical manifestations different from what is seen in humans infected with canine rabies.

9.2.4.1 Geographic Distribution

Rabies is widely distributed on all continents except Antarctica. Most industrialized countries have eliminated rabies from domestic dog populations. However, in the majority of developing countries, rabies remains endemic, poorly controlled and certainly underreported [67]. The actual incidence is unknown as several countries do not include rabies among notifiable diseases. Dog bites are the most frequent mode of transmission in most countries of Africa, Asia, Latin America, and the Middle East. In contrast, in North America, most documented human rabies deaths occurred as a result of infection from bat rabies virus [68].

9.2.4.2 Rabies in Transplant Recipients

The transmission of rabies virus through cornea transplantation has been described, but transmission through solid organ transplantation was not recognized before 2004. Seventeen cases of rabies have been reported in transplant recipients, and to date, all have been transmitted through the transplanted tissue or organ. Nine cases followed corneal transplantation, including eight deaths.

Two clusters (Texas in 2004 and Germany in 2005), totaling seven rabies cases, have occurred following SOT [69, 70]. Each of the donors died of an illness compatible with or proven to be rabies, even though the diagnosis was only suspected when the recipients died of rabies [71]. These cases followed the transplantation of liver, lung, kidney, kidney-pancreas, and iliac artery grafts. Donor-transmitted rabies may have a long incubation period. Patients developed encephalitis between 30 and 60 days post-transplant, and all symptomatic patients died. Patients in Germany received postexposure prophylaxis (PEP) and antiviral treatment, though not until postoperative day 45. The liver recipient in this cluster had been previously vaccinated (around 20 years before) and never developed disease [69].

In the SOT cases, the donors had a recent history of bat and dog bite which were not elicited or considered important. Since bat teeth are very fine, bat bites may be undetectable and the epidemiological risk underestimated. Recently, the investigation of a donor-transmitted rabies to a kidney transplant recipient highlighted the donor contact

with raccoons and wildlife [72]. Thus, a detailed history of bites, in contact with bats and wildlife should be obtained from organ donors' relatives and friends. In the absence of a clear history, physical signs and reliably performed rabies diagnostic tests, the safest strategy is to exclude any donor with neurological symptoms and signs.

9.3 Bacterial Infections

9.3.1 Tuberculosis

Tuberculosis (TB) remains a major global health problem, ranking as the second leading cause of death from an infectious disease worldwide after the human immunodeficiency virus (HIV).

Although the TB incidence rates (new cases per 100,000 population per year) are decreasing in most parts of the world and the TB mortality rate (deaths per 100,000 population per year) has fallen by 45% since 1990, the numbers are still impressive. The latest estimates show that there were 9.0 million new TB cases in 2013 (13% of those among people living with HIV) and 1.5 million TB deaths (1.1 million among HIV-negative people). Most of the estimated number of cases in 2013 occurred in Asia (56%) and the African Region (29%); smaller proportions of cases occurred in the Eastern Mediterranean Region (8%), the European Region (4%) and the Region of the Americas (3%). India and China alone accounted for 24% and 11% of global cases, respectively [73].

Since the rate of TB cure is lower among HIV-positive patients (74%) in comparison to HIV-negative (88%), transmission is facilitated in places where HIV infection is highly prevalent [73]. Other immunocompromised hosts, including solid organ and stem cell transplant recipients, are also more prone to reactivation of *Mycobacterium tuberculosis* infection [74].

One of the components of the WHO program for TB elimination is the recognition and treatment of latent tuberculosis infection (LTBI). There is clear evidence of benefit from systematic testing and treating of LTBI in the following groups: people living with HIV, adult and child contacts of pulmonary TB cases, patients preparing for organ or hematologic transplantation, patients initiating anti-TNF treatment, patients receiving dialysis and patients with silicosis [75]. Among transplant patients, lung transplant recipients have the highest risk, although the local incidence of infection better defines the risk rather than the organ transplanted [76].

The six countries that stand out as having the largest number of TB incident cases in 2013 were India (2.0–2.3 million), China (0.9–1.1 million), Nigeria (340,000–880,000), Pakistan (370,000–650,000), Indonesia (410,000–520,000) and South Africa (410,000–520,000) [73]. Almost all developing countries with active transplant programs, such as Argentina, Brazil, China, Egypt, India, Iran, Nigeria, Pakistan, South Africa, Taiwan, Thailand, Turkey, among others, have reported TB cases in transplant recipients, nicely reviewed in some publications [77–79]. The majority of the reports are in solid organ transplant recipients, especially after renal transplantation.

9.3.1.1 Transmission in Transplant Recipients

Tuberculosis among transplant recipients may arise from reactivation of quiescent foci of *M. tuberculosis*, transmission by the graft or contamination by actively infected persons. Graft transmission has been documented in renal, lung and hepatic transplantation, but accounts for less than 5% of all TB cases in transplant recipients [76, 77]. Cross-transmission of TB has led to an outbreak in a renal transplant unit but also appears to be a rare event [80]. Reactivation of LTBI accounts for the vast majority of TB cases reported in transplant recipients, and largely reflects the local incidence. In North America, the prevalence of LTBI among renal transplant recipients is 0.5–1%, in Northern Europe is 1–4%, and can reach 15% in India and Pakistan [81, 82].

Few studies have adequately described the incidence rate in the transplantation setting. The risk of TB in transplant recipients is estimated to be 20–50 times higher than in general population, even in developed countries. In Europe, recent series have shown an incidence varying from 0.45 to 0.9% [83, 84]. The highest incidence (2.6–6.4%) is observed in lung transplant recipients [85, 86]. Although mortality rate may have decreased due to better diagnostic techniques, it remains high varying from 9.5 to 17% in some series [79].

9.3.1.2 Pretransplant Management

Epidemiological risk: In recent years, a growing number of transplant programs have been implemented in developing countries where prevalence rates of TB are high. In these places, prompt investigation of epidemiological risk for LTBI is mandatory. Previous TB infection or contact with infected persons should be particularly investigated as well as careful radiological evaluation to check for images suggestive of previous healed TB.

Diagnosis of LTBI: LTBI can also be evaluated through the tuberculin skin test (TST), a delayed type hypersensitivity reaction to intracutaneous injection of antigens isolated from culture filtrate by protein precipitation. The sensitivity of the TST is lower in immunocompromised hosts and induration ≥5 mm is considered positive [75]. The specificity of TST in transplant patients from developing countries is also impaired because the delayed type hypersensitivity reaction may indicate infection with non-tuberculous mycobacteria or previous vaccination with the Bacille Calmette-Guérin (BCG), a live-attenuated mycobacterial strain derived from *Mycobacterium bovis* [87]. The role of TST as well as the new interferon gamma release assays (IGRAs) in the evaluation of LTBI in transplant recipients has not been fully investigated and prospective studies evaluating the predic-

tive value of those tests in the development of tuberculosis are lacking. A recent prospective study comparing TST and IGRA in HSCT candidates showed a substantial agreement between tests (Kappa index = 68.5%) [88].

The indication for screening with TST and/or IGRA should be guided by local incidence of TB in transplant recipients. Preventive chemotherapy against TB without prior screening for LTBI may be appropriate for all transplant candidates in regions of high TB incidence (≥100 per 100,000 population). In regions of medium TB incidence (≥20 per 100,000 population or in regions with medium local TB burden), all candidates should be screened for the presence of *M. tuberculosis* specific immune responses. In regions of low TB incidence, a decision for screening of transplant recipients for the presence of *M. tuberculosis* specific immune responses should include an individual risk assessment for LTBI [89].

Donor screening: While the majority of posttransplant TB occurs secondary to reactivation in recipients with unrecognized or untreated LTBI, transmission of *M. tuberculosis* through the allograft can occur. The management of TB in all organ donors requires accurate historical, clinical and laboratory data, which can be challenging especially with deceased donors. The following general recommendations were proposed by the Consensus Conference Report of donor-derived infections, endorsed by American Society of Transplantation, Canadian Society of Transplantation and The Transplantation Society [76]:

- Rule out active TB in the donor with any identified historical or epidemiologic risk factors. For suspected or confirmed TB, donation should be deferred except in dire circumstances.
- All SOT donors should have a careful epidemiologic and personal medical history, physical and a chest radiograph.
- TST and IGRA should be cautiously interpreted taking into account the epidemiologic history and chest radiograph findings. A negative result on TST or IGRA does not rule out active TB.
- For lung donors, bronchoscopy specimens should be obtained for mycobacterial testing for TB and atypical mycobacteria (AFB smear and culture) prior to donation.
- Molecular methods for mycobacterial culture and species identification are preferred to standard culture if available, due to the shorter turn-around time.
- There is insufficient evidence to recommend IGRA testing of all SOT donors. Further research is needed, especially in deceased donors where the tests have potential utility for identification of moderate or high risk of TB donors.
- Donation need not be deferred for the diagnosis of LTBI in any SOT donor including lung donors.
- Urinalysis with microscopy, genitourinary imaging and urine AFB smear and culture should be considered for organ donors in intermediate and high-risk countries, especially for kidney donors.

Prophylaxis: INH prophylaxis reduces the risk of development of active disease [90, 91]. All candidates from regions of high TB incidence (≥100 per 100,000 population) or those screened with a positive TST or IGRA test should receive preventive chemotherapy to reduce the risk for the development of TB. A preventive chemotherapy regimen of isoniazid 5–10 mg/kg *per* day for 6–9 months or longer is recommended [89, 91]. Alternative schedules may be considered on individual basis.

Fear about toxicity has hampered the implementation of INH prophylaxis especially in the setting of liver transplantation. However, previous and recent studies have shown that INH prophylaxis is effective and safe also in this population [92–95]. At most, toxicity is similar to expected in general population (less than 20%) with normalization of liver function tests after drug discontinuation [96]. A recent meta-analysis demonstrated that isoniazid prophylaxis was associated with reduced reactivation of tuberculosis in liver transplant recipients at risk for TB (0.0% versus 8.2%, $p = 0.02$), and isoniazid-related hepatotoxicity occurred in 6% of treated patients, with no reported deaths [90]. In general, liver biopsies often show chronic rejection, recurrent hepatitis C, or other causes when INH toxicity is suspected [97].

Living donors with a positive TST or IGRA should also be offered treatment for latent TB prior to donation. As completion of this treatment may delay the transplant and adversely impact the recipient, the prophylaxis need not be completed before the transplant occurs. In this case, the recipient should also receive INH prophylaxis [76].

9.3.1.3 Posttransplant Management

Risk factors and clinical findings: In areas of high prevalence of TB, a high index of suspicious should be kept in the first months after transplantation. About one-third to one-half of all cases of active TB after solid organ transplantation are disseminated or occur at extrapulmonary sites, compared to about 15% of cases in immunocompetent persons [76]. In HSCT recipients, lung is the organ more frequently affected [16, 95, 98, 99]. Extrapulmonary forms include renal, ganglionar, pleural, central nervous system, bone marrow, and miliary TB [100].

Risk factors for TB in SOT recipients include pulmonary images suggesting previous TB infection, the use of T-cell depleting antibodies, enhanced immunosuppression in the setting of rejection, chronic renal insufficiency or hemodialysis for kidney transplant recipients, diabetes mellitus, hepatitis C virus infection for kidney transplant recipi-

ents, chronic liver disease, or increased recipient age [77, 78, 84, 89, 101, 102]. By multivariate analysis, the RESITRA (Spanish network of infection in transplantation) identified recipient age (RR, 1.05; 95% CI, 1.0–1.1) and receipt of a lung transplant (RR, 5.6; 95%, 1.9–16.9) as independent risk factors for tuberculosis. In the setting of HSCT recipients, the intensity of immunosuppression, unrelated or mismatched related transplants, acute or chronic graft versus host disease (GVHD) and total body irradiation increase the risk of TB reactivation after HSCT [89, 95, 98].

Diagnosis and treatment: Diagnosis of TB is based on clinical grounds and laboratory confirmation by bacilloscopy and culture, and real-time PCR. Novel generations of automated nucleic acid amplification tests, such as the Xpert MTB/RIF test (Cepheid, CA, USA), could potentially improve the rapid diagnosis of TB in transplant patients. WHO currently recommend this test as the initial diagnostic test for adults and children suspected of having HIV-associated TB, in substitution to conventional microscopy and culture [73]. Treatment of TB is made for at least 6 months, with three (isoniazid, rifampicin, and pyrazinamide) or four drugs depending on the rate of isoniazid (INH) resistance. Ethambutol should be added if the rate of INH resistance is greater than 4%. A longer duration of therapy (12 months) has been recommended for the treatment of miliary disease, bone and joint disease and meningitis in infants and children. Also, longer treatment should always be considered if the response to treatment is slow and is mandatory if second-line drugs are used to replace first-line drugs.

The field of tuberculosis in transplant populations is rapidly evolving and some of the current worries will probably be answered in the next years. However, it is important to highlight the unsatisfactory compliance with the LTBI preventive recommendations, as shown by literature data. A recent study demonstrated that about one-third of the transplant recipients did not complete the screening for LTBI and isoniazid prophylaxis was given to only 46% of the high-risk patients [91]. Previous studies have already expressed the same concerns [84, 98].

9.3.2 Leprosy

Leprosy is a chronic infectious disease that affects the skin, the peripheral nerves, eyes, and upper respiratory tract mucosa. The infection is caused by *Mycobacterium leprae*, an acid-fast rod-shaped bacillus discovered by G.A. Hansen in 1873. Humans are the principal reservoir of *M. leprae* and the disease spreads by aerosolized droplets from multibacillary patients, and less commonly through direct skin contact [103]. Recent studies have suggested that direct contact with wild armadillos may contribute to the transmission of leprosy in some areas [104, 105].

The onset of leprosy can be insidious and the disease may be difficult to recognize. In a susceptible host, a skin lesion may develop after an incubation period averaging 2–4 years, varying from 3 months to 40 years [103]. This initial phase is called intermediate leprosy and in many patients the lesions can heal spontaneously or progress to a clinical spectrum depending on the host immune response to *M. leprae*.

According to the type of T-cell response, the granulomatous spectrum of leprosy is classified in tuberculoid (TT), characterized by few skin lesions and low bacterial loads, borderline tuberculoid (BT), borderline (BB), borderline lepromatous (BL) and lepromatous (LL), characterized by diffuse skin lesions and high bacterial loads [103]. A predominant T-helper 1 (Th1) response to *M. leprae* is encountered in lesions of patients with TT and BT forms, in contrast to the Th2 profile found in disseminated lesions of patients with BB, BL, and LL forms of leprosy. Patients are classified as having one of two leprosy types, paucibacillary (PB) or multibacillary (MB). Classifying leprosy is important to ensure appropriate treatment particularly for the MB form of the disease [106].

9.3.2.1 Geographic Distribution

The vast majority of the world's population is not susceptible to leprosy. Susceptibility appears to be determined by genetic characteristics [107]. Since the introduction by the WHO Leprosy Elimination Program of multidrug therapy (MDT) free of charge to all patients worldwide, most previously highly endemic countries have reached leprosy elimination (registered prevalence rate < 1 case per 10,000 population) [108]. Since 2000, the focus has moved from leprosy prevalence to incidence of new cases. A dramatic and sudden decline in new case detection of over 60% was observed from 2001 to 2005. However, the new case detection trends between 2010 and 2013 are remarkably stable suggesting stagnation in leprosy control [109]. Among the 18 countries reporting more than 1000 cases in 2011, India, Brazil, and Indonesia have the highest number of cases. Trends in new-case detection from 2004 to 2011 show that India and Brazil had a very slow decline since 2006 and 2007, respectively. Indonesia, after a plateau since 2006, had a significant increase in 2011. These three countries represented 83% of the new cases detected in 2011, with India contributing 58%, Brazil 16%, and Indonesia 9% [110].

9.3.2.2 Transmission in Transplant Recipients

In SOT recipients, 25 cases of leprosy have been described, 21 in renal, 3 in heart and more recently, 1 case was reported in a liver transplant recipient [111–115]. All cases occurred in patients who were living or had lived in leprosy endemic areas. The majority of the cases was exposed to *M. leprae* many years before transplantation and developed leprosy 5

months to 12 years after transplantation. In the scenario of HSCT, six cases of leprosy were reported in Brazil, all in allogeneic HSCT recipients [116]. Three patients did not report a previous history or had contact with persons with leprosy, and the source of *M. leprae* was unknown. The remaining three had leprosy before HSCT and the disease reappeared after transplant, two cases as BL and one as TT leprosy.

9.3.2.3 Pretransplant Management

Epidemiological risk: Leprosy should be inquired in transplant candidates and donors who live or have lived in endemic areas. A pro-active attitude to get information on epidemiological risks is needed to overcome social stigmas related to leprosy [117].

9.3.2.4 Posttransplant Management

Clinical findings: So far, there are no guidelines for the management of leprosy in transplant recipients. Physicians need to be trained in the differential diagnosis of skin lesions in their patients and to identify at least two cardinal signs of leprosy: anesthetic skin lesions and enlarged nerves [112]. This involves training, supervising and monitoring primary healthcare staff as well as continued education. Diagnosis based only on an anesthetic patch is likely to miss about 30% of the MB cases [108]. Leprosy should be investigated in all patients with erythema nodosum, especially in endemic areas; although leprosy cases have also been reported from areas of low endemicity [118].

Treatment: PB leprosy should be treated with the combination of rifampicin and dapsone (PB multidrug therapy or PB-MDT) for 6 months, and MB leprosy should be treated with the triple drug combination of rifampicin, dapsone and clofazimine (MB multidrug therapy or MB-MDT) for 24 months. According to the WHO recommendation, the rifampicin and part of the clofazimine component should be taken monthly under supervision.

Apparently, immunosuppression did not adversely affect the treatment of leprosy in most SOT patients. While most prescribed MDT as recommended by WHO for multibacillary disease, alternative drug schedules have been used because of fear of adverse effects of clofazimine and rifampicin [111, 119]. Other drug schedules include minocycline, moxifloxacin, and ethionamide [111, 118]. However, minocycline and ofloxacin should only be recommended in presence of adverse effects or drug interactions.

In the scenario of HSCT, 2 of the 6 patients responded to the treatment, even though a tempestuous course was observed in one of them. The remaining patient died soon after HSCT due to MRSA pneumonia and the response to the treatment could not be evaluated. Two patients (LL and BL forms, respectively) had a good response to the treatment, and in the remaining one (BT), the skin lesions had not healed after 8 months of clofazimine. Similar to SOT leprosy cases, alternative drug schedules were used in the HSCT recipients to avoid possible adverse events [116].

Almost 30% of MB patients develop reactions, which are acute immunological phenomena that occur during the normal course of the disease. Reactions can be disastrous as they cause acute nerve damage. It is important to recognize reactions early and initiate treatment with steroids that improves outcomes for about 50% of patients. It is essential that the primary healthcare staffs are trained to recognize and treat reactions early [112].

9.4 Protozoan Infections

9.4.1 Chagas Disease (American trypanosomiasis)

Chagas disease is caused by *Trypanosoma cruzi*, a protozoan parasite firstly described by Carlos Chagas, in 1909. The parasite is generally transmitted by feces of infected triatomine insects through penetration of the parasite into the bite wound, conjunctiva or other mucous membrane [120]. Transmission can also occur from mother to child, by organ transplantation, blood transfusion, laboratory incident, and more recently, some outbreaks due to the ingestion of contaminated food or drink have been reported [121, 122].

9.4.1.1 Geographic Distribution

Chagas disease is endemic in the Americas, from the south of the United States to the south of Latin America. In areas with intra-domiciliary vector transmission, typically children <5 years of age are infected [123]. In the last two decades, the countries more affected by the zoonosis developed successful programs to reduce vector and blood transmission.

In 1991, the Southern Cone Initiative against Chagas disease proposed the interruption of transmission by the elimination of domestic vectors and the screening of blood donors in Argentina, Brazil, Chile, Paraguay and Uruguay. Uruguay was declared free of Chagas disease transmission by *Triatoma infestans* in 1997, Chile in 1999 and Brazil in 2006. Transmission has been effectively eliminated also in substantial areas of Argentina, Bolivia and Paraguay. Similar initiatives took place in 1997 for the Central America and Andean Pact countries, and in 2004 for the nine countries of the Amazon basin [124]. Thus, global disease prevalence has been reduced from the 1990 estimates of 16–18 million people infected six million to seven million worldwide, mostly in Latin America [124, 125].

9.4.1.2 Transmission in Transplant Recipients

Although all modes of transmission are observed in endemic and non-endemic areas, transplant recipients from non-endemic countries are more likely to acquire *T. cruzi* infection through blood transfusion or by an infected graft, whereas infected recipients from endemic regions are at risk of reactivation of latent infection during immunosuppression.

Currently, migration within and beyond endemic countries is the main factor in Chagas disease transmission. In 2006, after a series of reports of blood- and donor-transmitted Chagas disease, the US Food and Drug Administration approved the Ortho *T. cruzi* ELISA Test System to screen blood donors in the United States. Two positive tests are necessary for serological confirmation of *T. cruzi* infection. In case of test disagreement, a third technique is recommended. By mid-2008, more than 500 confirmed *T. cruzi*-infected donations were reported [126].

Thus, both in endemic and non-endemic areas a careful investigation of the epidemiological risk of latent Chagas disease is mandatory. Are at great risk of *T. cruzi* infection: (1) Native population from endemic areas; (2) population who have received blood transfusion in endemic areas; (3) offspring of a mother who are native from endemic country; (4) population who have lived in an endemic area for more than 3 months [127–129].

Blood-borne transmission: Blood transmission is considered as the second most important method of acquiring Chagas disease. With the exception of blood derivatives, all blood components are infective. Transmission by blood transfusion was first suggested by Mazza in Argentina in 1936, and the first cases of transfusion-associated Chagas disease were published in Brazil in 1952. The true number of reported cases is possibly underestimated since no more than 350 cases have been published [130]. In non-endemic countries, cases of transfusion-associated transmission can go undetected because acute infections are often asymptomatic and the level of awareness of Chagas disease among clinicians is low. In endemic countries where mandatory screening tests have been implemented since 1991, the residual risk of infection is calculated to be around 1:200,000 units [131].

Transmission via graft: The first strong evidence of transmission via a graft was reported in Brazil in 1981 [132]. Four renal transplant recipients developed Chagas disease; all four had received grafts from infected donors in chronic phase of *T. cruzi* infection [133]. Other series have been published, mostly from Argentina and Brazil, which perform the greatest number of renal and liver transplants in South America [134, 135]. In the US, from 2001 to 2011, transplant transmission of *T. cruzi* was confirmed in 9 of the 19 recipients of organs from 6 donors. The median interval from transplantation to diagnosis of infection was 8 weeks (range 3–29 weeks) [136]. Although uninfected recipients who receive an organ from a *T. cruzi*-infected donor may develop acute *T. cruzi* infection, transmission under these circumstances is not universal and appears to vary by organ type. According to the reported series, prospective monitoring and prompt treatment seems to be a safe and effective strategy and is currently recommended rather than prophylaxis [136, 137]. It is important to highlight the results of a recent randomized study comparing benznidazole versus posaconazole in the treatment of patients with chronic Chagas disease and positive *T. cruzi* PCR. A sustained parasitic response (for at least 120 days after the end of treatment) was observed in the benznidazole group. By the end of follow-up, 94% of the patients receiving benznidazole were PCR negative in comparison to only 20% of the patients receiving high dose of posaconazole ($p<0.001$) [138]. Thus, it seems reasonable to treat Chagas positive living donors with benznidazole for 30–60 days before donation to decrease the risk of transmission [128].

Reactivation: Reactivation may occur in *T. cruzi*-infected patients receiving immunosuppressive drugs. Risk of Chagas reactivation is higher after heart transplantation (up to 75%). A study from Brazil evaluated the risk factors for Chagas' disease reactivation, which occurred in 26.5% of previously infected heart transplant recipients. Multivariate analysis showed that the number of rejection episodes, neoplasms, and use of mycophenolate mofetil were the risk factors independently associated with reactivation [139]. In Argentina, where blood monitoring is routinely performed in SOT and HSCT recipients with previous *T. cruzi* infection, reactivation rates of 9–16% have been observed in kidney transplantation, 50–100% in heart transplantation, and 17% and 40% in autologous and allogeneic HSCT, respectively [140].

Pretransplant treatment in transplant candidates with Chagas disease has been suggested by some authors [120]. However, no study has evaluated if treated candidates have a decreased risk of reactivation after transplantation. Moreover, experts from endemic countries who have managed Chagas disease patients for decades consider that *T. cruzi* monitoring in blood, followed by preemptive introduction of benznidazole is a safe and effective strategy [140].

9.4.1.3 Pretransplant Management

Epidemiological risk: The investigation of the epidemiological risk of Chagas disease in donor and transplant candidates is mandatory. The following questions are suggested: Was the donor/recipient born in Latin America (South America, Central America or Mexico)? Was the donor/recipient born in, or did s/he spend significant time in Latin America? Was the donor's mother born in Latin America? [129].

Serological tests: In endemic areas, serological tests for *T. cruzi* are routinely performed. Due to the increase of migrant population in non-endemic areas, this routine has been extended to those locations as well. Two positive results with different serological techniques are necessary to consider a patient to be infected. If the tests are not available, posttransplant monitor-

ing is strongly recommended in transplant recipients with epidemiological risk of *T. cruzi* infection.

Management of T. cruzi-infected donors: Individuals who died of acute Chagas disease should be excluded from donation. Cadaveric donors chronically infected by *T. cruzi* are excluded from donation of heart and intestines. In the case of cardiac transplantation, the use of a heart from a patient with chronic Chagas disease is an absolute contraindication due to the risk of chagasic myocarditis during the period of immunosuppression. Other organs can be accepted provided that a close monitoring is ensured, preferably with molecular methods (PCR). Living donors chronically infected by *T. cruzi* should receive benznidazole 5–7.5 mg/kg orally for 30–60 days before donation. A careful monitoring of the donor is necessary due to benznidazole-related adverse events [128]. If *T. cruzi* infection is confirmed or suspected in the donor, all recipients should provide appropriate informed consent concerning the risk of receiving a potentially infected organ [128, 129].

9.4.1.4 Posttransplant Management

Monitoring of T. cruzi infection or reactivation: In case of positive Chagas serology in the donor or transplant candidate, parasitemia surveillance is required after transplantation to prompt detection of *T. cruzi* primary infection or reactivation. Hemoculture, microhematocrit, and the Strout method can be used, but currently quantitative PCR is the method of choice [132, 141]. Monitoring for acute infection is recommended weekly for 2 months, every 2 weeks for the third month, and then monthly until at least 6 months post transplantation [126]. Few modifications such as biweekly surveillance until the sixth month and yearly thereafter have been proposed by other groups [128]. If the serologic status of recipient or donor is not available, monitoring is indicated in native population from endemic areas (Latin America countries), in population who received blood transfusion in endemic countries or who have lived in an endemic area for more than 3 months [128].

Diagnosis and treatment of Chagas disease: In the diagnosis of posttransplant *T. cruzi* infection, the Strout method and PCR are more frequently used. Serological tests are only useful in seronegative patients who have received an organ from a seropositive donor (seroconversion). In recipients already infected by *T. cruzi* (positive pretransplant serology), a positive result in the Strout method is considered as a sign of reactivation. In the case of PCR, a positive result in patients with previous negative PCR is considered as a sign of reactivation. However, if the previous PCR was also positive, reactivation is determined by the increase in the parasitemia level [128]. In symptomatic patients, parasitological tests may be performed on samples from skin lesion biopsy or endomyocardial biopsy or on cerebrospinal fluid (CSF). Among transplanted patients, the most common symptoms of acute Chagas disease are subcutaneous nodules (chagoma), panniculitis, and myocarditis with signs of heart failure, fever, meningitis, encephalitis, and stroke. Prompt treatment with benznidazole or nifurtimox should be started if parasitemia is detected. The standard course for adults consists of benznidazole 5–7.5 mg/kg orally for 30–60 days or nifurtimox 8–10 mg/kg for 90–120 days.

The recommendation for prophylaxis is controversial both in cardiac or other transplant recipients [140, 142]. Protocols that recommend prophylaxis with benzonidazole both pre- and immediately posttransplantation, do not have clear advantages according to the clinical experience [143]. In other transplant recipients, preemptive treatment should be started if there is evidence of reactivation.

9.4.2 Leishmaniasis

The term leishmaniasis designates a group of diseases caused by the genus *Leishmania*. Leishmaniasis is primarily a zoonotic infection, which includes animal reservoir hosts in the transmission cycle. Anthroponotic forms of leishmaniasis have been increasingly observed as humans enter the transmission cycle of the parasite and get infected. In anthroponotic forms, man is the sole source of infection for the vector.

The protozoan is transmitted to humans through the bite of an infected female mosquito from the genus *Phlebotomus* (in the Old World) or *Lutzomya* (in the New World). However, incidental transmission by blood transfusions or by needle sharing among intravenous drug addicts has also been described [144, 145]. There are two main clinical presentations of the disease, cutaneous or mucocutaneous leishmaniasis (CL) and visceral leishmaniasis (VL), also known as Kala azar.

Based on recent estimates, approximately 0.2–0.4 million VL cases and 0.7–1.2 million CL cases occur each year [146]. There is growing evidence that the true incidence of the disease is underestimated, especially in hyperendemic regions [147]. Assuming a case-fatality rate of 10%, it is estimated that VL causes 20,000–40,000 per year. Mortality estimates have more uncertainty than incidence estimates as a large proportion of VL deaths occur outside of health facilities and the cause likely never recognized [146].

The disease is emerging in immunocompromised patients undergoing hematopoietic stem cell or solid organ transplantation or treatment with biologic drugs [16, 147, 148]. In transplanted patients, VL is the clinical presentation more frequently reported accounting for more than 85% of the leishmaniasis cases.

9.4.2.1 Geographic Distribution

In the Old World, CL are caused by *Leishmania tropica*, *L. major* and *L. aethiopica*, and VL are caused by the *Leishmania donovani* complex, which includes two species, *L. donovani* and *L. infantum*. In the Americas, various leish-

mania species are able to produce cutaneous leishmaniasis, such as: *L. braziliensis*, *L. amazonensis*, *L. guianensis, L. pananmensis* and *L. mexicana*. Visceral leishmaniasis in the New World is caused by *L. chagasi* [149].

According to a recent publication, a total of 98 countries and 3 territories on 5 continents reported endemic Leishmaniasis transmission. More than 90% of global VL cases occur in just six countries: India, Bangladesh, Sudan, South Sudan, Brazil, and Ethiopia [146].

The control of leishmaniasis is based in the control of the anthroponotic foci which are the source of severe and life-threatening VL epidemics. Dogs are the main source of infection and canine enzooty usually precedes the occurrence of cases in humans. Policies include early treatment of humans cases of VL, passive and active notification of canine leishmaniasis, vector control, use of screens in doors and windows, continuous education, and if necessary, humanitarian elimination of infected dogs.

The diagnosis of VL can be performed by microscopy of bone marrow aspirates, culture, serology and/or PCR. Microscopy of bone marrow aspirates is the preferred method with a sensitivity of more than 80%. Leishmania culture is laborious and subjected to contamination. Moreover, the low sensitivity in asymptomatic patients precludes its use as a screening test. Sensitivity of serology is variable and specificity can be unsatisfactory as it may present a cross-reaction with other protozoa [150]. PCR is the most effective test for the diagnosis and follow-up of VL, is less invasive than bone marrow aspirates, and is superior to serology to detect cases of infection [151]. In addition, PCR has been reported to be useful in the follow-up of treatment efficacy, also in immunocompromised patients [152]. Thus, PCR or the combination of techniques is regarded as preferred method in the diagnosis and follow-up of VL transplant recipients [148].

9.4.2.2 Transmission in Transplant Patients

According to a recent review, more than 100 cases of leishmaniasis have been described in organ transplant recipients [153]. Most of the cases have been described in renal transplant recipients, possibly reflecting the greater number of renal as compared to other organ transplants worldwide.

Leishmaniasis in transplant recipients may occur due to (1) reactivation of latent infection in a previously infected recipient during immunosuppression; (2) de novo infection in transplant recipients living in or traveling to areas of endemicity [154]; (3) transfusion-associated leishmaniasis, as routine serology for blood or organ donors is not performed even in areas of high endemicity [144]; (4) via an infected graft, as asymptomatic infection is more frequent than symptomatic disease even in endemic areas [148]. This route of transmission is more likely to occur in organs that form part of the reticuloendothelial system, such as liver. A study conducted in an endemic area of Brazil, showed that 23.5% of blood, 17.7% of liver and 6% of spleen samples from asymptomatic liver donors tested positive for *L. infantum* by PCR [150].

9.4.2.3 Pretransplant Management

Epidemiological risk. Evaluation of donor and recipient's epidemiological risk of leishmaniasis is required. Patients who live in or have travelled to endemic areas of the disease are at risk of developing disease. Spain, Brazil, France, and Italy have the highest number of reported cases [148, 153]. In countries like Brazil, the great number of reports just reflects local endemicity [155] whereas in European countries, VL cases have occurred in migrant transplant recipients or in SOT recipients from non-endemic areas who have travelled to an endemic region of leishmaniasis [156].

Screening: Pretransplant screening is not routinely recommended because the value of serologic or molecular screening of asymptomatic donors and recipients remains unclear.

9.4.2.4 Posttransplant Management

Risk factors and clinical findings: Clinical signs and symptoms of VL are prolonged fever, weight loss, hepatosplenomegaly, and pancytopenia. However, atypical forms, such as mucosal and cutaneous forms, have occasionally been reported [148]. The median time of VL occurrence is 25 months (range, 1–118). Serology, direct detection of leishmania amastigotes in bone marrow biopsy samples and PCR should be performed in suspected cases [148, 150, 151].

A recent collaborative case-control study performed in Spain and Brazil evaluated the risk factors, clinical features and outcomes of VL in SOT recipients. Thirty-six VL cases were identified among 25,139 SOT recipients (0.1%) with a crude mortality rate of 2.8% [157]. Parasites were identified in 89% of the patients; the remaining cases were diagnosed by serology. Fever, hepatosplenomegaly and pancytopenia were present in 86%, 81% and 47% of the patients, respectively. Patients were diagnosed over 1 month after symptom onset in 25% of cases. VL occurred 5.7-fold more frequently in Brazil than in Spain, presenting at a median time of 11 months after transplantation. Treatment with high-dose prednisone in the preceding 6 months was the only factor significantly associated with VL. Interestingly, induction therapy with antilymphocyte globulins or intensity of baseline immunosuppression was not related to the occurrence of VL. The same was observed in a recent publication of 30 cases of VL in renal transplant recipients [151].

VL monitoring: If a donor or a recipient is known to be positive, strict monitoring in the post-transplant period is advised not only for this potential life-threatening condition, but also for the potential role of VL in graft dysfunction and loss. Monitoring *Leishmania* DNA levels every 3–6 months for the first 24 months after an episode of VL is advisable, as

most of the recurrences occur in the first 2 years after the initial episode.

Treatment: Liposomal amphotericin is the drug of choice in the treatment of VL. Other drugs such as *N*-methyl-glucamine and miltefosine have been less frequently used. Side effects are the main obstacles to the use of pentavalent antimony. Miltefosine is an oral drug approved for the treatment of VL and for cutaneous leishmaniasis for more than one decade in some developing countries, such as India. Initial cure rates of more than 95% have been reported in nontransplant population, but an increase in the rate of VL relapses in patients treated with oral miltefosine is of concern [158]. Few information is available concerning to the use and efficacy of miltefosine in the setting of transplantation.

VL relapses: Transplant recipients also have an increased risk of disease recurrences, varying from 1 to 5 (median 1.7) relapses after treatment, occurring at a median of 13 months (range, 1–60) after the initial episode [159]. Frequency of VL relapses may vary but in general is around 25%. Two recent studies observed VL relapses in 25.7% and in 26.7% of solid organ and kidney transplant recipients, respectively [151, 157]. The use of secondary prophylaxis to avoid relapses did not show significant benefit in a retrospective case-control study. Relapse was observed in 1 (8.3%) of the 12 patients receiving prophylaxis and in 8 (34.8%) of the 23 patients not receiving prophylaxis ($p = 0.19$) [157].

Since no prospective studies are available, the real incidence, risk factors, morbidity and mortality of cutaneous and visceral leishmaniasis in different transplant populations, are unknown. So far, no strong recommendation can be made concerning to the use of secondary prophylaxis to avoid VL relapses.

9.4.3 Malaria

Malaria is an acute systemic illness caused by infection with *Plasmodium falciparum*, *Plasmodium vivax*, *Plasmodium malariae*, or *Plasmodium ovale,* which are the human malaria species. *P. falciparum* tends to be more virulent than other species. Globally, an estimated 3.3 billion people in 97 countries and territories are at risk of being infected with malaria. Since 2000, a decrease in malaria incidence and mortality rates of 30% and 47%, respectively has been observed. Still, 198 million cases of malaria occurred globally and the disease led to approximately 584,000 deaths in 2013 [160].

Malaria primarily affects low- and lower-middle income countries. Within endemic countries, the most severely affected are the poorest and most marginalized communities, which have the least access to appropriate prevention, diagnosis, and treatment. Thus, malaria control is intimately linked with health system strengthening, infrastructure development, and poverty reduction. The burden is heaviest in Africa, where an estimated 90% of all malaria deaths occur, and in children aged under 5 years, who account for 78% of all deaths [160].

Plasmodium species are transmitted to humans by female *Anopheles* mosquitoes. The life cycle of the parasites has two phases; an asexual replicative phase in humans and a phase of sexual replication in the mosquito. In the human body, the parasites multiply in the liver, and then infect red blood cells. The symptoms, signs, and pathological features of malaria are caused by the asexual erythrocytic stage of the parasites that invade and replicate in erythrocytes over 2–3 days, rupture these cells and reinvade normal erythrocytes. This exponential parasite replication in the bloodstream increases parasite density by 5 to 30-fold every 2–3 days. In the case of *P. vivax* and *P. ovale*, a proportion remains dormant (hypnozoites) inside the hepatocytes and these forms are responsible for late relapses [161].

9.4.3.1 Geographic Distribution

People in 97 countries around the world are at risk of malaria infection, mostly in Africa, Asia, and in Central and South America [160]. Awareness of *Plasmodium* species endemicity is important to early introduction of appropriate treatment. *Plasmodium falciparum* is found in sub-Saharan Africa, South-East Asia, and the Indian subcontinent as well as in South America, Haiti, the Dominican Republic, Jamaica and areas of Oceania. *P. malariae* and *P. ovale* are present in sub-Saharan Africa. *Plasmodium vivax* is prevalent in areas of South-East Asia, the Indian Subcontinent, and Central and South America [160, 161].

9.4.3.2 Transmission in Transplant Recipients

In transplant recipients, malaria may be transmitted through infected blood products, via an infected organ or by natural exposure to *Plasmodium*-infected mosquitoes in endemic regions. In transfusion-associated malaria, symptoms generally develop earlier (1–3 days) than if the infection is transmitted through infected cells within the organ (more than 1 week) [161].

Blood-borne transmission: Transfusion-transmitted (TT) malaria is severe and often fatal. The use of antibody tests in the prevention of TT-malaria varies worldwide. In a recent international forum evaluating the preventive measures taken in non-endemic areas, only 4 of the 14 participating countries perform malaria antibody tests routinely (United Kingdom, Denmark, Finland, and New Zealand). In Brazil, the Amazon region is considered as endemic, whereas the rest of the country is considered non-endemic. In non-endemic areas, testing is not required nor performed. Donors are prevented from donating for 6 months if they have been to endemic areas or 3 years if they had had malaria or lived in endemic area, and definitely rejected for *P. malariae* infection at any period of their lifetime. In endemic areas an index of parasit-

emia (IPA) is provided according to each municipality and district. This IPA allows donors to be classified into low-, medium- or high-risk. Donors from high-risk areas are rejected, whereas medium and low-risk are submitted to a predonation test that may be a rapid test (antigenic) or the thick smear. Positive donors are excluded from donating for 1 year and referred for treatment. After 1 year they are allowed to donate provided they present a negative parasitologic test [162].

Graft transmission: *Plasmodium* species are capable of surviving more than 24 h in blood at 4 °C. Therefore, the time of cold preservation is generally not enough to prevent transmission, especially in heart and liver transplantation that requires shorter cold preservation time: 3–4 h for heart and less than 12 h for liver, in comparison to 24–48 h for kidney. The reports of malaria cases following multi-organ donation have supported the hypothesis of the graft as a source of *Plasmodium* in transplant recipients [163–167]. Malaria deaths in SOT recipients are generally associates with *P. falciparum* infection. In HSCT recipients, past geographic exposure of both donor and recipients seems to be the main source of *Plasmodium* infection, even though transmission by blood transfusion has also been reported [166, 168]. In most cases, the diagnosis was made by the identification of the parasite in blood smears of febrile patients with unexplained hemolysis and thrombocytopenia.

Persistent malaria is the greatest challenge in the pretransplant screening or blood transfusion policies. Donors or transplant candidates, who were born or have lived in an endemic area, harbor the highest risk of malaria infection. Those individuals generally have high levels of infection and frequent exposure to malaria parasites, leading to a dynamic balance between the infection and the immune response to it. Such individuals are categorized as "semi-immune," as they are asymptomatic, have high-titer antibody and the majority have a resolved infection. However, a small number may still be infected with a persistent low-level parasitemia [169]. We recently report a case stressing the difficulty in eradicating *P. vivax* parasitemia from a semi-immune HSCT donor who had nine episodes of malaria during his lifetime [170].

Clinicians caring for transplant recipients in developing countries of known endemicity should take into account that the parasite may persist in humans who survived to untreated malaria. In case of semi-immune transplant recipients, posttransplant immunosuppression disrupts the balance between persistent infection and immune response and a bout of parasitemia may occur. Persistence is estimated to be 1 year for *P. falciparum,* 3–5 years for *P. vivax* and *ovale* and as long as 40 years for *P. malariae* [170]. Some reports have described persistent *P. falciparum* malaria in immigrants currently living in non-endemic areas for more than 9 years [171, 172].

9.4.3.3 Pretransplant Management

Epidemiological risk: Investigation of the epidemiological risk for malaria is mandatory for both donors and recipients. In developing countries, a past history of malaria is not a contraindication for organ or stem cell donation. Donors who have traveled to or lived in endemic areas should be deferred from donation for 6 months and 3 years, respectively. Of the only donor available, empirical treatment before donation should be considered.

Diagnosis: Identification of *Plasmodium* species is important to guide treatment. If possible, serology, rapid antigen tests and/or blood smear examination should be considered for all patients and donors at risk. Thick and thin blood film microscopy examination remains the gold standard for diagnosis, but specific antibody-based rapid diagnostic tests that detect PfHRP2, pan-malaria or species-specific lactate dehydrogenase, or aldolase antigens in fingerpick blood are now used widely [173]. Because of their simplicity and speed, rapid diagnostic tests are particularly valuable in epidemic investigations and surveys. However, they are expensive and do not quantify parasitemia. Molecular methods such as PCR have been used mainly as a research tool [170].

9.4.3.4 Posttransplant Management

Clinical findings: Clinicians must be aware that malaria not always has the typical paroxysmal or cyclic pattern in transplant recipients and a high index of suspicion should be maintained when caring for patients with identifiable risk factors. Fever, anemia, and neurological alterations are frequent findings of malaria in transplant recipients. Mortality rates vary from 10 to 40%. Malaria is more harmful in naïve recipients from non-endemic areas. The prognosis of posttransplant malaria depends on the delay in diagnosis and initiation of treatment, the species of *Plasmodium* involved, the type of organ transplanted, and the type of immunosuppressive therapy. The majority of deaths are associated to *P. falciparum*. Especial attention should be paid to splenectomized patients who may develop more severe disease because the spleen is responsible for the removal of parasitized cells from the circulation.

Treatment: *P. falciparum malaria* is treated with artemisinin-based combined therapy (artemether 20 mg) and lumefantrine (120 mg), piperaquine (160 mg) or mefloquine (1250 mg). Mefloquine is still used in areas of susceptible *P. falciparum. P. vivax* and *P. ovale* are treated with chloroquine (25 mg/kg for 3 days), which is still used in some countries in the Region of the Americas and primaquine (0.5 mg/kg/day for ≥7 days), currently the only drug available to treat the liver stage (hypnozoite) of *P. vivax* infection [160]. If donors or recipients have history of mosquito exposure in regions of *Plasmodium vivax* or *P. ovale*, clinicians should have in mind that the parasites' exoerythrocytic schizogony in the liver makes eradication more difficult. The dormant hypnozoites forms can cause relapse up to 12 months later. Primaquine is not necessary in blood or graft-transmitted malaria, as hepatic hypnozoites are not established in these cases. Mefloquine, doxycycline, chloroquine, and primaquine may

increase calcineurin inhibitors levels. G6PD deficiency should be investigated before the use of primaquine to avoid hemolysis [160].

In conclusion, we are living in an increasingly globalized world in which transmission of infectious diseases has no boundaries. Tourism travels, international commerce, and immigration have acted as important factors for the emergence and re-emergence of specific infectious diseases. An important proportion of migrant population will naturally become part of the working force as well as part of blood bank, transplant donor, or transplant recipient population in destination countries.

Many of the pathogens that cause tropical diseases can be either transmitted via graft or blood transfusions or reactivated during immunosuppression. Healthcare workers in the field of transplantation need to be prepared to recognize the epidemiological risks and to manage tropical infections in transplant recipients.

10 Risks and Epidemiology of Infections Associated with Ventricular Assist Devices and Heart Transplantation

Amanda R. Vest, David DeNofrio, and David R. Snydman

The infectious complications of heart transplantation are similar to that seen in other solid organ transplants with respect to risk factors and timing. However, there are a number of unique aspects to the types of infections that occur in heart transplantation, by virtue of the location and type of surgery necessary to replace the organ, as well as the fact that cardiac muscle can carry certain unique pathogens, such as *Toxoplasma gondii* and *Trypanosoma cruzi*. In addition, the increasing utilization of ventricular assist devices (VADs) prior to transplantation provides its own unique challenges and often complicates the post-transplant course. Finally, the immunologic effects of viral infections such as cytomegalovirus (CMV) as well as other viruses can have profound impact on the coronary vascular system, contributing to allograft vasculopathy as well as acute and chronic rejection.

Infectious complications are very common in cardiac transplantation. In an analysis of 620 consecutive patients followed over a 16-year period at Stanford, approximately 1.67 infections occurred per patient to [1]. Infection was second to rejection as a cause of early death, but was the most common cause of late death. Among the episodes of infection, bacteria caused 43.6%, viruses 41.7%, fungi 10.2%, *Pneumocystis jiroveci* 4%, and protozoa 0.6%. Over the course of the study period, the authors noted marked improvements in outcome due to the prophylactic use of antivirals, antibacterials, and antifungals with a reduction of many of these infectious complications. This chapter will review those aspects of infection that are unique to cardiac transplantation. Donor screening, vaccination, and prophylaxis will generally be the same as that recommended in other solid organ transplant recipients. However, there are some unique aspects to donor screening cardiac transplantation that will be discussed in this chapter. The reader is referred to other chapters as appropriate for specific details as they pertain to general concepts of screening and prevention.

10.1 Continuous-Flow Left Ventricular Assist Devices and Total Artificial Hearts

Approximately 40% of patients in the United States undergo heart transplantation while supported with a surgically implanted VAD and therefore, an understanding of the infectious complications and management of such devices is essential. Heart failure affects approximately five million people in the United States and remains a highly fatal disease [2–4]. Despite improvements in medical therapy, it is estimated that over 250,000 people have refractory end-stage systolic heart failure [3–6].

The "gold standard" management of refractory end-stage heart failure is heart transplantation, but this intervention is limited by donor organ availability, limited to around 2400 transplants in North America annually [7]. In contrast, durable mechanical circulatory support utilization has risen exponentially over the past decade, with 3472 continuous-flow left ventricular assist device (LVAD) implants reported to the Interagency Registry for Mechanically Assisted Circulatory Support (INTERMACS) in 2013 [8, 9]. The inflow LVAD cannula is implanted into the apex of the left ventricle, through which blood is drawn into pump, and then delivered to the aorta via and outflow graft that anastomoses to the proximal aorta (Figure 10-1a). The driveline is a percutaneous conduit that carries electrical wires from the pump, through the abdominal cavity and subcutaneous tissues to the skin and then outside the body to the LVAD system controller worn externally. In recent clinical trials, LVADs have been demonstrated to both control heart failure symptoms and improve survival when placed either as a "bridge to transplantation" (BTT) or as "destination therapy" (DT) for individuals who are not transplant eligible. Major challenges to the success of LVADs are device infection, pump thrombosis, strokes, and gastrointestinal bleeding [8–10].

Although the rates of these complications are overall much lower in the current era of continuous-flow LVADs, as compared to original pulsatile devices, they remain a significant limitation to fully realizing the potential of this therapy.

The first generations of LVADs were pulsatile and were associated with large diameter drivelines, large abdominal pockets, and limited long-term mechanical durability. These devices have been superseded by continuous-flow technology. In 2007, a non-randomized study was published of 133 patients with end-stage heart failure awaiting heart transplantation who received a continuous-flow HeartMate II LVAD (Thoratec Corporation, Pleasanton, CA) [11]. This high-speed axial-flow, rotary pump was significantly smaller and lighter than the prior pulsatile pumps, with a reduced driveline diameter. At 180 days, 100 patients (75%) reached the principle outcome of heart transplantation, cardiac recovery, or survival with ongoing mechanical support and eligibility for transplantation. The survival rate was 68% at 12 months. At 3 months, there were significant improvements in New York Heart Association functional class, 6-min walk test results, the Minnesota Living with Heart Failure and Kansas City Cardiomyopathy questionnaires. Subsequently, the HeartMate II LVAD was FDA approved in April 2008 for use as durable BTT support [12]. The HeartMate II investigators also demonstrated the superiority of continuous-flow LVADs over pulsatile devices, in a DT cohort who were ineligible for heart transplantation [13]. The HeartMate II patients had superior actuarial survival rates at 2 years (58% vs. 24% in the pulsatile LVAD group, $p=0.008$). Mechanical failure, valve malfunction, infection, and the need for pump exchange were less frequent in patients receiving the continuous-flow device. Furthermore, there were significant improvements in quality of life and functional capacity in both groups. The extended results from the initial BTT trial were also published in 2009, with 222 of 281 patients (79%) reaching the endpoint of transplantation, LVAD removal for cardiac recovery, or ongoing LVAD support at 18-month follow-up [14]. This extended HeartMate II LVAD BTT study reported localized non-device-related infection in 30% of patients, sepsis in 17%, driveline infection in 14%, and pump pocket infection in 2%.

Subsequent continuous-flow LVAD publications demonstrated increasingly encouraging survival and infection rates. The HeartWare HVAD (HeartWare Inc., Framingham, MA) BTT trial studied a newer, smaller intra-pericardial continuous-flow LVAD with a centrifugal mechanical pump (Figure 10-1b) [15]. This was a non-randomized trial comparing HVAD recipients to a contemporaneous cohort of HeartMate II LVAD patients. A total of 140 patients received the HVAD pump, and 499 patients received a commercially available LVAD. Success, defined as survival on the originally implanted device, transplantation, or removal of the device for ventricular recovery at 180 days, occurred in 90.7% of HVAD recipients and 90.1% of HeartMate II LVAD controls, establishing non-inferiority of the investigational pump ($p<0.001$). At 6 months, median 6-min walk distance improved by 128.5 m, and both disease-specific and global quality-of-life scores improved significantly. Sepsis and driveline infections occurred in 11.4% and 12.1% of HVAD recipients, respectively. More recently, the HVAD has demonstrated non-inferiority to the HeartMate II LVAD for DT therapy in a preliminary report of the ENDURANCE trial [16]. Approximately 40% of LVADs are now implanted with a DT strategy, which brings with it an older and more comorbid group of patients who are more prone to infectious complications during support [8]. The high infection rate in the DT LVAD population of patients emphasizes the need for further studies directed toward effective antibiotic prophylaxis protocols prior to, at the time of, and following the LVAD procedure. Unlike the BTT population, the permanent therapy population does not have the opportunity to have the infected device explanted at the time of transplant, thus removing the source of infection and allowing adequate treatment of the infection. However, overall survival in continuous-flow LVAD recipients continues to improve, with the Sixth INTERMACS Annual Report describing actuarial survival among patients with continuous-flow pumps of 80% at 1 year and 70% at 2 years; DT survival exceeds 75% at 1 year and 50% at 3 years [8].

In patients who suffer refractory biventricular failure, it is sometimes necessary to mechanically support the right ventricle in addition to the left ventricle. This strategy is only pursued for BTT, not DT, patients. Depending on the clinical scenario and implanting center experience, the patient may receive a durable implantable right ventricular assist device (RVAD) in addition to their LVAD (thus requiring two driveline exit sites) or alternatively may undergo cardiac explanation and implantation of a total artificial heart (TAH). Patients requiring biventricular support (BiVAD) currently have inferior survival to LVAD recipients, with just under half of BiVAD patients alive at 12 months in the Sixth INTERMACS Annual Report [8]. Initially, all TAH recipients were confined to hospital until transplantation; however, with the introduction of a portable driver system some centers have successfully transitioned patients to home on the SynCardia TAH (SynCardia Systems Inc., Tuscan, AZ) [17]. One report of 47 recipients from centers across the world described systemic infection requiring intravenous antibiotics in 25 patients (53%). Driveline infections occurred in 13 patients (27%); in 2 of these patients (4%) the infection ascended into the mediastinum resulting in death. Five patients died of sepsis with multiorgan failure. There was an association between smaller body surface area and increased risk of infectious complications [18].

10.2 Left Ventricular Assist Device Infections

Infection remains a frequent complication in patients receiving continuous-flow LVAD support with incidence estimates ranging from 10 to 50% depending on the study cohort, time

frame, and diagnostic classifications. For example, the Sixth INTERMACS Annual Report describes 9.96 device infections per 100 patients-months in the first 12 months after continuous-flow LVAD or BiVAD surgery [8]. The extended HeartMate II LVAD BTT study reported localized non-device-related infection in 30%, sepsis in 17%, driveline infection in 14%, and pump pocket infection in 2% of patients enrolled. In the HeartWare HVAD BTT trial sepsis occurred in 11.4% and driveline exit site infections in 12.1% of recipients, which equates to 0.24 and 0.29 events per-patient-years, respectively [14, 15]. A single center study of 81 LVAD recipients reported that 51.9% of the cohort had at least one type of infection during continuous-flow LVAD support with a mean follow-up period of 9.2 months [19].

In the above report (Topkara et al.), patients with positive blood cultures, but no signs of systemic inflammatory response syndrome were categorized under systemic infections as a separate entity from sepsis. Local infections (non-LVAD related) were defined as those limited to any organ system or region without evidence of systemic involvement that requires treatment or is ascertained by standard clinical method. The LVAD-related infections (driveline or pump pocket) were defined as those that required treatment with antimicrobial therapy, when there is clinical evidence of infection such as pain, fever, drainage, and/or leukocytosis (Figure 10-2). Subgroup analysis revealed that post-implantation sepsis was significantly associated with increased mortality in the continuous-flow LVAD cohort (61.9% vs. 18.0% at 2 years, respectively, in septic and non-septic patients, $p < 0.001$). Resistant *Staphylococcus* and *Pseudomonas* species were the most common pathogens leading to device- and non-device-related local infections; however, development of driveline or pocket infection had no effect on survival in patients with continuous-flow assist device support ($p = 0.193$).

Sepsis especially early post-implant, VAD-related infective endocarditis and mediastinitis can have devastating consequences and have been associated with mortality rates as high as 70% [20]. Conversely localized driveline infections are often of limited clinical consequence if diagnosed and treated appropriately with local wound care and antibiotics. Infections in the abdominal wall pocket holding the device (for HeartMate II LVAD) or surrounding the pericardial location (for both HeartMate II LVAD and Heartware HVAD) require more aggressive treatment, including open drainage, debridement, and rerouting of the driveline through a fresh exit site. There is also limited experience with the implantation of antibiotic-coated beads to aid in control of the subcutaneous infection [21]. So long a device-related infection is controlled, it is not a contraindication to transplantation [22], and is often an indication for United Network Organ Sharing (UNOS) 1A transplantation status listing by exception. However, all device-related infections require careful review for appropriate ongoing management at the time of transplantation.

The International Society of Heart and Lung Transplantation (ISHLT) does not specify which antimicrobials should be administered as prophylaxis, but give class I recommendations for broad-spectrum Gram-positive and Gram-negative coverage, with at least one dose prior to surgery administered within 60 min of the first incision, and maintained in the therapeutic range throughout the duration of their use but not extended beyond 24–48 h (Table 10-1). They also support topical treatment for methicillin-resistant *Staphylococcus*

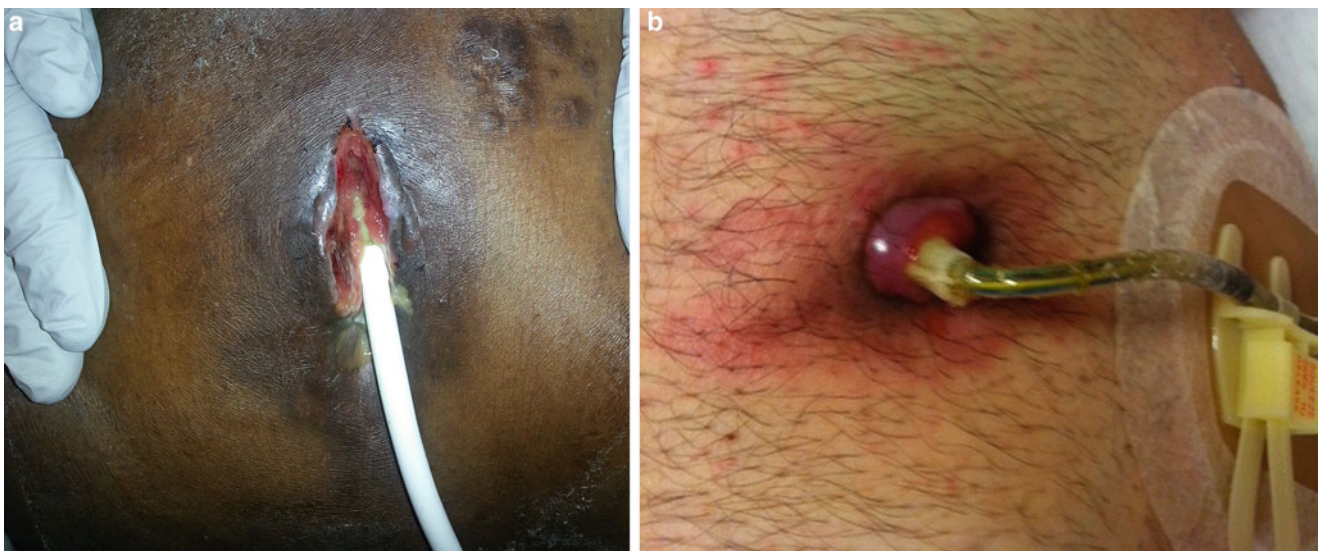

FIGURE 10-2. LVAD driveline infections. Photos of driveline infections in a patient with a HMII device (**a**) and a HVAD device (**b**), respectively.

TABLE 10-1. Recommendations for antimicrobial prophylaxis regimen from the 2013 International Society of Heart and Lung Transplantation Guidelines

Class I
1. Patients should receive preoperative antibiotics with broad-spectrum Gram-positive and Gram-negative coverage, as appropriate, prior to durable mechanical circulatory support implantation
Level of evidence: C
2. Routine antibiotic prophylaxis should include at least one dose prior to surgery administered within 60 min of the first incision, remain in the therapeutic range throughout the duration of their use, and not extend beyond 24–48 h
Level of evidence: C
3. Patients should have a nasal swab to screen for methicillin-resistant *Staphylococcus aureus and* receive topical treatment if positive prior to durable mechanical circulatory support implantation
Level of evidence: C

Reprinted from J Heart Lung Transplant, 32(2), Feldman D, Pamboukian SV, Teuteberg JJ, Birks E, Lietz K, Moore SA, et al., The 2013 International Society for Heart and Lung Transplantation Guidelines for mechanical circulatory support: Executive summary, 157–87, Copyright 2013, with permission of Elsevier.

aureus if a preoperative nasal swab is positive [23]. Other perioperative prevention strategies include making the driveline tunnel as long as possible. Once the lead has been tunneled in place, it is currently recommended that the Dacron-velour, which stimulates subcutaneous growth and sealing of the skin, is kept in the subcutaneous space so that only silicone is in contact with skin at exit site [23].

An ISHLT Infectious Diseases Working Group has sought to standardize the definitions and criteria for "VAD-specific infections," "VAD-related infections," and "non-VAD infections" (Table 10-2) [24]. Many studies have failed to elucidate risk factors for the development of LVAD infections. Obesity is one feature that may increase infection risks per a single-center report [25]. Patients who developed device-related infections had a significantly higher body mass index compared with the control group and continued weight gain over the course of LVAD therapy. Another potential contributor, although difficult to quantify, is driveline trauma, which is thought to contribute to infection onset due to loss of tissue in-growth at the exit site [26]. Patient and caregiver attention to the driveline site is clearly an important factor, although again difficult to quantify. Interestingly, one perspective multicenter study found that a history of depression was the strongest independent predictors of VAD infection (adjusted hazard ratio = 2.8, 95% CI 1.3–6.0, $p = 0.007$) [27].

Although bacterial infections predominate, fungal VAD infections are certainly not insignificant and carry a high morbidity and mortality rate. One center followed 300 VAD patients of which 108 developed a device-related infection; 85 were bacterial and 23 were fungal [28]. The most common bacteria were *Staphylococcus aureus*, coagulase-negative staphylococci, enterococci, and *Pseudomonas aeruginosa*. The most common fungal infection was *Candida albicans*. Only the use of total parenteral nutrition was associated with the development of a fungal VAD infection in multivariate analysis (odds ratio, 6.95; 95% confidence interval, 1.71–28.16, $p = 0.007$). Patients who experienced fungal VAD infection were less likely to be cured (17.4% vs. 56.3%, $p = 0.001$) and had greater mortality (91% vs. 61%, $p = 0.006$), compared with those who experienced bacterial VAD infection.

Recipients of LVADs are prone not only to device-related infection, but also to nosocomial infections, of which is commonest are respiratory tract infections [29]. The former occur as a result of the percutaneous driveline exiting the skin allowing the entrance of bacteria, LVAD pocket bacterial seeding at the time of surgery, or tracking of bacteria from the driveline site, and endovascular infections of the blood-contact device components that become seeded from transient bacteremia [30]. It is hoped that a future totally implantable VAD system that does not require a percutaneous driveline may markedly reduce rates of such infections. Nosocomial infections occur as a result of the patient's prolonged hospitalization, suboptimal nutritional status, immobilization, endotracheal intubation, and need for multiple intravascular and bladder catheters. Furthermore, there may be LVAD-associated defects in cellular and humoral immunity, including selective reduction in the number of $CD4^+$ T cells, defective proliferative responses of peripheral mononuclear cells, increased apoptosis of $CD4^+$ and $CD8^+$ T cells and B-cell hyperreactivity. However, these potential mechanisms of immunologic susceptibility to infection were identified in the pulsatile VAD era and may not be contributors in the setting on continuous-flow support [31–34].

10.3 Left Ventricular Assist Device Effect on Post-transplant Outcomes

There is conflicting data regarding the impact of LVAD bridging on subsequent post-transplant outcomes. Early reports included a Cardiac Transplant Research Database (CTRD) review of over 5880 patients transplanted between 1990 and 1997, comparing 502 patients receiving pulsatile LVAD support to 2514 patients receiving only intravenous inotropic support at the time of heart transplantation [35]. Survival between the two groups was comparable. The most frequent post-transplant causes of death in the LVAD patients were infection (27%), followed by early graft failure (18%) and acute rejection (10%). Interestingly in this analysis, the LVAD patients had a significantly lower overall freedom from first infection compared with medical therapy patients. Other studies from this era had similar findings, including that device-related infection was unassociated with post-transplant mortality [36, 37].

Table 10-2. Definitions of ventricular assist device-specific percutaneous driveline infection

	Surgical/histology	Microbiology	Clinical	General wound appearance
A. Superficial VAD-specific percutaneous driveline infection				
Proven—Surgical/histology criteria ± other criteria	• Involvement of tissues superficial to the fascia and muscle layers of the incision documented	• Aseptic skin culture positive or not cultured	• Local increase in temperature around the exit site	• Purulent discharge from the incision but not involving fascia or muscle layers or • Erythema spreading around the exit site[a]
Probable—No surgical/histology criteria with purulent discharge ± other criteria	• Surgical debridement not performed • No histology	• Aseptic skin culture positive or negative but patient already on antibiotic or had antiseptic used to clean wound	• Local increase in temperature around the exit site and • Treated as superficial infection with clinical response	• Purulent discharge from the incision but not involving fascia or muscle layers or • Erythema spreading around the exit site[a]
Possible—No surgical/histology or purulent discharge ± other criteria	• Surgical debridement not performed • No histology	• Aseptic skin culture positive or negative and patient not on antibiotics or had antiseptic used to clean the wound	• Local increase in temperature around the exit site and • Treated as superficial infection with clinical response	• No discharge • Erythema spreading around the exit site[a]
B. Deep VAD-specific percutaneous driveline infection				
Proven—Surgical/histology criteria ± other criteria	• Involves deep soft tissue (e.g., fascial and muscle layers) on direct examination or on direct examination during reoperation	• Culture positive or histology puncture positive for infection	• Temperature >38 °C	• A deep incision spontaneous dehiscence
	• An abscess is found on direct examination during reoperation		• Localized pain or tenderness	• Abscess deep to the incision around the driveline
Probable—No surgical/histology criteria with spontaneous dehiscence ± other criteria	• No surgical debridement • No histology	• Culture negative but patients already on antibiotics or had antiseptic used on exit site	• Temperature >38 °C or • Localized pain or tenderness and • Treated as a deep infection	• An incision spontaneous dehiscence
Possible—No surgical/histology criteria with positive ultrasound ± other clinical criteria	• No surgical debridement • No histology	• Cultures not reserved	• Localized pain or tenderness and • Treated as a deep infection with clinical response	• Positive ultrasound

VAD ventricular assist device.

[a]Erythema excluding stitch abscess (minimal inflammation and discharge confined to the points of suture penetration).

However, UNOS data on patients transplanted between 1995 and 2004 has a small excess in mortality in the first 6 months (hazard ratio 1.20, 95% confidence interval 1.02–1.43) and then also beyond 5 years post-transplant for those bridged by pulsatile LVADs [38]. In contrast to prior reports, infection appeared to be part of the reason for excess mortality during the early post-transplant period in the LVAD patients. The risk of infection-related mortality in the first 12 months following transplant was increased for patients with an LVAD (HR [95% CI], 1.41 [0.98–2.03]) compared to non-LVAD patients (Table 10-3). Similar results were obtained by a 2006–2012 UNOS data analysis focusing on continuous-flow LVAD patients who were UNOS status 1A at the time of transplantation [39]. A total of 2113 LVAD-supported status 1A transplant candidates were divided based on the presence (45%) or absence (55%) of device-related complications (DRCs). Device-related infection was the stated DRC in 513 patients (54% of DRC group). During the study period, the prevalence of Status 1A patients supported with continuous-flow LVADs whose listing status was attributable to DRCs increased from 20% in 2006 to 55% in 2012. Although all types of DRC increased over time, most of the increase was noted in the device-related infections category. Post-transplant survival was inferior for the DRC group

TABLE 10-3. Comparison of specific causes of death among patients with VAD vs. those within the first 12 months after transplant

	Number of deaths			Hazard ratio (95% CI)[a]	
Cause of death	UNOS status 1 ($n=9455$)	Intracorporeal VAD ($n=1433$)	Extracorporeal VAD ($n=448$)	Intracorporeal VAD	Extracorporeal VAD
Rejection	173	21	10	0.91 (0.54–1.55)	1.34 (0.67–2.69)
Infection	276	49	23	1.41 (0.98–2.03)	2.17 (1.35–3.46)
Cardiovascular	246	33	19	0.89 (0.59–1.35)	1.55 (0.93–2.58)
Pulmonary	75	7	5	0.60 (0.25–1.41)	1.48 (0.56–3.91)
Malignancies	23	3	1	1.17 (0.28–4.83)	2.36 (0.28–19.96)
Other	568	104	54	1.07 (0.83–1.37)	1.66 (1.21–2.26)

[a]Compared to other UNOS Status 1 patients.

compared to those without DRCs at 1 year (85.6% vs. 89.9%, $p=0.0143$) and at 3 years (77.9% vs. 82.7%, $p=0.0116$). Of the five categories of DRCs, survival was lower than in the non-DRC group only for the device-related infections category, both at 1 year (85% vs. 89.9%) and at 3 years (77% vs. 82.7%, $p=0.01$). This small decrement in early postoperative survival associated with LVAD infections may be related to the frequency of pre-transplant device infections resulting from impaired cellular immunity described in LVAD patients [30]. An alternative explanation could be that the sicker transplant candidates require more inpatient and outpatient hospital visits and are at increased of contracting and/or being diagnosed with a device-related infection. It is important to note that the same bacteria isolated pre-transplant may be found as a pathogen following transplantation and prophylaxis or treatment should be directed at the previously identified pathogen.

10.4 Anatomic and Surgical-Related Infections

Post-transplant mediastinitis is a potential complication of heart transplantation, occurring in approximately 5–10% of patients. Orthotopic heart transplant recipients have a higher risk of mediastinitis compared to other cardiothoracic procedures. Factors associated with an increased risk of mediastinitis include prior heart transplant, UNOS status 1 designation (the sickest patients), diabetes mellitus, reoperation for mediastinal bleeding, and coronary artery disease in addition to heart failure. In addition, the presence of *S. aureus* pneumonia postoperatively, or the need for treatment for rejection increase the risk [40, 41]. VAD infections that precede transplantation may also be a predisposing condition. One retrospective study of deep sternal wound infections found that body mass index over 30 kg/m^2, previous heart surgery, and previous VAD were associated with infection [41]. In-hospital mortality was increased in patients with this complication. If one can successfully treat the deep sternal wound infection, the long-term prognosis is comparable to patients who do not suffer this complication [42].

In a prospective observational study by the Spanish National Hospital Network (RESITRA) of 282 heart transplant recipients, 4.8% developed incisional surgical site infections, of which only one developed mediastinitis [43]. The median time from transplant to incisional site infection was 14 days (range 3–75 days). The organisms were mostly the patient's own flora, *S. aureus*, or coagulase-negative staphylococci predominate. But other pathogens can occur, including *Candida*. The prognosis with incisional site infections, other than mediastinitis, in the Spanish series was good.

Therapy of mediastinitis following heart transplantation is similar to that following other cardiac surgery. Debridement, a prolonged course of antibiotics, and potential use of muscle flaps or skin grafts may be necessary [42]. However, deep-seated wound infections can be devastating.

10.5 Other Bacterial Infections

Pneumonia is another common complication following heart transplantation. It may occur in up to 30% of patients [43–45]. In an analysis from the Mayo Clinic, the incidence was shown to decrease over three 5-year periods from 40 to 18%. Despite improvements in prevention of pneumonia, occurrence of pneumonia was independently predictive of mortality in heart transplant recipients.

Bacteremia following heart transplantation has been demonstrated to occur in approximately 16% of all heart transplant recipients [43]. Most common sources of bacteremia were lower respiratory (23%), urinary (20%), and intravascular catheter (16%). In this series from Spain, Gram-negative organisms were slightly more common than Gram positives. Risk factors for blood stream infection included the need for hemodialysis, prolonged intensive care requirements (defined as more than 5 days), and viral infections. Blood stream infection in heart transplant recipients was an

independent predictor of mortality (odds ratio of 1.8, with 95% confidence interval between 1.2 and 2.8). This increased risk of mortality from bacteremia has been demonstrated in other types of organ transplant recipients as well [46].

Endocarditis can occur following orthotopic heart transplantation. In one analysis, mortality was higher with a shorter median survival compared to patients who were not heart transplant recipients [47].

Among bacterial infections, the most common site of infection is the lung (35%), followed by the urinary tract (24%), blood stream (7.7%), and intra-abdominal (5.8%). *Escherichia coli* and *S. aureus* are the two most common pathogens, although *Pseudomonas*, *Klebsiella*, and *Enterobacter* species were quite common. The list of common bacterial pathogens generally follows what one might see as the list of common hospital acquired pathogens, reflecting the fact that most of the bacterial infections are nosocomially acquired.

Other less common bacterial infections, such as *Legionella*, *Listeria*, and *Nocardia*, which occur in immunocompromised hosts, are covered in more detail elsewhere (see Chaps. 20 and 23). In cardiac transplantation series, *Legionella* occurred in approximately 5% of the bacterial infectious episodes, as did *Nocardia* [48–51]. For *Legionella* and *Nocardia*, the lung was the most common site of involvement. *Listeria monocytogenes* occurred in approximately 2.5% of bacterial infectious episodes. There are no presentation or management issues that are unique to heart transplantation for these organisms.

Mycobacterial infection is a generally rare occurrence in cardiac transplantation in the United States [52]. Cases can occur at any time post-transplant. In one series only three cases of *Mycobacterium tuberculosis* were documented to occur in 620 transplant recipients. Atypical mycobacterial disease was more than twice as common, with eight cases being seen [53]. A recent observational cohort study of heart transplant recipients demonstrated that previous cardiac valve disease and chronic obstructive pulmonary disease was a risk factor for late infection, defined as that occurring more than 6 months post-transplant [54].

10.6 Fungal Infections Following Heart Transplantation

Aspergillus is the most significant fungus to affect cardiac transplant recipients [1, 55]. Among 109 fungal infections identified over a 20-year period (which did not include *P. jiroveci*), *Aspergillus* represented about 50%. The most common site was the lung, with disseminated disease occurring in 35% of cases. *Aspergillus* occurred most frequently in the first 3 months post-transplant. When dissemination does occur, the brain is often the most common site, and the presence of such an abscess or disseminated disease can be quite silent. *Aspergillus* is associated with the highest attributable mortality of any infection, and in one series disseminated disease had a mortality rate of 90%, and pulmonary disease of 40% [1]. In another series of *Aspergillus* infections post-cardiac transplantation, sepsis, multiorgan failure, and death were notable. Early onset cases (within 90 days of transplant) had traditional risk factors of hemodialysis, thoracic reoperation, and the presence of another case in the institution (reflecting perhaps a nosocomial problem). Later onset cases also included the need for hemodialysis as well as the need for augmented immunosuppression [56]. Targeted antifungal prophylaxis with caspofungin was shown to reduce invasive Aspergillosis in one outbreak among heart transplant recipients [57].

Candida infections are the second most common fungal infection in cardiac transplantation. In the Stanford series, about 33% of the fungal infections were due to *Candida*. Usually, the most common manifestation is mucosal infection of the oropharynx and in the Stanford experience this did represent one-third of all *Candida* infections. Other sites include dissemination, which can occur from esophagitis, or from an infection of an intravascular catheter, or from the driveline infection from the LVAD. The infections with *Candida* tend to occur in a more broadly distributed temporal pattern after the transplant. Often cases may be seen many months post-transplant. Most of these are mucosal in nature.

Coccidiomycosis and cryptococcosis occur rarely. They represent about 4% of the fungal infections seen at Stanford. In other series other endemic mycoses, such as histoplasmosis and blastomycosis, seem to affect cardiac transplant recipients at a rate similar to that seen in other types of solid organ transplantation [55].

P. jiroveci infection occurred in approximately 4% of all cardiac transplant recipients [1]. This complication has been reduced dramatically with the introduction of routine trimethoprim-sulfamethoxazole prophylaxis [58]. Cases still can occur many years post-transplant, and with any increase in immunosuppression, reactivation can occur.

Prevention strategies for fungal infections in heart transplantation are similar to other types of solid organ transplant recipients. Strategies include the use of mucosal prophylaxis such as nystatin swish and swallow, environmental controls, inhaled amphotericin B, or use of prophylactic systemic antifungals such as fluconazole, caspofungin or other echinocandins, or voriconazole. Since invasive fungal infection in cardiac transplantation is not as common as lung or liver transplants, routine use of systemic antifungal prophylaxis is not warranted. However, when patients are being treated for rejection, or have coexisting comorbidities, such as need for dialysis for renal failure, prophylaxis may be warranted. And as indicated above in an outbreak situation in which nosocomial cases of aspergillosis have arisen, some form of prophylaxis might be warranted. Routine use of trimethoprim-sulfamethoxazole for the first-year post-transplant is warranted, both for *P. jiroveci* prevention as

well as toxoplasmosis prevention (see antimicrobial prophylaxis). For a more detailed discussion of fungal infections, the reader is referred to Chaps. 39, 41 and 42.

10.7 Cytomegalovirus

Cardiac transplantation, like other forms of organ transplantation, carries with it a significant risk of CMV infection. CMV is the most important infectious factor that leads to a favorable or unfavorable outcome. In fact, the Stanford group described 20 years ago the impact of CMV infection on patient and graft survival [59]. The clinical risk factors for CMV in heart transplantation are identical to those seen in other forms of organ transplantation [60, 61]. The clinical presentation is also similar to that seen in other forms of organ transplantation with a couple of exceptions. One, CMV infection has been linked to coronary vasculopathy and accelerated atherosclerosis in heart transplant recipients, in contradistinction to the transplantation of other organs [59, 62]. The theory is that CMV can infect endothelial cells, and influence smooth muscle growth as well as migration, with proliferation within the coronary vasculature [63]. We also know that CMV infection upregulates proinflammatory cytokines, which leads to enhanced production of growth factors. There is also a procoagulant response which may also lead to vascular thrombosis [64]. This manifestation of the indirect effects of CMV is most pronounced in animal models and human studies. Two, there has been an association of CMV and left ventricular dysfunction as well [65]. There is evidence that effective CMV prevention strategies will actually reduce the incidence of intracoronary atherosclerosis, improve survival [66], as well as decrease the risk of opportunistic infections [67].

Another clinical feature of CMV in heart transplantation is the occurrence of myocarditis [68]. This is a relatively uncommon complication of CMV infection, but is generally seen only in and is unique to heart transplant recipients.

Prevention of CMV infection and disease in cardiac transplantation is similar to that recommended for other organs. Prophylaxis or preemptive therapy has been mainstay of prevention, depending upon program resources and patient population. Early studies with intravenous ganciclovir demonstrated that 1 month of intravenous ganciclovir dramatically improved the risk of CMV disease in all groups, but the CMV donor seropositive to recipient CMV seronegative mismatch [69]. Subsequent studies examining prophylaxis with oral ganciclovir as well as valganciclovir have demonstrated that CMV infection and disease can be prevented to a great extent in cardiac transplantation [70].

One difference in the prevention of CMV in cardiac transplantation compared to kidney or liver transplantation is the adjunctive use of CMV immune globulin, which is recommended by some authorities due to improvement in the degree or frequency of coronary vasculopathy in those receiving CMV immune globulin [71]. Limited data suggest that the use of CMV immune globulin with ganciclovir or valganciclovir is associated with an increase in the lumen size of coronary arteries as assessed by intracoronary ultrasound when compared to patients who just receive antiviral prophylaxis alone [67]. Further studies are needed to confirm these findings. In addition, there are cohort studies based on large patient registry sources of cardiac transplantation that show that antiviral CMV prophylaxis is associated with a decreased likelihood of graft loss [72] as well as improved survival [73]. A more complete discussion of CMV in solid organ transplantation is provided in Chap. 25. Regimens for CMV prophylaxis are outlined in Chap. 25.

Treatment of CMV disease, when it occurs in the heart transplant recipient, is the same as treatment given to other solid organ transplant recipients. The presentation of CMV disease, when it occurs, may be slightly different than that seen with other organs in that accelerated atherosclerosis, and even myocardial infarction may be a presenting sign or symptom of CMV infection. In addition, as mentioned earlier, myocarditis may occur as well, albeit rarely.

10.8 Other Viral Infections Following Heart Transplantation

Other viral infections in heart transplantation contribute to morbidity and mortality. It has been demonstrated that viral infections, including a variety of respiratory viruses contribute to the development of coronary vasculopathy and graft loss, presumably by upregulating inflammatory markers much like CMV [74]. One study of 553 endomyocardial biopsy specimens from 149 pediatric heart transplant recipients demonstrated the presence of viral genomes in the heart. Positive PCR for a viral genome was associated with an increase in cardiac adverse events over the ensuing months. Adenovirus was the most common viral genome detected [74].

Viral hepatitis can occur after heart transplantation, but transmission of hepatitis B is generally uncommon from the donor heart since donor screening to eliminate hepatitis B surface antigen (HBsAg) positivity is performed. Recipients with active hepatitis B carriage will reactivate in the setting of immunosuppression [75, 76]. Cardiac donors who are isolated anti-hepatitis B core (anti-HBc) positive can be used for heart transplantation with relatively little risk to the recipient [77]. Heart transplant recipients who are either hepatitis B or hepatitis C positive at the time of transplant tend to have a good prognosis, and their survival seems comparable to those without such infection according to several analyses [77, 78].

Post-transplant lymphoproliferative disease (PTLD), due to Epstein–Barr virus (EBV), has been reported to occur in about 3% of all heart transplant recipients, second to lung

transplant recipients in terms of risk [79, 80]. The exact reason for this increased risk is not entirely clear. Risk factors for PTLD in heart transplant recipients, namely primary EBV infection, as well as treatment with lymphocyte-depleting antibodies is similar to other types of organ transplants. Presentation of PTLD and treatment of PTLD does not differ from other forms of solid organ transplantation (see Chap. 24). It should be noted that the allograft may be involved when disease presents early, that is, less than 1-year post-transplant.

Human immunodeficiency virus (HIV) was previously considered an absolute contraindication to solid organ transplantation, but since the developed of anti-retroviral therapy there has been limited experience with heart transplantation in patients with HIV. Furthermore, there have been legal moves to prevent discrimination of potential transplant recipients based solely on HIV status [81]. An initial case report described a young male with prior opportunistic infections whose HIV viral load was undetectable prior to transplantation [82]. He had no opportunistic infections for the first 2 years post-transplant, but did have several asymptomatic cellular rejection episodes, anemia, thrombocytopenia, and fluctuations in his CD4 count. A single center subsequently reported 7 cases of HIV infection in heart transplant recipients; 5 were diagnosed with HIV before transplantation and 2 patients seroconverted after transplantation (at 1 and 7 years post-transplant) [83]. Five patients experienced asymptomatic rejection episodes. Cardiac allograft function remained normal in 6 patients. One patient who seroconverted to HIV-positive status 7 years after transplantation was diagnosed with cardiac allograft vasculopathy 5 years after transplant, resulting in ischemic cardiomyopathy. All patients were alive at a mean follow-up of 30 months (range, 3–88 months). The two patients who seroconverted to HIV-positive status after receiving transplant were initiated on anti-retroviral therapy. No AIDS-defining illness, low CD4 count, or detectable viral loads were documented in any patients post-transplant. A woman who seroconverted to HIV 1-year post-transplant also subsequently experienced cellular rejection, but was reported to have normal allograft function at 10 years post-transplant [84].

10.9 Parasitic Infections Following Heart Transplantation

A major distinction between heart transplant recipients and other organ transplants is the extent to which parasitic infection may occur due to transmission from the transplanted heart. *T. gondii* persists in cardiac muscle tissue and is thus transplanted via the donor organ. Thus, heart transplant recipients have the highest risk of toxoplasmosis. Among those who are mismatched serologically, that is, the toxoplasma antibody positive donor heart to the toxoplasma antibody negative recipients, 75% will develop primary toxoplasma infection in the absence of any intervention or prophylaxis [85, 86]. Among those who are seropositive for toxoplasma infection at the time of transplantation, reactivation can also occur [87]. The disease in cardiac transplants can be fatal disseminated disease, or myocarditis [88]. There has been some recent debate in the literature about the prognostic significance of toxoplasma serology on outcome following cardiac transplantation. Two reports suggested that being toxoplasma seronegative at the time of transplant was associated with a worse prognosis, but a subsequent study refuted those data in a larger cohort [89–91]. Prophylaxis with bactrim has fortunately reduced the risk of toxoplasmosis dramatically and is effective [1, 86]. Since it is used routinely for *P. jiroveci* prophylaxis, an added benefit is the prevention of toxoplasmosis. For more detailed discussion, the reader is referred to Chap. 44.

T. cruzi [92] is also quite important in heart transplantation since the parasite is dormant in cardiac tissue. Especially in Brazil and Argentina, a high proportion of organ donors will be seropositive for *T. cruzi*, and are capable of transmission [93]. Among those recipients with a donor who is seropositive for *T. cruzi*, about 20% will develop parasitemia within the first 6 months post-transplant [94]. In addition with immunosuppression reactivation may occur [95]. Intervention is possible with benznidazole. In addition, patients with *T. cruzi* cardiomyopathy may require transplantation. A recent analysis in the United States demonstrated a high number of patients having unrecognized Chagas cardiomyopathy having emigrated from endemic countries [96, 97]. Studies performed over the past two decades indicate that with proper management, that is, screening for parasitemia, and treatment with benznidazole 10 mg/kg/day for 60 days, mortality related to *T. cruzi* infection is very low and survival rates are comparable to heart transplants not infected with *T. cruzi* [97]. However, this agent is not available in the United States; only nifurtimox, a nitrofuran derivative is available through the Centers for Disease Control and Prevention. If patients do develop clinical Chagas disease, they may develop disseminated disease with myocarditis, subcutaneous nodules, and dissemination to other organs.

10.10 Hypogammaglobulinemia Following Heart Transplantation

Hypogammaglobulinemia has been shown to occur following cardiac and other organ transplantation [98, 99]. Severe hypogammaglobulinemia (defined as IgG levels < 350 mg/dL) occurred in 10% of heart transplant recipients followed prospectively at Cleveland Clinic [98]. Those with severe hypogammaglobulinemia were more likely to have treatment for more episodes of cellular rejection during the first 6 months post-transplant than those without such treatment. Severe hypogammaglobulinemia has been associated with an increased risk of bacterial and opportunistic fungal infec-

tions. In another study of heart transplant recipients, pre-transplant levels of IgG, below median values of 1140 mg/dL were shown to be associated with an increased risk of developing infections [100]. In addition, levels at 7 days post-transplant below the median value of 679 mg/dL were markedly associated with an increased risk for infection. These studies raise the question of the need for more intensive and routine monitoring of immunoglobulin levels.

Studies of replacement therapy with intravenous immune globulin, including CMV immune globulin, in the presence of severe deficiency have been shown to reduce the incidence of opportunistic infections and even rejection episodes in heart transplant recipients [101]. In cardiac transplant recipients it may be especially important to screen for the presence of hypogammaglobulinemia post-transplant to avoid such complications and to administer intravenous immune globulin to restore immunity and reduce the risk of infectious complications [101].

10.11 Antimicrobial Prophylaxis for Heart Transplantation

At the time of cardiac surgery, patients should receive antimicrobial surgical prophylaxis in accordance with Surgical Care Improvement Program (SCIP) guidelines. Forty-eight hours is all that is recommended. The use of trimethoprim-sulfamethoxazole, a single strength of 80 mg/400 mg per day for 6–12 months, or three times a week with the double strength, has been effective in reducing the risk of *P. jiroveci*, *T. gondii*, and even *Listeria monocytogenes* as well as *Nocardia*. The trimethoprim-sulfamethoxazole regimen has even been effective in preventing disseminated toxoplasmosis among the toxoplasma mismatched seropositive donor to seronegative recipient [102].

The recommendations for CMV prevention in general are outlined in Chap. 25. Among heart transplant recipients, prophylaxis with valganciclovir 900 mg orally once a day for 3 months is sufficient if one chooses this modality. For CMV seropositive donor to CMV seronegative mismatches, a recent study, which included heart transplant recipients, demonstrated that 6 months of prevention with valganciclovir is superior to 3 months, with a reduction in late onset disease [103]. Because of the potential immunomodulatory benefits of CMV immune globulin in cardiac transplantation, with reductions in allograft vasculopathy, some authorities recommend combining valganciclovir with CMV immune globulin for those patients who receive a CMV seropositive donor heart [72].

10.12 Immune Monitoring

There is an emerging body of literature that has looked at CD4 counts as well as other forms of immune monitoring. One analysis of T lymphocyte subsets suggests an independent association of opportunistic infections and CD4 nadir counts [104]. In another analysis from a program in Tel Aviv, the Immuknow assay (Cylex Inc., Columbia, MD) was used prospectively to follow patients at risk for rejection or infection [105]. The authors demonstrate a relationship between the assay, the development of opportunistic infection or rejection [105]. Subsequent follow-up of patients on everolimus confirm the utility of the assay for infection [106] but not rejection. If confirmed, assays such as these may become important to balance the level of immunosuppression to avoid both infection and rejection. Confirmatory studies with larger numbers of patients are clearly warranted but these data look promising. Another group has pursued the development of an immunologic score to reflect the level of immunosuppression. The score consists of an analysis of lymphocyte subsets at 1-week post-transplant along with immune globulin levels and complement levels [107]. They purport a very high hazard ratio for infection risk. These attempts to quantify levels of immune suppression and infection risk are promising, but require further analysis in large cohorts.

10.13 Summary

Infections in cardiac transplantation have declined over the past 30 years. The incidence of bacterial and fungal infections has declined quite dramatically, with rates dropping fivefold and sixfold, respectively. In addition, rates of CMV disease have also declined. Much of this is attributed to the routine use of prophylactic agents listed above as well as improvements in the surgical technique, intensive care unit management, and diagnosis of many of these infections.

The research agenda for the future includes the need for studies of optimal prevention and management of left ventricular assist device infections, including antibiotic prophylaxis. In addition, improvement in management of chronic graft rejection and vasculopathy are warranted.

Risks and Epidemiology of Infections After Lung or Heart–Lung Transplantation

Oscar Len, Antonio Roman, and Joan Gavaldà

11.1 Introduction

Currently, lung transplantation (LT) is an established therapeutic option for patients who have severe respiratory insufficiency [1–5]. Nevertheless, complications do frequently occur, and they can lead to intermediate-term or long-term graft dysfunction and decreased survival. According to the International Society for Heart and Lung Transplantation (ISHLT) registry, survival rates at the first, second, and fifth years are 80%, 65%, and 53%, respectively [6]. The prognosis of lung transplant recipients (LTR) has improved considerably in recent years, thanks to the careful selection of donors and recipients, advances in surgical techniques and postoperative care, and better methods for graft preservation.

LT can be either unilateral or bilateral. Single-lung transplantation is generally used for non-septic lung diseases, whereas double-lung transplantation is mandatory for septic lung diseases, such as cystic fibrosis (CF) and bronchiectasis. Infections and episodes of acute rejection are both significant complications soon after LT. Moreover, the main obstacle to the long-term success of LT remains chronic rejection, characterized histologically as bronchiolitis obliterans. It occurs in up to two thirds of patients [7]. The most relevant risk factor for the development of bronchiolitis obliterans syndrome (BOS) after the number of previous acute rejection episodes and the incidence of persistent rejection is cytomegalovirus (CMV) infection and disease [8]. Recent evidence also suggests a possible role for respiratory viruses (RV) as risk factors for chronic rejection in LTR [9, 10]. Finally, a restrictive allograph syndrome came up as a novel phenotype of chronic rejection with worse prognosis than BOS [11].

Infectious complications are a frequent cause of morbidity and mortality and the most prominent cause of death the first year. More than two thirds of them affect the respiratory tract [6, 12].

This chapter focuses on the epidemiology and prevention of bacterial, viral, and fungal infections in lung or lung–heart transplant recipients. Additionally, it addresses specific aspects of donor, residual, or native lung infection or colonization, as well as issues involving recipients with CF. One of the main problems with dealing with infection in LT is the paucity of randomized, controlled studies. So more controlled studies are needed to answer the questions regarding infection in LTR.

11.2 Risk Factors for Infection

The risk of infection in an LTR is determined by interrelationships among numerous factors related to the recipient, associated with the type of transplant and the surgical procedure, and inherent to the infecting microorganism and the state of permanent therapeutic immunosuppression required to avoid graft rejection. Table 11-1 summarizes these risk factor groups.

11.2.1 Recipient-Related Factors

The recipient's pre-transplantation clinical status is important; patients with renal failure, those on mechanical ventilation, and those with morbid obesity or malnutrition have a higher incidence of infection after LT [12–15]. Advanced age is also associated with an increased risk [16]. In some programs, mechanical ventilation is a major contraindication to LT as airway colonization with bacteria may lead to nosocomial infection and the associated respiratory muscle deconditioning may require prolonged postoperative ventilatory support. However, recent results have shown that pre-transplantation mechanical ventilation is not associated with a higher risk of later bacterial infection [17–19]. In fact, nowadays, most programs accept mechanical ventilation as a bridge for LT for candidates previously included on the waiting list.

Various treatments administered to the candidate before LT as well as underlying diseases (such as diabetes mellitus) may be relevant to the type and severity of infection after LT. Candidates treated with corticoids or antimicrobial agents before transplantation have a higher incidence of

P. Ljungman et al. (eds.), *Transplant Infections*, DOI 10.1007/978-3-319-28797-3_11

Table 11-1. Risk factors for infection in recipients of a lung or heart–lung transplantation

Recipient
Underlying conditions such as diabetes or hepatitis
Older age
Absence of specific immunity to CMV, HSV, VZV, EBV
Colonization of the recipient by bacteria or fungi
Latent infection due to TB, CMV, VZV, HSV, EBV
Previous therapy with antimicrobial agents, corticoids, or other immunosuppressors
Clinical state of the recipient at the time of transplantation:
Renal failure
Malnutrition
Low vitamin D levels
Obesity
Mechanical ventilation
Transplantation
Preservation lesion
Surgical factors:
Duration of procedure, meticulous technique
Surgical complications: suture dehiscence, hemorrhage, arterial ischemia
Repeated surgery required
Postoperative instrumentation:
Duration of mechanical ventilation
Intravascular catheters
Urethral catheter
Continuous exposure to the external environment
Denervation of allograft:
Diminished cough reflex
Abnormal mucociliary clearance
Reactive hyperresponsiveness
Interrupted lymphatic drainage (especially during first weeks)
Anastomosis site:
May enhance colonization
Airway dehiscence and mediastinitis
Bronchial stenosis and postobstructive infection
Donor lung may transmit infections:
From prolonged mechanical ventilation
From latent infections (TB, CMV, VZV, HSV, EBV)
From previous bacterial or fungal colonization
Native lung after single-lung transplantation:
Occult pretransplant infection (TB, *Aspergillus* spp., *Pneumocystis jirovecii*, etc. especially with immunosuppression before transplantation)
Sinus infection in cystic fibrosis and ciliary dysfunction syndromes
Bronchiolitis obliterans:
Enhanced immunosuppression
Impaired clearance
Bronchiectasis
Immunosuppression
Immunomodulating viruses
Graft rejection

Abbreviations: *CMV* cytomegalovirus, *HSV* herpes simplex virus, *VZV* varicella-zoster virus, *EBV* Epstein–Barr virus, *TB* tuberculosis.

infections due to bacteria and *Candida* spp. [16, 20]. On the other hand, low-dose pre-transplantation corticosteroid treatment has proved to be even beneficial; it allows LT in patients who cannot be completely weaned from such therapy [21]. In cases of single-LT plus pre-transplantation corticosteroid treatment, the remaining native lung may harbor opportunistic microorganisms, including *Aspergillus* spp. (IA), tuberculosis, or *Pneumocystis jirovecii* [22]. Therefore, performing a histopathologic study and culture of the resected lung to rule out these infections and to provide treatment when they are detected is extremely important. Finally, the indiscriminate use of antimicrobial agents before transplantation can lead to the selection of multidrug-resistant (MDR) strains that are difficult to treat. This often occurs in recipients with CF, as discussed below.

The absence of specific immunity in the recipient to some viral infections, especially CMV or Epstein–Barr virus (EBV), implies a higher risk of acquiring these infections when the donor lung harbors latent infection by these viruses. Such primary infection produces disease with greater frequency and more severity than do cases of reactivation.

Vitamin D deficiency is frequent in LT candidates and greater than in general population. Vitamin D plays a role in cell-mediated immunity as well as in innate immune response. A retrospective cohort study showed that 80% of LTR were deficient for vitamin D. Infectious episodes due to bacteria, CMV, fungi, and non-tuberculous mycobacteria (NTM) in this group were more frequent than in the non-deficient group within first year after transplantation (5.41 vs. 3.15; $p > 0.001$) [23].

11.2.2 Transplant-Related Factors

Initial dysfunction of the transplanted organ caused by arterial ischemia or severe preservation lesions secondary to a prolonged interval of ischemia influences the frequency and severity of post-transplant infections. Similarly, alloreactivity reactions against the graft make it more prone to infection by certain viruses. The most frequent sites of infection in the immediate postoperative period are the lung, the pleura, and the extrapulmonary chest cavity, since the integrity of the visceral pleura is not restored and the mediastinal space is lost due to communication with the pleural spaces.

With respect to the interval of graft ischemia, Fiser et al. [24] showed that a cold ischemia time longer than 6 h did not increase the risk of reperfusion injury, acute rejection, CMV infection, bacterial or fungal pneumonia, BOS, 1-month mortality, 1-year mortality, or 5-year mortality, after reviewing data from 136 LTR over a 10-year period. These findings have not been supported by results from other groups [16].

The length and the need for repeated surgery are the most important surgery-related risk factors for the development of

bacterial or invasive fungal infection (IFI) during the immediate post-transplantation period [16].

In LT, several special predisposing factors for the appearance of bacterial pneumonia are present. The state of ischemia for several hours after donor lung extraction, and reimplantation without reestablishment of the graft's lymphatic drainage and innervation clearly affect the graft's defense mechanisms. The airway mucosa is damaged, and the mechanism of mucociliary clearance is paralyzed. Anastomosis of the airway also decreases the clearance of respiratory secretions. Graft denervation eliminates the cough reflex, allowing secretions to accumulate. The interruption of lymphatic drainage prevents the immune system effector cells of the regional lymph system from reaching the lung, which in turn alters the immune response against antigens deposited in the lung [25]. Moreover, the graft's microenvironment consists of human leukocyte antigen incompatibility between the host alveolar macrophages and the donor alveolar lymphocytes [26]. Additionally, small inoculum of microorganisms extracted with the graft can produce severe pneumonia in the already immunosuppressed recipient [27]. Finally, the lung is in constant contact with ubiquitous airborne bacteria.

Finally, the most important predisposing condition for post-transplantation infection is BOS. LTR with BOS are usually profoundly immunosuppressed, and their lung function and mucus clearance are often markedly impaired. In fact, the most common cause of death in patients suffering from BOS is infection.

11.2.3 Lung Transplant Donor

Almost all donor lungs harbor microorganisms at the time of procurement [28]. Thus, the risk of donor-to-host transmission of infection is inherent; this has repercussions on donor selection and on the choice of prophylactic regimens administered to the recipient of a lung or heart–LT.

The authors' group has recorded data from donors of lung allografts transplanted to 49 recipients surviving at least 24 h after LT [28]. Overall incidence of donor infection was 73.4%. The types of donor infection included isolated contamination of preservation fluids (17.9%), graft colonization (69.2%), and bacteremia (12.8%). Donor infection rates did not differ statistically between those mechanically ventilated for 48 h or less or more than 48 h. Donor-to-host transmission of bacterial or fungal infection occurred in 15 (7.6%) LTR (Table 11-2). In our experience, 25% of donors with bacteremia and 14.1% of colonized grafts were responsible for transmitting infection. Two patients died because of transmitted infection (Table 11-2). Microorganisms for which it is extremely difficult to design effective prophylactic regimens caused five cases of infection: *A. fumigatus*, *Stenotrophomonas maltophilia* and methicillin-resistant *Staphylococcus aureus* (MRSA). Excluding these cases, prophylaxis failure occurred in 5.6% of procedures (5.6%).

Similarly, Low et al. [29] reported that 28 of 29 bronchial washings taken from donors grew at least one microorganism. The most common microorganisms identified were *Staphylococcus* spp. and *Enterobacter* spp. In 43% of these cases, similar microorganisms were isolated from the recipient tracheobronchial tree, and, of these, 21% had subsequent invasive pulmonary infections. Waller et al. [30] performed a retrospective comparison of the outcome of 123 donors in 125 consecutive, technically successful lung or heart–LT. Microbial contamination of routine donor bronchial lavage was about 60%. Five recipient deaths were due to donor-transmitted pneumonia.

A bronchial washing or aspiration for microbiologic sampling should be routinely performed in the lung donor to guide the choice of adequate recipient prophylaxis. Gram,

Table 11-2. Description of infection episodes due to donor-to-host transmission

Microorganism	Type of donor infection	Type of recipient infection	Outcome	Prophylaxis

methenamine silver, calcofluor (for fungi identification), and Ziehl–Neelsen staining; and specific cultures for bacteria, fungi, and mycobacteria should all be conducted [31]. The main problem is that culture results may not be available soon enough. Nevertheless, the finding of positive Gram stain or scanty purulent secretions should not be contraindications for accepting the lung for transplantation [31] because the outcome of these marginally suitable lungs is similar to that obtained with ideal grafts [32]. However, most groups consider the existence of pneumonia, aspiration of gastric juice, abundant purulent secretions that persist after bronchial washing, or the growth of filamentous fungi on a culture of fiber-optic bronchoscopy samples to be contraindications to transplantation. Since two of the authors' patients who received lungs contaminated with *Aspergillus* spp. developed invasive aspergillosis (IA) and died, the group excludes lungs for which calcofluor stain evidences hyphae. The heavy growth of *Candida* species in the donor bronchus makes these lungs risky because of the potential involvement of the vascular sutures or large vessels, which could lead to mycotic aneurysms and consequent rupture [33]; therefore, this represents a significant obstacle for accepting these organs. This is more important for heart–LTR. So, the graft should be excluded if the culture is pure and highly abundant. If this is not the case, an echinocandin should be initiated immediately after transplantation.

An experimental study in canine LT has provided evidence that antibiotic treatment of donors showing bacterial contamination prevents the development of pneumonia in recipients [34]; nevertheless, no consensus has been reached on whether antimicrobial treatment should be used in all human lung donors. Although this measure might decrease the risk of early bacterial pneumonia, it might also induce false negative results in cultures and thus may make recipient management after transplantation more difficult.

11.2.4 Cystic Fibrosis

Chronic infection of the respiratory tract before transplantation distinguishes patients with CF from patients with other diseases. Nonetheless, several studies report that recipients with CF receiving bilateral lung transplants do not have a higher risk of infection after the procedure despite the common presence of airway pathogens (*Pseudomonas* spp., *S. aureus*, and molds). Many patients show the same strains of *P. aeruginosa*, as demonstrated by electrophoretic DNA analysis, after transplantation, probably due to contamination during surgical graft placement or from the chronic sinusitis occurring in these patients [35]. Although the efficacy of surgical sinus drainage has not been established, some recommend this procedure [2–4, 36].

Some centers exclude patients with certain respiratory pathogens, such as *P. aeruginosa* resistant to all antibiotics, or those with other MDR bacteria, including *B. cepacia*, *S. maltophilia*, or *Alcaligenes xylosoxidans*. However, data demonstrating post-transplantation infection and survival rates that are similar to those of patients with sensitive strains suggest that this policy is unwarranted [2, 37–39]. The presence of *B. cepacia* is considered an absolute contraindication to LT in some centers because of its high associated risk of severe and often lethal postoperative pneumonia and sepsis and because transmission between patients is well documented [40]. Recent reports have documented lower survival in recipients previously colonized by *B. cepacia*, and specifically, by *B. cepacia* genomovar III strains [41, 42].

Aspergillus spp. is recovered from respiratory tract cultures in up to 50% of patients with CF. Its presence is not, however, predictive of subsequent allograft infection, and it should not be considered a contraindication to transplantation unless evidence shows mycetomas adhering to the chest wall.

An increase incidence of NTM has been observed [43]. All patients with CF should be evaluated for NTM pulmonary disease before LT. Patients with NTM disease should begin treatment before transplant listing. In case of progressive pulmonary or extrapulmonary disease despite optimal therapy or an inability to tolerate it, LT is a contraindication [44].

11.2.5 Native Lung

In single-LTR, the residual native lung can give rise to a large number of post-transplantation complications. In addition to bacterial or fungal pneumonia and bronchial anastomosis infections leading to dehiscence, the native lung can have noninfectious problems such as severe overinflation, perfusion mismatch, or pneumothorax. The incidence of native lung infectious complications in single-LTR ranges from 20 to 50% [15]. In patients with idiopathic pulmonary fibrosis treated with high-dose steroids, infection of the native lung by *M. tuberculosis*, *P. jirovecii*, and *A. fumigatus* may go unnoticed in the evaluation of the candidate and may result in a serious exacerbation of infection after transplantation. Pathologic and histologic analyses of the resected lung are essential. Native pulmonary aspergillosis is the most feared complication because it is difficult to diagnose and practically impossible to treat unless a pneumonectomy can be performed. Moreover, primary prophylaxis for IA is complex because of the problems in reaching acceptable concentrations of therapeutic drugs and the fact that nebulized amphotericin B (AFB) is not properly distributed in a lung with significant ventilation and perfusion defects.

11.2.6 Immunosuppression

LTR have a permanent deficit of immunity due to the immunosuppressive treatment required indefinitely to avoid rejection.

The use of OKT3 as an induction agent is now very limited due to an increase risk of infection [45]. In contrast, antithymocyte globulin (ATG) and basiliximab do not increase the rate of infections and have been associated with a survival benefit [46].

In patients treated with cyclosporine (CsA) or tacrolimus, the incidence of infection is quite similar [47]. The University of Pittsburgh performed a study that compared the effects of tacrolimus and CsA. The prevalence of bacterial infection was 1.5 episodes per 100 patient days in the CsA group and 0.6 episodes per 100 patient days in the tacrolimus group, although with no statistical significant difference. The prevalence of CMV and fungal infection were also similar in both groups [48].

The role of antimetabolites such as mycophenolate mofetil (MMF) and inhibitors of the mammalian target of rapamycin (mTOR) such as sirolimus or everolimus is discussed below when assessing CMV infection.

The incidence of serum immunoglobulin deficiencies can be as high as 44% in LTR and has been associated with community-acquired respiratory viral infections, IFI and BOS [49, 50]. However, a randomized, double-blind, placebo-controlled trial of immune globulin intravenous administration in LTR with hypogammaglobulinemia failed to demonstrate a reduction in the short-term risk of bacterial infection [51].

Infection by immunomodulating viruses, such as CMV, increases the net state of immunosuppression favoring the development of opportunistic infections [52]. An extensive study performed at the University of Pittsburgh assessed the risk factors for infection other than CMV in 250 transplantations (99 single lung, 102 bilateral lung, and 49 heart–lung) [16]. Early post-transplantation risk factors for infection included CMV mismatch (donor is CMV-positive, recipient is CMV-negative [D^+/R^-]), among others. Risk factors for late infection included again CMV mismatch, the absence of CMV prophylaxis, and CMV disease, among others [16].

11.3 Bacterial Infection

11.3.1 Epidemiology

Bacterial infection is the most frequent infectious complication for lung and heart–LTR. The rate of bacterial infections (mainly respiratory) is much higher than that observed in other SOTR. Of the total infections observed in different series, 35–66% were bacterial, and 50–85% of recipients presented a bacterial complication after transplantation. Frequently, patients experienced more than one bacterial infection and bacterial respiratory infection occurred most frequently [1, 5, 6, 12, 13, 16, 53, 54]. Beginning with persistent colonization, lung and heart–LTR can present with any of the clinical forms of this process (tracheobronchitis, sinusitis, pneumonia).

Table 11-3. Factors related to bacterial infections in LTR

Immediate post-transplant period	Late post-transplant period
Pre-transplantation colonization [55]	Increased immunosuppression due to rejection
The surgical procedure itself and technical complications (e.g., bronchial anastomosis dehiscence) [13]	Invasive diagnostic procedures
Intubation and/or prolonged hospitalization [16]	Development of BOS [16, 56]

Factors related to bacterial infections presenting in the immediate and late post-transplantation are depicted in Table 11-3.

The most frequent causal agents of nosocomial pneumonia are *P. aeruginosa*, Enterobacteriaceae and *S. aureus* [57, 58]. Other prevalent Gram-negative nosocomial bacteria include *Acinetobacter* spp. and *Stenotrophomonas maltophilia*. The period of maximum risk spans the first 3 weeks after transplantation. Nevertheless, its incidence during this interval has markedly decreased with the implementation of antibiotic prophylaxis; most cases of bacterial pneumonia now occur in the intermediate and late postoperative period. In fact, health care-associated pneumonia is more frequent than hospital-acquired pneumonia [58]. Stable, ambulatory transplant recipients after the postoperative phase can develop pneumonia from infection with microorganisms prevalent in the community (e.g., *Mycoplasma pneumoniae*, *Haemophilus influenzae*, or *Streptococcus pneumoniae*). Infection due to MDR bacteria is a widespread problem, especially early after the procedure in the setting of hospital-acquired/ventilator-associated pneumonia (VAP). Its appearance is associated with high rates of morbidity and mortality [59]. These bacteria (e.g., MRSA, MDR *P. aeruginosa* or *B. cepacia*) may colonize the recipient before transplantation (e.g., patients with CF) or can also be acquired after surgery (e.g., MDR *Acinetobacter baumannii*). Our group reviewed VAP incidence, etiology, and outcome in our cohort of LTR. VAP was diagnosed in 20% of LTR. *P. aeruginosa* was the most frequent microorganism isolated (60% MDR), followed by Enterobacteriaceae. Mortality was significantly higher in those patients diagnosed with VAP (OR 9, CI 3.2–25.1, $p<0.01$) [60]. In another study performed in RESITRA (Spanish Research Network for the Study of Infection in Transplantation), evaluating 85 pneumonia episodes in 236 LTR (with an incidence of 72 episodes per 100 patients-per-year), bacterial pneumonia (82.7%) was more common than fungal (14%) or viral (10.4%). Gram-negative bacilli were the etiology in 34 cases (*P. aeruginosa* in 14 and *A. baumannii* in 8). The absence of pneumonia caused by *Legionella pneumophila* was noteworthy and likely due to the effect of cotrimoxazole prophylaxis [61].

The physician must remember that even the growth of normal oral flora in a respiratory sample in the early transplantation period is considered a risk factor for bacterial

pneumonia. Therefore, laboratory workups should identify and perform susceptibility study of all strains isolated. In addition, the clinician should determine whether the anastomosis shows signs of ischemia. If these are present, they imply a greater risk of both infections to the anastomosis and suture dehiscence, and they might be an indication for the use of nebulized antibiotics to treat respiratory colonization or infection.

Deep surgical site infections (SSI) are an uncommon complication in LTR. In a retrospective study at a single center, 5% of LTR developed SSI [62]. Empyema was the most common (42%), followed by wound infection (29%) and mediastinitis (16%). However, the term "thoracitis," rather than mediastinitis, is more accurate because the mediastinal space does not exist as such; during lung implantation, the visceral pleura are not joined to create separate mediastinal space. Therefore, when infection occurs in this extraparenchymal thoracic space, the entire thoracic cavity becomes infected with purulent collections in several locations. Interestingly, 23% of SSI was due to pathogens colonizing recipients' native lungs at the time of transplantation suggesting surgical seeding [62]. One-year mortality associated with SSI was 35% [62].

Bacteremia in LTR is an early complication after transplantation almost related to catheter. The etiology is equally distributed between Gram-negative and Gram-positive bacteria. Nearly half the isolates correspond to MDR microorganisms [63].

Infections caused by *Mycobacterium tuberculosis* are reported because of reactivation, occult disease in the remaining native lung after single-lung transplantation, or transmission by the graft [64]. Within the authors' transplant program, pulmonary tuberculosis is diagnosed in about 6% of LTR. The mean post-transplantation interval at which *M. tuberculosis* is detected is 115 days. In 40% of the cases, the diagnosis was obtained from the explanted lungs. Despite immunosuppression, an adequate response to antituberculous treatment and a low incidence of adverse side effects is observed [65].

Episodic isolation of NTM is common in LTR with an incidence rate of 9/100 person-years [66]. Previous NTM colonization and treated acute rejection are risk factors for NTM disease [67]. The most common NTM isolated is *Mycobacterium avium complex* (69.8%), followed by *Mycobacterium abscessus* (9.4%), and *Mycobacterium gordonae* (7.5%). Most isolates occur among asymptomatic patients and are transient. Nevertheless, NTM disease rate is higher among LTR than in the other SOTR [68]. Moreover, infection due to *Mycobacterium abscessus* is a difficult-to-treat infection. The ISHLT published a study including 5200 LTR. Seventeen patients (0.33%) were identified with *M. abscessus* infection affecting the pulmonary allograft in 12, the skin/soft tissue in 3, or both in 2. Therapies included multiple antibiotics in 16, surgical debridement in 2, interferon-gamma in 1, or no therapy owing to presumed colonization in 1. Ten of 17 patients were considered cured while 2 patients died due to infection [69]. More recently, NTM infection has been associated with increased risk of mortality independent of BOS [67].

Table 11-4. Specific risk factors for *Nocardia* spp. infection in LTR

Frequent episodes of rejection
High-dose corticosteroid treatment
Renal impairment
Prolonged respiratory support

Nocardia spp. infections are uncommon in lung, or heart–LTR. Specific risk factors are shown in Table 11-4. One retrospective review of 540 heart, lung, or heart–LTR examined 10 patients (1.9%) with nocardia infection. It occurred at a median of 13 months after transplantation. All the patients had pulmonary disease and no evidence of extrapulmonary involvement. Nocardia infection did not contribute to patient deaths directly. Coinfection with other pathogens was present in six patients, and two had sequential infections [70]. A chart review from 1990 to 2007 revealed *Nocardia* spp. infections in 4 of 410 LTR despite prophylaxis [71]. All infections were confined to lung and occurred at a median of 315 days after transplantation. *Nocardia nova* was isolated in two patients, *Nocardia farcinica* in one, and unspecified *Nocardia* spp. in one. All isolates were susceptible to cotrimoxazole [71].

The incidence of *Clostridium difficile* infection (CDI) is rising in recent years up to 22.5% in LTR [72] and is higher than in other SOTR with the exception of pancreas [73]. Half the cases presents within the first month after transplantation. Previous administration of cephalosporins and corticosteroid use before transplantation has been considered as risk factors for CDI which, in turn, is not predictive of mortality [72, 73].

11.3.2 Specific Features of Antibiotic Treatment

The forthcoming treatment recommendations, as well as many of the other found in this chapter, are based mainly on the authors' experience in managing these patients and not only on scientific data.

No standardized regimen or guidelines exist regarding the choice of perioperative antibiotic therapy. Antibiotic prophylaxis in LTR should be initiated with broad-spectrum antimicrobials to cover *P. aeruginosa*, and *S. aureus*. For initial prophylaxis, the authors' group uses combined amoxicillin-clavulanate, 2 g, plus aztreonam, 2 g, every 3 h during surgery, and every 8 h thereafter. Recipients with septic lung disease (e.g., CF or bronchiectasis) should receive antimicrobial agents tailored according to their pre-transplantation sputum cultures. In this case, the authors also recommend nebulized tobramycin from the patient's arrival to the ICU

after surgery. The duration of prophylaxis depends on the results of donor and recipient respiratory sample cultures at the time of LT. When cultures are negative, prophylactic agents are withdrawn on the third to fifth days. When cultures are positive or in recipients with septic lung disease, antibiotic treatment is adjusted and maintained for 2 weeks or until cultures are negative. With this approach, the incidence of bacterial pneumonia in the early post-transplantation period (first 3 months) in the authors' lung transplant population is approximately 10%.

Whenever a clinically significant microorganism is isolated in a respiratory sample within the first 3 months, specific intravenous antibiotic therapy is started, even if the patient is asymptomatic. The only situations in which treatment should not be started are colonization with oral streptococci or plasmocoagulase-negative staphylococci. Combined and aminoglycoside treatment should be used for pneumonia. In the case of tracheobronchitis due *P. aeruginosa*, the authors combine a β-lactam with nebulized tobramycin at a dose of 100 mg every 12 h. Other indications in the authors' hospital for nebulized tobramycin or colistin include colonization with MDR Gram-negative bacilli, particularly *Acinetobacter* spp., *Pseudomonas* spp., and *S. maltophilia*; and episodes of tracheobronchitis in which signs of anastomotic ischemia are found.

From the third to sixth month after transplantation, only symptomatic episodes of infection are treated. Colonization is only treated when the microorganism is demonstrated in two respiratory samples taken at 1-week interval.

11.4 Fungal Infections

11.4.1 Epidemiology

Among SOTR, the lung and heart–lung have the highest associated incidence of fungal infection. The etiology is characteristically *Aspergillus* spp., in contrast to others in which infection by *Candida* spp. is the most common. A large study observed a 12-month cumulative incidence of 5.5% of IFI with *Aspergillus* spp. as the leading etiology (72.7%) [74]. Aspergillus infection in LTR is manifested in several ways, including airway colonization and various forms of tracheobronchitis (simple or ulcerative, with or without pseudo-membrane formation). Colonization with *Aspergillus* spp. occurs in 22–85% of LTR at some time after transplantation [36, 75]. Without prophylaxis, the incidence of IA ranges from 13 to 26%, and the related mortality is high (41–100%). With prophylaxis, the incidence of IA is 2–8% [75–77]. The incidence of tracheobronchitis is about 4–12% [75]. In our center, the incidence of IA and tracheobronchitis in 104 LTR given nebulized liposomal amphotericin B (n-LAB) prophylaxis was 0.9% and 1.9%, respectively. IA was classically considered a complication of the immediate post-transplant period, but a RESITRA study demonstrated that its incidence remains high after this period [76]. However, about two thirds of the episodes of ulcerative tracheobronchitis and IA occur at 6–9 months after transplantation. Mortality for tracheobronchitis is around 25%, but for IA rises to 67–82% [78].

Table 11-5. Risk factors for *Aspergillus* spp. infection in LTR

Previous colonization with *Aspergillus* spp. [73]
CMV pneumonitis [22, 78, 79]
Airway ischemia
Single-lung procedure [13, 22]
Single-nucleotide polymorphisms in the genes encoding interleukin-1β and β-defensin-1 [80]
Bronchiolitis obliterans syndrome

Significant risk factors for the development of IA in LTR are listed in Table 11-5. Surprisingly, no relationship with rejection or augmented immunosuppression has been recognized, but this possibility cannot be ruled out. BOS is a risk factor for IA but, on the other hand, LTR colonized with small conidia *Aspergillus* spp. (*A. fumigatus*, *A. nidulans*, and *A. terreus*) are prone to developing BOS [81]. Patients in whom *Aspergillus fumigatus* was isolated from airway samples during the first 6 months were 11 times more likely to develop IA than were those not colonized [79]. The relationship between colonization and invasive disease at 6 months to 1 year after transplantation is not so evident. No difference in the frequency of postoperative colonization is established between recipients with CF and recipients without [75]. The authors' transplant group does not consider previous colonization by *Aspergillus* spp. to be a transplant contraindication; however, in these patients, bilateral lung transplant is mandatory, and chest computed tomography (CT) scanning must be performed to rule out the adherence of mycetomas to the chest wall.

Tracheobronchitis is a characteristic type of aspergillosis almost exclusive to LTR [75, 82]. A spectrum of disease occurs, from simple bronchitis to pseudomembranous, nodular, and finally ulcerative tracheobronchial aspergillosis that is considered a form of IA. The anastomotic site is often affected, and this can lead to suture dehiscence, severe hemorrhage, or disseminated disease, invariably being fatal. Distinguishing between asymptomatic colonization and tracheobronchitis can be difficult as clinical symptoms may be absent or attributed to a concurrent clinical process (e.g., bacterial infection, rejection). When *Aspergillus* spp. is isolated from respiratory samples in the first 6–9 months, the authors perform a bronchoscopic study to rule out pseudomembranous or ulcerative tracheobronchitis. Likewise, early isolation of *Aspergillus* spp. from the airways identifies LTR at increased risk for the development of endobronchial abnormalities such as exuberant granulation tissue or stricture formation [83]. The authors believe that initiating treatment is mandatory whenever this microorganism is isolated from respiratory samples.

The diagnosis of IA is problematic because of the risk of colonization and contamination and the low predictive value of respiratory sample cultures (mainly sputum). For LTR, the presence of a new or progressive infiltrate or consolidation can be taken into consideration for diagnosis, although classical radiological criteria include the appearance of dense, well-circumscribed lesions, cavitations, or endobronchial lesions [84]. Galactomannan (GMN) detection in bronchoalveolar lavage (BAL) is useful in diagnosing IA. The role of GMN quantification was assessed in a study of BAL samples in 116 LTR. The authors found a sensitivity of 60% and a specificity of 95%, based on a cutoff of 0.5, that raised to 98% when the cutoff was 1.0 [85]. Another study reported sensitivity and specificity of GMN in BAL of 100% and almost 91%, respectively, using an index >1.0 as cutoff [86]. Finally, the ISHLT includes pan-*Aspergillus* PCR in BAL together with compatible symptoms and radiological imaging for the diagnosis of probable IFD in LTR based on a study that reported a sensitivity and specificity for diagnosing IA of 100% and 88%, respectively [87]. Nevertheless, the authors consider that PCR techniques warrant further studies and should not be used for routine daily diagnosis or treatment monitoring until standardization is performed.

Another distinctive issue is IA of the native lung in single-LTR. This may develop immediately after transplantation because of preexisting disease that was not detected, or it may represent de novo infection in patients with destroyed native lungs [13, 22, 88]. At times, IA is extremely difficult to diagnose. It occurs in patients with unilateral grafts who are diagnosed with *Aspergillus* tracheobronchitis; because of the unstructured nature of the native lung parenchyma, alterations are difficult to visualize on CT until the process is well advanced. This type of disease has poor prognosis, since achieving therapeutic concentrations of antifungal agents in the residual lung parenchyma is virtually impossible. In cases of tracheobronchitis in single-LTR, the authors employ BAL of each lung and initiate the same treatment used for IA when selective BAL of the native lung culture is positive. It is advisable to perform a native lung pneumonectomy if possible because it probably represents the only way to cure an established process.

Most cases of candidiasis occur during the first months after surgery. The main portal of entry is the gastrointestinal tract, followed by endovascular catheters and the urinary tract. Candida infections can manifest as peritonitis, empyema, candidemia [89], urinary tract infection, necrotizing bronchial anastomotic infection [90], mediastinitis, or esophagitis. Graft-transmitted candidiasis, which ends most often in fungal arteritis, has been described in heart and so can be in heart–lung transplantation [33].

The incidence of *P. jirovecii* pneumonia varies greatly among centers [13]. A prevalence of up to 88% has been described in patients without prophylaxis. Cotrimoxazole prophylaxis is effective in nearly 100% of patients, so its administration is mandatory. About one-third of *P. jirovecii* infections occur after the first postoperative year. Then, since recipients maintain steroid treatment, the authors recommend lifelong prophylaxis [91]. Dapsone may be an alternative for patients with contraindications or intolerability to trimethoprim-sulfamethoxazole.

The incidence of cryptococcosis ranges between 0 and 1.5% in American and European series of SOTR, and it is the third most common infection after candidiasis and IA [92]. The antifungal activity of calcineurin inhibitors may explain this low incidence [93] which, in turn, is higher in heart than in lung transplantation. *Cryptococcus neoformans* var. *grubii* has no particular geographical predilection and causes the most infections. *C. neoformans* var. *neoformans* is prevalent in northwestern Europe. and *C. gattii*, has emerged in the Pacific Northwest [94] and in Europe [95]. Patients who receive high doses of corticosteroids or monoclonal antibodies such as alemtuzumab and infliximab have the highest risk [96]. Cryptococcosis is typically a late-occurring infection; the time to onset usually ranges from 16 to 21 months post-transplantation. More than half of SOTR have disseminated disease or CNS involvement and as many as 33% have fungemia [97]. The mortality of cryptococcosis ranges from 14 to 27% [92, 93].

The incidence of infections by molds other than *Aspergillus* spp. has increased in recent years [98]. Most are caused by Mucorales (mucormycosis or zygomycosis), although infections by *Fusarium* spp. [99] and *Scedosporium* spp. are also recorded. Recent American and European series reported a frequency of mucormycosis lower than 3% among all SOTR with fungal infection [92, 100]. Renal insufficiency, diabetes, and previous administration of voriconazole or caspofungin have been described as independent risk factors for mucormycosis [101]. The most common site of mucormycosis is the lung, with a mortality of 45–50% [101]. Mortality can reach 73% in cerebral forms [102]. Infections by *Scedosporium apiospermum* account for 25% of IFI caused by molds other than *Aspergillus* spp., especially in single LTR and CF [103].

Endemic mycoses can potentially cause infection in LTR. These are especially important in endemic areas of the United States such as the Midwest for histoplasmosis. The first year is the period of highest risk for histoplasmosis as a consequence of reactivation of a latent infection, new exposure or donor-derived infection [104]. Urinary antigen appears to be a better diagnostic tool than the fungal antibody serology in LTR [105]. In patients whose explanted lung is found to have histoplasmosis, antifungal prophylaxis seems effective at preventing reactivation [105]. Coccidioidomycosis is typically acquired when patients are exposed to the desert soil of the Southwestern United States and Northern Mexico. The most common mechanism of infection in LTR is reactivation, but donor-derived transmission has also been reported. Patients, in whom there is evidence of prior coccidioidomycosis, either radiographically or serologically, may require lifelong antifungal prophylaxis [106].

TABLE 11-6. Prophylaxis for *Aspergillus* spp. in the lung and heart–lung transplant recipient [107]

Target population	Antifungal drug	Duration
All recipients	Nebulized liposomal amphotericin B 25 mg[a]	Indefinite or for a minimum of 12 months
Recommended strategy	Three times a week until resolution of bronchial suture	
	Once a week from 2 to 6 months	
	Once every 2 weeks thereafter	
or *Guided prophylaxis* in case of the presence of risk factors		
Induction with aletuzumab or thymoglobulin	Nebulized liposomal amphotericin B 25 mg	Determined by the presence of risk factors
Acute rejection	Three times a week for 2 weeks then once a week	
Single-lung transplant		
Aspergillus spp. colonization		
Acquired hypogammaglobulinemia (IgG <400 mg/dL)		

[a]Considered also nebulized amphotericin B lipid complex 50 mg.

11.4.2 Specific Features of Antifungal Treatment

The first pointto remember regarding fungal infection is that the risk period—a minimum of 1-year post-transplantation—for developing IA is quite long. This fact makes the parenteral administration of antifungal treatment unfeasible. Thus, two alternatives, nebulized AFB and oral voriconazole, remain.

Universal prophylaxis against *Aspergillus* spp. is generally accepted in lung and heart–LTR (Table 11-6) [107]. Since most *Aspergillus* infections in LTR affect the respiratory tree and airway colonization by the conidia precedes the infection, nebulized AFB appears to be an attractive approach. The authors' group conducted a study to evaluate the pharmacokinetics and distribution of nebulized AFB in LTR [108]. Airway concentrations of AFB after nebulization with 6 mg of AFB deoxycholate theoretically offer adequate protection. Concentrations in the alveolar lining were higher than those found in the proximal bronchial tree, but the latter were still sufficient to protect anastomoses. Additionally, distribution studies using ventilation and perfusion gammagraphy imaging with technetium-99 m-labeled AFB deoxycholate were performed. All demonstrated acceptable delivery of the agent to native lungs and allografts in amounts proportionate to their degree of ventilation. Prophylaxis with nebulized AFB decreased the incidence of IA below 3% [108]. In the authors' experience, the incidence of any kind of *Aspergillus* spp. infection in 226 consecutive LTR was 7.5%. However, administration of nebulized AFB every 8 h day after day is a considerable drawback. With the aim of prolonging the dosing interval, our group determined the airway concentrations of the drug after nebulization of 24 mg of the liposomal formulation (Ambisome®) [109]. We could demonstrate that AFB concentrations after n-LAB remained high enough for prophylaxis of *Aspergillus* spp. infection over 14 days. There was no significant systemic absorption of the drug and no effect was observed on respiratory function. Thus, the main advantages of nebulized prophylaxis are the lack of drug–drug interactions, the cost-effectiveness relationship, and the ability to achieve high levels of lung antifungal concentrations without systemic side effects [109]. One disadvantage is local irritation that leads to cough or bronchospasm. These effects occur in fewer than 10% of patients. The use of salbutamol or halving the drug concentration can improve the symptoms. Other disadvantages are the need for appropriate equipment and for the patient or family members to know how to administer it. The possibility of irregular distribution of the drug in the lung is another potential limitation [110]. Voriconazole is an alternative although there is also a lack of randomized studies [111]. Moreover, an increase in liver enzymes has been observed in up to 60% of LTR receiving voriconazole leading to discontinuation of the drug in 14% of them [112]. Skin cancer has also been reported in LTR with its prolonged use [113].

Colonization with *Aspergillus* spp. must be treated to prevent IA. The authors recommend n-LAB 25 mg/24 h for 7 days, then 25 mg/72 h, or nebulized AFB lipid complex 50 mg/24 h once every 2 days. In the case of intolerance, voriconazole should be considered (loading dose 400 mg/12 h PO, then 200 mg/12 h PO).

In the case of nodular or ulcerative tracheobronchitis, voriconazole plus nebulized lipid formulations at the doses above mentioned are recommended. A bronchoscopy should be performed every week or every 2 weeks to evaluate the extension of disease and to clear necrotic debris and fungus balls. A high-resolution CT scan should also be performed to rule out parenchymal extension.

In LTR with anastomotic tracheobronchitis due to *Candida* spp. the recommended treatment is n-LAB 25 mg three times a week, or nebulized AFB lipid complex every other day plus removal of the debris by repeated bronchoscopies. Echinocandins may be more effective than azoles for *Candida* spp. growing in the biofilms of the anastomoses.

When dehiscence of the bronchial anastomosis occurs, both surgical resection and stent placement may be necessary in addition to antifungal therapy, although the prognosis is poor. Other indications of surgery are shown in Table 11-7.

Table 11-7. Indications for surgery in IA

Massive hemoptysis
Hemoptysis due to lesions located near large vessels
Isolated or cavitated pulmonary lesions that progress despite the administration of appropriate antifungal treatment
Sinus disease
Infiltration of the pericardium, large vessels, bone, or subcutaneous thoracic tissue while receiving treatment

Table 11-8. Risk factors related to CMV replication and disease in LTR

CMV serology mismatch: positive donor and negative recipient
Absence of specific cell-mediated immunity [115, 116]
Cytolytic agents such as OKT3 [117] or antithymocyte globulin [118]
Acute rejection and its subsequent treatment with corticosteroids
MMF when the dose exceeds 2 g/day
mTOR inhibitors is associated with a lower risk

11.5 Viral Infections

11.5.1 Epidemiology

The second most frequent cause of infection after LT is CMV. The overall incidence of replication and disease without prophylaxis ranges from 53 to 75% [114], a much higher rate than those associated with other SOTR with the exception of small bowel transplantation. In patients without prophylaxis, the incidence of pneumonitis approaches 100% in CMV D^+/R^- cases, but, in contrast to other types of transplant, CMV-positive recipients also have a high incidence, estimated at 60–75%.

The risk factors for CMV disease (Table 11-8) have not been extensively studied in LT, but knowledge obtained in other SOTR can be applied. The most important risk factor for the development of CMV disease is CMV mismatch, which confers more than 50% risk in the absence of antiviral prophylaxis or preemptive treatment strategies [119]. However, cell-mediated immunity is known to be more important than humoral immunity in controlling CMV. CMV infection elicits a strong virus-specific $CD4^+$ and $CD8^+$ T-cell response that, currently, can be measured [120, 121]. As an example, those LTR considered negative or indeterminate to Quantiferon-CMV are at risk of developing CMV disease [115, 116]. In a trial comparing sirolimus to azathioprine, the overall incidence of any CMV event was lower in the sirolimus arm at 1 year (RR = 0.67, CI 0.55–0.82, $p > 0.01$) [122]. The relationship between CMV disease and other risk factors such as co-infection with Human Herpesvirus 6 (HHV-6) [123], hypogammaglobulinemia [124], polymorphisms in toll-like receptors (TLR2 and TLR4) [125], or low levels of mannose-binding lectin [126] has been demonstrated in other types of SOTR rather than lung. Thus, HHV-6 was not detected in 145 samples from 26 LTR, even though 30% of the samples were from 9 CMV DNA-positive patients in whom 13 episodes of CMV pneumonitis were recorded [127].

Transplantation of organs containing a large number of certain cells that can harbor latent or replicating CMV (e.g., macrophages and lymphoid cells) may provide the recipient with a higher initial CMV viral load, which then undergoes reactivation. Similarly, recipients with active CMV infection at the time of transplantation have a higher risk of post-transplantation CMV disease [128]. CMV viral load is an important and clinically useful correlate of CMV pneumonitis in LTR [129–131].

CMV pneumonitis is the second leading cause of pneumonia [15] and the most frequent disease in LTR without prophylaxis. The use of prolonged valganciclovir prophylaxis has changed the incidence of pneumonitis that has decreased in contrast with the viral syndrome that has increased. In addition, the time at which the disease appears is from 2 to 4 weeks after stopping prophylaxis. In the authors' experience, approximately 10% of episodes has a late onset, appearing during the second year. Encountering CMV disease after the second year is exceptional. CMV pneumonitis has an insidious onset, which is manifested by constitutional symptoms and fever, with a later progression to dyspnea and tachypnea. The only relevant sign in an otherwise normal respiratory auscultation is tachypnea. Arterial hypoxemia is almost always present. The clinician should remember that, when a sudden deterioration of respiratory function is observed during treatment for CMV pneumonitis, superinfection by Gram-negative bacilli or fungi must be investigated. The radiologic manifestations of CMV pneumonia are diverse. Bilateral, symmetric, interstitial, and/or alveolar infiltrates predominating in both lung bases are the most common radiologic features.

The diagnosis of CMV disease is based on the definitions that were established by Ljungman et al. [132]. Several studies have shown that quantification of the CMV load in the plasma or blood can be helpful in making the diagnosis and that it can even be used to anticipate the development of CMV disease [129–131, 133].

Ganciclovir-resistant CMV infection, an emerging problem in the transplantation setting, has been associated with CMV D^+/R^- status, a high CMV load, and prolonged exposure to ganciclovir. Limaye et al. described a nearly 10% rate of ganciclovir-resistant CMV infection, as defined by a UL97 mutation, and this was more frequent among D^+/R^- patients despite preemptive antiviral therapy or prophylaxis. Compared with other SOTR, ganciclovir-resistant CMV in LTR include an earlier onset (median of 4.4 vs. 10 months) and less-prolonged exposure to ganciclovir (median of 100 vs. 194 days) [134]. A trend toward more frequent detection of MDR and co-circulation of multiple resistant strains has been also shown in LTR [135].

CMV infection has also an indirect effect on the patient's immune state. The immunomodulation exerted by CMV has

two demonstrated effects. CMV infection induces a transient state of additional immunosuppression that makes the host more susceptible to the development of infection by opportunistic microorganisms [136], and it seems to play a role in the pathogenesis of graft rejection [114, 137]. The detection of CMV DNA in the BAL is associated with the development of BOS irrespective of the magnitude of viral replication, the presence of tissue invasive disease or whether viral replication is symptomatic or asymptomatic [138]. The association between augmented antiviral prophylaxis and reduced cellular rejection has been also identified in LTR [139, 140]. Although antiviral drugs adequately suppress CMV replication, LTR remain vulnerable to both clinical and subclinical CMV replication on cessation of prophylaxis that is associated with BOS. However, other studies [141] reported no increased risk of BOS in a cohort of patients with beta herpesvirus (CMV, HHV-6, and HHV-7) replication within the lung allograft.

Respiratory viruses have been increasingly recognized as common pathogens in LT. Previous cohorts have reported an incidence of RV infections in LT in the range of 7.7–64% [142, 143]. Our group conducted a 5-year prospective study including 98 LTR that demonstrated an overall incidence of RV of 0.85 per patient-year. Our results are similar to data recently published in another large prospective study [144]. Seasonal patterns of RV circulating in LT are comparable to those observed in the community. Picornaviruses (mainly rhinovirus), coronaviruses, and influenza virus were the most common etiological agents, accounting for 76.5% of microbiologically confirmed symptomatic infections. Rhinoviruses are the leading cause of RV infections. Rhinovirus were associated not only with mild self-limiting upper respiratory tract infection but also with lower respiratory tract infection, mainly in form of tracheobronchitis. Patients with paramyxovirus (especially respiratory syncytial virus) and influenza infection had a higher incidence of pneumonia and hospitalization rate [145–147]. The relationship between RV infections and acute rejection has not been clearly established in previous studies [144, 148, 149]. Our data showed a trend toward a significant clinical link between RV and biopsy-proven acute lung rejection including the acute phase of the viral infection (with no relation to clinical presentation) and a follow-up period of 3 months. It has also been advocated that patients with documented community respiratory viral pneumonitis are predisposed to high-grade BOS development [150]. Finally, RV infections have been described as a risk factor for developing bacterial and fungal superinfection [151].

The incidence of pneumonitis due to HSV type 1 ranges from 5 to 10% in LTR without prophylaxis [12]. Most of them are reactivations that appear in the first 2 months, but they can occur as early as 5–10 days after transplantation. HSV pneumonitis is often associated with bacterial or CMV pneumonia. In contrast to CMV pneumonitis, pulmonary involvement by HSV type 1 provokes respiratory insufficiency and bilateral alveolar infiltrates in the majority of patients affected. Valganciclovir prophylaxis for CMV disease also protects against HSV infection.

The incidence of EBV-related post-transplant lymphoproliferative disorders (PTLD) varies greatly, ranging from 2 to 33% [152, 153]. These differences are probably due to variations in immunosuppression regimens, the number of EBV seronegative recipients, and the percentage of pediatric patients included in the series. The risk for developing PTLD is higher in EBV seronegative LTR. However, late onset PTLD tends to present in seropositive recipients. Early onset PTLD involves predominantly the transplanted lung, whereas late onset PTLD does not [154]. Possible enhancement of EBV activity by the β-herpesviruses, such as CMV, HHV-6, or HHV-7, has not been conclusively established. Monitoring EBV DNAemia does not predict PTLD [153].

The incidence of pneumonitis due to adenovirus is quite low, affecting about 1% of all adult LTR. It tends to appear in the first 3 months after transplantation. It induces severe disease with progressive respiratory failure; in most cases, the clinical course is fatal. In contrast, adenovirus infection is a widespread problem in the pediatric LTR. The attack rate is almost 50%, and at least half of the patients die of respiratory failure because of diffuse alveolar damage. BOS develops uniformly in the survivors.

Recently, the experiences of 239 LTR with herpes zoster infection have been published. The calculated incidence was 55.1 cases per 1000 person-years of follow-up. The cumulative probability of herpes zoster was 5.8% at 1 year, 18.1% at 3 years, and 20.2% at 5 years' post-transplantation. Only 5.7% of the patients had disseminated cutaneous infection and none had visceral involvement. Recurrence of herpes zoster was observed in 13.8% of patients. Postherpetic neuralgia was detected in 20% of cases [155].

11.5.2 Specific Features of Antiviral Treatment

Two strategies exist for the prevention of CMV disease in SOTR. The first is prophylaxis, in which an antiviral agent is administered immediately after transplantation to those recipients at high risk for CMV disease (e.g., D^+/R^- cases or patients who require the administration of conventional T-cell receptor antibodies). The second strategy, preemptive therapy, consists of the administration of an antiviral agent when nucleic acid testing (NAT) evidences a level of viral replication highly predictive of CMV disease. An international survey showed the lack of uniformity when managing with CMV infection in LT. Although prophylaxis is the most commonly used preventive strategy, its duration is extremely variable (from 3 months to indefinite). Half the centers routinely decreased immunosuppression at the time of viremia while the other half did not take any measure [156]. In an attempt to avoid this issue, guidelines have been published [157].

The authors believe that prophylaxis plus preemptive therapy is the best strategy for the prevention of CMV disease in LTR. The authors' recommendation is intravenous ganciclovir at a dose of 5 mg/kg every 24 h until oral intake is tolerated, followed by a switch to valganciclovir at a dose of 900 mg once a day until 180 days after transplantation for seropositive recipients and 360 days for CMV mismatch. Valganciclovir at reduced doses to avoid toxicity should not be administered due to its association with CMV disease and increased risk of emergence of resistance [158]. During prophylaxis, we do recommend monitoring of viral load by NAT due to the possibility of breakthrough disease, particularly in seronegative recipients [158]. Once prophylaxis ends, surveillance should continue at every medical visit until the second year after transplantation and preemptive therapy with valganciclovir should be initiated. Treatment is initiated in the following situations: (1) in D^+/R^- transplant recipients, whenever evidence of viral replication is found, and (2) in CMV-seropositive recipients, when viral load is high (e.g., >5000 UI/mL in plasma) or when an increase is registered in two consecutive analyses. When the viral load is under the established cutoff for initiation of preemptive therapy, the analyses should be repeated within 1 week. The duration of preemptive therapy has not been established, but the authors prefer a minimum of 7–10 days when viral replication is negative.

When CMV disease is diagnosed, treatment is started with ganciclovir at 5 mg/kg every 12 h. Generally, tacrolimus and prednisone doses are not reduced, except in cases of pneumonitis, in which they are progressively tapered. MMF is withdrawn or the dose is halved. If ganciclovir-associated leukopenia develops and the polymorphonuclear count drops below 500 cells/mL, the patient is treated with granulocyte-stimulating factor until the polymorphonuclear count increases to more than 1000 cells/mL. In patients with pneumonitis, gammaglobulins at a dose of 200 mg/kg every 48 h are added during the first week of treatment. The viral load should be monitored, and a significant increase after the fourth or fifth day of treatment should raise the suspicion of ganciclovir-resistant CMV infection. However, an increase in viral load during the first 2 or 3 days of treatment is not infrequent. The duration of therapy is usually 15 days, except in cases of pneumonitis, in which therapy is prolonged to 21 days. Generally, viral replication is negative at the end of treatment.

Current evidence, although not based on high-quality studies, suggests that some benefit is derived from the use of oral ribavirin in LTR with non-influenza RV infections [159], especially respiratory syncytial virus [160].

11.6 Conclusion

Despite several advances in surgical technique, immunosuppression and prophylaxis, infection continues to be an important cause of disease and death in LTR. Avoidance of these infectious complications may not only lead to a decrease in the direct consequences of infection but also to a reduction in the subsequent causes of ultimate graft failure including both acute and chronic rejection. There is a need to explore new fields such as the relationship between microbiome and BOS, or to find new and better antivirals, especially for RV infections. But, without forgetting that there are current concerns that must be addressed such as the growing problem of antimicrobial resistance for which careful antibiotic stewardship is mandatory.

Infections in Kidney Transplant Recipients

Deepali Kumar and Atul Humar

Kidney transplantation is the most common type of transplant performed worldwide. Since 1988, more than 370,000 kidney transplants have been performed in the United States [1]. Kidney transplantation has been shown not only to benefit a patient's quality of life but is also more cost effective than dialysis. Transplantation can be performed using deceased or living donor kidneys. The native kidneys are generally left in situ and the transplant kidney is grafted in the right lower abdominal quadrant. The transplant procedure generally consists of anastomoses of the renal artery and vein to the native external iliac artery and vein, respectively. The donor ureter is anastomosed to the recipient bladder.

Posttransplant infections in renal transplant recipients occur in 44.9–81 % patients and include urinary tract infections (UTIs), bacteremia, pneumonia, wound infection, and cytomegalovirus (CMV) infection [2–6]. Severe sepsis posttransplant often causes graft dysfunction [7]. Although there is no specific classification of infections post kidney transplant, these generally follow the timeline of infections post solid organ transplant described previously by Fishman and Rubin [6, 8], with some caveats specific to renal transplantation. The specific infections unique in some aspect to kidney transplantation will be the focus of this chapter. Other infections that are common to all transplant patients are discussed briefly and serve to provide a contextual basis for understanding the global infectious disease burden in kidney transplant recipients.

Postoperative complications and early UTIs are seen in the first month posttransplant. Donor-derived infection should also be considered early in the posttransplant period. During months 1–6, opportunistic infections such as reactivation of herpesviruses, BK virus, and fungal and mycobacterial infections are seen. However, it is important to note that with ongoing prophylaxis and the use of potent antirejection therapies, the initial onset of some infections such as >*Pneumocystis jirovecii* and cytomegalovirus reactivation can occur after 6 months.

12.1 Pretransplant Evaluation of the Kidney Recipient

The pretransplant evaluation of the kidney transplant patient includes obtaining a history of infectious diseases, infectious exposures, and immunizations [9]. Generally, active infectious diseases should be resolved and/or adequately treated prior to undergoing kidney transplant. During the evaluation for transplant, serologic screening for human immunodeficiency virus (HIV), hepatitis C virus (HCV), hepatitis B virus (HBV), human T-cell lymphotropic virus (HTLV), CMV, EBV, herpes simplex virus (HSV), Varicella-Zoster virus (VZV), and syphilis is done and each result needs to be carefully evaluated. HIV is no longer a contraindication to kidney transplant and is discussed further in section Kidney Transplantation in the HIV-Positive Recipient [10]. The knowledge of CMV and Epstein–Barr virus (EBV) serologic status is important to guide antiviral prophylaxis posttransplant. Hepatitis C antibody and hepatitis B surface antigen positivity are not contraindications to renal transplant but the extent of liver disease should generally be delineated with pretransplant liver biopsy. If possible, attempts to treat these viruses should be made prior to transplant. Studies indicate that treatment of HCV with interferon-α and ribavirin posttransplant leads to a 60–70 % rate of allograft rejection [11, 12]. However, this is not an issue with the new protease inhibitors for HCV [13]. On the other hand, hepatitis C-positive recipients could be considered for a kidney transplant from a hepatitis C-positive donor.

Persons who are HTLV-I or -II positive should be assessed on an individual basis. In endemic areas, there is a risk of progression of 2–4 % to HTLV-I-associated myelopathy/tropical spastic paraparesis [14]. A positive syphilis screening test should lead to a confirmatory test specific for syphilis antigens. If a confirmatory test is positive, the patient should be treated prior to transplant. Tuberculosis (TB) skin testing should be routinely performed although a positive skin test is not a contraindication to transplant. False negative skin tests

P. Ljungman et al. (eds.), *Transplant Infections*, DOI 10.1007/978-3-319-28797-3_12

can occur in hemodialysis patients [15–18]. Interferon-γ release assays (IGRAs) for TB may also be used for screening in this population. These include the QuantiFERON-TB Gold and T.Spot.TB, both of which measure the amount of interferon-γ released in response to ex vivo cell stimulation with TB-specific antigens. Recent studies have shown that these assays may have improved test characteristics in the hemodialysis population when compared to the tuberculin skin test (TST) [15, 16]. Patients found to have latent TB can be initiated on therapy prior to transplant and complete the course posttransplant if necessary. This consists of isoniazid 5 mg/kg once daily or 900 mg thrice a week (plus vitamin B6) for 9 months [18]. A shorter 4-month course of rifampin may also be effective; however, rifampin will have significant drug interactions with immunosuppressives if transplant occurs while on treatment. An immunization record should also be obtained to ensure routine vaccinations are up to date [19]. Pretransplant, patients should have received tetanus toxoid and pneumococcal vaccine. Immunity to varicella, measles, mumps, and rubella should be determined. If immunity is absent, then varicella and MMR vaccines should be given; however, since these are live vaccines, the transplant should be on hold for 4 weeks after vaccine is given. Hepatitis A and hepatitis B vaccines should also be updated prior to transplant.

12.2 Donor Screening and Donor-Derived Infections

There are some important considerations with regard to donor infections and transmission in the context of kidney transplantation, which may be unique compared to other organs. First, since an alternative exists to kidney transplantation, that is, dialysis, the willingness of physicians or patients to undertake potential risks of infectious diseases transmission associated with certain types of donors may be different than those for other organs. For example, the risk benefit consideration for a critically ill patient with heart failure may be very different than a patient on dialysis. Second, since for deceased donors, usually two kidneys are transplanted, the opportunity exists for early diagnosis of a donor-derived infection that may be transmitted through the allograft, since both recipients may become ill at similar times.

Deceased kidney donors require appropriate screening for infectious diseases [9]. A history should elicit cause of death as well as previous infectious exposures including those potentially acquired during previous travel such as malaria, TB, and rabies. Donor screening generally includes serologic studies for HIV, HCV, HBV (surface antigen and total core antibody), CMV, EBV, and syphilis (discussed in detail in Chap. 7). Additional screening may include West Nile virus (WNV) nucleic acid testing (NAT), which may be dependent on local WNV activity, and the particular policies of the organ procurement organization. HTLV I and II screening is also done in some jurisdictions. Deceased donors should also undergo screening blood and urine cultures. Donors with a history of high-risk behavior may undergo additional testing (NAT) to determine whether they are in the "window period" of seroconversion for HIV, HBV, or HCV. For some OPOs it may be routine to offer NAT testing for all donors. Controversy exists whether organs from increased risk donors should be used for kidney transplantation or not. However, based on a decision analysis, utilization of high risk organs is beneficial even in kidney transplant recipients [20]. A standardized informed consent may increase patient acceptability of these organs [21]. Organs from HCV-positive donors may be considered for use in HCV-positive kidney transplant recipients. Alternatively, the situation may arise where a donor may have previously been treated for HCV and achieved sustained virologic response. In this case, it is controversial whether the kidney should be transplanted in a HCV-negative recipient, since the risk of transmission is largely unknown [22]. Recent consensus guidelines indicate that individual consideration should be given to use of isolated hepatitis B core antibody-positive donors with antiviral prophylaxis in the recipient as the risk of active hepatitis B is low [23]. It is impractical to screen donors for TB using TST; deceased donor screening with Quantiferon-TB in the research setting results in a high number of indeterminate tests [24]. Bacteremic donors are generally acceptable with antibiotic treatment of the recipient [25]. However, caution should be used when donors are bacteremic with multidrug-resistant organisms.

Unusual pathogens such as rabies and lymphocytic choriomeningitis virus (LCMV)/arenavirus have been transmitted to renal transplant recipients, although these cases are rare and difficult to predict [26–31]. There have been no LCMV seroprevalence studies in donors and it is unknown whether donors with rodents are at greater risk. To avoid transmission of unusual viruses, we recommend not to use organs from donors who had died of an unknown form of meningitis or encephalitis. Other pathogens that have been transmitted via donors to kidney transplant recipients include malaria and syphilis [32–35]. These are generally treated successfully if they are recognized early. Unusual fevers or illnesses posttransplant, especially in the first month posttransplant, are alerts for donor-derived infections. In these cases, it is important to revisit the original donor evaluation as well as to investigate whether recipients of other organs from the same donor are experiencing similar illness.

Living kidney donors also undergo screening similar to that of cadaveric donors. However, living donors should also be screened for latent TB using a TST. If determined to have latent TB infection, the donor should ideally complete therapy for latent TB prior to donation [36]. As an alternative, the recipient can be treated with isoniazid for 9 months posttransplant. In the latter case, treatment should be initiated as soon as possible posttransplant since the greatest risk of TB

reactivation is in the first year [37]. *Strongyloides* sp. antibody testing and screening for *Trypanosoma cruzi* (the agent of Chagas disease) should also be done in living donors from endemic areas [38].

12.3 Technical Complications Leading to Infection

Technical problems after kidney transplantation can arise due to either vascular or nonvascular complications. Infections related to these complications usually, but not always, present in the early postoperative period. Overall, the risk of such complications is generally lower than that of other types of transplants. Surgical wound complications are probably the most common and include wound infection, dehiscence, incisional hernias, and lymphoceles [39, 40]. Ureteral complications include urinary leaks and ureteral strictures. Other postoperative issues include vascular thrombosis or bleeding and hematoma formation. In one retrospective study of 870 patients who underwent deceased donor kidney transplant, at least one surgical complication occurred in 34 % [40]. Wound complications occurred in 10.5 % with isolated lymphoceles in 6 %. Risk factors for wound complications include obesity, older age of donor and recipients, as well as certain immunosuppressive drugs such as mycophenolate mofetil (MMF) and sirolimus [40, 41]. The incidence of posttransplant lymphocele is 0.6–18 %, the majority of which are small and asymptomatic [42]. However, approximately 6 % can be infected [43]. Generally, asymptomatic lymphoceles can be followed by ultrasound although clinical symptoms or unresolving lymphoceles should lead to further investigation with percutaneous aspiration and culture. Urinary leaks usually occur at the anastomosis (at the site of vesicoureteral junction) and may occur due to ischemia of the ureter, and can lead to the formation of a urinoma. Although uncommon, urinomas occasionally become infected primarily with Enterobacteriaceae, although other organisms may be seen [44]. Strictures also occur primarily at the anastomosis of the ureter to the bladder, and may be secondary to ischemia or rarely due to BK virus, and lead to recurrent graft pyelonephritis.

12.4 Urinary Tract Infections

By far, the most common infection in a renal transplant recipient occurs in the urinary tract. Incidence has been estimated to be 4–86 % in some series [45–47]. Risk factors for UTI can be divided into pretransplant, intraoperative, and posttransplant factors. Pretransplant factors include female sex, diabetes mellitus, pretransplant immunosuppression, urinary tract abnormality, and dialysis [45, 48]. Intraoperative factors include use of a JJ stent, prolonged catheterization, infected organ, and retransplantation. Routine ureteric stenting during transplant has been shown to decrease the risk of urologic complications but results in a 1.5 times increase in relative risk of UTI [49]. Postoperatively, the risk of UTI is increased if graft dysfunction is present. UTIs can occur at any time posttransplant and timing may in part be dependent on the use of prophylaxis. Symptomatic patients with cystitis may have dysuria, hematuria, frequency, urgency, suprapubic pain, or foul urinary odor. A urinalysis generally shows pyuria and a urine culture reveals significant bacterial growth. Significant growth in the nontransplant literature is generally defined as $>10^5$ colony forming units/mL of urine (or $>10^8$ cfu/L) of a single organism. Significant pyuria is defined as >10 WBCs per hpf. However, lower bacterial colony counts, and limited detection of pyuria, may also occur in renal transplant recipients with significant infection. Acute allograft pyelonephritis is diagnosed if in addition to the abovementioned clinical picture, fever or tenderness over the allograft is present. Bacteremia and a decline in renal function may also be the features of acute pyelonephritis. Atypical presentations are common, and include isolated febrile syndromes, isolated graft tenderness, and other presentations. Emphysematous pyelonephritis is a rare entity that can occur in kidney transplant recipients and often requires transplant nephrectomy in addition to antimicrobials [50, 51]. However, conservative management with antimicrobials and percutaneous nephrostomy has also been reported [52].

Antimicrobial therapy for simple UTIs or graft pyelonephritis should be directed at the organism recovered in urine culture. The duration of therapy for UTI in renal transplant recipients has not been well studied. Graft pyelonephritis can usually be treated with a 2- to 3-week course of appropriate antibiotic therapy. However, longer durations of antimicrobial therapy can generally be used for severe allograft pyelonephritis, recurrent UTIs, and those with structural abnormalities, such as ureteric stents, ureteric strictures, and stones.

Several studies have examined the consequences of UTI in the kidney transplant population. In the first 6 months, UTI appears to be associated with bacteremia and acute rejection [53]; UTI occurring after 6 months (termed late-onset UTI) is shown to be associated with death and graft loss in a large retrospective study [54]. Several mechanisms are postulated for impaired graft function including production of inflammatory cytokines and free radicals or associated acute rejection [45, 55]. Studies have shown that acute graft pyelonephritis can have a deleterious effect on long-term allograft function [56–59]. Giral et al. [57] reviewed 1387 renal transplant recipients, of which 13 % developed allograft pyelonephritis during the follow-up. Pyelonephritis within the first 3 months was significantly associated with poorer graft outcome. Microbial virulence factors have also been associated with acute allograft injury. In one study characterizing *Escherichia coli* isolates from kidney transplant recipients with UTI, the expression of P fimbriae in these isolates was significantly associated with acute allograft injury [60].

To prevent early UTIs, antibacterial prophylaxis with trimethoprim-sulfamethoxazole (TMP/SMX) up to 1 year posttransplant has been advocated by some investigators [61–63]. A small randomized trial of low-dose versus high-dose TMP/SMX showed a significant decrease in UTI occurrence in the high-dose TMP/SMX group (49.2 % versus 25 % patients, $P<0.05$). This suggests that doses used for *Pneumocystis* sp. prophylaxis do not necessarily prevent UTI. This approach is also limited by rising antimicrobial resistance to TMP/SMX. In one single-center review of UTIs in 161 kidney transplant recipients, 25 % of patients developed UTI despite receiving TMP/SMX prophylaxis [64]. Ciprofloxacin is also shown to be effective although quinolone prophylaxis would not prevent pneumocystis infections [65]. In a retrospective review comparing kidney transplant patients that received TMP/SMX versus ciprofloxacin prophylaxis, the latter group was found to have significantly less UTIs at 1 year posttransplant [66]. However, rising rates of fluoroquinolone resistance in solid organ transplant recipients were found in a study of gram-negative bacteremia and may also limit their use [4]. The increasing prevalence of multidrug-resistant organisms including carbapenem-resistant enterobacteriaceae is a major concern in many centers [67, 68]. In small case series, fosfomycin has been used safely to treat drug-resistant infections [69].

12.5 Asymptomatic Bacteriuria

Many kidney transplant programs will do routine urinalysis and culture frequently in the initial postoperative period and continue to monitor at regular intervals thereafter. There is no clear consensus on whether to monitor and if done then how often to monitor the UTI [70]. In many cases, a urine culture may be obtained routinely at the time bloodwork is drawn regardless of patient symptoms. It is unclear how many cases of asymptomatic bacteriuria progress to symptomatic infections or allograft pyelonephritis. However, many physicians will err on the side of treatment especially in the early posttransplant period [48]. Although there is little evidence to support this approach, early in the postoperative period, multiple factors may be present, such as induction immunosuppression, indwelling urinary catheters, urinary stents, and delayed graft function. One small study found that asymptomatic bacteriuria early posttransplant may be a risk factor for symptomatic UTIs—although not with the same organism [71]; others have found no benefit of treating asymptomatic bacteriuria [72]. Ultimately, although there is no clear consensus whether asymptomatic bacteriuria should be treated, there is evidence to suggest that subclinical UTIs may cause allograft damage. One study has shown increased levels of urinary inflammatory cytokines in patients with asymptomatic bacteriuria versus controls [55]. Dupont et al. [73] showed that allograft scarring could occur with asymptomatic bacteriuria even in the absence of vesicoureteral reflux and suggested prophylaxis for asymptomatic infection. Another situation where asymptomatic bacteriuria should be treated is in pregnant transplant recipients.

12.6 Recurrent Urinary Tract Infections

Recurrent UTIs in a renal transplant recipient is defined as ≥3 UTIs per year. Predisposing factors that should be ruled out include vesicoureteral reflux, neurogenic bladder, structural abnormality such as the presence of a ureteric stricture or calculi, or chronic bacterial prostatitis. A persistent renal or perirenal abscess could also serve as a focus of infection for recurrences. Patients with underlying polycystic kidney disease may have cyst infection of the native kidney. Ideally, abdominal imaging with a CT scan or ultrasound should be done to evaluate the transplanted and native kidneys. Referral to a urologist for cystoscopy may be necessary to rule out other structural abnormalities. In many cases, no correctable abnormality is found. If relapse occurs after a 2-week course of antibiotics, then a 4- to 6-week course of antibiotics can be attempted. In a few cases, patients will require long-term antibiotic prophylaxis. The goal is to suppress bacteriuria and one potential approach is to obtain routine cultures while on prophylaxis to see if bacteriuria is suppressed. If prophylaxis is instituted, patients should be reevaluated at regular intervals (e.g., every 6 months) to determine the need for ongoing therapy. If bacteriuria persists or a relapse occurs while on prophylaxis, then this strategy needs to be re-evaluated. Prophylaxis options include amoxicillin, fluoroquinolones, oral cephalosporins, TMP/SMX, and nitrofurantoin. Susceptibilities from the last urinary isolate can be used to guide prophylaxis. A major limitation of prophylaxis is the selection of drug-resistant organism, a common problem in these patients. One study showed that infection by a multidrug-resistant bacteria significantly increased the risk of recurrent UTIs [74]. A reduction in immunosuppression, if possible, and optimal control of other variables such as diabetes mellitus may also help. A summary of microbial etiology and management of various forms of urinary infection is provided in Table 12-1.

12.7 Candiduria

Candiduria is defined as the presence of $>10^5$ Candida organisms in mid-stream urine. There is no clear consensus on whether all candiduria in the kidney transplant setting should be treated. Safdar et al. [75] reviewed the epidemiology of candiduria in 192 renal transplant recipients. Predictors of candiduria in this population were similar to those in the general population and included female sex, intensive care unit admission, antibiotic use, and diabetes. Candiduria was

TABLE 12-1. Suggested management of various clinical presentations of urinary tract infection in renal transplant recipients

Clinical presentation	Microbial etiology	Suggested management
Symptomatic cystitis	Enterobacteriaceae, *Enterococcus* sp., staphylococci, *Pseudomonas* sp., *Candida* sp.	Empiric oral therapy: first line: ciprofloxacin 500 mg PO b.i.d. ± amoxicillin 500 mg PO tid. Then directed therapy once culture results available. Treatment duration 5–7 days
Allograft pyelonephritis	As above, if culture is negative, consider unusual causes—e.g., adenovirus, mycoplasma (see "Sterile pyuria" row below)	Empiric therapy with IV or oral antibiotics as above. Directed therapy once culture results are available. Treatment duration 2–4 weeks
Recurrent UTI	As above	Rule out structural causes or persistent focus of infection. Consider oral antibiotic prophylaxis and re-evaluate in 6 months
Asymptomatic bacteriuria	As above	No need for empiric therapy. Await culture and susceptibility for directed therapy. Repeat culture to rule out contamination. Treat if stent is present or within 6 months posttransplant or persistent bacteriuria with same organism
Sterile pyuria	*Mycobacterium* sp., *Chlamydia trachomatis, Ureaplasma urealyticum*, fungi	Urine culture for acid-fast bacilli, fungi, other special testing as indicated
Yeast	*Candida* sp., unusual causes—*Malassezia* sp., *Trichosporon* sp.	Remove risk factors (urinary catheter, broad-spectrum antibiotics), rule out fungal bezoar by imaging, repeat urine culture, if symptomatic or persistent funguria, treat with fluconazole 400 mg daily. If fails to eradicate, then speciate and do susceptibility testing. Avoid amphotericin products

associated with decreased survival, likely reflecting severity of illness; however, therapy of asymptomatic candiduria was not associated with increased survival. On the other hand, candiduria may be a marker of fungal aggregates along the urinary tract, which can cause obstruction [76–78]. An attempt should be made to reduce risk factors such as removal of urinary catheters or avoidance of broad-spectrum antibiotic therapy. Fluconazole can be used as empiric therapy although persistent candiduria should lead to abdominal imaging to rule out a persisting source and removal of urinary catheter if present. If funguria persists, the yeast should be speciated and undergo susceptibility testing. If the isolate is found to be fluconazole resistant, therapy can be escalated to expanded spectrum azoles or echinocandins depending on susceptibility patterns.

12.8 Graft-Site Candidiasis

In a large review of 18,617 kidney transplants, the incidence of graft-site candidiasis was 1 per 1000 [79]. The majority of these infections have occurred in the first 3 months posttransplant. Many of these infections involved a fungal arte rial aneurysm. Usually, these are secondary to a single *Candida* sp. (primarily *C. albicans*) although bacterial coinfection has been found. Over 20 cases of fungal arterial aneurysm have been described in the literature from 1972 to 2015 [80–82]. In several, but not all, cases, *Candida* sp. was also recovered from organ preservation fluid. The significance of recovering *Candida* sp. from graft preservation fluid is unclear. Matignon et al. [83] have shown that of eight kidneys transplanted where preservation fluid was infected with *Candida* sp., none developed arterial aneurysm after 1–2 years of follow-up. Albano et al. [79] reviewed the cases of graft-site candidiasis in renal transplant centers in France from 1997 to 2005. Of the 18 cases found, 13 were due to *C. albicans* and others due to other *Candida* sp. Although most cases were that of fungal arteritis, infected urinoma, graft-site abscess, and surgical site infection also occurred. Treatment of fungal arteritis consists of antifungals and surgical ligation of the external iliac artery. Transplant nephrectomy is required in 50–70 % of cases and death has occurred in 17–50 % of cases especially where diagnosis is delayed. This is a serious complication of transplantation and important to recognize since massive bleeding can quickly lead to death.

12.9 Cytomegalovirus

CMV remains one of the most common opportunistic infections post kidney transplantation. While CMV is discussed in detail in Chap. 23, there are several important aspects unique to kidney transplantation. CMV reactivates in up to 50 % of renal transplant recipients depending on other risk factors such as donor/recipient serostatus, use of prophylaxis, and type of immunosuppression [84, 85]. In the current era, reactivation of CMV after renal transplantation most commonly presents as detection of asymptomatic viremia. In patients who present with symptoms, the majority has a flu-like illness with one or more of fever, malaise, and myalgias termed "CMV syndrome." CMV may also cause end-organ disease including enteritis, hepatitis, and pneumonitis, and rarely allograft nephritis. CMV has also been shown to have "indirect" or "immunomodulatory" effects in the transplant population. In the renal transplant setting, CMV has been associated with acute kidney rejection although the association of CMV with chronic allograft dysfunction is less certain [86–89]. A study comparing CMV prophylaxis

versus preemptive therapy demonstrated improvement in long-term graft survival with the use of prophylaxis [90].

The greatest risk of reactivation is in patients who are seronegative but receive an organ from a seropositive donor (D+/R−). For this group, universal prophylaxis with antivirals for 3–6 months posttransplant has been suggested [85]. The majority of large randomized controlled trials have either had a majority of kidney recipients or included only kidney recipients. In many instances, these results have been extrapolated to other transplant populations. The IMPACT trial compared 3 months with 6 months of valganciclovir prophylaxis in 319 D+/R− kidney transplant recipients. The incidence of CMV disease in the two arms was 36.8 % versus 16.1 %, respectively [91]. Longer term follow-up of these patients did not reveal an increased incidence of late onset CMV disease beyond the first year posttransplant in the group that received 6 months prophylaxis [92]. Routine viral load monitoring for CMV after the prophylaxis period is employed by some centers although its utility is unknown [93, 94]. Other tools such as cell-mediated immunity assessment may be of better utility for predicting late-onset CMV disease [95]. Various regimens are available for prophylaxis and include oral valganciclovir, oral ganciclovir, and valacyclovir [96, 97]. However oral ganciclovir is no longer available in many jurisdictions. Valacyclovir prophylaxis has only been extensively studied in the renal transplant population and appears to be effective [98]. Use of valacyclovir in D+/R− patients was also associated with a significant reduction in acute rejection episodes [98] but this finding has not been replicated in more recent studies [91]. Recipients that are seropositive are also at risk especially when antithymocyte globulin preparations are used for induction immunosuppressive therapy. These patients are either given antiviral prophylaxis for the first 3–6 months posttransplant or monitored at regular intervals with molecular assays (pre-emptive therapy) [85].

Treatment of CMV consists of induction doses of intravenous ganciclovir 5 mg/kg b.i.d. or oral valganciclovir 900 mg b.i.d. until viremia is at a low or undetectable level. Thereafter, maintenance doses can be used. In a randomized, multicenter study of intravenous ganciclovir versus oral valganciclovir for CMV disease, success rates were not significantly different, and current recommendations suggest that oral therapy can be used first line for mild to moderate CMV disease [84, 99]. It is worth noting that the majority of patients included in randomized treatment study were renal transplant recipients. In addition, long-term clinical or virologic recurrences were not significantly different between groups [100].

12.10 Polyomavirus

Polyomavirus-associated nephropathy (PVAN) is an important cause of graft dysfunction and graft failure. The incidence of PVAN ranges from 1 to 10 %; the majority of infections are due to BK virus-associated nephropathy (BKVAN) and very rarely PVAN may be due to JC virus alone [101]. In the modern immunosuppressive era, BK virus is one of the most important causes of infections after kidney transplantation and is discussed fully in Chap. 30. The pathogenesis, epidemiology, and management are briefly described in the following text.

After primary infection, the virus establishes latency primarily in the urogenital tract including renal cortex, medulla, urothelial cells, and bladder. The majority of viral reactivation occurs in the first year posttransplant. Reactivation of polyomavirus in the ureter can lead to stenosis whereas bladder reactivation can manifest as hemorrhagic cystitis. However, both of these are uncommon complications after kidney transplantation. Reactivation, replication, and inflammation within the kidney result in BKVAN. Usually, the only clinical manifestation is a rise in serum creatinine. A definitive diagnosis of BKVAN is made by kidney biopsy that demonstrates varying degrees of inflammation and/or fibrosis, often with intranuclear viral inclusions. Immunohistochemical staining using antibody directed against the SV40 T antigen or VP capsid proteins shows a characteristic nuclear staining reaction. Since disease may be patchy, a biopsy may occasionally be false negative.

Various risk factors for BKVAN have been suggested in several studies [102–106]. These include human leukocyte antigen (HLA) mismatches, history of acute rejection and use of antilymphocyte therapy, recipient age > 55, and recipient seronegativity. However, a large study of 1001 renal transplant recipients, 4 % of whom developed BKVAN, did not find any specific risk factors [107]. Recently, the use of more aggressive immunosuppression protocols such as with ABO incompatible transplants have been associated with a higher risk for BKVAN [108]. In another study, BK viremia was associated with the use of tacrolimus-mycophenolic acid combination versus cyclosporine-based immunosuppression [109].

The cornerstone of therapy for BKVAN is reduction in immunosuppression. All other options are less well studied and randomized controlled trials are lacking. Cidofovir, which is a nucleotide analogue of cytosine, has activity against DNA viruses. Results of case reports and series with cidofovir are difficult to interpret due to the concomitant decrease in immunosuppression [110]. Brincidofovir is a lipid conjugated oral formulation with decreased toxicity and appears to have activity against BK virus [111]. Further studies are ongoing. Leflunomide also appears to have antiviral properties in addition to its immunosuppressive action. Josephson et al. [112] showed stabilization of renal function in the majority of patients with BKVAN treated with leflunomide [112]. However, in a study of 52 patients treated with leflunomide, there was no association with viremia clearance and no correlation between serum concentrations of its metabolite A77 1726 and clearance [113]. Although leflunomide has been used as a treatment option, its adverse effects include hemolysis, transaminitis, and pancytopenia. Other experimental therapies that have been attempted or proposed

include fluoroquinolones, intravenous immunoglobulin (IVIg), and rituximab [114]. However in a recent randomized trial of 3 months of levofloxacin versus placebo for prevention of BK viruria and viremia, no benefit was demonstrated [115]. In addition, in a placebo controlled trial for treatment of BK viremia, in 39 patients, no beneficial effort of levofloxacin was observed [116]. Finally, the risk of recurrence after retransplantation for graft loss secondary to BKVAN does not appear to be increased [117].

It is well established that BK viruria and viremia are a prerequisite for histologically proven BKVAN. Given the lack of specific treatment for BKVAN and the high incidence of graft loss, routine screening for BK virus for early detection in the first year posttransplant is now recommended by most authorities [118]. Screening may be done by NAT testing of urine or plasma/blood. Detection of virus in the urine in itself has poor predictive value for BKVAN, but should trigger testing in blood or plasma. Detection of viremia is a better predictor of BKVAN and early intervention with judicious lowering of immunosuppression prevents the development of BKVAN.

12.11 Other Viral Infections Post Kidney Transplant

12.11.1 Adenovirus

Adenoviruses are non-enveloped DNA viruses with at least 52 known serotypes that are capable of causing a variety of illness in immunocompetent and immunocompromised hosts [119]. This includes upper and lower respiratory tract infection, conjunctivitis, keratoconjunctivitis and pharyngoconjunctival fever, hepatitis, and disseminated disease. Although adenovirus disease may manifest with these clinical syndromes in kidney transplant patients, several cases of adenovirus-related disseminated disease, pyelonephritis and hemorrhagic cystitis have also been described [120, 121]. Hofland et al. [122] reviewed 37 cases of adenovirus hemorrhagic cystitis in kidney transplant patients. All cases occurred within the first year posttransplant and the majority presented with fever and dysuria and hematuria. Graft dysfunction was present in the majority of patients and viral changes or acute rejection may be seen in kidney biopsies. Adenovirus species B predominates with serotypes 7, 11, 34, 35 causing most of the diseases. Diagnosis can be made by indirect methods such as serology or methods that directly demonstrate the presence of virus such as plasma polymerase chain reaction (PCR) and culture. In situ hybridization, immunohistochemistry, or PCR of fixed tissue can also identify adenovirus. Routine monitoring for adenovirus is not beneficial. In a surveillance study using blood PCR for adenovirus, it was found that self-limited adenoviremia can occur in 7 % of solid organ transplant patients with 58 % being asymptomatic [123]. There is no specific therapy for adenovirus, although clinical studies have focused on cidofovir and ribavirin. As discussed above, brincidofovir is a new oral lipid-conjugated cidofovir that has in vitro activity against many DNA viruses including adenovirus, and may be an option in the future. Immune reconstitution plays an important role in the clearance of adenovirus; therefore, decreasing doses of immunosuppressive medication is important.

12.11.2 Parvovirus B19

Parvovirus is a single-stranded DNA virus of the genus *Erythrovirus*. Although most infections are nonspecific flu-like illnesses, specific clinical syndromes have been described. In children, parvovirus infection is termed “fifth disease” that causes a facial rash resembling “slapped cheeks”; adults with parvovirus can develop a polyarthropathy syndrome; the virus can also lead to transient aplastic crisis in those with chronic hemolytic anemia and hydrops fetalis leading to intrauterine fetal death in pregnant women. Infection in transplant recipients is unlike that of immunocompetent patients in that viral replication can persist for prolonged periods of time [124]. Recurrent parvovirus infections have also been described [125]. Onset of parvovirus-associated syndromes can occur at any time posttransplant and has been described as early as 2 weeks. One study of 60 adult kidney transplant patients showed a 10 % rate of parvovirus viremia in the first year posttransplant [126]. The mode of acquisition of the virus is unknown in renal transplant recipients. Possibilities include inhalation of infected aerosols as in the immunocompetent host but also transmission from the donor. The possibility of viral reactivation also exists such as in the case of herpesviruses although little is known about parvovirus latency or cellular reservoirs. Parvovirus has well-established association with hematologic abnormalities including pure red cell aplasia and acute or chronic anemia in kidney transplant recipients. Since anemia is such a common problem in renal transplant recipients, it is important that physicians keep this diagnosis in mind especially for cases of severe, unexplained, or recalcitrant anemia. In one series, 3 out of 8 (38 %) of renal transplant patients with erythropoietin-resistant anemia (Hgb < 10 g/dL) were parvovirus positive by qualitative plasma PCR [127]. Other cell lineages may also be affected and lead to leucopenia and thrombocytopenia. Less well-developed associations exist with transient allograft dysfunction, collapsing glomerulopathy, acute rejection, and thrombotic microangiopathy. Other associations in renal transplant recipients have also been described such as hepatitis, encephalitis, and cerebral angiitis. Serologic studies have limited utility since they can be hampered by transfusion or immunoglobulin therapy. In addition, transplant recipients may not mount an antibody response. Instead, direct detection of virus by qualitative or quantitative DNA PCR is the most useful method. There is no specific antiviral therapy for parvovirus infection although

various management options have been suggested. These consist of a decrease in immunosuppression and/or IVIg. Various dose regimens of IVIg have been used and range from 0.4 to 1 g/kg for 4–10 days.

12.11.3 West Nile Virus

WNV is a flavivirus that has established itself in North America. WNV is most commonly transmitted via mosquito bites but can also be transmitted through blood transfusion and organ donation. Several series of WNV infection transmitted from infected donors to recipients have now been described with the majority of recipients developing encephalitis [128–132]. Donor screening with WNV NAT has been instituted in most organ procurement organizations to reduce the risk of transmission. Donor screening is usually done during periods of high WNV activity or year-round. Community-acquired cases also continue to occur and WNV encephalitis has been described in several kidney and kidney–pancreas transplant recipients [133–136]. A seroprevalence study in organ transplant recipients estimated the risk of neurologic disease to be 40 % compared to <1 % in immunocompetent hosts [137]. Diagnosis of WNV is based on an appropriate clinical picture, a lymphocytic pleocytosis in the cerebrospinal fluid (CSF), and WNV IgM in CSF and serum. A salient feature in transplant recipients is the absence of IgM or delayed positivity. In these cases WNV NAT may be used for diagnosis. There is no specific antiviral therapy for WNV although in the majority of the described cases, immunosuppression was significantly reduced. The successful use of WNV hyperimmune globulin obtained from healthy Israeli blood donors has been described for a liver transplant recipient who developed donor-derived WNV [138]. In addition, IVIg has been successfully used for transplant recipients with WNV [139]. Some studies suggest benefit with ribavirin or interferon-α but this has not been specifically studied in the transplant setting [140, 141]. As a result, many transplant programs advise patients to use personal protection measures such as longsleeved clothing, insect repellent containing *N*,*N*-diethyl-metatoluamide (DEET), and avoidance of outdoor activity at dusk and dawn, a time when mosquitoes are most active.

12.12 Kidney Transplantation in the HIV-Positive Recipient

Traditionally, infection with the HIV was considered to be a contraindication to transplant. However, in the last two decades, the increasing use of HAART (highly active antiretroviral therapy) has significantly increased the life span of HIV-infected individuals [142]. Recent estimates indicate up to 2–17 % of HIV-positive patients have chronic renal disease although rates vary significantly worldwide [143]. A major cause of end-stage renal disease in this population is HIV-associated nephropathy (HIVAN), which is a collapsing glomerulopathy that is more common in African Americans with HIV as well as focal segmental glomerulosclerosis. HIV itself may be a cause of IgA nephropathy. In addition, glomerulonephritis associated with HBV and HCV can also occur in coinfected patients. End-stage renal disease can also be compounded by toxicities of antiretrovirals such as indinavir, tenofovir, and ritonavir.

Recent studies have shown that both graft and patient survival of HIV-infected patients undergoing kidney transplant are similar to HIV-negative patients [144]. However, HIV-infected patients who are coinfected with HCV have significantly lower 5- and 10-year graft and patient survival than HIV-negative/HCV-positive patients [144, 145]. Over time, kidney transplant outcomes for HIV-infected patients have improved [146]. Using the Scientific Registry of Transplant Recipients data from 2003 to 2011, Locke et al. determined that HIV+ patients have a twofold greater risk of acute rejection compared to the HIV-negative group; however, HIV+ patients that received antithymocyte globulin induction had 2.6-fold lower rejection rates than those that received no induction [147]. Acute rejection rates have ranged between 13 and 50 % of patients likely due to variability in patient selection and posttransplant induction and maintenance immunosuppressives [148, 149]. HIV viremia has generally been well controlled. Most centers performing transplants in HIV-positive setting have carefully selected patients for transplant based on CD4 counts, undetectable viral load, and lack of significant opportunistic disease including progressive multifocal encephalopathy, CNS lymphoma, chronic intestinal cryptosporidiosis, and visceral Kaposi's sarcoma [149]. In addition, HIV genotypic and phenotypic testing predictive of suppression on HAART therapy as well as patient compliance are important factors in selection [150].

Posttransplant, drug interactions between immunosuppressives and anti-retrovirals need to be considered. Maintenance immunosuppression consists of steroids, calcineurin inhibitors (CNIs), and MMF. Although both CNIs can be used, patients on tacrolimus had lower rejection rates [149]. There is significant interaction between CNIs and protease inhibitors that inhibit the cytochrome P450-3A system. In this case, CNI doses need to be reduced appropriately. Conversely, CNI doses need to be increased with non-nucleoside reverse transcriptase inhibitors (NNRTIs) such as efavirenz that induce cytochrome P450-3A. Nonetheless, frequent measurement of levels is required to reach the optimal dose. The management of adverse events such as bone marrow suppression is also complicated since HAART, transplant immunosuppressives, and prophylactic antimicrobials (e.g., TMP/SMX, valganciclovir) can be myelosuppressive.

Preventative strategies post kidney transplant in the HIV patient are similar to those in the HIV-negative transplant population with some exceptions. Antipneumocystis pro-

phylaxis is usually given life long rather than the 6- to 12-month prophylaxis regimen used by many centers. TMP/SMX is the standard prophylaxis with alternatives such as dapsone and atovaquone for TMP/SMX intolerance or allergy. Patients with very low CD4 counts may require prophylaxis for other organisms such as mycobacterium avium complex and toxoplasmosis.

Recently, transplantation of kidneys from HIV+ donors into HIV+ recipients has been studied in South Africa where the availability of dialysis is limited [151–153]. In their cohort of 27 transplants, Muller et al. have found 74 % and 84 % patient and graft survival, respectively, at 5-years. At 3-years, the rejection rate was 22 % and HIV viral loads remained undetectable. In the United States, approval of the HIV Organ Policy Equity (HOPE) act in 2013 will allow for increasing research in this emerging area [154]. The field of transplanting HIV-positive patients is relatively young. Changes in selection of patients, optimal immunosuppression regimens, and knowledge of posttransplant infections will increase as results of ongoing studies become available.

12.13 Infectious Risks of Transplant Tourism

Given the limited supply of deceased donor kidneys, a significant proportion of patients from Western countries travel to Eastern countries where kidney transplantation can be performed on a pay basis. Often this involves the illegal trafficking of organs [155]. In this setting, a kidney is harvested from a live donor who needs money to support his/her family or repay debt. The transplant is performed for cash and the patient returns home to be managed by his/her transplant physician. Unfortunately, the standards for organ procurement do not necessarily meet those of registered transplant centers worldwide. Often the patient returns home with no or minimal medical records. Basic information such as donor CMV, EBV, and hepatitis serologies may be unknown. There is an increased incidence of postoperative complications including wound infections, perinephric abscess, colonization, and infection with multidrug-resistant organisms including extended-spectrum beta-lactamase-producing gram-negative bacteria [156–159]. Other issues, although less common, may include malaria (donor-derived or community acquired), donor-derived TB, fungal infections, acquisition of HIV, and hepatitis. To address the issue of organ trafficking and transplant tourism, an international consensus took place in Istanbul that outlined the strategies needed to increase donation and ensure safety of living donors [160]. Physicians caring for individuals who have received transplants in this manner should be aware of the potential exposures.

12.14 Antimicrobials and Nephrotoxicity

Given the unique susceptibility of the allograft to a number of insults, it is reasonable to avoid antimicrobial agents with a high risk of nephrotoxicity. Additive or synergistic nephrotoxicity can occur with antimicrobials and immunosuppressive drugs, especially CNIs. Specific agents that can cause nephrotoxicity include aminoglycosides (e.g., gentamicin, tobramycin, amikacin), intravenous colistin, and standard amphotericin B as well as lipid amphotericin preparations. Routine use of these agents should be avoided especially if an alternative antimicrobial agent can be used. Consideration should be given to the risks and benefits when using these agents with careful monitoring of renal function and drug levels when possible. Other agents such as vancomycin, high-dose TMP/SMX, and high-dose quinolones may be nephrotoxic when combined with potentially nephrotoxic immune suppressants. When possible, antimicrobial levels should be monitored.

12.15 Posttransplant Vaccinations

Vaccinations in renal transplant recipients follow the guidelines for vaccinations in all solid organ transplant recipients [19]. Both inactivated and live vaccines (such as those for VZV (Varivax; Zostavax)) can be given prior to transplant. If the opportunity exists, a vaccine is likely more effective if given pretransplant as early as possible in the course of progressive renal disease. If a live vaccine is given pretransplant, one should wait approximately 4 weeks before transplantation to avoid vaccine-related disease. In the posttransplant period, vaccinations generally begin no sooner than 3–6 months. Although vaccinations could be administered earlier, there are limited data regarding immunogenicity. Yearly influenza vaccine is recommended for all transplant patients. There is no evidence for a link between vaccination and allograft rejection. Renal transplant recipients appear to have a reasonable humoral response to a single dose of influenza vaccine whereas double dose vaccine does not appear to be beneficial [115]. One study showed better graft survival in patients who received influenza vaccine in the first year [161]. Family members and household contacts of the transplant patient should also be vaccinated with annual influenza vaccine. Pneumococcal vaccine is also recommended for renal transplant recipients. In a randomized trial of renal transplant recipients, the pneumococcal conjugate vaccine had an increased trend to greater humoral responses compared to the polysaccharide vaccine [162]. There was a significant decline in titers in the same cohort followed for 3 years with either vaccine [163]. Therefore, most vaccine authorities now recommend one dose of conjugate vaccine followed by one dose of polysaccharide vaccine with a minimum interval of 8 weeks [164]. Other inactivated vaccines generally follow the guidelines for non-transplanted individuals.

12.16 Pneumocystis Prophylaxis

Antimicrobial prophylaxis is recommended post kidney transplant, although there is a wide variety of practices [165]. Prophylaxis for *P. jirovecii* pneumonia (PCP) is generally instituted in the early posttransplant period. PCP appears to be more common in renal transplant recipients who have undergone treatment for multiple rejection episodes and received polyclonal/ monoclonal antibodies [166]. Corticosteroid use has classically been associated with the occurrence of PCP. However, anti- B-cell therapies such as rituximab for the management of antibody-mediated rejection in this population may also increase risk of PCP [164]. PCP prophylaxis is generally instituted for the first 6 months to 1 year posttransplant. Consideration can be given to continuation or reinstitution of prophylaxis beyond this time if the patient remains on high-dose corticosteroids or receives monoclonal antibodies for rejection. In the past 5 years, clusters of late PCP infections have been reported by some investigators suggesting re-emergence of this pathogen [167–169]. The primary agent for prophylaxis is TMP/SMX. Doses used are one single-strength tablet once daily or one double-strength tablet thrice a week. However, a proportion of patients will have toxicity such as leucopenia, rash, and drug-induced hepatitis. In addition, higher doses of TMP/SMX can lead to renal dysfunction. Alternatives to TMP/SMX are once monthly inhaled pentamidine, oral dapsone, or atovaquone [170].

12.17 Summary

In summary, infectious complications continue to be an important cause of morbidity and graft dysfunction in kidney transplantation. With evolving immunosuppression regimens, infectious etiologies are also changing. A prime example of this is BK nephropathy, which has emerged as an important cause of graft loss only in the era of more modern immunosuppression. Traditional infections associated with kidney transplantation, such as CMV, also pose challenges but modern management strategies have reduced the burden of such infections significantly. UTIs and related bacterial infections are very common in these patients and this is an area where clinical trials are needed to better define appropriate therapeutic strategies.

Risks and Epidemiology of Infections After Pancreas or Kidney–Pancreas Transplantation

Atul Humar, Roberto Lopez, and Abhinav Humar

After experiencing continuous improved rates and growth in total numbers in the 1980s and 1990s, pancreas transplants have suffered a steady decline in procedures performed and new listings in the last decade [1]. Despite this, they still represent the most reliable way to consistently achieve euglycemia for insulin-dependent diabetics, with islet transplantation alone as a promising alternative [2]. For a diabetic patient who has progressed to end stage renal disease (ESRD), the treatment of choice is a pancreas transplant (in conjunction with a kidney transplant). Dramatic improvements in outcomes have resulted from refinements in surgical technique, superior immunosuppressive regimens, and a better understanding of donor and recipient risk factors. By 2010, nearly 36,000 pancreas (1 AG) transplants had been performed worldwide; however, the number of transplants in the USA has steadily decreased from 2000 performed in 2004, to almost a 50 % decline in 2013 when just over a 1000 cases were reported [3], despite the increase in half-life for an SPK pancreatic graft in the last 14 years [4, 5].

The causes for this decrease are uncertain, but likely can be attributed to better glycemic controls with current insulin regimens, worsening in the donor quality due to the increased prevalence of obesity, or to more stringent controls in outcome translating into an increased selectivity in donors and recipients for individual transplant centers.

Yet, despite the improvements, the incidence of complications remains high after a pancreas transplant. In fact, the surgical complication rate is the highest of all routinely performed solid organ transplants [6]. Technical failure is the most common cause of pancreas graft loss in the first-year posttransplant, most notably manifesting as vascular thrombosis in half of the cases of technical graft loss or infections in close to one-fifth of them [7].

Pancreas recipients are at significant risk for infectious complications posttransplant, which can lead to significant morbidity and mortality. Numerous risk factors include long-standing diabetes with multi-organ involvement (especially renal failure), which can lead to an immunosuppressed state even before any immunosuppressive drugs are begun, impaired tissue healing, and poor vascular flow. The donor pancreas graft contains a hollow viscera (i.e., the duodenum) that is contaminated and is thus a potential source of infective organisms. The transplant surgery itself involves opening non-sterile viscera in the recipient (i.e., either the bladder or the small bowel), with potential for further contamination. Posttransplant, higher levels of immunosuppression is generally required than other solid organ transplants. Moreover, pancreas recipients have an increased incidence of acute rejection, which requires bolus doses of immunosuppressive drugs. All of these factors combine to explain why pancreas recipients have the highest incidence of infections of all solid organ transplant recipients [8].

13.1 Spectrum and Classification of Infections

The spectrum of possible infections after a pancreas transplant is wide. No completely satisfactory classification system exists for the types of infections seen in pancreas recipients. They may occur in the early (0–30 days), intermediate (30–180 days), or late (beyond 180 days) posttransplant period [9]. They may be related directly to the surgical procedure or to some complication that develops afterwards or may be opportunistic, resulting from the recipient's overall immunosuppressed state (Table 13-1).

Classification by pathogen into bacterial, viral, or fungal infections is not always clinically useful. One type of pathogen may be involved in several different types of infections, or a number of different pathogens may be involved in a single infection (e.g., an intra-abdominal abscess with several different bacterial and fungal pathogens). Classification by timing posttransplant, into early, intermediate or late infections, has some merit, because many infections follow a typical temporal pattern. Again, however, this information may not be very useful when making clinical decisions about treatment.

P. Ljungman et al. (eds.), *Transplant Infections*, DOI 10.1007/978-3-319-28797-3_13

Table 13-1. Summary of infections after pancreas transplant, risk factors, and methods of prevention

Infection	Risk factors	Preventive measures
Surgical		
Intra-abdominal infections	• Older donor age • Donor obesity • Prolonged cold ischemia • Recipient obesity • Prolonged pretransplant peritoneal dialysis • Graft pancreatitis posttransplant • Duodenal leak posttransplant	• Careful donor selection • Minimize cold ischemia • Prompt diagnosis and treatment of duodenal leaks
Duodenal leaks	• Prolonged cold ischemia • Duodenal devascularization during preparation of graft • Impaired bladder emptying in recipient • Late CMV infections of transplant	• Minimize cold ischemia • Careful attention to donor duodenum blood supply • Pretransplant bladder assessment in recipient
Recurrent UTI	• Bladder-drained graft • Neuropathic bladder • Foreign body exposed in bladder	• Enteric drainage of graft if possible • Oversewing of exposed staple lines in bladder
Wound infections	• Longer operative procedures • Intraoperative duodenal spillage • Recipient obesity • Intra-abdominal infection	• Prophylactic antibiotics preoperatively • Minimize recipient risk factors
Medical		
Cytomegalovirus	• Pretransplant serostatus (D+/R− at highest risk; also frequent in D+/R+ and D−/R+ groups) • Degree of immunosuppression; especially use of antilymphocyte therapy	• Multiple strategies, but usually universal prophylaxis to all at-risk patients • Usually oral valganciclovir for 3–6 months • Longer duration prophylaxis preferred for high-risk patients (e.g., 6 months)
EBV-related posttransplant lymphoproliferative disease	• Intensity of immunosuppression (especially antilymphocyte therapy) • Pretransplant EBV serology (EBV D+/R− at highest risk)	• Uncontrolled studies suggest antiviral prophylaxis may be of benefit • Strategies to prevent CMV disease may also reduce EBV-related disease • Minimize immunosuppression • Avoid antilymphocyte therapy • Consider monitoring viral loads with preemptive changes to immunosuppression in response to increasing viral loads

Classification by the primary method of treatment, into surgical and medical infections, is useful in a broad sense. Surgical infections are those that require some invasive intervention as an integral part of their treatment. These types of infections generally occur soon after the transplant operation itself and are usually related directly to it or to some complication occurring as a result of the operative procedure. Surgical infections are less likely to be related to the recipient's overall immunosuppressed state, though obviously this plays some role. Typical examples of surgical infections include generalized peritonitis, intra-abdominal abscesses, wound infections, and, in bladder-drained pancreas grafts, recurrent UTIs.

In contrast, medical infections are primarily treated with antiviral, antibacterial, or antifungal agents. They tend to occur in intermediate and late posttransplant stage and are usually related to the recipient's overall immunosuppressive state [9]. Typical examples include infections secondary to cytomegalovirus (CMV), polyomavirus-induced nephropathy, pneumonias, and Epstein–Barr virus (EBV)-related posttransplant lymphoproliferative disorder (PTLD).

13.2 Transplant Procedure

A brief review of the surgical procedure itself is necessary in order to better understand the infections (especially surgical infections) that may develop in these pancreas recipients (see Figures 13-1 and 13-2).

Pancreas transplants are performed in insulin-dependent diabetics who may or may not have coexisting kidney failure from diabetic nephropathy. Most pancreas transplants in the USA are in diabetics with ESRD who also require a kidney transplant [5]. The two organs may be transplanted either

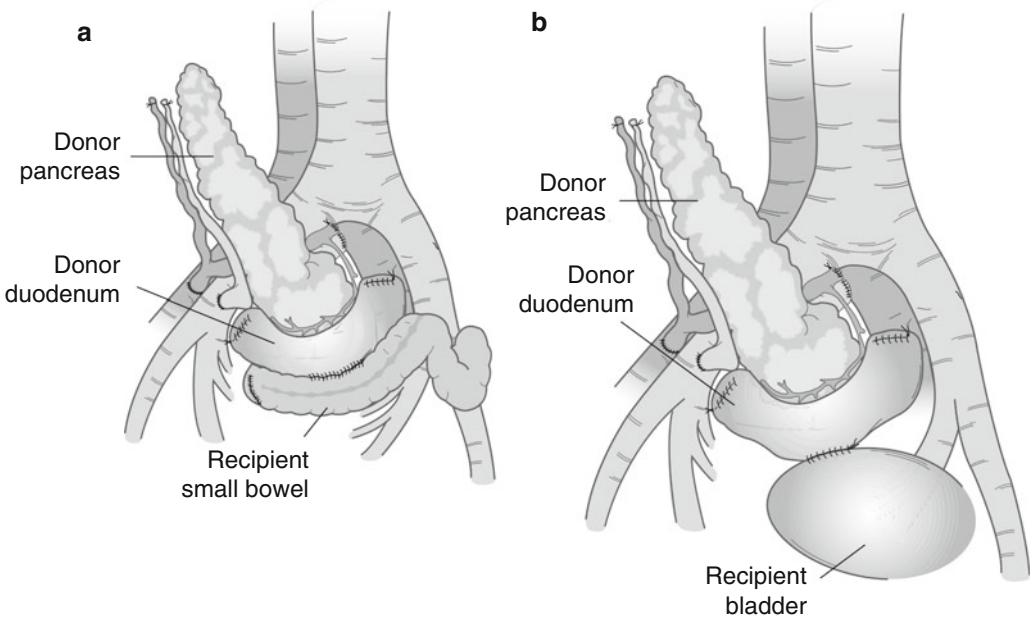

FIGURE 13-1. (**a**) Pancreas transplant with enteric drainage of the pancreas. (**b**) Pancreas transplant alone with bladder drainage of the pancreas.

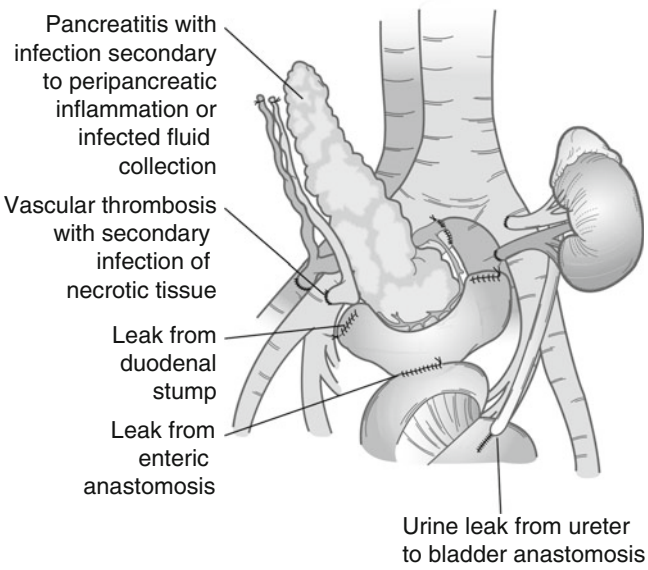

FIGURE 13-2. Potential sources of surgical infections after simultaneous pancreas–kidney transplant.

simultaneously (SPK—simultaneous pancreas–kidney) or sequentially: first the kidney transplant, followed at a later date by the pancreas (PAK—pancreas after kidney). For diabetic patients who retain kidney function, a pancreas transplant alone (PTA) may be indicated. Overall, SPK transplantations accounted for approximately 72% of total pancreas transplants in 2010, PAK for 17%, and PTA for 7% [1].

Ideal PTA candidates include those with widely fluctuating glucose levels, hypoglycemic unawareness, frequent insulin reactions, or recurrent episodes of diabetic ketoacidosis. These three pancreas recipient categories—SPK, PAK, PTA—do not differ with regard to the possible infections that may result. Rather, as discussed later, the relative risk for certain infections may differ in the three groups.

Donor operation [10]: A pancreas from a deceased donor is removed en bloc with the duodenum and spleen. Many centers routinely flush the donor duodenum with some antibiotic solution to decrease the degree of contamination, but there is no good proof that doing so decreases the risk of subsequent intra-abdominal or wound infections [11]. Before the pancreas is implanted in the recipient, it is generally prepared on the "back table." A donor splenectomy is performed, the donor duodenum is trimmed, and any vessels that may potentially bleed are oversewn or ligated. Careful preparation of the pancreas can help decrease the risk of subsequent intra-abdominal infections. Trauma to the pancreas can lead to graft pancreatitis, a risk factor for intra-abdominal infections [12]. Similarly, large hematomas from unligated vessels may predispose to intra-abdominal infections.

Recipient operation [13]: Whether the pancreas transplant is performed by itself or in conjunction with a kidney transplant, the pancreas graft is placed in an intraperitoneal position. This placement is important to keep in mind, as it influences the area of spread of subsequent infections originating around the graft itself. Usually, the pancreas graft is placed in the right lower quadrant, with inflow and outflow

of blood achieved by anastomosing the graft vessels to the recipient iliac artery and vein. Another option is to anastomose the venous outflow of the graft to the recipient mesenteric vein, thus draining the endocrine secretions (i.e., insulin) into the portal (instead of systemic) circulation. The exocrine secretions (i.e., amylase) of the pancreas can be drained either into the bladder (BD—bladder-drained) or into the small bowel (ED—enteric-drained) (Figure 13-1). The method of drainage has important implications for complications that may occur, especially graft duodenal leaks. ED is more physiologic, but a duodenal leak with ED grafts may lead to more devastating infections than seen with BD grafts. If a leak occurs with a BD graft, urine leaks within the peritoneal cavity; with ED grafts, enteric contents leak into the abdominal cavity. The choice of ED or BD varies with the clinical situation and with the individual center's preference. BD is associated with increased urologic complications (such as recurrent urinary tract infections (UTIs)) but makes monitoring the function of the graft easier (by measuring the amount of amylase in the urine) [14]; however, reliance solely on clinical parameters such as hyperglycemia, serum amylase and lipase, C-peptide levels, hemoglobin-A1C, or (if bladder-drained) urinary amylase are insufficient because they are either too late or too nonspecific, risking a graft rejection going undetected, which is associated with graft failure [15, 16]. ED does away with the urologic complications, but may be associated with more severe intra-abdominal infections. Most centers now generally drain all pancreas grafts into the small intestine. In 2010, ED was used in 91 % of SPK, 89 % of PAK, and 85 % of PTA patients [17]. Our preference is to wait until after reperfusion of the pancreas before making the final decision. If there is evidence of significant reperfusion injury of the graft with reperfusion pancreatitis or poor perfusion of the duodenum, it is generally safer to drain the graft into the bladder.

13.3 Risk Factors for Infections

The risk factors for infections in pancreas recipients depend on the site and type of infection. For example, the factors predisposing to wound infections posttransplant are completely different from those associated with CMV infections. In general, risk factors can be classified into those present in the recipient pretransplant, those related to the donor, those related to the recipient intraoperatively, and those that occur posttransplant.

Pretransplant latent infections or infectious exposures can reactivate or worsen early posttransplant, once heavy-dose immunosuppression is initiated. Pretransplant immunity, or lack of immunity, to certain viral pathogens can be an especially important risk factor for posttransplant infections. For example, recipients seronegative for CMV or EBV have a high incidence of posttransplant infections with these viruses, especially if the donor was seropositive [18, 19]. The recipient's overall medical status may play an important role in posttransplant infections. All pancreas recipients have long-standing diabetes as a risk factor. In addition, some may have these additional risk factors as well: poor nutritional status (especially those who have brittle diabetes or who have been on dialysis long term); advanced peripheral vascular disease; or frequent hospitalizations pretransplant. Recipient obesity is a well-known risk factor for posttransplant infectious complications, especially involving the wound [20].

Donor factors may play an important role in patients at risk for posttransplant infections. Transmission of infections from the donor, especially bacterial, is very uncommon [21]. But viruses such as CMV, EBV, hepatitis B or C, and HIV can certainly be transmitted to any recipient who has not had previous exposure to them [22]. Besides direct donor transmission, other donor variables may also affect posttransplant infections in the recipient. Older donor age (i.e., ≥45 years old) and donor obesity are both associated with increased risk for posttransplant complications such as pancreatitis and graft thrombosis, which can lead to intra-abdominal abscesses or wound infections [23, 24].

Intraoperative risk factors for infections include a longer operative procedure with significant bleeding, prolonged cold, and warm ischemia of the graft, and the SPK category of transplant type. Grafts with prolonged ischemia times are more prone to develop pancreatitis, duodenal leaks, and thrombotic complications—all of which may predispose to intra-abdominal infections and various other infectious complications [25]. SPK recipients generally have a higher incidence of intra-abdominal and wound infections, as compared with PAK or PTA recipients [5, 8]. The possible reasons are that SPK recipients undergo a longer operative procedure (with more extensive dissection required), are often sicker at the time of the transplant, their poor nutritional status, and the fact that they receive not one but two transplanted organs that may develop complications.

Posttransplant risk factors for infection are generally related either to the development of posttransplant complications or to the level of immunosuppression. Almost any complication that requires a reoperation will predispose to wound infections [26]. Complications such as pancreatitis or vascular thrombosis of the graft can result in fluid collections or in devitalized, necrotic tissue, which can become secondarily infected. Clinically significant peripancreatic fluid collections (PPFCs) can be seen in 16 % of pancreas transplants, and are usually seen within 3 months after transplantation. Sometimes, they can be resolved by radiological drainage though often they will require laparotomy [27]. The strongest risk factor for intra-abdominal infections posttransplant is a leak from the duodenal cuff or anastomosis [28]. The level of immunosuppression is an important risk factor, especially for opportunistic infections. The higher the level of immunosuppression, the greater the risk. Long induction regimens involving powerful antilymphocyte agents or bolus antirejection treatment have been clearly identified as risk factors for a variety of infections [28, 29].

13.4 Immunosuppression

As mentioned earlier, higher levels of immunosuppression are generally associated with a higher likelihood of infection, especially with opportunistic viral and fungal pathogens. The amount of immunosuppression given to an individual recipient is usually related to the immunologic risk. PTA recipients generally have a higher risk of rejection than do SPK or PAK recipients, and therefore they tend to receive higher levels of immunosuppression [30]. The risk of rejection in all three pancreas recipient categories is highest early after the transplant; hence, most centers use induction therapy immediately posttransplant, generally an antilymphocyte intravenous agent such as anti-thymocyte globulin alemtuzumab, or basiliximab [31, 32]; the use of OKT3 for induction therapy has fallen out of favor over the past couple of decades due to the concern of possible increased PTLD risk [33]. After induction therapy, recipients are maintained on some combination of antirejection agents, usually a calcineurin inhibitor (cyclosporine or tacrolimus), an antimetabolite (mycophenolate mofetil or azathioprine), and prednisone. Newer, more powerful agents are becoming available that more specifically inhibit the immunogenic response. There is concern, however, that higher level of immunosuppression seen with such agents may increase the risk of infection.

The level of maintenance immunosuppression may be dramatically increased if the recipient requires short-term treatment for acute rejection. High-dose steroids or antilymphocyte preparations may be used. Infections may then develop.

13.5 Intra-abdominal Infections

Of the infections that may develop after pancreas transplant, intra-abdominal infections are generally the most serious, and most likely to be life threatening. They may range from diffuse peritonitis to localized abscesses. Their presentation, management, and clinical course will, in part, depend on their location and on the recipient's overall condition.

The incidence of intra-abdominal infections in this population has steadily decreased over time. During the 1980s, the reported incidence was very high, close to 30 % [34]. The high incidence of mortality or graft loss in pancreas recipients who developed intra-abdominal infections was also very high. By the 1990s, the incidence of intra-abdominal infections had decreased to 15–20 % [35]. By 2000, the incidence of major intra-abdominal infections had decreased to 5–10 % [36]. At present, this incidence has remained relatively stable [37]. The exact reason for this lower incidence is likely multifactorial. Better surgical technique, better preservation methods, and better immunosuppressive regimens (resulting in a lower incidence of acute rejection) have all likely played a role.

Although the incidence has decreased over time, intra-abdominal infections continue to be a major problem in pancreas recipients and are still a common technical reason for graft loss (other causes being vascular thrombosis, pancreatitis, and hemorrhagic pancreatitis) [38, 39]. Some of these infections probably originate because of contamination from the donor duodenum, which is opened during the transplant procedure. Some correlation has been shown between organisms identified from cultures of the donor duodenum and later cultures from the intra-abdominal infection [40].

Duodenal leaks (DL) are probably the most significant risk factor for intra-abdominal infections, especially with ED grafts; in one recent study, DLs were accountable for a quarter of all 1-year graft losses [41]. But, donor factors also play an important role in one multivariate analysis of risk factors for intra-abdominal infections, older donor age was found to be a strong risk factor for intra-abdominal infections [36]: if the pancreas donor was older than 40 years, the incidence of intra-abdominal infections was 16.2 %; if younger than 40 years, 2.9 % ($P=0.009$). Donor obesity is another factor predisposing the recipient to infectious complications. In one analysis, if the donor body mass index (BMI) was >25 kg/m^2, the incidence of intra-abdominal infections was 11.7 %; if the donor BMI was >30 kg/m^2, the incidence was 21.0 % ($P=0.07$) [43]. Often, the pancreas from obese donors has a significant amount of extra fatty tissue on the graft. This fat may become necrotic after the transplant and serve as a nidus for infection. Recipient risk factors for the development of intra-abdominal infections include obesity and the presence of occlusive peripheral vascular disease. This is an important issue given that the US donor population is becoming increasingly old, obese, and diabetic and only approximately 15 % of US deceased donors in 2013 donated a pancreas for transplantation [42, 43].

Graft pancreatitis developing early posttransplant may also lead to infection. Pancreatitis and hemorrhagic pancreatitis are important causes of technical failure of the pancreas graft [39]. Graft inflammation and swelling early posttransplant is likely a manifestation of reperfusion injury after cold ischemia. Inflammation of the graft or the surrounding peripancreatic tissue can lead to fluid collections around the graft and often to subsequent infections. Necrotic pancreatic tissue from severe pancreatitis can become secondarily infected; this almost always requires removal of the graft to manage adequately.

Other risk factors for intra-abdominal infections include the pancreas recipient category and the type and duration of dialysis pretransplant. Prolonged pretransplant dialysis, especially peritoneal dialysis, is associated with a higher incidence of posttransplant infections [44]. As with infections in general, SPK recipients have a slightly higher incidence of intra-abdominal infections than do PAK or PTA recipients [5].

The clinical presentation of intra-abdominal infections will depend on their severity and location. Generalized peritonitis is usually associated with some catastrophic event, such as graft duodenal leak with spillage of enteric contents or urine into the peritoneal cavity. It may also occur as a result of perforation of some other viscus, unrelated to the transplant (e.g., perforated gastric ulcer, perforated cecum). Generalized peritonitis is diagnosed clinically; the physical exam is the most helpful tool. Such patients appear ill, with tachycardia, elevated temperature, falling blood pressure, and diffuse tenderness with guarding on palpation of the abdomen. A plain film or CT of the abdomen is not usually necessary, but may demonstrate free air. Treatment involves prompt return of the recipient to the operating room to determine the reason for the peritonitis and will often depend on the degree of contamination. If a duodenal leak is identified and the spillage is of brief duration and localized, then a primary repair of the duodenal stump or anastomosis, followed by copious lavage of the abdomen, often has a good chance for success. However, if significant inflammation and contamination is noted in and around the pancreas, the graft should probably be removed, to adequately deal with the inciting process. Again, depending on the degree of contamination, the recipient may need to return to the operating room on several occasions, so that the abdomen can be adequately "washed-out."

Fortunately, most intra-abdominal infections do not fall into the generalized peritonitis category. Instead, most of them consist of localized fluid collections in and around the pancreas graft. Presentation is usually systemic, with symptoms such as fever, nausea, vomiting, or abdominal distention, with localized pain and guarding over the region of the fluid collection. A CT scan with contrast is the best diagnostic tool in this clinical situation.

About half of these localized abscesses are monomicrobial; common isolates include *Enterococcus*, *Escherichia coli*, *Klebsiella*, and *Pseudomonas* [45]. The others tend to be polymicrobial, containing two or more bacteria or both bacterial and fungal species. The most common fungal species isolated was *Candida albicans*, but recently *Candida kruzei* and *Candida glabrata* have been increasing in incidence (likely related to the widespread use of agents such as fluconazole for prophylaxis). One benefit of routine prophylaxis has been that the incidence of intra-abdominal infections with fungal pathogens has significantly decreased [36].

Treatment of localized intra-abdominal infections involves adequate drainage and appropriate antimicrobial or antifungal coverage. These infections can often be drained percutaneously under radiologic guidance, at least as a good initial approach. But if the infected fluid is not adequately drained or if the recipient does not improve clinically, a laparotomy should be performed to achieve adequate drainage of all infected fluid. The rate of early laparotomy for first time pancreas transplantation has been reported be close to 30 % in pancreas transplant recipients [46]. If the pancreas graft is obviously involved with the infection or appears tenuous with areas of necrosis, a graft pancreatectomy should be performed. Or, if despite adequate drainage of infected fluid, the recipient continues to deteriorate, then the graft should be removed (in case there is infection within the graft itself).

Intra-abdominal infections, especially those that are fungal in origin, can sometimes lead to uncommon complications, such as mycotic pseudoaneurysms of the iliac artery [47]. Usually, such pseudoaneurysms are at the site of the anastomosis of the "Y-graft" to the recipient iliac artery, but other locations are possible. These pseudoaneurysms may rupture into the abdominal cavity, causing hypotension, abdominal pain, and distention. Or, they may rupture into the pancreas graft, bladder, or small bowel, causing massive hematuria or gastrointestinal bleeding. Treatment in the case of rupture requires emergency laparotomy, and usually, removal of the graft and reconstruction of the artery. Usually, this reconstruction requires use of autogenous tissue such as saphenous vein because of the underlying infection.

The development of intra-abdominal infections after a pancreas transplant has a significant detrimental impact on patient and graft survival. Adequate treatment of these infections requires graft removal in 50–60 % of recipients—even more if the infections are polymicrobial with fungus present [45]. In one series of 213 pancreas recipients, graft survival at 1-year posttransplant was 82 % in those without an intra-abdominal infection vs. 60 % in those with ($P=0.01$) [12]. The mortality rate associated with intra-abdominal infections ranges from 6 to 20 % [45]. Again, higher mortality rates are associated with polymicrobial and fungal infections.

13.6 Duodenal Leaks

Leaking from the donor duodenum may occur either at the site of anastomosis (to the bladder or bowel) or at the duodenal stumps. A leak results in spillage of pancreatic enzymes as well as either enteric contents (with ED) or urine (with BD). In either case, there is spillage of contaminated contents, resulting in either a localized or a generalized intra-abdominal infection.

The reported incidence of duodenal leaks is between 5 and 15 % [48, 49] and has not changed appreciably in the last 10–15 years [41]. Most leaks occur early posttransplant, usually in the first few weeks. Excluding a technical problem with the anastomosis or with the closure of the duodenal stumps, most leaks probably occur as a result of ischemia of the duodenum. Disruption of the blood supply to the duodenum, especially at its ends, may occur during the back-table preparation of the graft. Prolonged cold ischemia with subsequent ischemic reperfusion injury of the duodenum is a definite risk factor for a subsequent leak. In one analysis of 294 pancreas recipients, duodenal leaks developed in 23 (7.8 %) [25]. If cold ischemia time was <15 h, the incidence of leaks

was 1.4 %. But if cold ischemia was 15–20 h, the incidence increased to 5.8 %; 20–25 h, 14.1 %; and >25 h, 16.7 %.

Other risk factors for duodenal leaks include impaired wound healing caused by immunosuppressive therapy, most notably high-dose steroids or the newer immunosuppressive agents [50]. Other predisposing factors include bladder dysfunction with poor emptying, leading to high pressure within the bladder and to stress on the anastomosis of the BD graft [51].

Duodenal leaks may also occur late posttransplant. In contrast to early leaks, late leaks are usually not due to technical causes, but rather due to ischemia or infection. CMV infections leading to duodenal ulcers and perforation have been described [41, 50].

Clinical presentation will vary, depending on whether BD or ED was used. With ED, a leak usually presents with generalized peritonitis as enteric contents spill into the peritoneal cavity. With BD, symptoms are generally less severe; usually there is pain, often associated with elevated serum amylase level (both of which improve with placement of a Foley catheter).

Diagnosis is based on the clinical presentation and radiologic imaging. With ED grafts, a leak can be difficult to diagnose with current imaging techniques. A CT scan may show some free air and fluid in the peritoneal cavity, but these findings are not diagnostic. With BD grafts, however, a CT cystogram or a fluoroscopic cystogram are sensitive and specific.

Treatment of duodenal leaks may be either surgical or medical. With ED grafts, all such leaks require operative repair. If there is significant contamination and infection around the pancreas graft, a graft pancreatectomy should be performed. With BD grafts, leaks (especially small ones) may often be managed conservatively. A Foley catheter is inserted to decompress the bladder and left in place until imaging studies demonstrate no further leak. If catheter placement is not successful, or if the recipient is unwell clinically, then operative repair is necessary. It may involve either direct repair of the leak site with some form of patch (most commonly omentum) or conversion to ED. About 20 % of duodenal leaks with BD grafts require operative repair [50].

13.7 Recurrent Urinary Tract Infections

UTIs are very common after a pancreas transplant, especially with BD grafts. Common organisms include *Enterococcus*, *Candida*, and *Pseudomonas*. Several factors may predispose the recipient to recurrent UTIs. The defense mechanism of the bladder may be altered by pancreatic secretions, leading to an increased chance for infections. Other risk factors include a diabetic neuropathic bladder with incomplete emptying, alkalization of the urine from bicarbonate in pancreatic secretions, presence of a Foley catheter, and contamination from the transplanted duodenum. Lastly, foreign bodies in the bladder, in the form of staples or sutures at the anastomosis, may serve as a nidus for infection [52].

The incidence of recurrent UTIs in pancreas recipients ranges from 10 to 40 % [8, 53, 54]. The vast majority of these infections will respond to appropriate antibiotic therapy. If the infection is recurrent or if it does not respond to therapy, then cystoscopy should be performed. If foreign bodies, such as staples, are identified that may be serving as a nidus for infection, they should be removed. If UTIs still persist, the graft should be converted into ED.

13.7.1 Wound Infections

Infections involving the surgical wound are much more common after a pancreas transplant as compared with a kidney transplant alone. Most involve the layers of the abdominal wall superficial to the fascia. Sometimes, however, the fascia and muscle layers can be involved with a devastating, necrotizing type of infection. The reported incidence of wound infections is 7–35 % [8, 48, 55]. They may occur in isolation, but a significant number of them are associated with deep, intra-abdominal infections. In one series of pancreas recipients, 38 (18 %) had wound infections. Of these 38 recipients, 21 (10 %) had isolated involvement of the superficial wound and 17 (8 %) had a coexisting intra-abdominal infection [48].

Several factors account for the higher incidence of wound infections after a pancreas transplant. Most prominent is the fact that the donor duodenum is a contaminated hollow viscera; spillage from it while the anastomosis is being done can contaminate the surgical wound. With ED, enteric contents can spill onto the wound.

The typical pancreas transplant recipients' long-standing history of diabetes also plays a role; the general surgery literature shows diabetes to be a risk factor for wound infections [56]. Compared to kidney transplant recipients, these patients undergo a longer operative procedure, which is another risk factor. The even longer operative procedure that SPK (vs. PTA or PAK) recipients undergo is also associated with a higher wound infection rate [4]. Another significant risk factor for wound infections in pancreas recipients is obesity [43].

The pattern of microbial agents found in wound infections depends on the existence of any underlying intra-abdominal infection. An isolated wound infection is usually monomicrobial, with Gram-positive bacteria being most commonly involved. But with an underlying intra-abdominal infection, more than 50 % of such wound infections are polymicrobial and may involve fungi (most commonly *Candida* species).

Local signs and symptoms include wound pain, erythema, and drainage from the wound. Treatment consists of opening the wound, regularly changing dressing, and packing the wound. Antibiotics are used if there are systemic signs of infection or significant cellulitis around the opened wound.

A CT scan of the abdomen should be done to rule out an underlying intra-abdominal infection, especially in the presence of systemic symptoms.

13.8 Prophylaxis

Infection rates remain high after pancreas transplants [8] but they have decreased significantly in the last decade. One reason is the use of better prophylaxis. Most centers now use some form of routine antibacterial, antiviral, and antifungal prophylaxis for all pancreas recipients.

The main purpose of antibacterial prophylaxis is to diminish the likelihood of wound infections. Generally, a wide spectrum antibiotic is used to target the Gram-positive and Gram-negative organisms that may contaminate the wound at the time of surgery. Many centers also routinely use antifungal prophylaxis in all pancreas recipients. A typical regimen consists of copiously irrigating the abdominal cavity with amphotericin B solution, followed by 1 week of oral fluconazole immediately after surgery. The incidence of fungal intra-abdominal infections has decreased significantly with use of routine prophylaxis [36]. Given the generally poor outcomes with fungal intra-abdominal infections, some form of antifungal prophylaxis is warranted.

Other preventative regimens include ganciclovir for CMV prophylaxis (for 3–6 months posttransplant, or for 6 weeks after bolus antirejection treatment) and trimethoprim/sulfamethoxazole for *Pneumocystis* prophylaxis.

13.9 Cytomegalovirus Infections

13.9.1 Epidemiology

Pancreas recipients are generally considered to be at high risk for CMV infection and disease. In addition to the standard risk factors such as pretransplant CMV serostatus (the highest risk being donor positive and recipient negative or D+/R− [57, 58]) several factors are more specific to pancreas transplants. The result may be higher rates of CMV infection and disease compared to some other solid organ recipients. Pancreas recipients often require higher levels of immunosuppression than do other solid organ recipients. They may also have an increased incidence of acute rejection, which requires more aggressive immunosuppressive therapy—specifically antilymphocyte products, known to be a major risk factor for CMV [57, 58]. Also, the amount of lymphoid tissue within the pancreatico-duodenal graft is quite high, probably serving as a source of donor-acquired latent CMV and resulting in a high viral inoculum into the recipient. Finally, many studies have reported a high rate of baseline recipient CMV seronegativity in pancreas recipients [59–62], which increases the number of CMV-mismatched (D+/R−) recipients.

In the absence of specific CMV prophylaxis, the rate of CMV disease is quite high. In one study of 34 pancreas recipients on quadruple immunosuppression with antilymphocyte therapy induction but no CMV-specific prophylaxis, 71 % of them developed CMV infection [59]. Of the total of 34 pancreas recipients in the study, 17 (50 %) developed symptomatic CMV disease, at a mean of 43 days (range, 15–63 days). Symptomatic CMV disease was most common in the CMV D+/R− group [59]. It was also frequent in the lower risk D+/R− and D+/R− groups and may also occur in D−/R− patients who receive unscreened or unfiltered blood products. As in other solid organ recipients, CMV disease may present in pancreas recipients as a viral syndrome or as tissue-invasive disease. Tissue-invasive disease is relatively common (although likely lower in the current era of prophylaxis, and early treatment) and may include hepatitis, pneumonitis, and gastrointestinal disease; it may also involve the pancreas graft, resulting in CMV pancreatitis, although the latter is relatively infrequent compared to other forms of tissue-invasive disease such as colitis [59, 62–64]. Disease rates in pancreas recipients on specific CMV prophylaxis are lower, and disease tends to occur later in the posttransplant period. Moreover, reported disease rates and presentations may differ from center to center, depending on immunosuppressive regimens and on the type and duration of CMV prophylaxis.

13.9.2 CMV Prevention

Given the high rates of CMV infection and disease in pancreas recipients, most centers use some form of universal antiviral prophylaxis. Generally, prophylaxis is given to all “at-risk” patients (donor or recipient CMV seropositive). Randomized controlled trials of CMV prophylaxis in pancreas recipients are scarce, and most studies are retrospective, single-center reviews or are trials involving predominantly kidney transplant recipients with a small number of pancreas transplant patients included.

A number of agents are available for CMV prophylaxis but oral valganciclovir is likely the best option in these patients primarily based on data from large randomized trials in other groups of organ transplant recipients. In a large international trial comparing 3 months of valganciclovir prophylaxis vs. oral ganciclovir prophylaxis for D+/R− patients, both regimens had similar efficacy [65]. However, only a small number of pancreas transplant recipients were included in this trial. Nonetheless, these results have been supported by smaller nonrandomized trials. Oral ganciclovir is currently no longer available in many jurisdictions. Prior to ganciclovir, acyclovir-based prophylaxis was commonly used. However, the use of acyclovir as CMV prophylaxis is no longer recommended [57].

The major problem with prophylaxis in pancreas transplant recipients appears to be the high incidence of late-onset

CMV disease [66]. That is, CMV disease occurs after the discontinuation of prophylaxis and early diagnosis may be missed if patients are no longer followed as closely by their primary transplant program. Fallatah et al. reviewed 130 pancreas transplant recipients who received antiviral prophylaxis [67]. Despite prophylaxis the incidence of CMV infection or disease was 24 % and was especially high in the D+/R− cohort (44 %). The median duration of prophylaxis was 104 days CMV infection/disease occurred a median of 34 days following discontinuation of prophylaxis. In a review of 252 pancreas transplant recipients (the majority of whom received antiviral prophylaxis) by Parsaik et al. [62], the cumulative incidence of CMV infection/disease was 15 % at 1 year and again was significantly higher in the D+/R− group. The majority of infections occurred within 1 year of transplant although late infections were not infrequent. The risk of late CMV disease appears to be higher as compared with kidney recipients and liver recipients on similar prophylactic regimens. In one study of 240 solid organ recipients given 3 months of oral ganciclovir, late CMV disease occurred in significantly more D+/R− SPK recipients (42 %) as compared with D+/R− kidney recipients (10 %) and D+/R− liver recipients (7 %) [68].

The occurrence of late-onset CMV disease has led many centers to prolong antiviral prophylaxis beyond the standard 3 months, especially in D+/R− patients [69]. In a study of 326 D+/R− kidney transplant recipients, patients were randomized to receive either 200 days vs. 100 days of valganciclovir prophylaxis [69]. The incidence of symptomatic CMV disease by 12 months posttransplant was 16.1 % vs. 36.8 % in the two arms, respectively (p =<0.0001). Although this trial did not include pancreas transplant recipients, a reasonable strategy in D+/R− pancreas transplant recipients would be to prolong prophylaxis to 6 months. Another approach to prevention is preemptive therapy. In uncontrolled trials, preemptive antiviral therapy (generally with oral valganciclovir or intravenous ganciclovir) in recipients given antilymphocyte therapy appears to be of some benefit [70, 71]. More commonly, preemptive therapy refers to s virologic monitoring (e.g., by PCR) with subsequent preemptive antiviral therapy [72, 73]. This approach has its advantages and disadvantages compared to prophylaxis but has not been well studied in pancreas transplant recipients. Commonly many centers will use a hybrid approach in which frequent virologic monitoring is performed following a period of prophylaxis [57]. Again, the benefit of such a strategy has not been well evaluated in pancreas transplant recipients.

In summary, CMV prophylaxis is generally recommended for all pancreas recipients at risk for CMV disease. Oral valganciclovir for 3–6 months is a reasonable strategy, with the 6-month duration likely preferable in those who are D+/R− or who have recurrent rejection or high intensity of immunosuppression.

13.9.3 Management

Treatment of active CMV disease in pancreas and other solid organ transplant recipients is similar. Initial therapy is generally started with either intravenous ganciclovir or oral valganciclovir. In a randomized trial comparing 3 weeks of intravenous therapy to oral valganciclovir in 321 patients, both regimens had similar rates of viral clearance [63]. In patients who are very ill, or in whom gastrointestinal absorption may be impaired, initial intravenous therapy is preferred. The duration of initial therapy is usually 2–4 weeks, but it should be based, in part, on clinical and virologic responses. Pancreas recipients may have a very high rate of CMV disease recurrence. In one study of 332 cases of CMV disease in kidney and SPK recipients, CMV disease recurred after an initial course of treatment in 31 % of them (all were initially treated with 2 weeks of intravenous ganciclovir, followed by 10 weeks of oral acyclovir) [74]. However, the recurrence rate was significantly higher in SPK recipients (39.8 %) than in kidney recipients (20.5 %). According to a multivariate analysis, this increased rate of recurrence was primarily attributed to increased treatment of acute rejection episodes.

Based on the high risk of recurrence, a reasonable strategy is to give secondary prophylaxis with oral valganciclovir, after initial treatment therapy, especially in recipients with recent or recurrent episodes of acute rejection. With the widespread use of prophylaxis, ganciclovir resistance may be a problem in SPK recipients. Oral ganciclovir, in particular, has a low bioavailability (6–9 %) and therefore may promote ganciclovir resistance in heavily immunosuppressed patients. In one review of 240 liver, kidney, and pancreas recipients, all on 100 days of oral ganciclovir prophylaxis for CMV, ganciclovir-resistant CMV disease was observed in 5 (7 %) of 67 CMV D+/R− recipients [68]. Of these five recipients, four were pancreas recipients. Thus, the rate of ganciclovir resistance in D+/R− pancreas recipients with CMV disease in that study was 21 % (4 of 19) and was attributed to high levels of immunosuppression. The use of high than normal doses of intravenous ganciclovir or foscarnet may be required to treat ganciclovir-resistant CMV disease. The ongoing development of investigational anti-CMV compounds including brincidofovir, and letermovir, may ultimately prove useful in this setting [75, 76].

13.10 Epstein–Barr Virus and Posttransplant Lymphoproliferative Disease

EBV is associated with most cases of PTLD [77, 78]. The epidemiology of PTLD may vary from center to center, again depending on immunosuppressive regimens and other factors.

The largest single center study to date on pancreas recipients and PTLD retrospectively reviewed a single center experience in 787 pancreas and 569 kidney–pancreas recipients [79]. The 5-year cumulative incidence of PTLD ranged from 1.0 to 2.5 % with a trend towards increased rates in more recent times. PTLD tended to be more aggressive in pancreas recipients compared with liver or kidney recipients, with multiple sites involved at the time of presentation. A significant number of patients were noted to have T-cell lesions.

A recent study evaluated the UNOS database of pancreas transplants to identify factors that predicted PTLD [80]. In a total of 4205 pancreas transplants, the incidence of PTLD was 1.0 % (43 patients). In a multivariate analysis, recipient EBV seronegativity, and use of an immunosuppression regimen that did not include tacrolimus were among the risk factors associated with the development of PTLD.

An additional risk factor for PTLD is the intensity of immunosuppression, particularly the use of antilymphocyte products [77]. In an analysis of French registry data [81] which gathered data on the 10 year cumulative incidence of PTLD in kidney transplant recipients, SPK recipients had a higher likelihood of developing PTLD (adjusted hazard ratio 2.52). Induction therapy, and EBV mismatch were also identified as risk factors. Meador et al. [82] reviewed their cases of PTLD in pancreas recipients over a 6-year period. Of 337 pancreas recipients, 8 (2.4 %) developed PTLD, including 5 (2.8 %) of 179 SPK recipients, 1 (0.9 %) of 106 PAK recipients, and 2 (3.8 %) of 52 PTA recipients. PTLD occurred a mean of 137 days posttransplant (range, 34–348 days). PTLD involved the pancreas graft alone in three recipients, the graft and extra graft tissue in three, and extra graft tissue alone in two. Histologically, the tumors ranged from polyclonal B-cell hyperplasia to B-cell lymphoma. On ultrasound and CT imaging, five of the eight recipients had a diffusely enlarged pancreas graft, a finding that may be radiographically indistinguishable from acute rejection or pancreatitis.

In a study of 52 cases of PTLD in pancreas recipients that included data from the Israel Penn International Transplant Tumor Registry, the mean time to diagnosis was 18.9 months (range, 0.9–91 months). Sites involved were the lymph nodes alone (15.3 %), the lymph nodes plus other sites (38.4 %), the pancreas or kidney graft (27 %), the central nervous system (19 %), the liver (19 %), the gastrointestinal tract (17 %), and the spleen (11.5 %). The overall mortality was 61 %; those with central nervous system disease had a worse survival [83].

The available data on PTLD in pancreas recipients can be summarized as follows: The incidence of PTLD in most settings is likely in the range of 1–2.5 %. Most early cases are EBV-related B-cell PTLD. The most important risk factor likely relates to the EBV D+/R− transplant in which primary infection occurs in the absence of preexisting host immunity. The intensity of immunosuppression, and specifically the use of antilymphocyte products, is a major risk factor for the development of PTLD (as in other solid organ recipients). The broad pathologic and clinical spectrum of PTLD is similar to that seen in other solid organ recipients. However, PTLD commonly involves the pancreas graft, where it may result in a diffuse infiltrative pattern or in focal masses. Uncontrolled studies suggest that the use of antiviral prophylaxis may have some beneficial effect for prevention of PTLD in pancreas recipients [84]. A case–control study has also suggested that ganciclovir, more than acyclovir, may be beneficial for prevention of PTLD [85]. Also, because antiviral therapy may lead to a reduction in CMV infection (an independent risk factor for PTLD) it may indirectly have a beneficial effect on EBV and PTLD [86]. A potential approach is to measure EBV viral loads in high-risk patients (EBV D+/R−), with subsequent reductions in immunosuppression in patients with high or rising viral loads [78]. This strategy has not been well studied in pancreas transplant recipients. Once PTLD has occurred, treatment strategies, as with other solid organ groups, include reduced immunosuppression, antiviral therapy, rituximab, or chemotherapy, but mortality rate remains relatively high [78].

13.11 Other Infections

Given their high levels of immunosuppression, pancreas recipients are at risk for infections caused by numerous other opportunistic and nonopportunistic pathogens, including other herpesviruses, community-acquired pneumonia organisms, and environmental fungi [60, 87, 88]. Infections may occur because of environmental exposure or reactivation of endogenous latent organisms. The timeline is similar to that observed in other solid organ transplant recipients [88] although epidemiologic studies are lacking.

In the last decade, polyomavirus nephropathy or BK virus nephropathy (BKVAN) has been recognized as an important problem in kidney recipients. Large epidemiologic studies of polyomavirus infection of the kidney graft in SPK or PAK recipients are few in number and are generally retrospective. In a review of 146 SPK recipients, Lipshutz et al. [89] identified nine patients with BKVAN (calculated incidence 6.2 %), an average of 359 days posttransplant. In this cohort, BKVAN was the leading cause of renal graft loss in the first 2 years posttransplant. However, in another report, the incidence of BKVAN in 243 SPK recipients was 2.9 % with only three patients ultimately losing the kidney graft [90]. Pancreas graft involvement with polyomavirus has not been described. Interestingly, in one PTA recipient, polyomavirus nephropathy and kidney dysfunction in the native kidneys has been reported [91]. Current guidelines [92] for the prevention of BK nephropathy in kidney transplant patients should be followed for SPK patients and possibly for PAK patients who receive an augmentation in immunosuppression at the time of their pancreas transplant. This generally includes regular monitoring of plasma BK viral and reduction in immunosuppression in patients with high or rising viral loads.

Risks and Epidemiology of Infections After Liver Transplantation

Roberto Patron, Shimon Kusne, and David Mulligan

Liver transplantation is now a widely accepted mode of therapy for patients with end-stage liver disease. Despite the improvement in surgical techniques, reduction in operative times, prolonged graft and patient survival, and progress in therapeutic treatment options over the last few decades, the rate of major infectious complications remains high in this population. Kusne et al. [1] and Paya et al. [2] reported rates of major infections of 67 % and 54 %, respectively, in their two series from two decades ago. More recent studies [3–5] did not show much improvement in the rate of infectious complications; the infection rate in liver transplantation is substantially higher than that of renal and heart transplant recipients [6] but lower than that of lung and small bowel transplant recipients [7, 8]. The main determinants of infection risk in this population include the mechanical aspects of the surgery itself, a myriad of host and donor factors [9], and the effects of the immunosuppression.

14.1 Infections Related to Mechanical Complications of Surgery

14.1.1 Early Postsurgical Infections

Liver transplantation is associated with a high rate of postsurgical infectious complications due to the technical complexity of the surgery and the frequent moribund state in which many of the recipients undergo the operation. Although the improved surgical techniques have resulted in shorter operative times, less blood product transfusions, reduced use of veno-venous bypass, and fewer biliary stents/T-tubes, the age and quality of the donors currently available for transplantation are much less favorable than the young trauma victims used most commonly previously [10]. The infections within the first month of transplant are largely due to bacterial and fungal pathogens. Although liver transplant recipients suffer from routine postoperative complications, such as pneumonia, urinary tract infections, and line sepsis, the most common sites of infection by far are intra-abdominal and the surgical wound [1, 11]. In a study by George et al. [11], one third of bacterial infections occurred in the first week after transplantation and more than one half within the first 2 weeks. The incidence of bacteremia ranges between 21 and 33 % [1, 2, 6]. The culprit organisms are usually enteric flora, including *Enterococcus* species and gram-negative *Enterobacteriaceae*, along with *Staphylococcus aureus* and coagulase-negative *Staphylococcus* [3, 12]. The rate of infection with antibiotic-resistant pathogens, such as vancomycin-resistant enterococcus (VRE) and methicillin-resistant *S. aureus* (MRSA), is high, as liver transplant candidates are often "antibiotic-experienced" with a history of frequent hospitalizations. A lengthy posttransplant intensive care unit (ICU) stay and spillage from the gastrointestinal (GI) tract at the time of biliary anastomosis exacerbate this problem.

Invasive fungal infections (IFIs) also occur most frequently in the first few weeks after surgery. The incidence of IFI after liver transplantation ranges from 5 to 42 % in various studies [1, 2, 12–16], with the case fatality ranging from 25 to 69 %. *Candida* species are the most frequent organism involved, followed by *Aspergillus* species. Abdominal wound infection by *Candida* is often a part of polymicrobial sepsis by enteric bacterial pathogens. Pathogenesis of abdominal IFI starts with the colonization of the GI tract with yeast, with the subsequent breach in mucosal integrity due to surgery, leading to contamination and the infection of the peritoneum. The presence of indwelling urinary and intravascular catheters facilitates the direct invasion of fungal organisms into the bloodstream.

The most consistently identified risk factors in the early posttransplantation period are the duration of surgery and retransplantation [1, 3, 11]. Figure 14-1 shows that the frequency of severe infection has an almost linear correlation with the total time spent in the operating room. Lengthy surgery presumably reflects technical difficulties and an attendant increase in stress from blood loss, hypothermia, tissue hypoperfusion, and prolonged exposure to microbiologic contaminants, whereas the tissue concentration of prophylactic antibiotic falls. The intraoperative transfusion requirement is closely related to infectious complications [3, 11–14, 17]. This is undoubtedly related to the duration and complexity of surgery and, more specifically, to the amount of

P. Ljungman et al. (eds.), *Transplant Infections*, DOI 10.1007/978-3-319-28797-3_14

intraoperative bleeding, which leads to tissue hypoxia and the formation of hematomas vulnerable to microbial seeding. Blood in the peritoneum also have an inhibitory effect on leukocytes [18]. There have also been studies showing that allogeneic blood transfusion causes downregulation of surveillance mechanisms of the immunity leading to tolerance and more infectious complications, which is not the case with autologous blood transfusion [19]. In addition to the length of surgery, the degree of early graft function can impact intraoperative blood loss, hemodynamic stability, and metabolic state (i.e., acidosis) in the recipient. Bacterial and fungal infections can be transmitted from the donor, both in the tissue and bile ducts/gallbladder. The presence of significant donor steatosis, advanced age, complications during organ procurement, and prolonged total ischemia time can exacerbate early graft function and set the stage for increased early posttransplant infection. In the past, the use of veno-venous bypass was common in an effort to stabilize the hemodynamic profile of the recipient during engraftment and as a tool to allow for additional time as needed to train surgical fellows in the techniques of the vascular anastomoses. Currently, due to the higher risks seen in our older and less high-quality donors, the additional time necessary to place a patient on bypass has essentially replaced its use to only very select cases. The surgical techniques most commonly used at present employ the "piggyback" technique that allows the retrohepatic inferior vena cava (IVC) to be left in place in the recipient (Figure 14-2). Instead, the right, middle, and left hepatic veins are combined into a single outflow tract or orifice upon which is attached the suprahepatic IVC from the donor liver graft, thus preventing the additional operating time, the hemodynamic instability of clamping the recipient IVC, and reducing the total number of vascular anastomoses to three rather than four. Unless the recipient has an anatomically abnormal distal common bile duct, current practice is to perform a duct-to-duct anastomosis. This reduces operative time, violation of the enteric system with inherent contamination, and additional enteric anastomoses that can contribute to increased postoperative ileus. Most transplant centers have abandoned the use of T-tubes (Figure 14-3), as their assessment of the quality of the bile produced early after transplant has greatly been replaced by other imaging and laboratory tools, thus reducing the 25 % incidence of leaks associated with these tubes and foreign body colonization of bacteria and fungi.

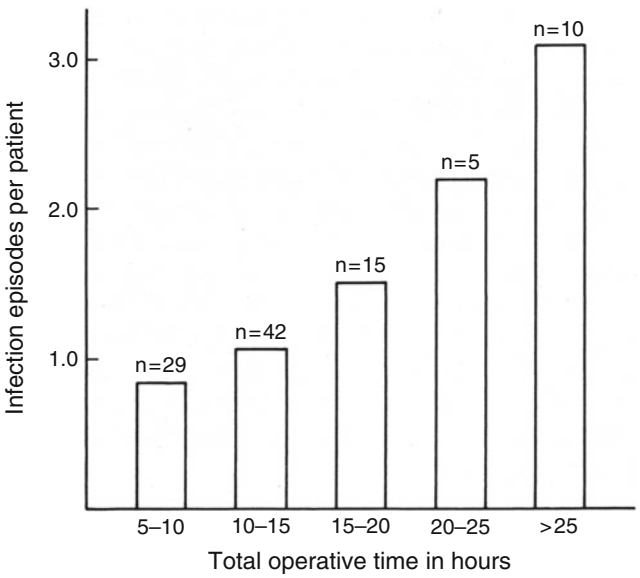

FIGURE 14-1. Frequency of severe infections in relation to the total operative time per patient in hours (Reproduced from Kusne S, Dummer JS, Singh N, et al. Infections after liver transplantation: an analysis of 101 consecutive cases. Medicine (Baltimore). 1988;67:132–143, with permission).

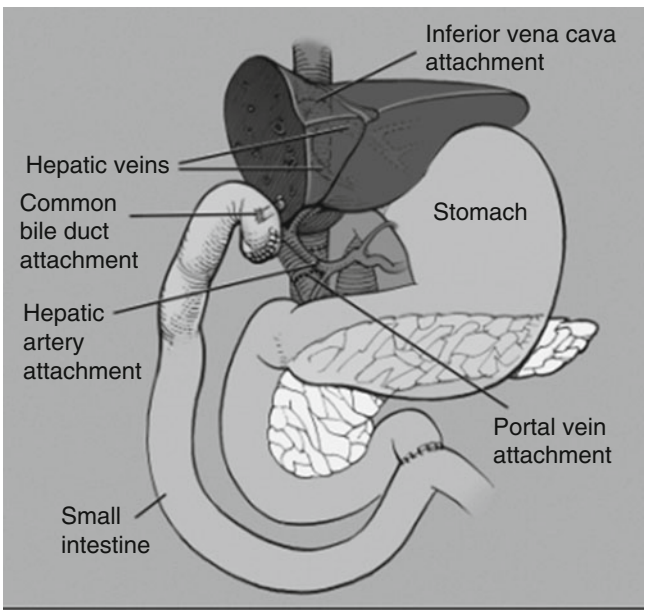

FIGURE 14-2. Living donor liver transplantation with piggyback caval technique allows recipient IVC to remain open and decreases abdominal vascular congestion, minimizing bacterial translocation from the gut. The recipient hepatic veins are clamped, leaving the IVC open, and a common orifice is created joining all three hepatic veins for anastomosis to the donor IVC. In this figure, only the hepatic vein was used to create the piggyback anastomosis (Reproduced from Marcos A, Fisher RA, Ham JM, et al. Right lobe living donor liver transplantation. Transplantation. 1999;68(6):798–803, with permission).

14.1.2 Mid-to-Late Postsurgical Infections

The usual options for biliary reconstruction during the transplant surgery are (a) end-to-end or side-to-side choledochocholedochostomy (CC) without a T-tube, (b) CC with a T-tube (Figure 14-3), or (c) Roux-en-Y choledochojejunostomy (CJ) (Figure 14-4). As previously mentioned, most practices currently employ CC without a T-tube unless the recipient has ana-

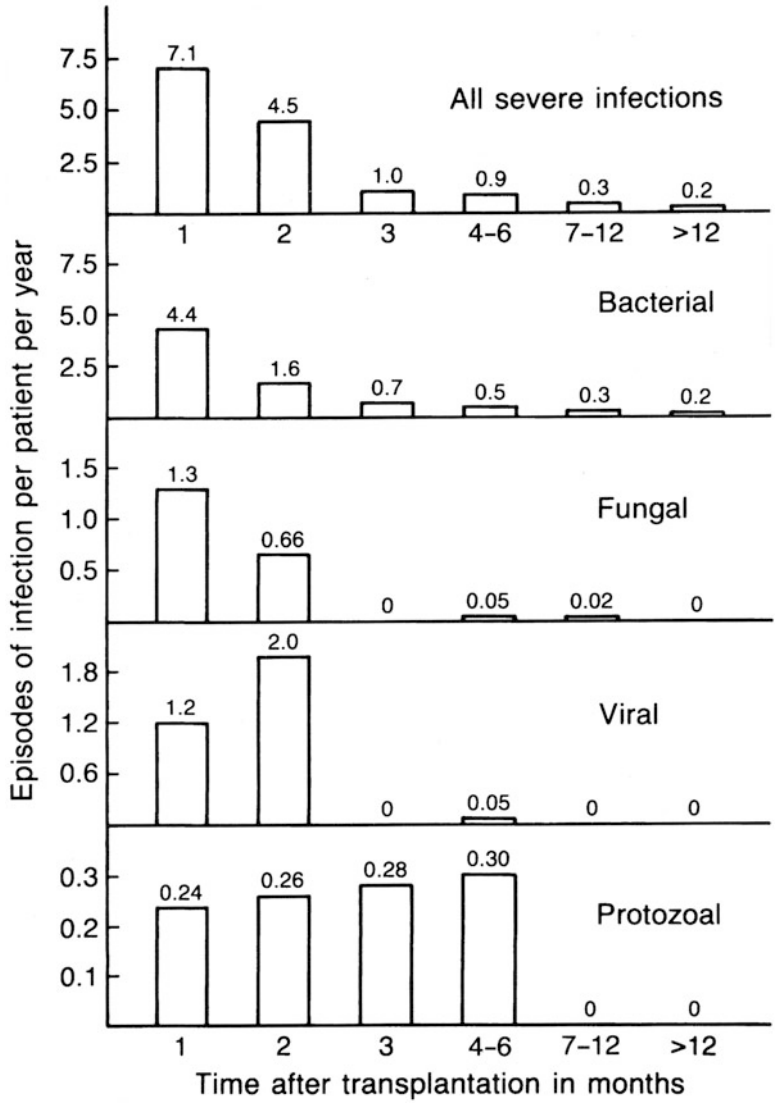

FIGURE 14-3. Classic liver transplant with full retrohepatic IVC and T-tube choledochocholedochostomy. Potential contamination with T-tube removal leading to bile leak (Reproduced from the Mayo Foundation, with permission).

tomically abnormal distal common bile duct, such as in patients with primary sclerosing cholangitis (PSC). In living donor liver transplantation (LDLT), most surgeons employ the use of direct duct-to-duct anastamoses, even in cases of multiple ducts, so that postoperative endoscopic studies may be more easily performed. For pediatric liver transplants and others where suitable recipient anatomy is unfavorable, Roux-en-Y hepaticojejunostomy (HJ) is preferred. Several studies suggest that patients who undergo CJ have a higher rate of early biliary complications, such as biliary stenosis, leaks, and infectious cholangitis, compared with those who undergo CC [1, 20]. Among the patients who have CC, those with T-tube placement have more biliary complications, including infections [21, 22]. On the other hand, the presence of the T-tube may delay the onset of biliary complications until after its removal, which usually occurs 2–3 months after transplantation. At that time, the immune system is not as suppressed as it is during the early postoperative phase [23]. The treatment of cholangitis involves the correction of the structural abnormality, such as strictures and leaks with percutaneous drainage and either percutaneous transhepatic or endoscopic stents, as well as administration of the appropriate antibiotic therapy for responsible organisms.

Hepatic artery thrombosis (HAT) is a major cause of morbidity and graft loss after liver transplantation. The reported incidence of HAT ranges from 1.6 to 20 % [24–26], with the higher incidence in children. According to the experience at the University of Pittsburgh, the overall incidence of HAT is 3.4 % in adults and 11.8 % in children [26]. In patients undergoing LDLT, HAT can occur in up to 20 % due to the greater technical difficulties facing the anastomosis of smaller vessels. HAT can present early (less than 7 days post-op) as arterial ischemia leading to fulminant

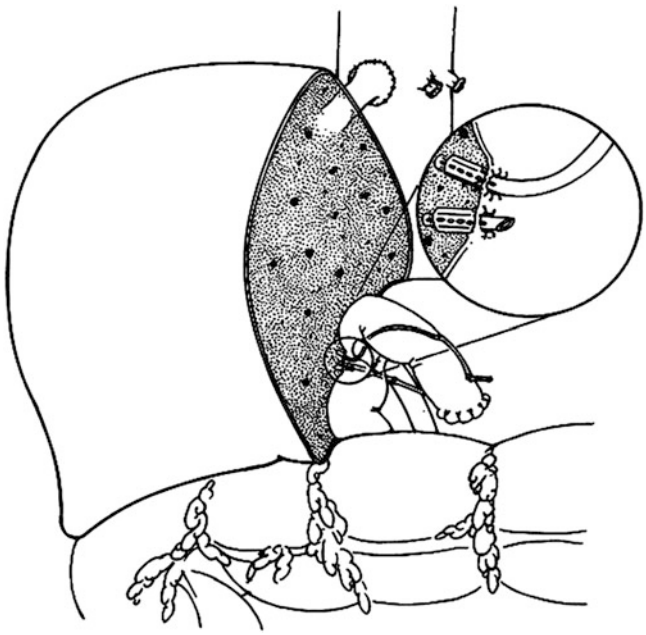

FIGURE 14-4. Living donor liver transplant with Roux-en-Y hepaticojejunostomy (HJ). Large cut surface of liver can lead to bile leaks and potential for intestinal content contamination from HJ leak (Reproduced from the Mayo Foundation, with permission).

hepatic failure. On the other hand, late HAT often presents insidiously, with impaired hepatobiliary perfusion leading to biliary necrosis with leaks, strictures, and, ultimately, allograft failure [6]. HAT is frequently associated with recurrent hepatic abscesses. Despite a combination of medical therapy and drainage of infected collections, the treatment of HAT-related hepatic abscesses is challenging, partly because of the difficulties in eradicating the infection in the absence of proper arterial circulation. Presentation with multiple small abscesses not amenable to drainage is common; in these cases, prolonged empiric antibiotic therapy with broad-spectrum enteric coverage is the therapy by default. According to one study [27], breakthrough bacteremia has been reported in 70 % of patients with HAT-related hepatic abscesses, with polymicrobial sepsis accounting for more than half of these cases. *Enterococcus* species and enteric gram-negative bacteria were the organisms most frequently isolated. Mortality was high in this group (37.5 %) regardless of the therapeutic approach. Revascularization surgery has been used with limited success [26]. In most cases, medical therapy is only a temporary solution until the patient can undergo retransplantation, which is considered the ultimate treatment for HAT and associated hepatic abscesses [24–27].

Liver abscess formation is unique to liver transplant recipients. Out of 2175 recipients of solid organ transplant from Cleveland Clinic Foundation between 1990 and 2000, 12 patients developed liver abscess and all of them were liver recipients [28]. The predisposing factors in eight (67 %) of them were HAT. Other predisposing factors may include hematomas, biliary complications, and, rarely, liver biopsy. Patients who have bacterial colonization of the biliary tree, such as those with biliary stents violating the sphincter of Oddi and recipients reconstructed with Rous-en-Y CC or CJ, are at increased risk for infection associated with liver biopsy and probably should receive prophylactic antibiotic therapy prior to and following the biopsy. Infected collections of bile are called by many authors "infected bilomas."

Infected bilomas or collections of bile inside or outside the liver may present like an intra- or perihepatic abscess and may need drainage and antibiotic treatment. Aggressive treatment of these bilomas, whether infected or not, is usually warranted as their presence in proximity to the hepatic artery frequently causes local inflammation and over time can lead to HAT. When bilomas are associated with HAT, retransplantation is usually needed. Diagnosis is usually made by CT or ultrasound. In one series from University of Wisconsin [29], 44 % of the patients presented with fever, 40 % had abdominal pain, and a third of the patients were asymptomatic; 79 % had liver enzyme abnormalities [29]. In that series the pathogens involved included *Enterococcus* (37 %), coagulase-negative *Staphylococcus* (26 %), *Candida* species (26 %), gram negatives (16 %), and anaerobes (5 %).

14.2 Host Factors of Infection

The underlying disease that caused the liver failure and other comorbid medical conditions contributes to the rate and type of infectious complications after transplantation. The most common causes of liver failure requiring transplantation are infection by hepatitis C virus (HCV) and hepatitis B virus (HBV), alcoholic liver disease, autoimmune hepatitis, PSC, and primary biliary cirrhosis (PBC). Patients with chronic viral hepatitides as the underlying disease are at considerable risk for the development of persistent or recurrent viral hepatitis after transplantation, compared with those with fulminant viral hepatitis [30, 31]; in the latter group, the virus is usually cleared by the immune system at the time of the transplantation. Patients with PSC as the cause for liver failure have the highest postoperative biliary complication rate, including the development of anastomotic stricture, which is associated with a higher rate of bacterial cholangitis and cytomegalovirus (CMV) disease [22]. It is important to remember that these patients are routinely reconstructed with CJ anastomoses, which have higher complication rates. Diabetes mellitus and invasive candidiasis have been associated with an increased rate of bacteremic infection [32, 33]. Patients with iron overload have a higher risk for fatal infections, especially those of fungal etiology [34]. In one series, hepatic iron overload assessed by the amount of stainable iron in the explanted liver was found to have a strong association with posttransplant fungal infections [35]. Transplant recipients with renal insufficiency suffer from infectious complications more frequently [13, 36]. Another study reports that high serum bilirubin at the time of transplantation is associated

with an increased rate of posttransplantation bacterial infection [11]. The hyperbilirubinemia in this setting may be reflective of the severity of the liver disease before transplantation, or it may be an indirect indicator of an undiagnosed infection at the time of transplantation. Subclinical infection before transplantation may manifest after transplantation under augmented immunosuppression. Similarly, a latent infection may reactivate after transplantation and can cause fulminant infection. This phenomenon is particularly important when caring for patients from geographic areas endemic for pathogens capable of reactivation under immunosuppression, such as *Mycobacterium tuberculosis*, endemic mycoses, and parasitic infections (e.g., Chagas disease or strongyloidiasis) [37, 38]. Also, a study by Nierenberg et al. identified pretransplant lymphopenia (<500 cells/mm^3) and CMV as independent predictors of CMV disease and non-CMV invasive infections after liver transplantation [39].

Liver transplant centers have started offering liver transplants to patients with chronic human immunodeficiency virus (HIV) infection. Most of these patients had HCV or, to a lesser degree, HBV infection as their underlying disease. Earlier experience with HIV-positive liver transplant recipients prior to the widespread use of highly active antiretroviral therapy (HAART) had shown that they had poorer outcomes, compared to those of non-HIV-infected individuals [40–42]. After the routine use of HAART, centers started offering liver transplantation to HIV-positive individuals. The largest single-center series of HIV-positive patients came from University of Pittsburgh, reporting 29 transplants performed after 1997 with 1-year survival of 89 % [43]. The indications for liver transplant included HCV (89 %), HBV (7 %), and fulminant liver failure (4 %). A prospective multicenter study was initiated in 2003 by the University of California, San Francisco, funded by the National Institutes of Health. The purpose of the study was to evaluate the safety and efficacy of liver transplantation in HIV-positive individuals [43, 44]. Eligibility for enrollment required CD4 count higher than 100 cells/mm^3 and undetectable viral load.

Most centers do not exclude from transplantation, patients who have opportunistic infections that are well controlled by HAART. Contraindications for transplantations include resistant fungal infections, progressive multifocal leukoencephalopathy (PML), and chronic cryptosporidium infection and visceral Kaposi infection [43, 44]. Consideration of the interaction between HAART and immunosuppressive agents is crucial in the management of these patients, and experience dictates how to best manage these patients. Newer antiretroviral agents, including the integrase inhibitors raltegravir, dolutegravir, and elvitegravir, have no significant interactions with tacrolimus, sirolimus, or mycophenolate, allowing HAART post liver transplantation without the need to alter traditional dosing of immunosuppressive agents. Elvitegravir has a potential interaction with cyclosporine, causing increased elvitegravir exposure. Most notorious is the interaction between protease inhibitors and CyA, tacrolimus, and sirolimus, which causes an increase in the level of these immunosuppressive agents via inhibition of the cytochrome p4503A enzymes. Most centers use steroids, CyA, or tacrolimus and mycophenolate mofetil (MMF) and do not use induction therapy agents like OKT3 and thymoglobulin [43, 44].

Of 109 HIV-infected subjects that received liver transplantation between 1999 and 2010 in a single transplant center, 37 % developed at least one episode of infection, 26 % had an episode of bacteremia, 4.6 % developed CMV infection, and only 3.6 % developed an HIV-related OI. After a median follow-up of 45.7 months, 43 patients (39.4 %) died, but infection-related mortality occurred in 9 (7 %), and in 20 (42.5 %) it was due to HCV recurrence. None of the patients died of an OI [45]. In a comparison of HIV-infected liver transplant recipients with a cohort of matched HIV-noninfected liver transplant recipients, Locke et al. found a 1.68-fold increased risk for death and a 1.70-fold increased risk for graft loss, albeit the risk in HIV-infected, HCV-noninfected recipients was similar to non-HIV-infected recipients in the modern transplant era [46].

14.3 Effect of Immunosuppression

The last decade has shown the emergence of multiple new immunosuppressive agents used in solid organ transplantation (SOT), with some used for induction therapy as lymphocyte depleting agents [47]. Agents used for immunosuppression after transplantation can be generally divided into the following categories: (a) corticosteroids; (b) cytotoxic agents, such as azathioprine and mycophenolate mofetil; (c) calcineurin inhibitors, cyclosporine, and tacrolimus; (d) TOR inhibitors, sirolimus, and everolimus; (e) monoclonal antibodies including murine anti-CD3 monoclonal immunoglobulin OKT3, the anti-CD25 monoclonal antibodies basiliximab and daclizumab, and alemtuzumab a relatively new monoclonal antibody used as a lymphocytic depleting agent for induction and for rejection therapy; and (f) polyclonal antilymphocyte antibodies including rabbit polyclonal antithymocyte gamma globulin (Thymoglobulin) and equine polyclonal antithymocyte gamma globulin (equine antithymocyte globulin [ATG]) [47, 48]. The pretransplantation use of corticosteroids is associated with an increased risk of systemic *Candida* infection in liver transplant recipients [16]. With the current practice of maintaining patients on low-dose corticosteroids, except in the case of acute rejection, steroid-related opportunistic infections are not as common as they used to be when a higher dose was routinely used.

Calcineurin inhibitors are now the mainstay of the immunosuppressive therapy in solid organ transplant recipients. Tacrolimus is a much more potent agent than cyclosporine, and it is associated with fewer rejection episodes and prolonged graft survival. Studies comparing the two agents in liver transplantation show that patients receiving tacrolimus have a tendency to contract fewer infections [3, 49]. This

may be related to the reduced requirement for corticosteroids and antilymphocyte agents in the tacrolimus group. The use of MMF was not found to be associated with increased risk of infection [50]. Sirolimus was introduced to immunosuppressive protocols because of its lack of nephrotoxicity but has been associated with increased rates of infection [51]. Antilymphocyte monoclonal murine antibody OKT3 has been associated with increased CMV infection [52, 53]. Patients who have been treated with OKT3 also have an increased rate of symptomatic herpes simplex virus (HSV) reactivation, *Pneumocystis carinii* infection, and posttransplant lymphoproliferative disease [1, 52, 54]. Current use of OKT3 is rare. Thymoglobulin has been used with increasing popularity by centers wishing to avoid steroids. Alemtuzumab has been found to be associated with increased rate of opportunistic infection when given for treatment of rejection but not when given for induction therapy [55].

14.4 Infecting Microorganisms: Epidemiology, Risk Factors, and Prevention

Many factors influence the incidence of posttransplantation infections, including surgical techniques, the degree of immunosuppression, and donor and recipient factors as already discussed. Whether a patient develops a certain type of infection at a given time is also highly dependent on the time elapsed since transplantation, as Figure 14-5 illustrates. Table 14-1 summarizes risk factors for infections by different classes of pathogens. Table 14-2 lists commonly used prophylactic agents against several important infective agents that affect liver transplant recipients.

14.5 Bacterial Pathogens

Most bacterial infections in liver transplant recipients occur within the first month after transplantation [11]. Table 14-3 shows the breakdown by type of bacterial infections as seen in several studies from the 1980s. Intra-abdominal infection (IAI), including peritonitis, intra-abdominal and hepatic abscess, and cholangitis, was the most common type of infection. Aerobic gram-negative bacilli (e.g., *Escherichia coli*, *Enterobacter*, *Pseudomonas*) were most frequently implicated, followed by *Enterococcus* and *Staphylococcus*. Centers using selective bowel decontamination (SBD) saw significant decreases in gram-negative pathogens but increases in aerobic gram-positive organisms in both adult and pediatric transplant population [2, 56, 57]. Anaerobes other than *Clostridium difficile* were recovered in less than 10% of the infections [11]. Although infections by gram-negative bacilli still confer substantial morbidity and mortality in this population, the worsening antibiotic resistance

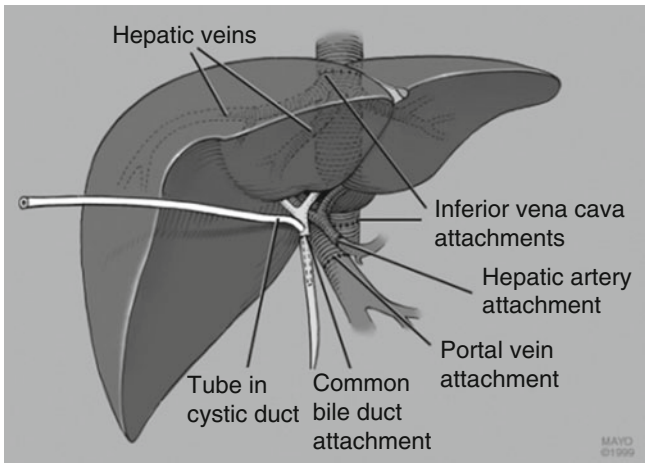

FIGURE 14-5. Incidence in episodes of infections per patient per year and time of occurrence after transplantation when severe infections occurred (Reproduced from Kusne S, Dummer JS, Singh N, et al. Infections after liver transplantation: an analysis of 101 consecutive cases. Medicine (Baltimore). 1988;67:132–143, with permission).

patterns in nosocomial gram-positive pathogens, such as MRSA and VRE, are becoming increasingly problematic.

A recently published meta-analysis by Ziakas et al. [58] reported an 8.5% MRSA pretransplant colonization rate in solid organ transplant, as well as a high VRE colonization rate of 11.9% pretransplant and 16.2% posttransplant. MRSA colonization was associated with a 6–11-fold increase in MRSA infection. A bundled intervention study by Schweizer et al. [59] consisting of *Staphylococcus aureus* preoperative screening, decolonization with mupirocin intranasally, and chlorhexidine daily washes and targeted MRSA preoperative prophylaxis in orthopedic and cardiac surgeries have shown a significant reduction in postoperative infections [59].

MRSA nasal colonization is correlated with the increased MRSA infection in liver transplant units [60–62]. Usage of nasal mupirocin only temporarily eliminated nasal colonization and does not prevent MRSA infection. Strict infection control measures were effective in decreasing significantly both *S. aureus* colonization and infection [63]. Bakir [64] noted a VRE colonization rate as high as 55% among liver transplant recipients, two thirds of whom acquired the organism after transplantation, thus suggesting cross-contamination in the ICU. Singh [65] also reported a high rate of infection by resistant bacteria among liver transplant recipients. MRSA was implicated in 91% of all infections by *Staphylococcus* species, and VRE in 50% of all enterococcal infections. A large proportion of gram-negative infections were from multiresistant *Pseudomonas* species (47%) and *Enterobacteriaceae* (60%) [65]. Invasive infection by VRE, in particular, as a part of IAI or catheter-related bacteremia is commonplace in many liver transplant ICUs. Linden compared in 1996 the outcome of consecutive liver transplant recipients with *Enterococcus faecium* bacteremia resistant

TABLE 14-1. Major risk factors for various infections after liver transplantation

Type of infection	Surgery-related factors	Host-related factors
Bacterial	Prolonged surgical time	Diabetes mellitus
	Retransplantation	Hyperbilirubinemia
	High transfusion volume	Recipient with primary sclerosing cholangitis
	Choledochojejunostomy	Previous granulomatous disease
	Hepatic artery thrombosis	
Viral	Not clearly defined	Use of antilymphocytic antibodies and steroids
		Seropositive donor and seronegative recipient (CMV, EBV)
		Acute fulminant hepatitis as indication for transplant
		Donor positive for hepatitis core antibody (HBV)
Fungal	Prolonged surgical time	Diabetes mellitus
	Retransplantation	Iron overload of recipient
	High transfusion volume	Use of corticosteroids
	Poor function of allograft	Use of antilymphocytic antibodies
		Renal insufficiency
		CMV infection
		Fungal colonization
		Previous endemic fungal infection
		Treatment with multiple antibiotics

Abbreviations: *CMV* cytomegalovirus, *EBV* Epstein-Barr virus, *HBV* hepatitis B virus.

TABLE 14-2. Prophylactic regimen used for various pathogens after liver transplantation

Pathogen	Prophylaxis
Bacterial	
Routine postoperative infection	Perioperative IV antibiotics for GI pathogens for 48 h, selective bowel decontamination with PO polymyxin E and gentamicin in some centers
Streptococcus pneumoniae	Pneumococcal vaccine pretransplant and an additional revaccination after 5 years
Mycobacterial (TB)	Isoniazid for 9 months
Fungal	
Candida	PO nystatin, PO fluconazole, short-course IV liposomal amphoB
Aspergillus	Surveillance cultures and possibly galactomannan antigen
Pneumocystis	TMP/SMX
Protozoan	
Toxoplasma	TMP/SMX, pyrimethamine
Viral	
CMV	IV ganciclovir, oral ganciclovir, oral valganciclovir, CMV IVIG
HSV	PO acyclovir
HBV	HBIG, lamivudine
HCV	No clear recommendation
Influenza	Yearly influenza vaccine and antiviral agents (zanamivir, oseltamivir) in an outbreak setting

and susceptible to vancomycin [66]. VRE bacteremia was associated with refractory infection with serious morbidity and higher mortality [66]. More recent investigation by Pelz [67] has not found differences between vancomycin-sensitive or vancomycin-resistant enterococcal infection in terms of cost of ICU care and mortality [67]. This may be most likely related to the use of agents with anti-VRE activity, such as linezolid and Synercid (quinupristin/dalfopristin) and daptomycin. The emergence of VRE resistant to linezolid has already been reported [68]. Strict enforcement of contact precautions using barrier methods and scrupulous handwashing cannot be overemphasized in this vulnerable population.

While resistant gram-positive bacterial infections dominated the medical literature in the past two decades, both, a resurgence of multidrug-resistant GNR (MDR-GNR) and the scarcity of newer antimicrobials with activity against MDR-GNR, have made the treatment of these infections more complex with poor outcome. A report from Kalpoe et al. [69], in a cohort of 175 consecutive liver transplant recipients from January 2005 to October 2006, illustrates the change. Within

Table 14-3. Rates and locations of bacterial infection after liver transplantation at different centers

Authors (ref.)	Study period	Number of patients evaluated	Patients with major bacterial infection (%)	Perioperative prophylaxis	Total number of bacterial infection	Number of episodes of bacteremia	Number of episodes of infection by type	
							Type	Number
Colonna [64]	1984–1985	35	NR[a]	PO erythromycin, neomycin pre-op., IV ampicillin, and gentamicin post-op. for 5 days	37	11	IAI	10

Abbreviations: *IAI* intra-abdominal infection, including abscess, cholangitis, and peritonitis.
[a]Percentage of all infection (including fungal and viral) was 66%; separate bacterial infection rate not specified.
[b]All bacterial infection, both major and minor; severity of infection not specified.

1 year of liver transplantation (LT), 35% of patients ($n=61$) have developed 91 bacterial infections. Sixty-one episodes (67%) of bacteremia occurred in 34 patients, 45 episodes of peritonitis, and 35 episodes of IAI. Polymicrobial infections were seen in 31% of the episodes. Gram-negative bacteria caused 69% of the episodes. Enterococcus was the most commonly isolated in 43 of the episodes, followed by *Klebsiella* species in 37%. Multidrug-resistant *Klebsiella* (both carbapenem-resistant and carbapenem-susceptible extended spectrum beta-lactamase producer) was the most commonly isolated strains of *Klebsiella* species representing 28/34 isolates (82%). One-year survival was lower in patients with a bacterial infection (67% vs. 90%). Seventy-one percent of the 14 patients with CrKp infections died a median of 15.5 days from infection diagnosis [69]. Treatment of CrKp infections is not standardized yet, and only few antibiotics retain activity. Options include monotherapy or combination therapy with tigecycline, colistin-polymyxin B, and ceftazidime-avibactam. Others have used meropenem in combination with tigecycline or colistin.

Multidrug-resistant organisms, named ESKAPE pathogens (*Enterococcus faecium*, *Staphylococcus aureus*, *Klebsiella pneumoniae*, *Acinetobacter baumannii*, *Pseudomonas aeruginosa*, and *Enterobacter* spp.), are becoming more frequently isolated in posttransplant infections. A retrospective review of episodes of bacteremia in solid organ transplant recipients from 2007 to 2012 showed that 19.6% of bacteremias were due to ESKAPE organisms. The median time to bacteremia was shorter that other organisms (59 vs. 331 days). Risk factors included a history of prior transplantation, septic shock, and prior antibiotic treatment. More importantly, 41% of subjects received initial inappropriate antimicrobial treatment, and the case fatality rate was higher (35.2% vs. 14.4% [70]).

Carbapenem-resistant *Klebsiella pneumoniae* (CrKp) has become an increasingly challenging organism to treat. CrKp infections in liver transplant recipients are associated with increased mortality (50% survival at 1 year vs. 93% survival if no *Klebsiella* infection). Predictors of CrKp infection included MELD score at the time of transplantation, the presence of hepatocellular carcinoma, Roux-en-Y choledochojejunostomy, and formation of bile leak [71].

The causative organisms in postoperative bacterial infections usually originate from the patient's endogenous flora. The commensal flora of a transplant recipient frequently changes in the postoperative period, with more extensive colonization with nosocomial pathogens occurring with longer hospital stays after transplantation [72]. Breaches in infection control practices propagate the patient-to-patient spread of such pathogens through contact. Infections from purely exogenous sources, such as *Pseudomonas* species from contaminated bronchoscopes [73] or *Legionella* species from contaminated water supplies [74], have been reported, but these are relatively uncommon. Another major bacterial agent that has been implicated in postoperative infection is *C. difficile*, which has been reported in 3–6% of liver transplant recipients [1, 11]. Prolonged ICU stay and the frequent use of broad-spectrum antibiotics with antian-

aerobic activities, which have long been identified as significant risk factors for *C. difficile*-related diarrhea, are common in this group of patients [75]. Although *C. difficile* colitis is readily treatable, in this population, it may have a fulminant presentation that leads to toxic megacolon, the need for a colectomy, and death. Between 2000 and 2003, a new strain of *C. difficile* with increased virulence and resistance emerged and caused outbreaks in six states in the United States including Georgia, Illinois, Maine, New Jersey, Oregon, and Pennsylvania, leading to increased morbidity and mortality [76]. A large retrospective review from the 2009 Nationwide Inpatient Sample database extracted information on 49,198 cases of SOT. Overall, 2.7 % of cases acquired *Clostridium difficile* infection, with liver transplant recipients having the highest incidence of 3.8 %. *Clostridium difficile* infection in the SOT group was associated with approximately 2.5 times higher in-hospital mortality, 10 days longer hospital stay, and $70,000 in additional charges in patients with SOT [77]. Current treatment options for *Clostridium difficile* include metronidazole, oral vancomycin, and fidaxomicin. Close surveillance of patients at risk, the prompt discontinuation of unnecessary antibiotics, and diligent infection control practices are vital in reducing the rate of infection by *C. difficile*. Overall, the mortality rate directly attributable to bacterial infections in liver transplant recipients ranges from 3.8 to 13.3 % [1–3, 11, 17].

In 2004, a consensus document was published that summarized the surgical infection prevention guidelines regarding bacterial prophylaxis [78]. Antibiotics chosen for prophylaxis are given within 60 min before the first incision and if surgery continues two half-lives after the first dose, a second dose is administered. It is usually not recommended to continue bacterial prophylaxis more than 24 h after the operation [78]. The main goal of prophylaxis is to prevent wound infection by using agents that are active against expected organisms in the operation [78]. The liver transplantation wound is considered clean contaminated unless spillage from the GI tract occurs.

Most liver transplant centers administer routine surgical prophylaxis with broad-spectrum antibiotics for 48 h after the surgery [11]. Some agents include ampicillin and cefotaxime, ceftriaxone, ampicillin and gentamicin, ampicillin and sulbactam, and cefoxitin. These antibiotics are specifically chosen for their efficacy against enteric gram-negative bacilli and *Enterococcus* organisms. Researchers from Mayo Clinic, Rochester [2], had noted a disproportionately low infection rate caused by gram-negative organisms in their series and hypothesized that the routine use of "selective bowel decontamination" targeted against gram-negative organisms in their institution selected for gram-positive pathogens. Several studies have examined the role of SBD in the prevention of infection in liver transplant recipients without reaching conclusive results regarding its benefits [79–83]. The rationale for SBD is to eradicate or to minimize GI colonization by gram-negative pathogens and yeasts. Earlier studies did suggest some benefits in reducing gram-negative infections, particularly pneumonia. However, two recent randomized, controlled trials using oral polymyxin E, gentamicin, and nystatin vs. a placebo [80] and nystatin alone [83] did not show any improvement in overall bacterial or fungal infection. One study showed a trend toward reduced infection in "key sites" (i.e., abdomen, bloodstream, surgical wound, and lungs) when the prophylaxis was given for longer than 3 days before transplantation [80]. The lack of benefits and the concerns regarding the selection of resistant gram-positive pathogens have curtailed the widespread use of SBD in transplant centers.

14.5.1 Fungal Pathogens

Liver transplant recipients encounter fungal infections more often than recipients of other solid organs. The reported incidence of IFI ranges from 4 to 42 %, with a case fatality rate of 24–69 % [1, 2, 12–16]. Most fungal infections occur within the first month of the transplantation [13].

14.5.1.1 Risk Factors

Risk factors for IFI include elevated creatinine levels, prolonged operation time, poor function of the allograft, high transfusion requirement, retransplantation, and CMV infection [1, 13–16, 36, 84–86]. Some studies show an association between IFI and the preoperative use of steroids, the use of multiple antibiotic therapy, and vascular complications [14, 16]. Colonization with *Candida* species was shown to be a significant predictor for invasive candidiasis, although the risk of infection did not rise with an increasing number of sites of colonization [13]. Other risk factors for candidiasis include hyperglycemia that requires insulin and exposure to multiple antibiotics [32]. At least one study [84] showed that prophylactic intravenous (IV) ganciclovir was an independent risk factor for invasive candidiasis. The reason for this finding was unclear; the authors hypothesized that ganciclovir may reduce neutrophil or macrophage function. The need for an intravascular catheter for ganciclovir administration may also have contributed by becoming a portal of entry for *Candida* organisms. Because the number of patients with invasive *Aspergillus* infection is small in most series, finding specific risk factors for this infection is more difficult. In a large series of *Aspergillus* infection in liver transplant recipients, Kusne et al. [36] identified cumulative surgical time, laparotomies excluding those done for transplantation, creatinine level at the time of the diagnosis, and OKT3 monoclonal antibody administration as risk factors for invasive aspergillosis in univariate analysis, but only creatinine level and OKT3 were shown to be independent risk factors in the multivariate analysis. Immunosuppression plays an important role in the risk for cryptococcosis. Use of systemic corticosteroids at the time of the diagnosis has specifically been shown to have an association with an increased rate of cryptococcal infection [85–88].

14.5.2 Candidiasis

The most commonly implicated fungal pathogen is *Candida* species, which account for approximately 80 % of all IFIs [14, 72, 84]. The rate of GI colonization with *Candida* is about 30–60 % in healthy subjects, but it approximates 100 % in liver transplant recipients [89, 90]. A high rate of colonization before transplantation, the subsequent breach of mucosal integrity through surgery, and the frequent postoperative use of broad-spectrum antibiotics in this population all contribute to predisposing these patients to IFIs. Surgical wounds and the abdominal cavity are the most common sites of infection by *Candida* species, followed by bloodstream infection associated with the central venous catheter, esophagitis, and disseminated disease. Recently, the incidence of infection by non-albicans species, such as *Candida glabrata* or *Candida krusei*, has been rising [91]. This is related to routine administration of antifungal prophylaxis, specifically fluconazole, and is associated with higher mortality [92]. An infection with non-albicans candidiasis usually requires therapy with amphotericin B (amphoB). The introduction of echinocandins (caspofungin, anidulafungin, and micafungin) has added new therapeutic armamentarium against invasive *Candida* infections. Some advantages of echinocandins are their fungicidal activity, in vitro increased activity against *Candida*-forming biofilm, and postantifungal effects. Disadvantages include the lack of therapeutic concentrations in CSF, urine, and aqueous/vitreous humor and the need for intravenous administration. There is improved clinical success using an echinocandin for treatment of *Candida glabrata* fungemia. On the other side, *Candida parapsilosis* has a higher MIC, and there is no outcome difference between an echinocandin and azole treatment [93]. The use of amphoB is problematic, given its nephrotoxicity and the high rate of pre-existing renal insufficiency in liver transplant recipients, as well as the concurrent use of other potentially nephrotoxic medications, such as cyclosporine and tacrolimus. In 2002, a double-blind trial demonstrated that caspofungin, an echinocandin, was as effective as amphoB for treatment of invasive candidiasis and at the same time has fewer adverse effects compared to amphoB [94]; cases in the two arms were equivalent in severity of illness and rate of neutropenia. According to the Infectious Disease Society of America (IDSA) Clinical Guidelines [95], the initial coverage of candidemia and disseminated candidiasis include caspofungin or fluconazole or amphotericin B.

14.5.3 Aspergillosis

Aspergillus species are the second most frequent cause of IFIs in this population, and they are associated with an extremely high mortality rate that ranges from 75 to 100 % [1, 13–16, 84]. A large case series reported that 32 of 2180 patients (1.5 %) were diagnosed with aspergillosis over the period of 10 years [36]. In 41 % of the cases, the diagnosis was made postmortem. Twenty-seven (84 %) had pulmonary involvement, two had intra-abdominal disease, and one had central nervous system (CNS) infection. The diagnosis was made in 90 % of the patients within the first 50 days of the transplantation. Although the authors identified a group of patients with a positive culture for *Aspergillus* species who did not have evidence of tissue invasion, most patients (68 %) whose culture was positive did have invasive aspergillosis. Therefore, the authors concluded that the isolation of *Aspergillus* species from the respiratory tract of transplant recipients could not be ignored as simple colonization, as it often is in patients with normal immune systems. With the advent of effective new antifungal agents against *Aspergillus* species, such as liposomal amphoB and voriconazole, the mortality rate of invasive *Aspergillus* infection has improved in liver transplant recipients. A small case series [96] described several liver transplant recipients with invasive aspergillosis who were treated successfully with a prolonged course of amphotericin lipid complex, followed by oral itraconazole. Linden et al. compared the outcome in a retrospective study of liver transplant recipients with invasive aspergillosis treated with amphoB lipid complex to those treated with conventional amphoB [97]. The 60-day survival was statistically higher in the lipid formulation-treated patients [97]. In a randomized trial, Herbrecht et al. compared the treatment of invasive aspergillosis with voriconazole vs. deoxycholate amphoB in allogeneic hematopoietic cell transplantation and acute leukemia [98]. Better response and better survival was observed in the voriconazole arm [98]. In the IDSA 2008 Clinical Practice Guidelines, voriconazole is recommended for primary treatment of invasive aspergillosis [99]. Alternative treatments include liposomal amphotericin B, caspofungin, micafungin, posaconazole, and itraconazole [99].

Some centers use combination antifungals to treat refractory cases of invasive aspergillosis. This approach is controversial with conflicting in vitro and in vivo reports. A recent in vitro study suggested that the combination of amphotericin B and voriconazole was more effective than monotherapy [100]. A randomized trial, combining anidulafungin and voriconazole for treatment of invasive aspergillosis in patients with hematological malignancies and stem cell transplantation, suggested a reduced mortality in the combination therapy arm (19.3 % vs. 27.5 %) [101]. Resistance of aspergillus to azoles has become more frequent. Fuhren et al. [102] reported on 21 of 105 *Aspergillus fumigatus* resistant in vitro to at least one azole (voriconazole, posaconazole, or itraconazole), and 16.2 % (17/105) were resistant (MIC>2 mg/L) to voriconazole in high-risk patients (ICU and hematology ward). The authors suggested to check for resistance prior to initiation of treatment. A recently approved azole, isavuconazole, has broad activity against mold, including *Aspergillus fumigatus* and *A. flavus*, as well as activity against some *Mucorales* and dimorphic fungi. In a recent randomized, double-blind clinical trial for treatment of invasive

aspergillus infection, isavuconazole was noninferior to voriconazole; there was no difference in day 42 all-cause mortality and overall success (complete and partial response) [103].

14.5.4 Cryptococcosis

Contrary to infections by *Candida* or *Aspergillus* species, infection by *Cryptococcus neoformans* tends to occur several months after transplantation. In a series of ten cases of *Cryptococcal meningitis* in liver transplant recipients, Jabbour et al. [104] reported the median time elapsed since transplant to the diagnosis as 3.5 months (range of 2–36 months). A large review by Husain et al. [105] that researched cryptococcosis in all types of solid organ transplant recipients suggested an even later onset of infection. The median time of onset was 1.6 years after transplantation in that study, with 59 % of the cases occurring more than 12 months after transplantation. The infection did occur earlier in liver and lung transplant recipients, compared with that of heart and kidney transplant recipients, possibly as a result of the more aggressive early immunosuppressive regimen used in these groups of patients. The rate of cryptococcosis was not as high in liver transplant recipients as it was in those receiving heart transplants. The most commonly involved site was the CNS (72 %), followed by the lungs (25 %), skin, soft tissue, joints, and bones, with 24 % of the patients having more than one site of infection. The overall mortality in the series was 42 %. The incidence of the infection also differs according to geographic areas. For example, cryptococcosis is much more common in the eastern United States than it is in the western part of the country. Men are more frequently affected than women [106]. Mortality was associated with organ failure, liver failure in liver transplant recipients [107], and renal failure in all transplant organ recipients [86].

Cryptococcal meningitis or other severe cryptococcal disease infection is usually treated with induction treatment with liposomal AmB 3–4 mg/kg daily or ABLC 5 mg/kg per day together with flucytosine 100 mg/kg daily for 2 weeks [108]. This is followed by oral fluconazole 400–800 mg/day for 8 weeks (consolidation therapy) and then fluconazole 200–400 mg daily for 6–12 months (maintenance therapy). Induction therapy can also be given with daily 4–6 weeks of liposomal AmB 6 mg/kg or ABLC 5 mg/kg or AmBd 0.7 mg/kg [108].

Between 2004 and 2010, *Cryptococcus gattii* emerged as an important pathogen in the Pacific Northwest [109]. This species had appeared first in animals and humans in Vancouver Island and in 2004 in mainland British Columbia, and only 38 % of the patients were immunosuppressed including solid organ recipients [109]. Forrest et al. described 11 solid organ transplant recipients in the Oregon outbreak [110]. Solid organ transplant recipients had higher rate of dissemination and higher mortality compared to nonimmunosuppressed host [110].

14.5.5 Prevention Strategies

Two strategies to prevent IFIs in liver transplant recipients, universal prophylaxis and targeted prophylaxis, have been used, but a consensus has not been achieved regarding the optimal regimen for prevention. Oral nystatin administered as part of SBD has been shown to reduce oropharyngeal and rectal colonization with *Candida* species, but no evidence appears to indicate that it reduces the rate of IFI [79]. Nonetheless, several centers routinely use it because it is an inexpensive and benign therapy. Oral fluconazole has been examined in two randomized, controlled studies for its potential for the prevention of IFI caused by *Candida* species [111, 112]. One study compared a low-dose fluconazole, 100 mg daily, with oral nystatin for a month after transplantation. The fluconazole group showed a trend toward lower IFI rates, without significant toxicity or interference with cyclosporine among the study group patients [95]. A larger study by Winston et al. [112] used a fluconazole dose of 400 mg daily. The benefits of fluconazole prophylaxis were clearer in this study, with a reduced rate of IFI (9 % vs. 43 % in the control group) and fewer deaths secondary to fungal infection in the fluconazole group. The tradeoff was a higher cyclosporine level in the study group, which translated into increased neurotoxicity. However, the all-cause mortality was similar in the two groups. Interestingly, none of the studies showed an increased rate of infection by fluconazole-resistant *Candida* species, such as *C. glabrata* or *C. krusei*. An earlier study by Tollemar et al. [113] looked at the protective effect of low-dose liposomal amphoB (AmBisome), 1 mg/kg daily, compared with a placebo; both were administered during the first 5 days after the transplantation. None of the 40 patients in the AmBisome group contracted IFI, whereas 6 of 37 patients in the control group developed IFI (5 cases of invasive *Candida* infections and 1 case of *Aspergillus* pneumonia). The problem with this strategy lies mainly with the prohibitive cost of AmBisome, although the low dosage and short duration of prophylaxis help mitigate the issue.

The IDSA guideline is to use prophylactic antifungal therapy during the early postoperative period in high-risk liver transplant recipients [95]. According to some reports, universal antifungal prophylaxis, specifically fluconazole, has been associated with increased rate of IFI secondary to non-albicans isolates [92, 114]. Also, the azole antifungals interfere with the metabolism of immunosuppressive agents, leading to increased creatinine secondary to accumulation of tacrolimus and cyclosporine. Compared to universal prophylaxis, targeted prophylaxis is defined as the selective targeting of only patients at high risk for IFI, such as patients with renal insufficiency, long operative time, and significant intra-abdominal bleeds. The following are two examples of usage of this strategy. Fortun et al. [115] administered a lipid formulation (cumulative dose of 1–1.5 g of AmBisome or Abelcet) to high-risk liver transplant recipients and saw a decrease of IFIs (17–6 %) and aspergillosis

(10–4 %), compared to a historical group [115]. Hellinger et al., at Mayo Clinic, Florida [116], stratified patients during targeted prophylaxis intervention into risk-groups and administered Abelcet 5 mg/kg to those at high risk for development of IFI. During the intervention with targeted prophylaxis, there was only 1 % invasive mold infection compared to 5 % before institution of targeted prophylaxis [116].

14.5.6 Viral Pathogens

14.5.6.1 Cytomegalovirus Infection

CMV is one of the most common infections, and it is a major source of morbidity and mortality in liver transplant recipients. Studies done prior to the widespread use of CMV prophylaxis or preemptive therapy showed that 60 % of all liver transplant recipients developed CMV infection, with symptomatic infections appearing in 32–56 % [52, 117].

Along with common presentations of symptomatic CMV disease, such as viral syndrome, CMV gastroduodenitis, colitis, and pneumonitis, CMV disease in liver transplant recipients often presents as hepatitis, an entity that is rarely observed in recipients of other organs. In a study of 50 liver transplant recipients with CMV infection, CMV hepatitis was observed in 13 (26 %) [117]. In that study, the most important risk factor for CMV infection for both symptomatic and non-symptomatic cases was mismatched donor and recipient serostatus, in which CMV-seronegative recipients received CMV-seropositive organs [53, 117, 118]. The use of OKT3 anti-CD3 monoclonal antibody was a significant risk factor for symptomatic CMV infection, especially in those who were CMV seropositive before transplantation [119]. More recently, the use of polyclonal antithymocyte antibodies (rabbit, Thymoglobulin, and equine, ATG) was associated with CMV reactivation. A prolonged prothrombin time and the diagnosis of acute fulminant hepatitis as the underlying liver disease have also been associated with an increased rate of CMV infection [53]. Moreover, studies indicate that CMV infection alone is an independent risk factor for IFIs [13, 85], thus strengthening prior claims that the virus itself is an immune modulator and has depressive effects on cellular immune function [120, 121].

Because of the high prevalence of, and morbidity associated with CMV infection, considerable efforts have been made to determine the best strategy for preventing CMV disease in this population. Acyclovir and ganciclovir have been studied as both universal prophylaxis and preemptive therapy. Although at least one trial has attested to the efficacy of acyclovir in the prevention of CMV infection in liver transplant recipients [122], subsequent studies have shown acyclovir to be inferior to ganciclovir in both prophylactic and preemptive strategies [123–127]. Subsequently, IV ganciclovir has been established as the mainstay of CMV prophylaxis and treatment. When IV ganciclovir is used as an agent of universal prophylaxis for 100 days after transplantation, it dramatically reduced the rate of CMV infection in both seropositive and seronegative liver transplant recipients, compared to that seen with acyclovir use [123]. The protective effect of IV ganciclovir was preserved but blunted when it was administered for only 2 weeks, followed by oral acyclovir [125]. IV ganciclovir was also effective when it was used in preemptive therapy guided by results of the surveillance CMV pp65 antigenemia test [126, 128].

The oral form of ganciclovir has the advantage of ease of administration over that of the IV formulation. Despite several studies that demonstrate the efficacy of oral ganciclovir in both prophylactic and preemptive strategies [124, 126, 129], many clinicians have expressed reservations about the routine use of this agent due to its suboptimal bioavailability and concerns about fostering resistance. Oral valganciclovir (Valcyte) is the L-valyl ester of ganciclovir and is rapidly converted into ganciclovir and has a good bioavailability [130]. In a randomized prospective trial of 900 mg once a day of valganciclovir vs. 1000 mg three times a day of oral ganciclovir for 100 days, in high-risk solid organ recipients, CMV disease was observed in 12.1 % and 15.2 % in the valganciclovir and the oral ganciclovir arms, respectively, within 6 months from transplantation [131]. But in a subgroup analysis, the rate of CMV disease in liver transplant recipients was higher in the valganciclovir arm compared to the oral ganciclovir arm (19 % and 12 %, respectively) [131]. Valganciclovir has a black box warning from the FDA for the use of prophylaxis in liver transplantation. Despite this warning, most transplant centers use valganciclovir for prophylaxis and preemptive therapy in liver transplant recipients. Although in the seropositive-recipient setting both prophylaxis and preemptive therapies are practiced, in the high-risk setting, most clinicians would use 3 months of valganciclovir prophylaxis [132]. In recent years, more attention has been given to delayed and late CMV infections. With the increase in antiviral prophylaxis use, especially in high-risk transplant recipients, more patients present with CMV infection after finishing their course of prophylaxis. In the Limaye et al. series, the median onset of CMV disease was 4.5 months after transplantation and occurred mostly in high-risk individuals and was associated with increased risk of mortality [133]. Occasionally CMV disease can be encountered more than a year after transplantation (late CMV). This occurs usually in seropositive transplant recipients, most likely secondary to reactivation [134].

Newer therapeutic agents for treatment and prevention of CMV disease are in development. Brincidofovir (CMX001), a new broad anti-DNA virus agent, has shown in a recent study a significant reduction in the incidence of CMV disease in recipients of SCT (10 % vs. 37 % with placebo) [135]. There was no increased myelosuppression and no nephrotoxicity, and none of the recipients of CMX001 at a dose of

100 mg twice a week developed CMV disease nor viremia above 1000 copies [135]. No published data on the use of CMX001 in liver transplant population is available yet.

Letermovir, a novel terminase inhibitor, is in development for the prophylaxis and treatment of CMV. In a phase 2 randomized, controlled, multicenter, open-label trial, two doses of letermovir (40 mg BID or 80 mg daily) were compared with standard of care in adult kidney transplant recipients with active CMV replication. Despite a small sample, and a short treatment of 14 days, no patients in the three study arms developed CMV disease, and no severe adverse events were reported [136]. A phase 2 study using letermovir for CMV prophylaxis in SCT recipients showed a dose-dependent reduction in the incidence of CMV prophylaxis failure (48 % at a daily dose of 60 mg, 32 % at a dose of 120 mg, and 29 % at a dose of 240 mg vs. 64 % with placebo) with no significant hematological toxicity or nephrotoxicity [137].

Leflunomide, an antirheumatic medication with antiviral and immunosuppressive properties, has been used for the past 10 years to treat CMV. In a retrospective series from the University of Chicago, five kidney transplant recipients with ganciclovir-resistant CMV were treated with leflunomide as "consolidation" therapy after clearance of viremia with IV foscarnet without any relapses of CMV viremia while on leflunomide treatment [138].

Maribavir, a promising oral agent with potent in vitro activity against CMV, was evaluated as a prophylactic agent in liver transplant recipients at a dose of 100 mg twice a day and was compared to oral ganciclovir 1000 mg three times a day. Maribavir was found to be inferior to ganciclovir at the study dose, with confirmed CMV disease or viremia in 20 % of ganciclovir recipients vs. 60 % of maribavir recipients at day 100 and 53 % vs. 72 % at 6 months [139].

14.5.6.2 Herpes Simplex Virus

HSV infection appears within 2–3 weeks of transplantation in recipients who do not receive antiviral prophylaxis [140, 141]. The disease occurs mainly through viral reactivation in seropositive individuals, although primary infection that may cause fulminant disease is possible. Orolabial mucocutaneous manifestation is the most common presentation, followed by anorectal disease and HSV esophagitis. Disseminated disease, which usually causes hepatitis, is uncommon (0.3 %) but devastating when seen. In a series from Pittsburgh [140], 42 % of all liver transplant recipients with HSV hepatitis developed widespread disease and disseminated intravascular coagulopathy (DIC). All patients who developed DIC died [121]. Several studies have shown that prophylaxis against HSV infection with acyclovir is effective in renal and liver transplant recipients [140, 142]; many centers therefore include this as a part of the routine postoperative regimen. Valganciclovir which is used commonly as a CMV antiviral prophylaxis in solid organ transplant recipients is also an effective agent for HSV prophylaxis [143].

14.5.7 Adenovirus

Adenovirus, which is a nonenveloped DNA virus, may affect both normal and immune-compromised hosts including transplant recipients, especially pediatric but occasionally also adult [144]. The clinical presentation may be confused with CMV infection because inclusion bodies can be seen with histology and unless special stains for adenovirus are performed clinicians may be misled by initial clinical impressions.

Similar to CMV, adenovirus infection may be asymptomatic or symptomatic causing invasive disease. In pediatric liver transplant recipients, hepatitis is the most common invasive disease [145]. Other infections include hemorrhagic cystitis, gastroenteritis, pneumonitis, and disseminated infection. In one series, 49 (10 %) of 484 children on cyclosporine and steroids developed adenovirus infection at a median of 25.5 days after liver transplantation and 20 (41 %) developed symptomatic infection and nine died [146]. There was a statistical trend of OKT3 use in patients with invasive disease compared to noninvasive infection. Nine (64 %) of 14 children who developed adenovirus hepatitis were type 5 and the others were types 1 and 2 [146]. Patients with adenovirus hepatitis were systemically ill with high temperature and their transaminase levels were elevated [147]. Liver biopsy demonstrated parenchymal punched-out lesions with some necrosis and a scant number of intranuclear inclusions [147]. Extensive necrosis can be seen in fulminant adenovirus hepatitis [147]. Cidofovir has in vitro activity against adenovirus and has been used with mixed results. Successful outcomes were reported in cases where immunosuppression was reduced, and treatment was instituted relatively early in the course of the infection [147, 148]. Most recently, quantitative PCR has been used by some investigators to follow patients' clinical progress with adenovirus infection as high viral load correlated with severe symptomatic infection [147, 148].

14.5.7.1 Recurrent HBV

HBV and HCV are two of the most common indications for liver transplantation. Although HBV infection has been declining as an indication for liver transplantation, HCV infection, which often goes unrecognized for years, is rising; it currently is the most common cause for end-stage liver disease requiring liver transplant in the United States [88]. Patients with HBV or HCV who undergo transplantation have a considerable risk of recurrent infection and may develop cirrhosis at an accelerated rate.

HBV recurrence occurs in more than 80 % of liver transplant recipients who have HBV before transplantation [149, 150]. Active HBV viral replication and the presence of the HBe antigen before transplantation have been associated with an increased risk of recurrent hepatitis secondary to HBV, whereas those with fulminant hepatitis as the indication for transplant or superinfection by the delta virus have been shown to have lower rate of recurrent infection [30].

Hepatitis B serology of the donor may determine whether the recipients with HBV-related cirrhosis develop viral hepatitis after transplantation. According to one study, HBV-positive transplant recipients who received organs from donors with positive anti-HB core antibody show 2.5 times the risk of recurrent HBV hepatitis after transplantation compared to those who received organs from donors without HBV markers [151]. However, the study did not show any difference in graft or patient survival. De novo hepatitis B infection in HBV-naive recipients who received an organ from seemingly "immune" donors (i.e., those with positive anti-HB surface, as well as core antibodies) has also been reported [152]. To prevent de novo hepatitis B in recipients of HBcAb + livers, most centers use antiviral prophylaxis [153].

Recurrent hepatitis by HBV usually occurs within the first 6 months of the transplantation, with the subsequent development of chronic active hepatitis within 9–12 months and of cirrhosis by 2–3 years after transplantation [150]. The strategy to prevent recurrent HBV infection after liver transplantation has evolved over the years. Monotherapy with hepatitis B immune globulin (HBIG) was used in earlier years. In one study [154], HBIG reduced HBV hepatitis recurrence, defined as reappearance of HBsAg after transplantation, from 76 to 19 %. Most centers administered HBIG after transplantation at 10,000 IU daily for 7 days starting immediately after transplantation, followed by reinfusion every 3–4 weeks for life to achieve and maintain serum levels of HBIG above 100 IU/L or above 500 IU/L to achieve more protective titer [88, 154, 155]. For HBV-viremic patients, the daily administration of the nucleoside analog lamivudine at a dose of 100 mg orally until the resolution of viremia was also used, as this drug has been shown to reduce the rate of HBV recurrence by its antiviral replication activity [88, 156]. Many centers used lamivudine before transplantation to control viremia, with the option of reintroducing the drug in those who develop breakthrough viremia despite HBIG after transplantation.

Long courses of lamivudine administration have been associated with emergence of lamivudine resistance. In one study, the rates of HBV DNA polymerase mutants were detected in 20 %, at a median of 26- and 38-month follow-up in pre- and posttransplant patients treated with lamivudine monotherapy [157]. Alternatively, lamivudine may be continued along with HBIG for those who were previously viremic, regardless of the result of surveillance HBV PCR after transplantation [88]. The combination of HBIG and lamivudine together allowed investigators to administer lower doses of HBIG and achieve lower rate of HBV recurrence at a reduced cost [158]. With the emergence of lamivudine resistance, alternative antiviral agents, such as adefovir and entecavir, have been used with or without HBIG administration [159, 160]. In recent years tenofovir and entecavir became the favorable antivirals because they are potent drugs with low rate of resistance [153, 161].

Despite the fact that these preventive strategies have been effective in reducing recurrence of HBV infection, occult infection of the graft can be demonstrated by molecular techniques in most HBV-related cirrhosis patients after liver transplantation; this suggests that long-term HBV prophylaxis is required in this population [162]. The type of prophylaxis depends on viral replication (i.e., detectable HBV DNA) before and at the transplant operation. Most investigators do not recommend antiviral suppression before transplantation when there is no evidence of viral replication, only when replication is documented [153, 161]. Lifelong combination of HBIG and antivirals is offered after transplantation in active viral replication. In the case of lack of HBV DNA, a short course of low-dose HBIG IM or IV with antivirals, followed by antiviral monotherapy, is recommended [153, 161].

14.5.7.2 Recurrent HCV

HCV recurrence is more problematic. As many as 90 % of liver transplant recipients who had HCV infection as the underlying cause of liver failure acquire detectable HCV RNA virus after transplantation. Seventy-five percent of these patients develop signs of liver damage, and 25 % go on to cirrhosis within 5 years [88, 163–165]. The risk factors for the early recurrence of HCV in allograft include the presence of HCV genotype 1B, steroid use, and treatment for acute rejection [165, 166]. Concurrent CMV infection may also increase the rate of recurrent HCV infection [166, 167]. Many studies show that combinations of interferon and ribavirin are effective for chronic HCV infection [168, 169]. A few investigators who treated patients awaiting liver transplantation with a combination of interferon and ribavirin demonstrated 30–50 % response at the end of treatment and sustained viral response around 20 %; this treatment was beneficial after transplantation in some of the patients who remained free of virus [170, 171].

The advent of direct antiviral agents in treatment of hepatitis C has changed the way hepatitis C liver transplant candidates and those after liver transplant is managed [172]. The availability of treatment protocols without interferon before and after transplantation made hepatitis C management more tolerable. According to the AASLD Practice Guidelines [173], treatment of HCV before liver transplantation leading to sustained virologic response (SVR) would usually prevent HCV recurrence after transplant. Treatment with sofosbuvir and ribavirin (up to 48 weeks), in patient awaiting transplant with MELD score up to 14 and Child-Pugh score up to 8, was well tolerated leading to SVR of 69 % after transplant [173]. Daily sofosbuvir and ribavirin in patients with compensated recurrent HCV after liver transplant lead to SVR of 70 % at 12 weeks [173]. According to the EASL preliminary guidelines [174], the following regimens (12–24 weeks) are recommended to liver transplant recipients with HCV recur-

rence: genotype 2, sofosbuvir and ribavirin; genotypes 1 and 3–6, sofosbuvir and daclatasvir ± ribavirin; and genotypes 1 and 4, sofosbuvir and simeprevir ± ribavirin [174]. With the emergence of all these new antiviral agents, it is expected to see significant change in the management of HCV in liver transplantation the next few years.

Currently, many centers employ the use of HCV-seropositive donors with favorable histology at liver biopsy for transplantation into recipients with HCV-related cirrhosis. Most cases demonstrate viral superinfection with nearly 50 % seroconverting to the donor genotype after liver transplant. In large series, these recipients of HCV-seropositive grafts have equivalent to slightly better outcomes than if they received grafts from naïve donor livers.

Acknowledgment. We would like to acknowledge the help of Dr. E. J. Kwak from University of Pittsburgh Medical Center who assisted in writing the previous edition of this chapter.

Risks and Epidemiology of Infections After Intestinal Transplantation

Kyle A. Soltys, Jorge D. Reyes, and Michael Green

15.1 Historic Background

The field of intestinal transplantation has developed significantly since the first reports involving dogs in the late 1950s [1]. Although small series demonstrated some short-term success of intestinal transplantation in the 1960s [1, 2], long-term success was not reported until tacrolimus was introduced into clinical transplantation in 1990. Subsequently, dramatic and rapid progress in donor and recipient selection processes, evolution of surgical techniques, and enhancements in early perioperative care led to a significant improvement in early postoperative patient and graft survival in this challenging population. Key lessons were learned from the early failures in intestinal transplantation, as most graft loss was attributable to overwhelming rejection due to the inability to provide effective immunosuppression to this complex population in the face of such a lymphoid-rich, bacteria-containing graft [1]. Additional causes of early graft loss included ischemic injury of the allograft resulting in poor reperfusion and technical complications. Each of these early factors can be associated with infections occurring after transplant in association with severely damaged allografts rich in pathogens within the intestinal lumen [2]. Finally, morbidity and mortality were also encountered as a result of the mobilization and engraftment of donor-derived lymphocytes leading to graft-versus-host disease (GVHD) [3].

The introduction of tacrolimus immunosuppression in 1989 combined with the use of multidrug immunosuppressant protocols and donor and recipient anti-lymphocyte preconditioning markedly altered the results of intestinal transplantation. As a consequence, intestinal transplants are now performed worldwide with good overall results and long-term survival. Unfortunately, the high levels of long-term immunosuppression necessary to prevent and treat cellular and humoral rejection in ITx recipients have been an important contributor in the majority of deaths following intestinal transplant which have been directly related to infection and malignancy. Indeed, the future success of intestinal transplant relies on balancing the risks of immunologic complications associated with under-immunosuppression and the often fatal consequences of over-immunosuppression.

15.2 Patient Population and Risk Factors for Infection

Patients requiring intestinal transplantation have intestinal failure (IF) and require parenteral nutrition (PN) to maintain a normal state of fluid, electrolyte, and nutritional balance. IF is a result of either an anatomic loss of their intestine (e.g., congenital intestinal atresias or acquired disorders, such as volvulus, necrotizing enterocolitis, trauma, or vascular thrombosis) or poor function involving motility (e.g., intestinal pseudoobstruction, Hirschsprung disease), absorption (e.g., microvillus inclusion disease), encasing tumors (e.g., desmoids), or Crohn's disease. PN has changed the outcome for patients who have intestinal failure by effectively providing temporizing benefits parallel to those seen with hemodialysis in patients with kidney failure. However, long-term survivors of PN can experience morbidity associated with development of catheter sepsis, venous thrombosis-induced loss of vascular access, and PN-induced cholestatic liver disease. Liver disease and the secondarily dilated short gut seen with intestinal adaptation facilitate intestinal bacterial overgrowth, enteritis, bacterial translocation, the seeding of venous catheters, and line sepsis. Severe bloodstream infections can result in metastatic infectious foci, endocarditis, multisystem organ failure, and death. In addition, the infectious complications of IF may contribute to the development and progression of parenteral nutrition-dependent liver injury [4].

Life-threatening complications occur in as many as 20 % of patients on long-term PN. Without intestinal transplantation, patients with IF who develop complications of PN will die at a significant rate, with 1-year and 3-year survival rates of 84 % and 74 %, respectively [5, 6].

P. Ljungman et al. (eds.), *Transplant Infections*, DOI 10.1007/978-3-319-28797-3_15

Younger patients (<1 year old) have a higher risk of dying of infectious complications, possibly because they have an earlier onset of severe liver disease [4]. The most common infectious complication in patients with intestinal failure remains line sepsis, occurring with a frequency of 8.9 new catheter-related bloodstream infections (CRBSI) per 1000 catheter days [5]. Another single center study found an incidence of 3.49 septic episodes per child, with similar mortality risk at 2 years [7].

The "nonsterile" environment of the intestine defines the epidemiology of bacterial infections before and after transplantation. Many of these patients have a history of multiple catheter-related bloodstream infections and have been exposed to repetitive and/or long-term antibiotic therapy, which can facilitate bacterial overgrowth and translocation. The recurrent exposure to antimicrobial agents may lead to colonization and subsequent infection with antimicrobial-resistant bacteria and to the overgrowth of yeast and other fungi. Although prophylactic use of antimicrobial and ethanol lock therapy [8–10] or the use of antibiotic-coated catheters [11] may decrease the need for systemic antimicrobial therapy, catheter-associated bloodstream infections still represent a significant source of pre-transplant morbidity and mortality.

By definition, intestinal transplantation is conducted in a contaminated environment. The logistics of donor organ procurement does not allow for adequate bowel preparation prior to the procurement of the intestinal organs and although intestinal decontamination formulas are given to the deceased donor, effective mechanical cleansing is logistically impossible. Therefore, the succus entericus of the donor is transplanted with the intestinal allograft. Donor gastrointestinal flora in the lumen of the intestinal allograft may result in bacterial infections if significant preservation damage to the mucosa of the allograft intestine occurs due to ischemia–reperfusion injury. Subsequently, a similar breakdown of mucosal integrity may occur as a result of rejection which can also lead to bloodstream infections.

In addition to the usual sources of posttransplant sepsis (surgical site infections, abdominal abscesses, ventilator-associated pneumonias, etc.), many patients who have undergone a successful intestinal transplant continue to require central venous access for fluids, antibiotics, and antiviral therapy for a period of months after successful intestinal transplantation. While the central lines remain in place, the risk of catheter-related infections remains.

Pediatric intestinal transplant recipients present unique challenges. On average, the pediatric recipients are a young population, with a mean age of 7.2 +/− 6.5 years at the time of transplant [12] who may be "immunologically naive," thus having a higher risk of acquiring primary infections with *Cytomegalovirus* (CMV), Epstein–Barr virus (EBV), and other common community-acquired infections. Consequently, any requirement for higher baseline levels of immunosuppressive drugs to prevent rejection of the intestinal allograft predictably places them at an increased risk of developing opportunistic infections. This alone might explain the higher rates, prolonged disease states, higher morbidity, and increased mortality due to CMV and EBV infections that occur in these patients.

15.3 Anatomy, Pathology, and Pathogenesis of Infections

A number of different variations of intestinal transplantation can be carried out to ideally suit the anatomic and functional needs of the recipient; the etiology for intestinal failure dictates the type of intestinal allograft used. The need for associated stomach, pancreas, or colon in addition to the small bowel allograft is determined on the basis of the functional or vascular disease of those organs in the recipient. The diagnosis of end-stage liver disease as a consequence of TPN will determine the need for liver replacement. Consequently, intestinal transplantation procedures may provide the isolated intestine, the combined liver and intestine (with or without the pancreas), complete multivisceral intestinal allografts which include the entire gastrointestinal tract (i.e., stomach, duodenum, pancreas, and small bowel) along with the liver, and modified multivisceral grafts, which include the entire gastrointestinal tract (i.e., stomach, duodenum, pancreas, and small bowel) and exclude the liver [4]. Patient and graft survivals during the early posttransplant period vary according to the transplantation procedure. The best early survivals are associated with the isolated intestinal transplant, and the worst outcomes are observed in recipients of multivisceral allografts. The reason for this stems from the fact that recipients of isolated intestine allografts are relatively stable, when compared to patients with TPN-induced liver failure (portal hypertension, pancytopenia, coagulopathy) who will also require the larger composite grafts (liver/intestine or multivisceral grafts). The morbidity and mortality associated with outcomes after multivisceral transplantation stem from the difficulty of the resection portion of the operation and of the immediate posttransplant management. The risk of infection inherently determines short-term and long-term survivability.

Damage to the protective barrier of the intestinal mucosa can occur early from ischemia and reperfusion damage and later from rejection or GVHD of the intestinal allograft. Factors that determine risk for ischemia and reperfusion of the intestinal allograft are similar to those seen with other solid organs; they focus on a history of cardiac arrest and on the subsequent hemodynamic instability of the cadaveric brain-dead donor.

Prolonged episodes of cardiac arrest and hypotension and the need for multiple vasopressor drug therapy to maintain the blood pressure in the donor may herald the inevitable ischemia of the intestinal allograft. Such episodes of ischemia may be reflected in donor liver functions (elevated transaminase and bilirubin levels).

After the implantation of the intestinal allograft, ischemia/reperfusion syndromes may develop and be manifest by hemodynamic instability, fibrinolysis, and bleeding. Serial biopsies of intestinal allografts at the time of surgery and in the postoperative period reveal the severity of damage and the potential for recovery. In this setting, bacteria within the succus entericus brought with the intestinal allograft can traverse the intestinal epithelium and enter the splanchnic venous system. With isolated intestinal transplantation, the consequences of such an efflux of bacteria and endotoxin will depend on how the graft is drained. If drained into the recipient's portal or superior mesenteric vein, transient elevations in liver function tests may occur. If it is drained into the systemic circulation via the recipient's inferior vena cava, more significant manifestations of bacteremia may be seen, including adult respiratory distress syndrome (ARDS). In addition to the potential deleterious effects of luminal bacteria, work is being done to determine the relationship between the intestinal allograft microbiome, pathologic bacterial overgrowth and intestinal rejection [13, 14].

As the mucosal barrier is broken with immunologic injury, clinical sepsis can also accompany severe rejection in which breakdown of the allograft mucosal barrier occurs due to damage from native immunocytes of the recipient. More commonly, rejection episodes tend to be mild to moderate, without such infectious consequences; however, acute rejection should be considered as a potential etiology of any bacteremia with enteric organisms. The overall incidence of rejection of the intestinal allograft has been high (greater than 85%), with the average patient experiencing between one and five episodes of rejection per graft [6, 12, 15]; more recent progress in immunosuppression management has introduced the ability to minimize immunosuppressive load, thereby resulting in less rejection and consequently less infection. This high frequency of rejection of varying severities likely accounts for the high frequency of bloodstream infections seen in intestinal transplant recipients. The clinical signs of rejection include abdominal pain, distention, diarrhea, nausea, vomiting, and fever; however, these can also suggest the presence of a concomitant bacterial or fungal infection. The diagnosis of rejection is based on the findings from endoscopic biopsies of the intestinal allograft mucosa. Such confirmation is critical, particularly in long-term patients who present with minimal symptoms, and fever as opportunistic infections, such as CMV and EBV, can produce similar symptoms. In addition, episodes of enteritis secondary to infections with EBV and CMV may also be accompanied by damage to the mucosal barrier and associated bloodstream infections with bacteria and fungi.

Although rare, technical complications associated with intestinal allograft implantation complicate 7.6% of cases [16]; these include intestinal anastomotic leaks resulting in infectious peritonitis, vascular complications such as arterial thrombosis with consequent graft ischemia, and intestinal volvulus. These technical issues are certainly associated with severe septic and infectious complications and prompt surgical correction is required for survival.

15.4 The Intestinal Transplant Timetable

The unique timetable for infectious complications after intestinal transplantation is noted in Table 15-1. Bloodstream infections consequent to surgery-related (i.e., donor and implantation operation) and catheter-related infections continue to occur for at least the first month after transplantation. Because the mucosal barrier of the intestinal allograft is continuously exposed to the external environment, any breaks in the mucosal surface may result in transient bacteremia. Furthermore, indwelling intravenous catheters may be required for up to a year or longer after transplantation, placing these recipients at a higher risk of bacteremia. The high risk of CMV and EBV diseases carries a proportionately higher morbidity and mortality as well. The baseline immunosuppression levels—higher than those for other solid organs—that are required for a long term to maintain the intestinal allograft place these patients at a higher risk for symptomatic disease from these pathogens. Children may also be serologically naive for CMV and EBV, thus increasing the already high risk for disease. The chronic, higher level of immunosuppression required by these patients also raises the risk for severe infections from community-acquired pathogens (e.g., influenza, respiratory syncytial virus [RSV], adenovirus, streptococcal pneumonia, and *Pneumocystis jiroveci* pneumonia). However, despite high baseline immunosuppression, most intestinal transplant recipients who develop these infections tolerate them quite well because of their improved overall health status.

Patient and graft survival after intestinal transplantation is inherently related to the risk of rejection, the need for antirejection therapy, the high levels of baseline immunosuppression, and the risk of posttransplantation infections. In addition, the relationship between patient and graft survival is inherently dependent on the reversibility of the

Table 15-1. Timetable for infections after intestinal transplantation

Early (0–90 days after transplant)	Late (3–6 months after transplant)
Surgical site—usually intra-abdominal	Catheter-associated bacteremia
Catheter-associated bacteremia	Rejection-associated bacteremia
Pneumonia	EBV/PTLD
Rejection-associated bacteremia	Opportunistic infections
Donor derived infections	Candidemia
Early viral infections (adenovirus, influenza)	Pneumocystis jiroveci
CMV	Herpes simplex
	Varicella zoster

Abbreviations: *CMV Cytomegalovirus*, *EBV* Epstein–Barr virus, *PTLD* post-transplant lymphoproliferative disease.

type of transplant performed. For example, if a patient who has undergone an isolated intestinal transplant develops a life-threatening complication of the intestine or immunosuppression (e.g., uncontrollable rejection or posttransplant lymphoproliferative disorder [PTLD]), the intestinal allograft can be safely removed and the immunosuppression discontinued. Unfortunately, patients who have undergone combined liver and intestinal transplants have a much poorer outcome after the removal of the intestine and discontinuation of immunosuppression with the rapid development of allograft liver disease and death. Until recently, this was responsible for a progressively declining survival curve up until 3–4 years, at which time it plateaus (Figure 15-1). This curve contrasts with that of recipients of liver or kidney allografts in whom, after the first posttransplantation year, the baseline levels of immunosuppression are lowered, with a declining risk of rejection or infectious complications in the later posttransplant years. This resulted in a higher rate of survival at all posttransplant times.

Furthermore, the intestine is a large lymphoid-rich organ, the immunologic role of which cannot be underestimated.

15.5 Early Infections After Intestinal Transplantation (<90 days)

Although clinically useful to diagnose and empirically treat suspected infections after transplant, the timeline for infectious complications is not absolute. In addition, certain pathogens can be either donor derived or present in the recipient at the time of transplant, making the pre-transplant

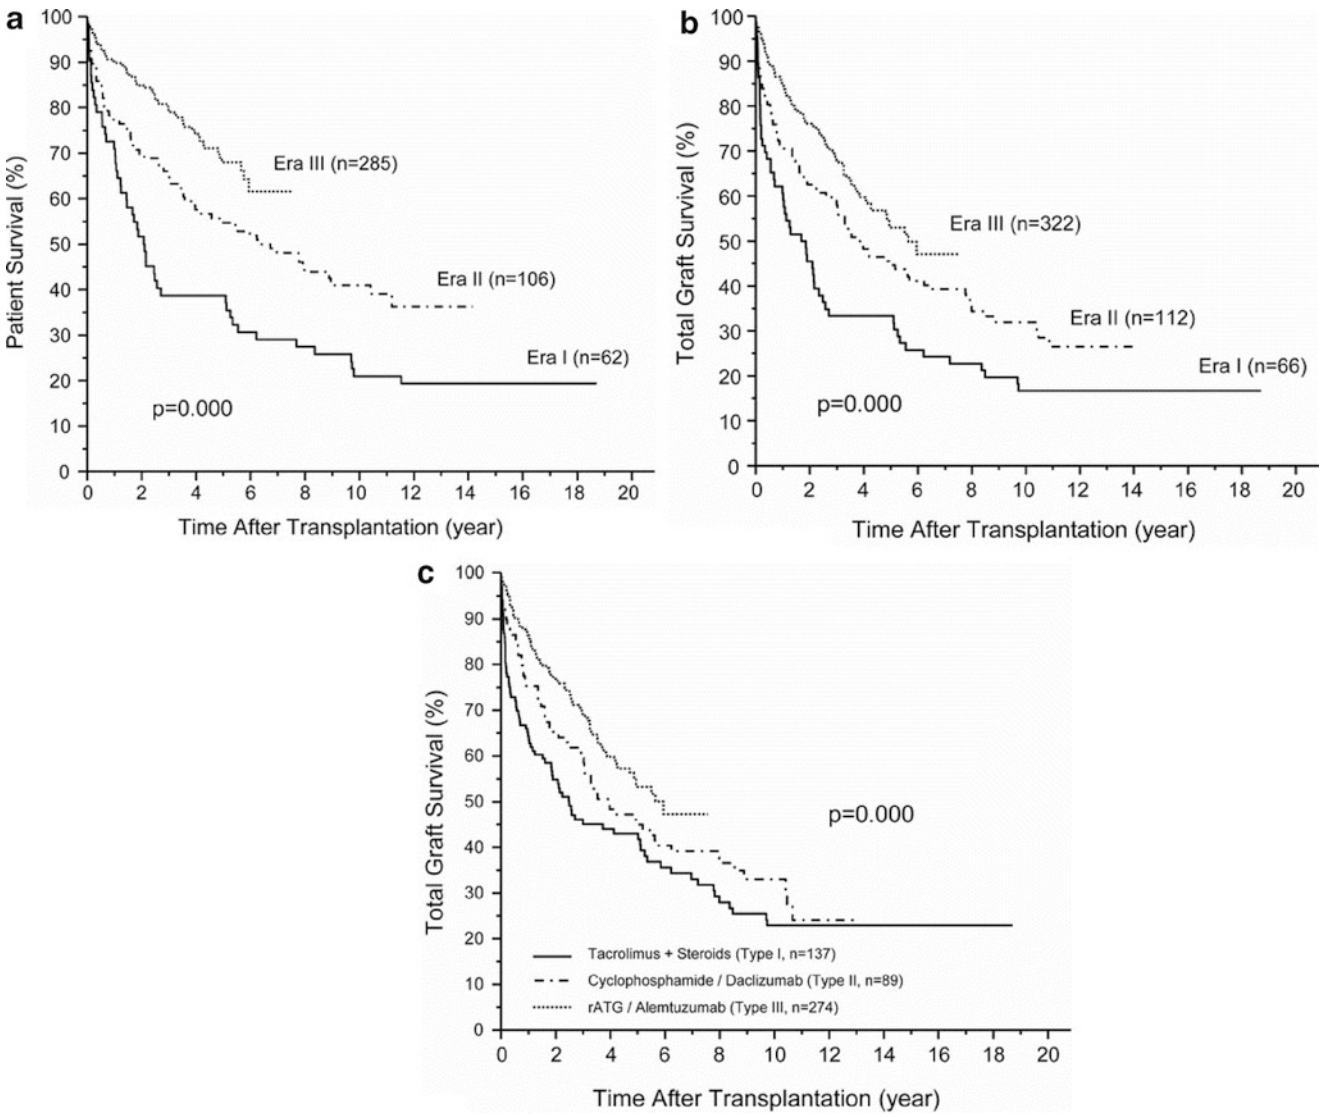

FIGURE 15-1. Graft and patient survival based on the era of immunosuppression at the time of transplant. From Abu-Elmagd KM, Costa G, Bond GJ, et al. Five hundred intestinal and multivisceral transplantations at a single center: Major advances with new challenges. Ann Sug 2009; 250: 567–81.

screening of both the donor and recipient imperative [17]. Even minor and common viral infections in the pre-transplant immunocompetent host can blossom into severe and life-threatening infections after preconditioning of the recipient. In addition, infectious complications in the early period lead to significant increases in the length of stay [18]. Likewise, unsuspected infections in the donor can rapidly manifest in the immunosuppressed recipient. Thus, although these timelines are useful for discussion, it should be kept in mind that common entities causing perioperative infections can also be acquired late after transplant.

15.5.1 Bacteremia and Fungemia

Based on the aforementioned clinical characteristics of intestinal transplantation, it is not surprising that the rates of bacterial and fungal infections observed after intestinal transplantation are higher than those reported for patients undergoing other types of solid organ transplantations, such as those for the liver, heart, or kidney.

Bacterial infections account for close to 60 % of all infections after intestinal transplantation [19]. Bacteremia has been shown to be the most common type of infection identified in children undergoing intestinal transplantation, with 69 % of children developing a bacteremia in the first postoperative year [20] and at a rate of approximately 1.4–1.7 episodes per patient per year. Similar infectious morbidity and frequency have been observed in adult recipients, with a rate of 1.55 episodes per patient after intestinal transplantation [17, 21]. The incidence of bacteremia after intestinal transplant does decrease over the course of the first year, declining from ~80 % in the first 8 weeks to roughly 3 % per month after the first 6 months [22–24].

The overall incidence of bacteremia after intestinal transplantation can be higher than 60 %; enteric organisms, including *Enterobacter*, *Klebsiella*, and *Pseudomonas* species are the most frequent organisms recovered [25]. These gram-negative organisms reveal a trend toward polymicrobial infection with multiple-antibiotic-resistant organisms, but other combinations of isolated gram-negative Enterobacteriaceae and coagulase-negative staphylococci also occur. While disruptions of the mucosal barrier of the allograft are frequently present, an obvious source of bacteremia is often not identifiable. This may be because the majority of the surface area of the intestinal allograft is not visible, as endoscopy reveals only the most distal or proximal portions of the intestine.

Although abnormal allograft histology does not have to be accompanied by bacteremia, in the presence of significant gastrointestinal pathology, enteric pathogens historically have been recovered in more than 50 % of cases [25]. Consequently, correlations between bacteria identified in the stool and those identified in the blood are high. The authors believe that bacterial overgrowth, which is defined as a bacterial count of more than 10^9 colony-forming units (CFUs) per milliliter of stool, may be a determining factor in the development of translocation in the setting of intestinal mucosal damage.

This association of enteric bacteremia (and CLABSI) and loss of mucosal function leads to the clinical caveat that if enteropathogens are identified in blood culture specimens, consideration should be given to performance of an endoscopy to identify the presence of underlying pathologies, such as rejection or enteritis (i.e., CMV or EBV). The treatment for suspected bacteremia should take into account the antimicrobial susceptibility patterns of bacterial pathogens associated with prior episodes of infection both before and after transplantation. Changes to the immunosuppressive drug strategy inherently parallel the treatment of any infection in patients after ITx. If the cause of mucosal breakdown and translocation is viral enteritis (CMV, EBV, adenovirus), judicious reduction of the immunosuppression is warranted. Paradoxically, in the face of allograft rejection, higher levels of immunosuppressive medication and antirejection therapy will be required.

Finally, it is worth noting that fungemia is also seen at higher frequencies in ITx recipients compared with recipients of other types of solid organ transplantation, occurring in 23–59 % of intestinal transplant recipients [26–28]. The majority of those infections were found to be due to *Candida* spp., accounting for 80–100 % of infections, and early candida infections are often associated with intra-abdominal abscess or intestinal leak [26]. Although *C. albicans* remains the dominant species isolated (37–46 %) after intestinal transplant, *C. glabrata* and *C. parapsilosis* are also common, representing 25 % and 13 % of isolates, respectively. There is some debate as to whether candidal infections have a negative impact on survival after intestinal transplant, with one study showing a significant decrease in survival with only *C. glabrata* species [27]. Antibiotic therapy and preoperative PN use are significantly associated with candidal infections in pediatric intestinal recipients.

In addition to bacteremia, significant morbidity is associated with respiratory tract infections in the early postoperative period, accounting for roughly 15 % of bacterial infections in this population. Health-care-associated respiratory infections account for the majority of these infections, with a similar microbiology to other hospitalized populations [19, 22].

15.5.2 *Cytomegalovirus* Infection

The success of clinical intestinal transplantation after 1990 under immunosuppression with tacrolimus was accompanied by an unexpectedly high prevalence and marked severity of CMV disease. These higher rates and levels of disease severity were attributed to the higher burden of immunosuppression required to prevent rejection. The overall incidence

of CMV infection at the authors' center and throughout the International Intestinal Transplant Registry has been reported to be as high as 20 % [29]. Fortunately, the incidence of CMV disease has decreased as experience with viral monitoring, immunosuppressive strategies, and preemptive treatment therapies has evolved. Our most recent series of intestinal transplants was found to have a 7 % incidence of CMV disease, compared to a 35 % incidence in patients transplanted using different immunosuppressive and preventative strategies [16].

Analysis of this historical high rate of CMV disease (38 %) in adult recipients after intestinal transplantation at a single center stratified the rates of CMV disease by the serologic status of CMV in the donor and recipient (D/R) as follows: D−/R−, 0 %; D−/R+, 50 %; D+/R+, 50 %; and D+/R−, 75 % [30]. Similar rates of CMV disease have been seen in these groups in more recent studies, and in general, patients can be stratified into high-risk (D+/R−), low-risk (D−/R−), and intermediate-risk groups, based on serologic data. These groups can then be used to develop strategies for CMV disease prevention.

In a recent international survey of intestinal transplant centers, 40 % of programs used universal ganciclovir or valganciclovir prophylactic therapy for prevention of CMV disease in high-risk (D+/R−) populations. In addition, 35 % of programs administered high-titer CMV-immunoglobulin (CMV-IVIG) prophylaxis to the high-risk group. Recipients who were CMV positive at the time of transplant were more frequently treated with frequent monitoring for viremia and preemptive therapy; however, 12 % of centers administered prophylactic antiviral therapy and 20 % of centers still utilized CMV-IVIG as part of the prophylaxis for CMV. Despite these strategies, 20.3 % of patients still developed CMV infection [31].

CMV has a propensity to involve the gastrointestinal tract, particularly the intestinal allograft. Indeed, CMV enteritis accounted for more than 80 % of all episodes of illness. Risk factors, such as rejection and the need for steroids or OKT3, associated with the development and/or recurrence of CMV disease in this patient population were similar to those seen with other solid organ transplants, but they had a higher impact [32]. Interestingly, rejection was not found to be a risk for CMV disease in a recent study [33] and invasive CMV enteritis has been seen in patients without associated CMV viremia [34].

Although CMV disease historically occurred at a higher frequency, it remained a treatable disease, with a similar 1-year survival rate among patients with or without a history of CMV. Because ganciclovir prophylaxis had been ineffective in preventing the disease in children and adults in the 1990s, several centers would avoid CMV-seropositive donor organs in CMV-negative candidates awaiting isolated intestinal transplantation. This policy did not generally apply to patients waiting for combined liver and intestine transplants; due to the excessive mortality risk, end-stage liver disease places these patients at a higher risk of dying while waiting for organ allografts. However, the availability and effectiveness of prophylactic strategies, as well as changing patterns of CMV disease potentially associated with the use of induction immunosuppressive therapies, may affect the prevalence and outcome of CMV disease. Indeed, most recent studies have confirmed almost nonexistent mortality from CMV disease, even in high-risk patient populations [16, 33].

The experience with CMV disease in the pediatric population had been similar, although less morbidity and minimal mortality were seen [35]. The intestinal allograft was infected with CMV in more than 90 % of patients experiencing CMV disease. In addition, the native intestinal tract was infected in 20 % of CMV-affected children. Recurrent and persistent CMV disease was common. As in adults, the D+/R− group of recipients had the highest frequency and morbidity. However, rates of CMV disease have declined with aggressive use of CMV-preventive strategies combined with modifications in immunosuppressive strategies. Experience from our center in pediatric ITx recipients receiving induction therapy with thymoglobulin identified that only 1 of 36 children developed CMV disease [12].

Ganciclovir remains the primary agent used to treat CMV disease, though there are several centers that utilize oral valganciclovir for both prevention and treatment of CMV [31]. Although this remains an attractive strategy, it should be done with some degree of caution and close monitoring, as there has been a reported increase in CMV tissue invasive disease in patients receiving valganciclovir, compared to intravenous ganciclovir [36]. The disadvantage of prolonged treatment with antiviral agents remains the significant adverse effects seen with these agents, primarily marrow suppression (anemia, leukopenia, and thrombocytopenia) and nephrotoxicity (survey paper). In addition, controversy exists regarding the proper dose of oral valganciclovir in the pediatric population [37, 38]. Strategies for the treatment of CMV infections also need to prevent recurrent infection, which can occur in up to 85 % of cases. This risk may be minimized by utilizing prolonged prophylaxis after treatment of the primary infection with either ganciclovir or oral valganciclovir.

The management of CMV disease with intravenous ganciclovir, alone or in combination with CMV-specific hyperimmune globulin, has resulted in clinical cures in 90 % of children with CMV disease with no alteration in long-term patient or graft survival [35]. The addition of CMV-IVIG for the treatment of CMV is generally recommended, although little data exists to support its use. Despite a lack of strong evidence to support its use, immunoglobulin administration remains a standard therapy in several treatment protocols for prevention and treatment of CMV disease in intestinal transplantation [31, 39].

Isolated cases of disseminated CMV in intestinal recipients have been reported that correlate with clinical manifestations suggestive of ganciclovir resistance; these were

accompanied by progressive rises in CMV antigenemia despite an appropriate regimen of ganciclovir and CMV-IVIG. Foscarnet provided eventual resolution in these cases [35]. Ganciclovir-resistant CMV infection occurs in up to 15 % of patients after lung transplant and has been found to be due to mutations in the CMV UL 97 or UL54 genes, which respectively encode the viral DNA phosphotransferase and the CMV DNA polymerase. Invasive infections with ganciclovir-resistant CMV are associated with 25 % mortality despite treatment with IVIG and foscarnet and a 78 % rate of foscarnet-induced toxicity [40]. Case reports using the prodrug leflunomide suggest its inclusion as a potential tertiary agent for treatment of resistant CMV infection [41]. In addition to drug therapy, studies in the HSCT literature are emerging that successfully utilize adaptive immunotherapy to treat CMV disease resistant to multidrug therapy [41]

In summary, CMV has been a frequent and important cause of morbidity after intestinal transplantation. CMV has a unique propensity to involve the intestinal allograft and the native gastrointestinal tract, which makes surveillance practical. At present, the use of long-term prophylactic therapy (3-month to 6-month courses) with ganciclovir (either IV or oral valganciclovir) in combination with CMV-specific hyperimmune globulin should be considered for CMV +/– patients [42]. The use of "hybrid" strategies using shorter courses of chemoprophylaxis followed by serial measurements of the CMV viral load in CMV-seropositive recipients may be effective but data are needed before this strategy can be widely recommended [42]. Prompt diagnosis and treatment of CMV viremia decreases the rate of invasive disease, though little data exists to determine the proper duration of treatment to avoid recurrent disease. Ganciclovir-resistant CMV disease exists and can be associated with significant morbidity and mortality in the lung transplant population. The emergence of immunotherapy as a potential modality for treatment of resistant disease may improve the results in these patients.

15.5.3 Adenovirus

Adenovirus is a ubiquitous DNA virus that can be either transmitted from the donor or can be acquired from the community. Like EBV, adenovirus can remain latent in the lymphoid tissue, allowing for its transmission and also accounting for the possibility of reactivation after transplant or during periods of augmented immunosuppression. Although the intestinal allograft is the most common site of infection, adenovirus can disseminate and can also infect a large variety of organs, including the brain, liver, lungs, and pancreas. The intestine was infected in 83 % of cases in a recent study [43]. Adenoviral infection is most common in younger recipients and is generally thought of as an "early" pathogen, with almost 70 % of cases occurring in the first 6 months after transplant. Overall, adenovirus infection has been observed frequently in pediatric recipients of intestinal transplantation with rates of adenovirus infection in this population ranging from 20.8 to 100 % [17, 21].

Adenoviral enteritis generally presents as an osmotic diarrhea, often without associated fever or systemic illness. The gross morphology of infection is one of hyperemic mucosa and ulceration, often difficult to distinguish from cellular rejection [44]. Histologically, there is severe villous injury and characteristic cytopathic adenoviral inclusions in the villi. Crypt apoptosis can also be seen in cases of severe adenoviral enteritis, potentially confusing the underlying diagnosis difficult [45]. Immunohistochemistry allows for better delineation of the inclusions in these cases and serum and tissue DNA polymerase chain reaction can also be used, if needed to confirm the diagnosis [44]. Adenovirus can also present as an invasive disease [46]. Risk factors for invasive disease include failure to clear virus, isolating virus from more than one site, and intensified immunosuppression [21].

It is very difficult to presumptively diagnose infection due to adenovirus in ITx recipients, as fever, hepatitis, and pneumonia may be caused by a variety of other pathogens. In addition, high stool output after IT is nonspecific and can also occur with rejection. The presence of high-grade fevers and symptoms suggestive of adenovirus infection should prompt serial cultures for viruses (including adenovirus) or PCR of the blood and evaluation of graft biopsies. Unexplained hepatitis should warrant consideration of a liver biopsy. Similarly, an increase in stool output, with or without fever, should prompt endoscopic evaluation of the intestinal allograft. Histologic examination for the presence of adenoviral inclusions as well as the use of immunohistochemical stains of biopsy specimens from either site should be undertaken to help confirm this diagnosis.

Unfortunately, there is no definitive treatment for adenoviral infection at this time [47]. The treatment of adenoviral infections is thoroughly discussed elsewhere (Chap. 34). The most important component of therapy is supportive care along with a judicious and carefully monitored reduction in immunosuppression. The role of antiviral agents is unproven, although there is increasing experience and enthusiasm for the use of cidofovir [48, 49].

15.6 Late Infections After Intestinal Transplantation (>90 days)

15.6.1 Epstein–Barr Virus-Induced Infection and Posttransplant Lymphoproliferative Disease

EBV is a gamma herpesvirus that infects the B cell population. EBV has a 95 % seroprevalence in the adult population worldwide, with roughly 50 % of the population in developed countries being exposed by the age of five. EBV is

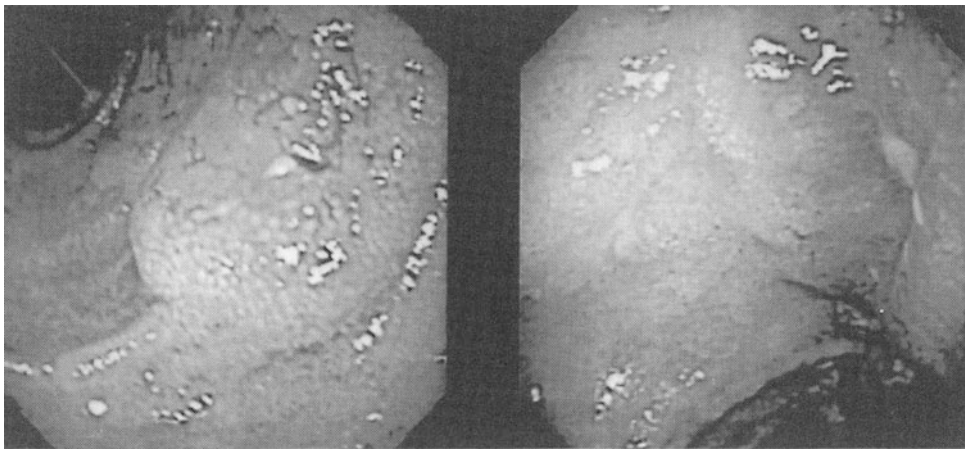

FIGURE 15-2. Endoscopic image of posttransplant lymphoproliferative disease lesion in an intestinal allograft.

directly responsible for the development of the clinical syndrome of infectious mononucleosis in immunocompetent people and also leads to EBV-driven diseases in organ transplant recipients and other immunosuppressed individuals [50]. The early experience in intestinal transplant under either cyclosporine- or tacrolimus-based immunosuppression identified EBV disease and PTLD as a major cause of morbidity and mortality. The ability to directly monitor for EBV viral replication with PCR allowed us to better define the spectrum of EBV infection and disease in recipients of intestinal transplantation and devise methods to avoid the development of lymphoma in these patients. EBV infection is often discovered as asymptomatic viremia. If unrecognized and left untreated, EBV viremia can progress in immunosuppressed hosts to invasive EBV disease and can then potentially further progress to polyclonal and potentially monoclonal PTLD including lymphoma. EBV infection can also present clinically as a febrile syndrome, nonspecific lymphadenopathy mimicking mononucleosis.

In the early era of intestinal transplant, OKT3-based immunosuppression and the lack of EBV-monitoring protocols lead to the development of PTLD in 25 % of recipients [51]. With the development of preemptive therapy protocols and refined immunosuppressive protocols, the PTLD incidence and mortality were significantly reduced to 7 % [51].

Similar to CMV, the most common location for invasive EBV disease is the allograft itself, with the intestine being involved in 71 % of the recipients. Historically, the diagnosis of EBV infections and of PTLD is typically in the first year after transplant, with the average time from transplant to the diagnosis of PTLD in pediatric ITx recipients being 9 months [52, 53]. However, later cases do occur and PTLD is diagnosed after the first year in roughly 30 % of cases [52, 53]. Prior to monitoring protocols, EBV disease was frequently found with endoscopy or a computed tomography after nonspecific abdominal findings or peripheral lymphadenopathy in an ill patient [12]. The pattern of EBV disease in intestinal

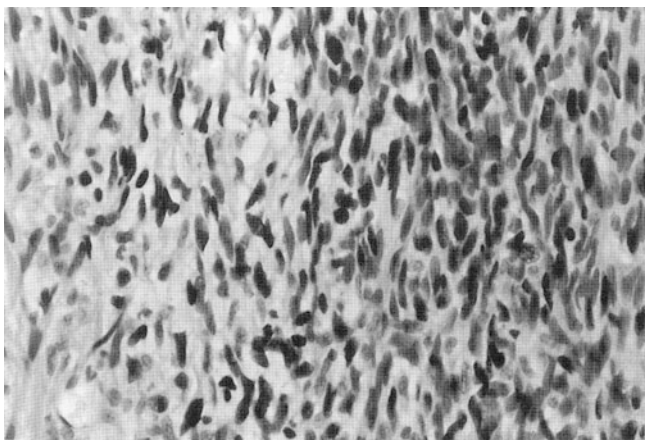

FIGURE 15-3. Posttransplantation spindle cell lesion (PTSD).

transplant recipients is similar to patterns historically seen with other solid organs, in which a nonspecific viral syndrome may eventually progress to PTLD. It can present clinically as a febrile syndrome, nonspecific lymphadenopathy mimicking mononucleosis, PTLD, or lymphoma. Similar to CMV, the most frequent site of involvement is the intestinal allograft; however, the native gastrointestinal tract is also frequently involved. The classic presentation is lymphadenopathy (although this may be limited to intra-abdominal location), blood in the stools, and an endoscopic finding of nodular ulcerated tumors in the intestinal allograft or the native gastrointestinal tract (Figure 15-2).

The histology of EBV disease is also similar to that described in other solid organ transplant recipients, with both polymorphic and monomorphic disease and variations in clonality being seen. Of interest, however, is the fact that the authors have cared for several patients who developed EBV-associated spindle cell tumors (Figure 15-3). These children had previously experienced an episode of EBV-associated PTLD. The EBV-serologic status prior to transplantation is unique to this population because, in con-

trast to other organs where EBV seronegativity is a major risk for EBV disease and PTLD, PTLD has been observed in seropositive patients as frequently as in seronegative patients (20.7 % vs. 19.4 %) [53].

The high frequency of, and the mortality associated with, EBV disease prompted the development of a prevention and preemptive treatment strategy for EBV infection in intestinal transplant recipients and has been a useful adjunct in the management of patients with established disease as well. In 1994, the authors began monitoring the EBV viral load in the peripheral blood using a quantitative competitive polymerase chain reaction (QC/PCR) assay. This monitoring was coupled with a preemptive therapy (PT) strategy in an effort to diagnose early EBV infection rather than after established disease or PTLD is present. This strategy included the use of ganciclovir and intravenous immune globulin and the judicious weaning of immunosuppression. The management of EBV disease and PTLD in intestinal transplant recipients is more complex than that with liver transplant recipients, because significant decreases or withdrawal of immunosuppression, which are the mainstay for management in other solid organ recipients, can result in severe breakthrough intestinal allograft rejection. This strategy is even more challenging as ITx recipients can present with evidence of concomitant EBV disease and rejection. Thus, the morbidity and mortality in the setting of PTLD can stem from the lymphoproliferative process, concomitant infections with CMV and bacterial pathogens, and/or severe intestinal allograft rejection [52, 53].

Patients with active EBV disease typically have an elevated EBV viral load in the peripheral blood; however, elevated loads may be present in otherwise asymptomatic individuals. These individuals are amenable to PT with intravenous ganciclovir (10 mg/kg/day), CMV IVIG (300 mg/kg every 2 weeks), and possible reduction in immunosuppression. At our institution, this therapy is instituted for elevated and/or rapidly rising viral loads. The exact level of EBV load to initiate PT will vary according to which assay is used to measure the load. In addition, we have typically initiated PT at very low loads for EBV-seronegative recipients experiencing primary infection while we have used cutoffs close to levels where EBV disease and PTLD are observed for those who are EBV seropositive prior to transplant. Although the effectiveness of each of the individual components of this strategy remain unproven, the combined use of this approach along with evolutions in immunosuppression algorithms for these patients has resulted in decreases in the incidence, morbidity, and mortality attributable to EBV disease and PTLD in this population [53].

Interestingly, this protocol also led to the recognition of a subgroup of children (roughly 20 % of children) who fail to resolve their EBV viremia. This results in the development of a high-load carrier state, in which patients have a significant EBV viremia (>16,000 EBV copies/mL whole blood at our institution) on >50 % of samples for more than 6 months, following either asymptomatic viremia or resolution of invasive EBV disease/PTLD. Management of these patients is challenging as 37 % will develop EBV disease with PTLD being diagnosed in 11 %, despite appropriate preemptive treatment and reduction in immunosuppression [54, 55].

In addition to judicious reduction in immunosuppression and institution of antiviral therapies, one must carefully monitor patients with EBV viremia for the development of invasive disease and PTLD. Because the lesions most frequently are found in the intestine, any patient with symptoms should have a lower and/or proximal endoscopy, followed by CT of the neck, chest, abdomen, and pelvis. Evidence supports a potential role for PET scans for the diagnosis and follow-up of PTLD in selected patients, though specific guidance on its use is not available [56].

Biopsies of suspicious lesions will provide histologic confirmation of the diagnosis of PTLD; however, the use of immunohistochemical stains for the presence of EBV (Epstein–Barr early RNA stain [EBER stain]) is a helpful adjunct for distinguishing EBV-infected cells from nonspecific lymphocytic infiltrates. Such EBV infiltrates may also produce apoptosis in the intestinal crypt epithelium, thus mimicking rejection. In addition, biopsies of lesions should be evaluated for the expression of the cell marker CD20 that predicts the response to potential treatment options.

The historic management of EBV disease and PTLD has centered on significant reductions in, or withdrawal of, immunosuppressive medications, thus allowing the immune system to develop a cytotoxic T-cell lymphocyte response to control the infectious process. With intestinal transplant recipients, such manipulations of immunosuppressive drugs have resulted in high rejection rates, complicating the management of EBV disease and PTLD. More recent immunosuppressive management strategies using antilymphocyte globulin induction and tacrolimus at low levels (10 ng/mL) and no steroids have allowed for significant improvement in the incidence and severity of rejection and also the ability to minimize immunosuppression in a similar fashion as with other organs. This has resulted in improved survival and also in a significantly lower rate of CMV and EBV/PTLD [12] (Figure 15-4). The majority of patients will demonstrate some evidence of a clinical response within 2–4 weeks after modulation of medications. The impact of EBV viral load monitoring on the incidence and outcome of EBV disease and PTLD cannot be overemphasized. Rates of EBV disease and PTLD using this approach have dropped dramatically when compared to a cohort of children undergoing intestinal transplantation at the authors' institution prior to the availability of this approach [54]. Therefore, early diagnosis does affect the outcome of EBV disease, and judicious reductions of immunosuppression in this setting allow resolution with a lower incidence or absence of rejection of the intestinal allograft.

The mortality of this disease during the authors' initial experience was pervasive (50 %), principally due to the asso-

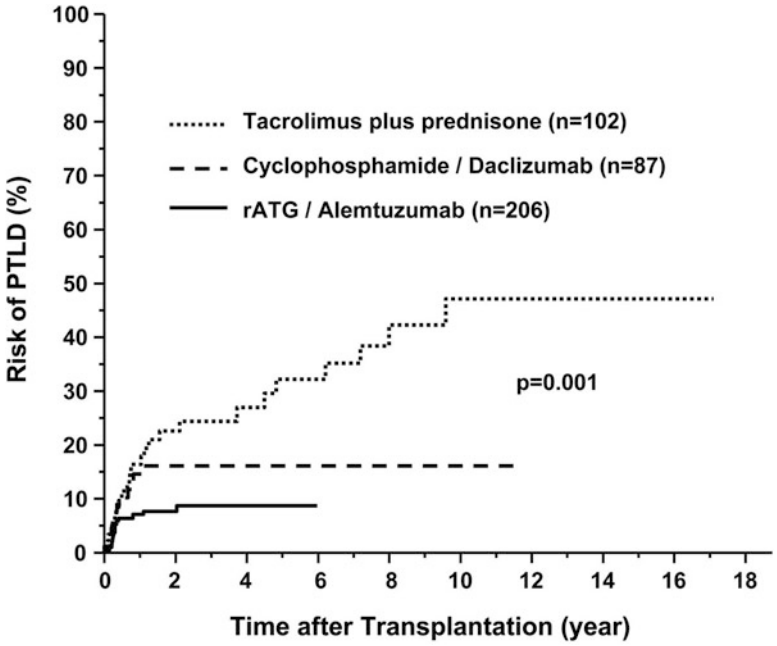

FIGURE 15-4. Cumulative risk of PTLD in three eras of immunosuppression. Note the striking differences in PTLD rates in patients receiving rATG preconditioning (*solid line*). From Abu-Elmagd K, Mazariegos G, Costa G, Soltys K, et al. Lymphoproliferative disorders and de novo malignancies in intestinal and multivisceral recipients: Improved outcomes with new outlooks. Transplantation 2009; 88:926–34.

ciated rejection during the treatment for PTLD. During this early experience, the results of treatment of lymphoproliferative disorder were further limited by the fact that 30 % of the surviving patients experienced chronic and/or recurrent episodes of EBV disease after successful therapy [52]. This contrasts sharply to the recurrence rate of 5–10 % seen with other solid organ transplants. This likely results from the ongoing need of the intestinal transplant recipient to continue with high baseline levels of immunosuppressive therapy, which limits the body's ability to generate a cytotoxic T-cell lymphocyte response against EBV. Of note, evolutions in the management of ITx recipients, including evolving immunosuppression strategies and the use of EBV load monitoring, have resulted in a marked improvement in the outcome of PTLD [51]. Unfortunately, this will not be adequate treatment in some PTLD lesions that are no longer under control of EBV and behave more like true malignancies [50]. The authors recommend a trial of immunosuppression reduction unless there is concurrent rejection or histologic evidence of true malignancy. In addition to IS reduction, antiviral and immunomodulating medications can be used as potential therapy, with failure leading to the use of cytotoxic chemotherapy.

Newer therapies for the treatment of EBV disease and PTLD are also showing promise [57, 58]. Rituximab is a chimeric humanized antibody against the B-cell antigen CD20. Studies have demonstrated variable success in using rituximab in treatment of PTLD that has not responded to IS reduction. Studies in children have shown good short-term response rates of 80 %, though there is a significant recurrence rate of 25 % [58]. Rituximab has become a key component of treatment of CD20-positive PTLD in some intestinal recipients, especially those with concurrent rejection or those not responding to the combination of immunosuppression reduction and antiviral/immunoglobulin therapy. Vigilant posttreatment follow-up is required as recurrence is possible and occurred in roughly 20 % of responders in one large French study, at a median of 7 months after treatment. In addition, a significant percentage of patients will develop hypogammaglobulinemia and should be appropriately treated [58]. Additionally, encouraging results have been obtained using a combination of low-dose chemotherapy and rituximab in the treatment of PTLD in setting of solid organ transplant. Studies have shown 2-year relapse-free survival rates of 70 % [59]. While the use of EBV-specific cytotoxic T-cells (CTL) to treat EBV-related PTLD (which has shown to be effective in bone marrow recipients) is of interest, experience to date has not been able to demonstrate definitive success in SOT recipients. As an alternative approach, Haque and colleagues have developed a bank of 100 EBV-specific CTLs, using healthy blood donors in the UK. Using this bank, the authors used HLA "best fit" CTLs in a phase II multicenter trial to treat PTLD that was refractory to other methods with 52 % overall response rate. Of those patients that had a response, an impressive 82 % were complete [60] with documented long-term survival in responders [61]. Finally, transplant physicians should also recognize the importance of allograft enterectomy to allow for complete withdrawal of immunosuppression in cases where such an approach can be taken (isolated intestinal transplant), especially for those not responding to first- or second-line therapies.

15.6.2 Respiratory Illnesses

Respiratory viruses remain a major source of morbidity and mortality in immunocompromised organ transplant recipients (Table 15-1). The majority of lower respiratory tract viral infections (LRTRVI) are caused by RSV, influenza, parainfluenza, adenovirus, and rhinovirus. Fortunately, advances in qualitative and quantitative RT-PCR technology have allowed for the rapid and reliable detection of specific LRTRVI pathogens with 95 % overall sensitivity and specificity [62].

In a recent retrospective review of 25 children who had undergone intestinal and/or liver transplant, the Miami group reported a high rate of rhinovirus as an etiology of LRTRVI. Although the overall mortality associated with LRTRVI was from 13 %, no children with rhinovirus succumbed to the disease. Interestingly, RSV infection was associated with a 40 % mortality, and was the direct cause of death, despite reduction in immunosuppression and administration of palivizumab [63]. Due to the potential morbidity and mortality associated with RSV LRTRVI [64], some experts recommend immunoprophylaxis with an RSV-specific monoclonal antibody (palivizumab) for children less than 1 year of age who are transplanted or are receiving antilymphocyte treatment during RSV season. Treatment of RSV is limited, though careful reduction in baseline immunosuppression should be considered if clinically warranted. Aerosolized ribavirin is currently approved for the treatment of severe RSV LRTRVI and is generally used in combination with palivizumab, though data supporting this are limited. Intravenous ribavirin has also been used for treatment; the benefit of this agent must be weighed against the potential for the development of complication, specifically hemolytic anemia [65]. An in-depth discussion of other respiratory viruses (influenza, parainfluenza, and coronaviruses), their treatment, and prevention with vaccination strategies before and after transplantation can be found elsewhere (Chaps. 30 and 32). However the authors would stress the importance of *avoidance* of infection with well-thought-out policies regarding timing of vaccination and/or immunoprophylaxis in this challenging population.

Pneumocystis jiroveci also represents an important pathogen to be considered in intestinal transplant recipients. Based on older studies done prior to the routine use of prophylaxis, up to 15 % of organ transplant recipients experienced an infection with *Pneumocystis*. The clinical course of *Pneumocystis jiroveci* pneumonia is generally one of dyspnea and hypoxia out of proportion to physical and radiographic findings. Rapid diagnosis is important and although PCP can be suggested by the presence of diffuse bilateral pulmonary infiltrates on radiographs and CT scans, diagnosis requires confirmation by direct detection of the organism in secretions. Direct staining of secretions from either induced sputum or bronchoalveolar lavage can be accomplished with immunoflourescent antibody stains and direct staining with Giemsa, Wright, and Gomori methenamine silver preparations. Treatment is with trimethoprim–sulfamethoxazole. Inhaled pentamidine has also been utilized and adjuvant corticosteroids may improve oxygenation in cases associated with significant hypoxia. Long-term prophylaxis in all intestinal patients is recommended. The ideal agent for prophylaxis is TMP–SMX, which is generally well tolerated and provides excellent prophylaxis against toxoplasmosis and *Nocardia*, both potentially fatal opportunistic infections in immunosuppressed patients [66–68].

15.6.3 Diarrheal Illnesses

Infectious diarrhea is a frequent complication after intestinal transplant and represents a frequent and clinically challenging differential diagnosis. Significant osmotic diarrhea in a patient with an intestinal allograft is rejection until proven otherwise. Fever is as likely to be a manifestation of intestinal rejection as infection and cannot be used to differentiate the two and the treatment of intestinal rejection, augmentation of immunosuppression, is the polar opposite of that for infectious diarrhea. Inappropriate use of immunosuppression to empirically treat rejection in a transplant patient can, and has been, a fatal mistake. Conversely, delayed treatment of severe rejection due to a suspected infectious cause can lead to exfoliative rejection and graft loss. Unfortunately, gross inspection of the allograft is nonspecific and requires histologic inspection to adequately differentiate between severe allograft enteritis and rejection. In addition, the ability to make the diagnosis is further confounded by the possibility that the two processes can occur simultaneously or that rejection can rapidly follow an episode of infectious enteritis, making serial endoscopic investigations necessary. In the end, the differentiation between infection and rejection relies on the balance of clinical suspicion, presentation, and direct inspection of the allograft. Rapid processing and rapid availability of biopsy samples is required to aid in the timely differentiation between the two entities.

Rotavirus. Historically, rotaviral enteritis (RVE) is a common cause of diarrhea in children and has been a significant cause of intestinal allograft enteritis, manifested as severe osmotic diarrhea without blood or abdominal pain. Fever is not generally a feature and the illness is generally self-limited, lasting roughly 10 days. Close follow-up is required for patients experiencing RVE of the intestinal allograft, as the postinfectious period is associated with a dramatically increased risk of cellular rejection, with 70 % of patients experiencing rejection, either concurrently or at a mean of 22 days after the RVE [69, 70].

Other Agents. The intestinal allograft can be affected by any of the other common infectious etiologies of diarrhea. Adenoviral enteritis was found in an additional 20 % of cases [70]. Interestingly, the most discussed agents, CMV and

EBV, were not frequent causes of diarrhea in intestinal recipients. *Clostridium difficile* is another common cause of infectious diarrhea after SOT (including intestinal transplant recipients) with a prevalence of 2.7 % in a recent report of patients undergoing SOT [71]. Although specific reports describing the course of CDI in intestinal transplant recipients are lacking, however it was found to be the etiology of diarrhea in 15 % of these patients and responded to standard antibiotic therapy [70]. Recurrent CDI has been shown to be associated with risk factors such as increased LOS, prolonged antibiotic courses, high levels of immunosuppression, and other comorbid conditions [71]. Parasitic enteritis is also seen n ITx recipients. Infection due to *Cryptosporidium* sp. has been reported in intestinal recipients [70] as has infection due to *Giardia lamblia* [70]. Recent attention has begun to focus on norovirus as a cause of enteritis in SOT recipients. Despite its self-limited course in the general population, norovirus has been demonstrated to be the cause of prolonged diarrhea with severe dehydration in pediatric intestinal transplant recipients and infection is associated with a prolonged viral shedding [72]. Diagnosis can be difficult, as intestinal epithelial apoptosis is a common finding in human calicivirus enteritis, making differentiation for rejection difficult. If clinically suspected, however the diagnosis can be confirmed with PCR analysis of biopsy specimens or effluent [73].

Part III
Specific Sites of Infection

16 Pneumonia After Hematopoietic Stem Cell Transplantation

Catherine Cordonnier

Pneumonia is the most common infection after transplantation, and the infection with the highest mortality. Roughly two thirds of pneumonia observed after HSCT are of infectious origin, and this observation should be a priority leading the investigations. While the infection-related mortality has decreased after HSCT over time [1], it is not sure that the incidence of pneumonia decreased in parallel. Up to 30% of the patients may develop pulmonary symptoms within the first 100 days after allogeneic HSCT [2]. Even in T-cell-depleted allogeneic HSCT where the incidence of pneumonia seems to be low [3], the occurrence of pneumonia significantly impacts on survival. The rates of bacterial, viral, and polymicrobial pneumonia do not seem to be different during the first 3 months after transplant between allogeneic and autologous HSCT recipients, while the rate of invasive fungal disease (IFD) is much higher after allogeneic HSCT [2], due to a more severe and prolonged immune defect which also favors late infectious complications [4].

Factors enhancing the risk of infectious pneumonia are many and include donor and recipient serologies; previous pneumonia, which may warrant secondary prophylaxis; graft source; choice of donor and conditioning; graft-versus-host disease (GVHD); and also environmental factors. One of the main concerns in pneumonia evaluation is to distinguish infectious and noninfectious pneumonia since many noninfectious causes may mimic infection. Additionally, pulmonary coinfections are frequent. This makes that the results of indirect markers, even though extremely useful in practice, should be cautiously considered as it may identify only part of the responsible pathogens. Only a direct investigation of the lung as provided by bronchoalveolar lavage (BAL), combined with the use of well-chosen indirect markers, gives the best chances to identify several causes of pneumonia.

This chapter focuses on the factors that make the lungs particularly susceptible to infections after HSCT, the main specificities of clinical and imaging presentation of pulmonary infections, and the principles of diagnosis and management.

16.1 Altered Pulmonary Defense After HSCT

The lungs of HSCT candidates may have been exposed to toxic insults from their underlying diseases, prior infection, and prior chemotherapy and irradiation which may compromise normal surveillance barriers. Conditioning before transplant and subsequent immunosuppressive therapy and infection all may impair native defenses and increase the risk for pulmonary infection.

The ciliated and squamous epithelium, from nasopharynx to distal bronchioles, is the first line of defense. Significant impairment of the ciliary epithelium has been reported even years after transplant [5]. The respective role of viral or mycoplasma infection or of GVHD or radiation in this finding cannot be precisely determined. However, these abnormalities were found in 17 of 20 long-term allogeneic HSCT survivors and are probably underestimated in routine practice.

Alveolar macrophages act as phagocytes and secrete cytokines and chemokines providing a next level of defense. Their functions may be altered by immunosuppressive agents and viral infection. During prolonged neutropenic phases, the number of alveolar macrophages decreases, and this could favor infection from pathogens, which are normally phagocyted at the alveolar level [6]. Additionally, after allogeneic HSCT, the recipient alveolar macrophages are progressively replaced by cells of donor origin, and this may partly explain the numeric and functional impairment of the alveolar macrophage population during the first months after transplant [7, 8].

16.2 Evolution of the Problem

The occurrence of infectious pneumonia relates to the interrelationship of infectious exposure or reactivation, the condition of the lungs, and the degree of immunosuppression. The changes in many transplant procedures, including various

P. Ljungman et al. (eds.), *Transplant Infections*, DOI 10.1007/978-3-319-28797-3_16

prophylaxes, and the availability of new diagnostic tools over the last decade should have changed the incidence of pneumonia after HSCT. However, there is no clear data to support this hypothesis, and one may consider that these changes have more resulted in a change in timing and causes of pneumonia rather than in incidence or mortality. The increasing use of reduced intensity conditioning (RIC) regimens has significantly decreased the formerly high rate of early bacterial pneumonias. However, concomitantly, multidrug-resistant (MDR) bacteria have become a global concern in most hematology wards [9, 10]. The use of RICs has also changed the kinetics of many complications, delaying the onset of GVHD and the subsequent infections [11, 12]. Preemptive and prophylactic strategies of CMV infection have also considerably reduced the incidence of CMV pneumonia which nowadays affects less than 6% of the patients [13, 14]. However, pneumonia due to respiratory viruses has become common. New antifungal agents have improved therapeutic options for *Aspergillus* infection, but non-*Aspergillus* molds, especially mucormycoses, are being seen with increasing frequency [15–18]. Finally, despite significant progresses, the morbidity and mortality of pneumonia after HSCT remains one of the highest of any transplant.

The timing of infectious pneumonia follows the timing of other infections according to the type of transplant and occurrence and severity of GVHD which is the main factor prolonging the infectious risk after the neutropenic phase [4]. HSCT recipients are both at risk for nosocomial and community infections according to the phase of transplant. These environmental risks cannot always be prevented, on the contrary of the reactivation risks which must be evaluated before transplant.

16.3 Main Causes of Infectious Pneumonia After HSCT

Although changes in the transplant procedures have impacted on the infectious complications and their timing (see Chap. X), infectious pneumonia after HSCT occurs in predictable risk periods. After allogeneic transplant, early bacterial pneumonia mainly complicates myeloablative transplant, while opportunistic fungal and viral infections may affect the patient irrespectively of the type of conditioning. After autologous transplant, most pneumonias occur during the neutropenic phase, especially in myeloma patients [19], and few of them are of fungal origin [16].

16.3.1 *Bacterial Pneumonia*

Bacterial pneumonia occurring during the initial neutropenia are caused by pathogens common to all neutropenic patients or to those with comparable mucositis in the ward. The clinician should also consider the possibility of streptococcal pneumonia or ARDS related to streptococcal sepsis. These infections are particularly due to *Streptococcus viridans* and have been correlated with the presence of mucositis, the use of prophylactic quinolones, and the administration of high doses of cytarabine (see Chap. 20). The approach to bacterial pneumonias early after transplantation is similar to that in other neutropenic hosts, and it should include coverage for *Pseudomonas* species and eventually MDR in case of previous colonization or infection [20, 21].

Most patients are maintained on indwelling intravenous catheters throughout this period, and seeding of the lungs from bacteremia continues to be a potential risk. After recovery from neutropenia, allogeneic transplant recipients continue to be at risk for any nosocomial infections as long as they stay in the hospital (see Figure 16-1). Bacterial infections occurring in the late posttransplantation period may be favored by persistent immunoglobulin deficiency, which increases the risk of pneumonia caused by encapsulated bacteria.

Invasive pneumococcal infection occurs significantly more often after allogeneic, than after autologous, transplantations and especially in case of chronic GVHD [22–24]. They may be rapidly fatal. In a prospective study from the European Blood and Marrow Transplantation Group [22], no pneumonia developed in seven cases of invasive infection observed before day 100, whereas it was seen in 18 of 44 (41%) cases observed after day 100, and half of the fatal cases of late infection were associated with pneumonia. Early immunization with the 13-valent conjugate vaccine, completed by the 23-valent polysaccharide later, or a fourth dose of the conju-

FIGURE 16-1. This 56-year-old patient has received an allogeneic HSCT from an unrelated donor for acute myeloid leukemia. He was smoker and suffered from chronic bronchitis before transplant. He was rehospitalized at 7 months after transplant for severe chronic GVHD and was treated with steroids. He developed febrile pneumonia after 9 days of hospitalization. The lung CT scan showed ground-glass, patchy infiltrates of the left lower lobe. The bronchoalveolar lavage was positive for coronavirus, and the culture of protected aspiration (10^3 CFUs/mL) and the culture of the lavage fluid (10^4 CFUs/mL) were both positive for *Klebsiella pneumoniae.*

gate vaccine in case of GVHD could reduce the incidence of pneumococcal infection over time [25, 26] (see Chap. 48). Similarly, *H. influenzae* may cause pneumonia and sinus infection, usually past the third month after transplantation. Immunization with a conjugate vaccine against type b is recommended from 6 months after transplant.

Pneumonias from *intracellular pathogens* are rarely reported, but they may recur in previously exposed patients. Pneumonia due to *Legionella* species has occasionally been reported in the setting of outbreaks, most often as a nosocomial infection. The radiologic findings may be variable; they may mimic fungal nodules, and they may not be apparent at the onset of high fever and pleuritic pain. Invasive nocardiosis, reported in 0.3–1.7 % after allogeneic transplant, mainly occurs in patients who are not receiving TMP-SMX and is often difficult to differentiate from fungal pneumonia [27, 28].

Mycobacterial infections due to *M. tuberculosis*, *Mycobacterium avium-intracellulare* complex, or other species are rarely reported. Generally, they are diagnosed at 2–18 months after transplantation, but they may develop early when prior infection has occurred (see Figure 16-2) [29, 30].

16.3.2 *Fungal Pneumonia (including pneumocystis pneumonia)*

Fungal pneumonia: *Aspergillus* is the most worrisome cause of IFD after allogeneic HSCT. It reportedly occurs after 0–20 % of transplantations; the most common site is the lung, and GVHD is the main risk factor (see Chap. X). A first peak of incidence occurs during the neutropenic period after myeloablative conditioning regimens, particularly in patients with leukemia. The second incidence peak is generally seen later in patients with acute GVHD and receiving corticosteroids. The availability of antifungal azoles for anti-aspergillus prophylaxis has significantly reduced the incidence [31–33]. However, the mortality of *Aspergillus* remained close to 50 % in recent series. This infection must be considered in any case of fever, particularly in that occurring in the patient on broad-spectrum antibiotics, or of any pneumonia, whether of new onset or a previously diagnosed condition that does not resolve with appropriate therapy (see Figure 16-3). A negative bronchoscopy result, even when combined with testing of galactomannan in the BAL fluid, does not diminish the suspicion for this pathogen. Without secondary prophylaxis eventually combined with surgical removal of the main lesions, the risk of relapse of prior *Aspergillus* infection after HSCT has been estimated around 20 % [34].

FIGURE 16-2. This 37-year-old woman received an allogeneic HSCT from her HLA-identical brother for poor-risk acute myeloid leukemia. She had a past history of pulmonary tuberculosis 10 years ago, but was intolerant to secondary prophylaxis. Three months after transplant, while she was well with no GVHD, she developed an insidious fever. Chest X-ray was normal. The lung CT scan showed diffuse micronodular infiltrates and a sub-parietal nodule of 1.5 cm in diameter in the upper left lobe. The bronchoalveolar lavage was positive for *M. tuberculosis* in culture.

In addition to being found in the lung parenchyma, *Aspergillus* may be isolated in the tracheobronchial tree where it may be responsible for significant airway obstruction. White, adherent plaques may be seen on bronchoscopy, particularly in the setting of chronic GVHD and steroid use. This infection must be differentiated from worsening bronchiolitis, so that inappropriate and dangerous increases in immunosuppression can be avoided.

Pneumonia due to *Candida* species is rarely reported, partly because no firm criteria for differentiating invasive infection from colonization based on bronchoscopy without biopsy exist. The lungs may be involved in any systemic *Candida* species infection.

Pneumonias due to endemic fungi, such as *Histoplasma* or *Coccidioides* species, particularly in North America, must be considered in these patients, as should the emerging fungi, including *Trichosporon*, *Alternaria*, and *Fusarium* [16].

A special attention should be paid to the possibility of *Mucorales* after allogeneic HSCT (see Chap. 39). Its mortality rate is between 50 and 80 % [18, 35–37]. Mucormycosis shares with aspergillosis common risk factors but usually occurs later, and often after voriconazole administration, although the role of a selection pressure is debated [35]. There is no indirect available marker of mucormycosis except PCR test currently in evaluation [38]. The classical presentation of mucormycosis after transplant mostly mimics aspergillosis, but galactomannan is negative (see Figure 16-4). Differentiating mucor from aspergillus infection is, however, of great importance due to different therapeutic implications. As long as there is a doubt between the two infections, the patient must be treated with liposomal amphotericin B.

Pneumocystis jirovecii Pneumonia (PjP) Historically, the incidence of PjP in patients not receiving prophylaxis in the 1980s was found to be 16 % during the first 6 months after transplant [39, 40]. This incidence has dramatically decreased between 1 and 2.5 % [41, 42] with the use of trimethoprim-sulfamethoxazole (TMP-SMX) prophylaxis, but the mortality in established PjP remains around 50–70 % [43–45].

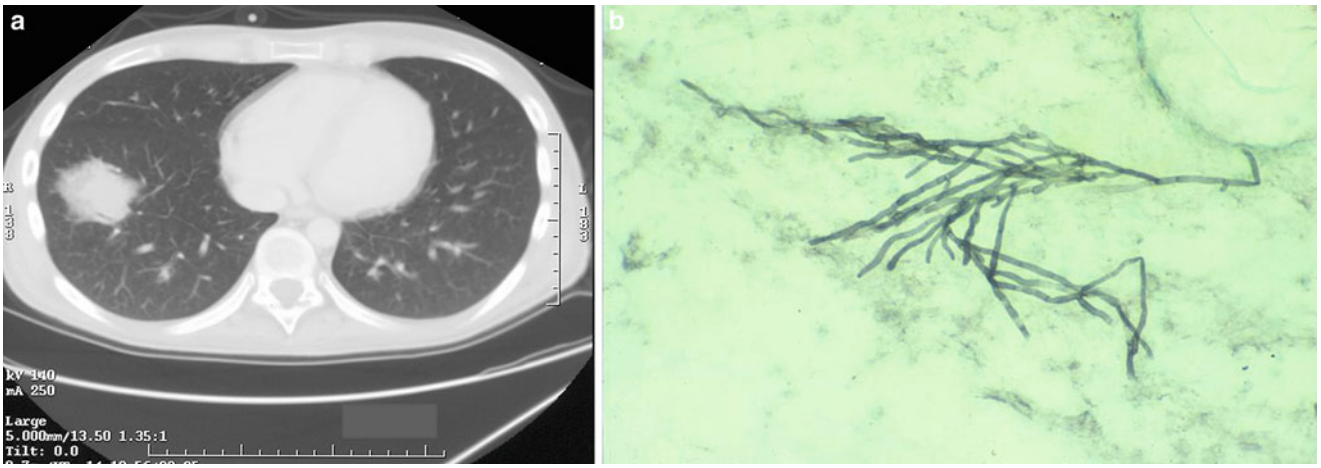

FIGURE 16-3. This young patient, 20 years old, received an allogeneic HSCT from an unrelated donor for acute lymphoblastic leukemia in second remission. He got severe acute GVHD and was not compliant to anti-mold azole prophylaxis. He developed an acute right chest pain with fever. (**a**) Both X-ray and CT scan showed a macronodular and isolated lesion of the right lower lobe. Serum galactomannan assay was negative. (**b**) The bronchoalveolar lavage smears showed hyphae characteristics of aspergillus (Gomori-Grocott stain). The culture of BAL fluid grew to *Aspergillus fumigatus.*

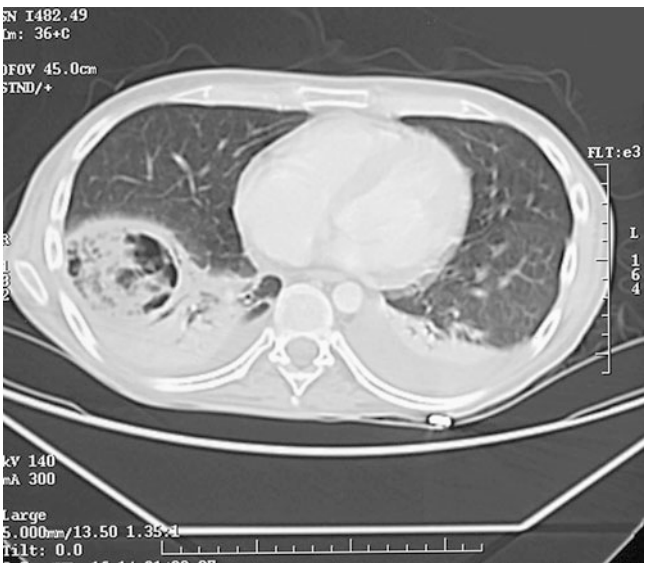

FIGURE 16-4. This 28-year-old patient had received an allogeneic HSCT for acute lymphoblastic leukemia from an unrelated donor. He got severe, cutaneous, and gut GVHD and was treated with steroids. At 4 months after transplant, while still on 0.7 mg/kg of prednisone, he developed a nodular lesion of the right lower lobe. A galactomannan test was positive in serum. He refused fibroscopy and was treated for aspergillus infection with voriconazole. He then did not attend the consultations for 1 month and came back with bilateral thoracic pains and fever. The CT scan showed bilateral pleural effusion and a voluminous round, necrotic lesion surrounded by an area of consolidation in the right lower lobe. Rhizopus grew from the BAL fluid.

However, in patients receiving dapsone prophylaxis, an incidence of 7.2 % was reported after allogeneic HSCT [43]. PjP usually manifests with fever, nonproductive cough, dyspnea, and diffuse interstitial pneumonitis. In HSCT recipients, the presentation of PjP may be extremely abrupt, and the patient may quickly deteriorate and require intensive care unit (ICU) [46–48]. Rarely, the disease may reveal by an isolated low-grade fever and a normal chest X-ray at the beginning. In such cases, if the cause of fever is not rapidly found, a CT scan will show pulmonary ground-glass lesions and prompt a BAL [49]. The elevation of LDH is poorly helpful [46]. Most patients present with nodular infiltrates or other pattern of diffuse interstitial pneumonia. Pleural effusion and pneumothorax are uncommon [44]. Most cases occur between 3 and 24 months after transplant, in patients with acute or chronic GVHD or in relapse of the underlying disease [42, 43, 49, 50]. Most are receiving steroids, especially at a phase of tapering off, or after recent withdrawal, and do not receive, or are not compliant to, TMP-SMX prophylaxis [51]. Whether a low CD4 count is a main risk factor for developing PjP after HSCT is unknown.

P. jirovecii is not cultivable in vitro. It may be identified by microscopic detection, direct or indirect immunofluorescence (IF), or nucleic acid tests (NAT) (see Figure 16-5). Several stainings may be used for microscopic detection of trophic forms and cysts in any respiratory sample such as Giemsa to identify trophic forms and toluidine blue O or calcofluor white to detect cysts, without significant difference in their diagnostic performance. IF has a better sensitivity than conventional stainings [52, 53]. The combination of one classical staining and IF allows the detection of both cystic and trophic forms. PCR is the most sensitive diagnostic assay to identify pneumocystis [54–56], although no study defines a clear cutoff of positivity [57, 58].

HSCT recipients, as other non-HIV-infected patients, are known to be infected with low burden of cysts [53, 59, 60]. As there is a decreasing gradient of the pneumocystis burden from upper to lower respiratory airways, this probably explains

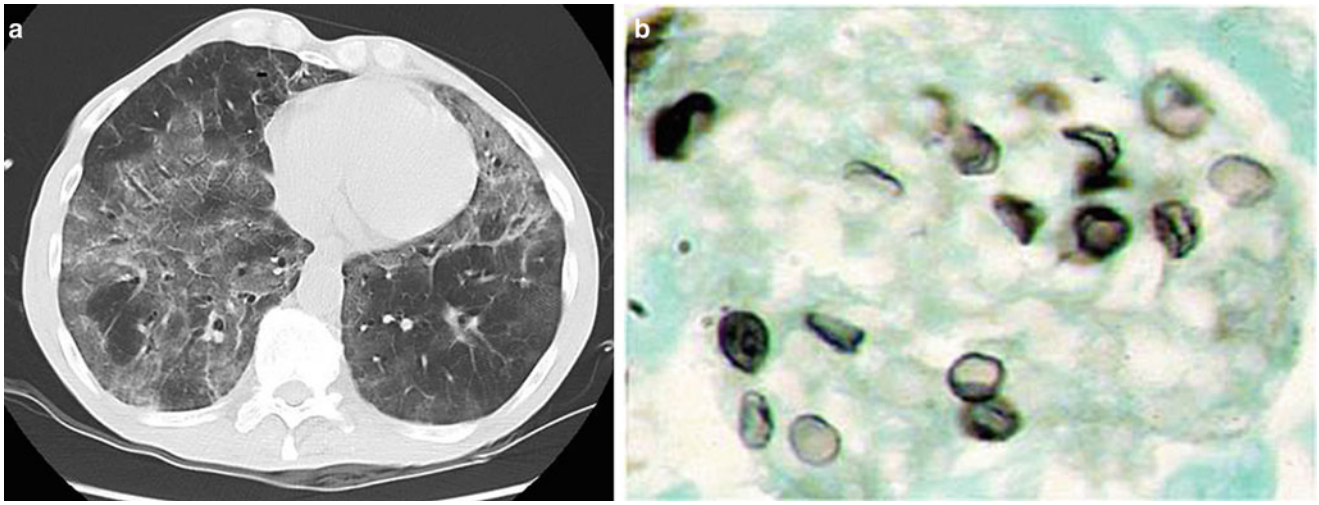

FIGURE 16-5. This 62-year-old patient received an autologous peripheral blood stem cell transplantation for non-Hodgkin lymphoma. He developed a severe rash under trimethoprim-sulfamethoxazole at the end of the first month after transplant. He was therefore switched to atovaquone for *P. jirovecii* prophylaxis. Five months after transplant, he developed fever and rapid respiratory failure with hypoxemia. A chest X-ray showed slight interstitial, bilateral lesions. (**a**) The CT scan showed bilateral ground-glass lesions predominant on lower lobes. (**b**) The bronchoalveolar lavage showed characteristic cysts of *P. jirovecii* on Grocott staining. IF and qPCR were also positive.

the difficulties to identify *P. jirovecii* in induced sputum or other upper respiratory samples with conventional techniques in non-HIV-infected patients. Therefore, BAL fluid is the preferred specimen for the diagnosis of PjP in HSCT recipients. Another argument for BAL is that half of the PjP cases in non-HIV-infected patients are associated with coinfections, especially with bacteria, CMV, and *Aspergillus spp*. [44, 46, 61] which require identification and treatment.

In case a BAL cannot be done, upper respiratory tract (URT) specimens, like induced sputum, oral washings, nasal swabs, or nasopharyngeal aspirates, can be used, but with a lower expected diagnostic value than with BAL. Serum (1-3) β(beta)-D-glucan is a major cell wall component of *P. jirovecii*. Two meta-analyses [62, 63] have shown its excellent sensitivity, but due to its panfungal nature and the frequency of other IFD after HSCT, it can be only a screening tool for PjP. On the other hand, its use in BAL fluid is not recommended, due to a poor sensitivity and reproducibility [64, 65]. The recent guidelines of the fifth European Conference on Infections in Leukemia [66] propose a practical algorithm for the diagnostic of PjP in non-HIV-infected patients, based on the examination of BAL fluid with IF and qPCR. The positivity or negativity of both techniques signs the presence or absence of PjP. When IF is positive, and qPCR negative, this should reflect a technical problem, mainly of qPCR. When qPCR is the only positive assay, although no quantitative cutoff can be uniformly proposed, a high fungal burden favors a diagnosis of PjP. The concomitant positivity of serum (1-3) β(beta)-D-glucan is an additional argument favoring PjP. When BAL is not possible because the patient is too hypoxemic or refuses the procedure, serum (1-3) β(beta)-D-glucan can be helpful in conjunction with URT samples. When the clinical suspicion of PjP is high and the BAL cannot be done immediately, an empirical treatment with TMP-SMX should be started as soon as possible since it will not impair the diagnostic yield of investigative procedures before at least several days. TMP-SMX at the dose of 15–20 mg/kg of TMP plus 75–100 mg/kg of SMX, by oral or preferably IV route, is the first choice for treatment [67], even in patients who were supposed to take TMP-SMX prophylaxis as the presence of dihydropteroate synthase mutations does not significantly affect the treatment efficacy [68]. The addition of steroids for the more hypoxemic patients (PaO2 while breathing room air <70 mmHg), although well established in HIV-infected patients [69], is debated in others.

PjP prophylaxis is strongly recommended from engraftment for at least 6 months after allogeneic HSCT and longer as far as any immunosuppressive drugs are administered [70, 71] and for at least 3–6 months after autologous HSCT [70]. No large prospective series compare the respective prophylactic efficacy of TMP-SMX with alternatives in HSCT recipients. However, strong arguments from both acquired immunodeficiency syndrome prospective studies and HSCT retrospective series suggest that TMP-SMX is the best prophylactic regimen [43, 72], any alternative to TMP-SMX—dapsone, atovaquone, or pentamidine—being inferior [71].

16.3.3 Viral Pneumonia

During the neutropenic phase of transplant, the incidence of herpes simplex virus (HSV) reactivation and disease—including pneumonia—has fallen sharply with the wide use of prophylactic acyclovir or valaciclovir [73].

Until the beginning of the 1990s, CMV was the most significant pathogen for pneumonia after allogeneic transplant, affecting 15 % of the recipients. Preemptive and prophylactic strategies have greatly decreased its incidence, currently in the range of 1–5 % [14, 74–76]. It is generally a febrile disease in which the radiographic patterns are primarily interstitial but sometimes alveolar. Coinfections are frequent. The optimal approach to identify the virus in the lungs is the combination of IF and rapid culture of BAL fluid. The identification of CMV through PCR on BAL fluid has been shown to have limited correlation with the development of CMV pneumonia and therefore is not considered as criteria for CMV pneumonia [77] (see Chap. 24). Therefore, as most of the laboratories abandon IF assays to more automated qPCR techniques, a careful examination of the BAL smears by an experimented cytologist is important to detect the cytological hallmarks of CMV pneumonia, knowing that the identification of the characteristic inclusions in alveolar cells is a sign of advanced infection [78] (see Figure 16-6).

Other herpesviruses, including varicella-zoster virus, EBV, and *Human herpesvirus* 6 (HHV-6), have been reported as causes of pneumonia in HSCT recipients. High levels of HHV-6 DNA have been found in the lung tissue of patients with idiopathic or CMV interstitial pneumonitis [76]. However, the clinical significance of this finding, and the need for specific therapy, is still unclear.

Pneumonia caused by respiratory viruses has become a main concern in HSCT recipients. The list regularly enlarges [79, 80]. The main risk factors for death are the early onset after transplant, neutropenia, lymphopenia, GVHD, steroid administration, and older age [79, 81–83]. Recently, an immunodeficiency scoring system has been proposed to predict poor outcomes and better identify patients infected by respiratory syncytial virus and who should benefit the most from antiviral therapy [83]. The incidence is lower after autologous than after allogeneic transplant [84]. Identification by NAT in respiratory samples is the recommended technique and may be performed on nasopharyngeal or throat swabs, bronchial aspiration, or BAL fluid [79, 85, 86] with multiplex assays. Diagnosing these patients early has several benefits: [1] some of these infections may be efficiently treated (e.g., oseltamivir in influenza infection or ribavirin for respiratory syncytial virus); [2] all of them imply isolation and barrier measures to prevent transmission to other patients or staff; [3] respiratory viral infections early after allogeneic transplant predict the development of alloimmune lung syndrome, including bronchiolitis obliterans and idiopathic interstitial pneumonia [79, 87, 88]. When respiratory viruses are detected before transplant, delaying the transplant should be considered [89].

Measles pneumonia has rarely been reported after HSCT but may be an expected event in the setting of outbreaks [90] and may occur without a rash. Adenovirus pneumonia is a very rare but potentially life-threatening event occurring in the setting either of disseminated adenovirus infection or of usually upper and then lower respiratory tract infections [91] (see Chap. 33) and occur more frequently in children than in adults and in unrelated transplants or after T-cell depletion.

16.3.4 Other Causes

Reports of pulmonary *toxoplasmosis* are rare; it is usually seen in the setting of disseminated infection resulting from reactivation, during the first year after transplantation in seropositive recipients not receiving TMP-SMX. The pattern is usually a diffuse interstitial disease, and neurologic symptoms may be absent. *Toxoplasmosis* may be identified in BAL fluid and blood by IF and qPCR. A prospective screening by qPCR in the patients at risk may allow a preemptive therapy [92].

16.4 Differential Diagnosis to Infectious Pneumonia: The Main Noninfectious Processes Affecting the Lungs After HSCT

The lung is the site of numerous noninfectious injuries causing one third of pulmonary infiltrates after HSCT. This needs to be considered because they may require specific treatments. Pulmonary edema, pulmonary embolism, and acute respiratory distress syndrome may occur at any time, but more often during the early phase of transplant, without any special presentation in transplant recipients and will not be detailed here. Other noninfectious processes affecting the lung deserve specific consideration as they are either frequent or specifically observed in HSCT recipients. These noninfectious processes may be associated with infections, increasing the difficulty to propose optimal treatment. The best identification is however of crucial importance since steroids may be indicated in several noninfectious processes while they will be deleterious in most infections. The probability of their occurrence may vary by time after transplantation and type of transplant.

Alveolar hemorrhage (AH) is a frequent noninfectious process affecting the lung after any HSCT, with an incidence rate of 6–41 % [93–95]. AH is diagnosed on the basis of either a bloody aspect of the BAL fluid—usually transient—or the presence of ≥20 % of siderophages among alveolar macrophages (see Figure 16-7) [96]. AH after HSCT may be an autonomous process favored by thrombocytopenia, other coagulation disorders, or renal failure [96] and by any rupture of the alveolar-capillary barrier such as in pulmonary edema, but it may also be associated with infections, like aspergillus or CMV, in two thirds of the cases [94, 97].

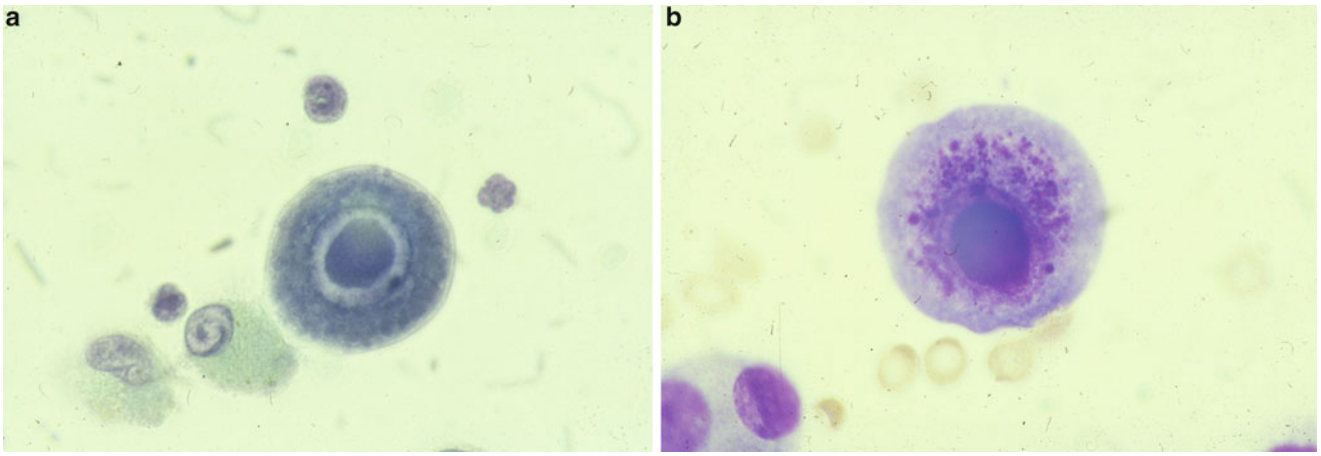

FIGURE 16-6. Bronchoalveolar cytocentrifuged smears in CMV pneumonia. (**a**) Papanicolaou staining: The slide shows the cytomegaly of an infected alveolar macrophage and, additionally, typical haloed "owl-eyed" basophilic intranuclear inclusions (Papanicolaou staining). (**b**) May-Grunwald-Giemsa staining: Intracytoplasmic inclusions, which are pathognomonic of CMV infection.

Neither clinical presentation nor imaging are specific of infectious or noninfectious forms [97].

Secondary alveolar proteinosis (**AP**) is rare, occurring mostly during prolonged neutropenia. It is the result of a complex process probably combining pneumocyte II stimulation and quantitative and functional defects of the alveolar macrophages. This results in an impaired clearance of pulmonary surfactant and the accumulation of a lipoproteinaceous periodic acid-Schiff (PAS)-positive material in the alveolar space (see Figure 16-8) [98, 99]. It usually mimics an insidious pulmonary edema. The diagnosis may be suspected on the sticky aspect of the BAL fluid and then by difficulties to count the cells. The usual stainings do not identify AP. The cytologist must be aware of this possibility and examine the alveolar material on PAS or Black Sudan staining. Secondary AP rarely complicates with severe respiratory failure [99]. When it occurred during neutropenia, it usually improves at neutrophil recovery. However, as for AH, some cases are associated with infections.

Pulmonary veno-occlusive disease is a very rare event after HSCT. It mainly manifests by pulmonary arterial hypertension, but with a normal pulmonary artery occlusion pressure. The diagnosis is extremely difficult. By analogy with liver veno-occlusive disease, it is hypothesized that it is due to chemotherapy and/or radiation toxicity on the small vessels [100, 101].

The engraftment syndrome may be observed during neutrophil recovery, at a median onset of 16 days after transplant, and usually associates ≥2 of the following criteria: fever, skin rash, weight gain due to capillary leakage, and respiratory failure without other identified cause [102]. It is hypothesized that degranulation of upcoming neutrophils could induce lung injury. Engraftment syndrome is associated with a large dose of mononuclear cells infused, the use of G-CSF or GM-CSF, early neutrophil recovery, non-myeloablative conditioning, the use of amphotericin B therapy, and autologous rather than allogeneic transplant [102–105]. An incidence up to 48 % has been reported in children after allogeneic myeloablative transplant, one fourth of them suffering from pulmonary symptoms. As severe patients may require steroids [104, 105], it is important to quickly rule out an infection.

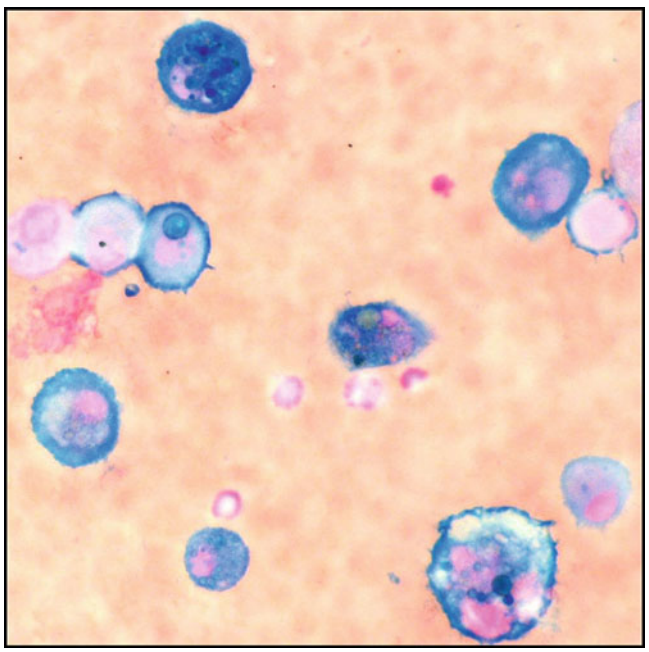

FIGURE 16-7. Alveolar hemorrhage: Bronchoalveolar lavage cytocentrifuged slide stained by Perls' Prussian blue method. The hemosiderin-laden macrophages (siderophages) characteristic of alveolar hemorrhage are identified by their blue cytoplasm (Courtesy of Dr. Jeanne Tran Van Hieu, Pathology department, Henri Mondor University Hospital, Créteil, France).

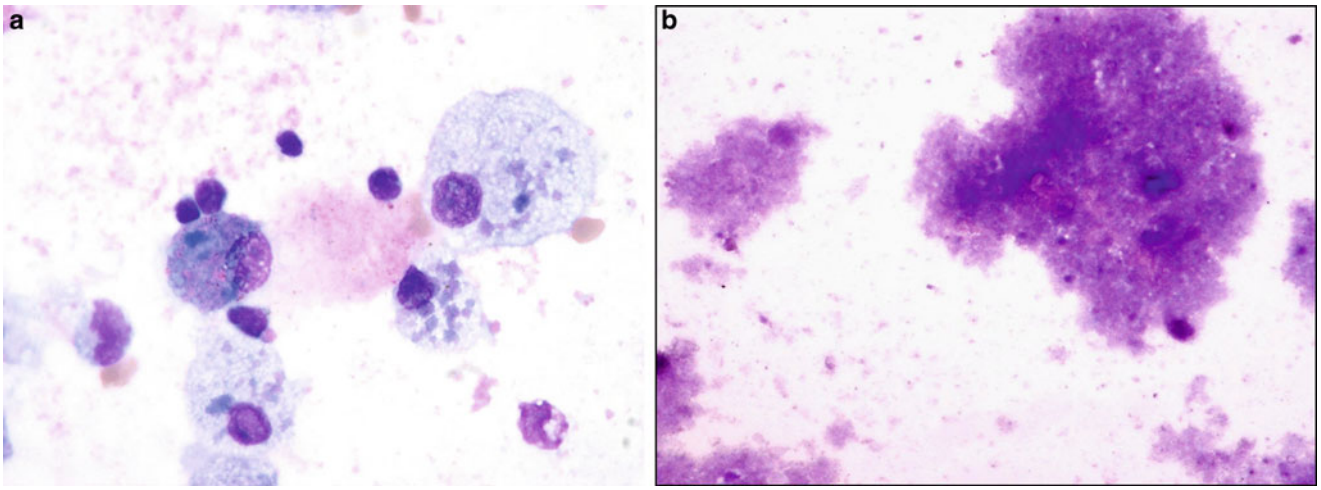

FIGURE 16-8. Secondary alveolar proteinosis: Bronchoalveolar lavage, May-Grünwald-Giemsa (MGG) staining. The presence of eosinophilic pale floccular material between alveolar macrophages and inflammatory cells on MGG-stained slides is highly suggestive of lipoproteinous material (**a**). This can be confirmed using the periodic acid-Schiff (PAS) method that showed positive staining (**b**) (Courtesy of Dr. Jeanne Tran Van Hieu, Pathology department, Henri Mondor University Hospital, Créteil, France).

Idiopathic (noninfectious) interstitial pneumonia is a complication reported in most allogeneic HSCT studies, with a high mortality rate. This diagnosis implies to have ruled out at least the main infections classically presenting as diffuse interstitial pneumonia, especially viral pneumonia and PjP, cardiac dysfunction, and fluid overload [106]. In myeloablative transplant, it has been associated with leukemia or myelodysplastic syndrome, severe acute and chronic GVHD, high-dose total body irradiation, and older age. In allogeneic HSCT, its incidence has been reduced from 8.4 % after myeloablative to 2.2 % after non-myeloablative conditioning [107]. A recent study showed that among 69 HSCT recipients who had developed an idiopathic pulmonary syndrome between 1992 and 2006 in Seattle, a retrospective microbiological screening of BAL material for 3 bacteria, 25 viruses searched with NAT, and galactomannan identified that 56.5 % of the patients had one pathogen (mainly HHV-6, rhinovirus, CMV, and aspergillus), and this finding was associated with an increased mortality at day 100 [76]. This confirms that the rate of "idiopathic" pneumonia is highly depending on how far infection is searched.

Bronchiolitis obliterans (BO or obliterative bronchiolitis) is an important factor contributing to death usually from 6 months after HSCT. Reported only after allogeneic HSCT, the condition has been related to older age, unrelated donor, total body irradiation, decreases in serum immunoglobulin G, and chronic GVHD, with a frequency of 3–10 % in patients with chronic GVHD who survive 120 days [108]. It seems to be prevented by T-cell depletion of the graft [109]. BO usually occurs insidiously, with cough, dyspnea, and wheezing, but may complicate with fever and mimic bronchopulmonary infection. Its hallmark is airway obstruction. The lung CT scan shows hyperinflated bronchiectasis, with a mosaic pattern. BAL and other endoscopic samples are of limited value as they just aim to rule out infection. As no noncontributory BAL can definitely rule out infection, it is preferable to perform two consecutive BALs at 1–2 weeks interval to increase the chance to not miss any pathogen. It is often associated with sinusitis and complicated by infections, especially those caused by *Haemophilus influenzae*, *S. pneumoniae*, *Aspergillus* species, and respiratory viruses. Despite immunosuppressors, the prognosis is poor.

Alveolar or nodular infiltrates may be seen in the setting of allogeneic HSCT as a result of **bronchiolitis obliterans organizing pneumonia** (BOOP)—also called cryptogenic organizing pneumonia [108, 110]. BOOP is much less common than BO and is also considered a manifestation of GVHD but has also been reported after autologous HSCT. It occurs earlier than BO, usually in the first 3 months following transplant. The CT scan shows nodular opacities and patchy consolidations. Pulmonary function tests show a restrictive defect. A histologic diagnosis is strongly recommended because BOOP may mimic infection, but can be reversible with corticosteroid therapy.

Malignant lung lesions may be seen after HSCT, either due to a primary or secondary cancer, localized relapse of the hematologic malignancy (see Figure 16-9), or EBV lymphoproliferative diseases (see Chap. X).

16.5 Principles of Management

Management of pneumonia after HSCT requires a high degree of suspicion and the early use of diagnostic procedures. The increasing availability of indirect markers of infection tends to decrease the early use of BAL. However, BAL remains the easier and safer procedure to identify both infectious and noninfectious causes of pneumonia. More invasive diagnostic

procedures such as transbronchial or lung biopsy need to be selected in situations in which BAL is noncontributory while weighing the risk of increased morbidity.

16.5.1 Clinical Approach to Pneumonia

A systematic approach to pneumonia in any HSCT recipient should include consideration of the following: history, clinical presentation, and imaging.

16.5.1.1 History

Knowledge of a patient's exposure, travel, environmental risks, and previous documented infection, the hospital epidemiology, and the pretransplant donor and recipient serologies particularly with regard to CMV and toxoplasmosis are essential. A history of recurrent MDR bacterial infection may require special consideration in choosing antibiotics [21]. Evaluation of the patient's compliance to anti-infective prophylaxis, especially to TMP-SMX, may be essential in evaluating the risk of PjP [51]. Whether the patient is neutropenic, lymphopenic, or hypogammaglobulinemic at presentation may be important to list the main infectious hypotheses.

16.5.1.2 Clinical Presentation

Symptoms and signs of pneumonia may or may not be typical of a known infectious cause. However, none is very specific. As in all immunosuppressed patients, few findings may be present, so any symptoms must be carefully and quickly evaluated, because of the consideration that any infection can rapidly progress. Fever, cough, or sputum production may be absent. Hypoxemia may be the sole finding, and even if the X-ray is normal, in case a chest CT scan cannot be obtained quickly, a bronchoscopic evaluation should be considered. The presence of any such symptom may, however, reflect a noninfectious etiology. Acute thoracic pain, with or without hemoptysis, may indicate embolic disease but may also denote *Aspergillus* infection. Pneumothorax may reveal—or complicate—PjP, mycobacterial or *Aspergillus* infection, or fibrosis. The rapid onset of pneumonia is mainly consistent with bacterial pneumonia, PjP, pulmonary edema or hemorrhage, or thromboembolism, but this may also occur with viral infections in immunosuppressed patients. A subacute onset more suggests IFD, although it may present abruptly.

16.5.1.3 Imaging

Posttransplantation pneumonia may be focal, multifocal, diffuse and interstitial, alveolar, or mixed. Every effort must be made to quickly obtain chest X-rays of optimal quality and/or a high-resolution chest CT scan when easily available. X-rays in supine position are rarely helpful. Additionally, most X-ray patterns are nonspecific and many patients have mixed types of infiltrates. When an X-ray appears negative or shows only minimal changes, there is good evidence that a chest CT may reveal abnormalities. CT scan has the best negative predictive value to rule out pneumonia and will show lung images 5 days before chest X-ray [111]. CT may additionally provide localization of the lesions, guiding invasive procedures, and inform on their proximity to pulmonary vessels. This information is also important to evaluate the

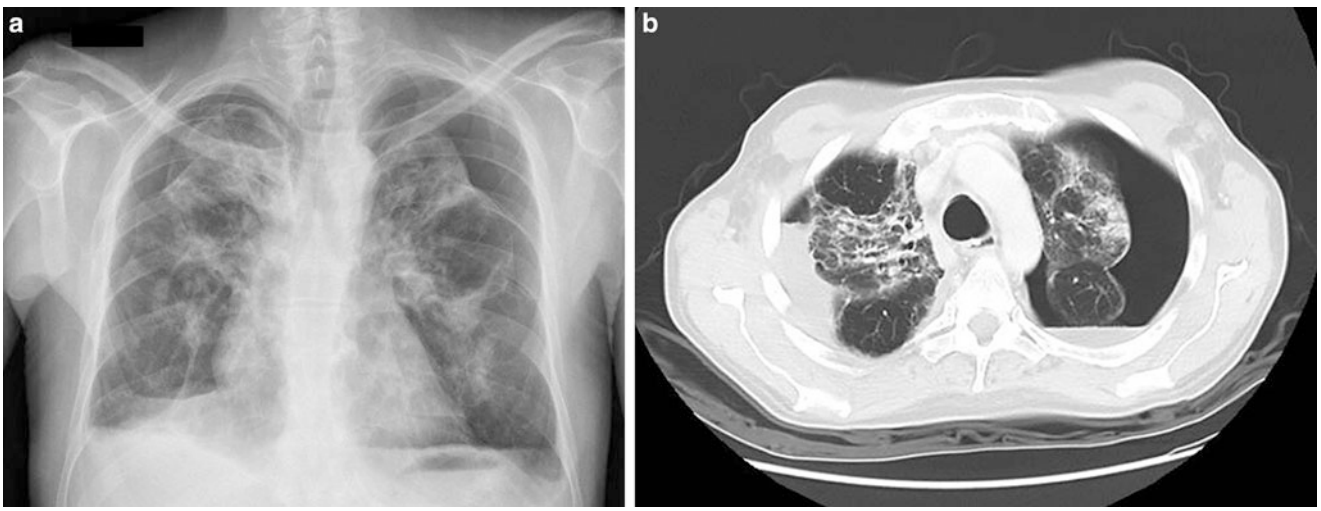

FIGURE 16-9. This 37-year-old patient received an allogeneic HSCT from his HLA-identical sister for refractory Hodgkin disease 20 months ago. He developed chronic respiratory failure due to concomitant causes: Hodgkin pulmonary relapse documented at 18 months and pulmonary fibrosis likely favored by previous mediastinum irradiation. (**a**) The chest X-ray shows bilateral partial pneumothorax, more important on the left side, bilateral pleural effusions, and multiple condensations. (**b**) The CT scan confirms the multiple retractile lesions of the lungs with bronchial dilatations and pleural thickening. It also confirms the left pneumothorax.

risk of hemoptysis in aspergillosis. CT may also detect small pleural effusions. Some CT findings may suggest the presence of particular infections. For example, the halo sign—a macronodule (≥1 cm in diameter) surrounded by a perimeter of ground-glass opacity—is very evocative of early aspergillosis during neutropenia [112], but may also be seen in other infections (e.g., legionella, mycobacterial infection, mucormycosis, or viral infections). Similarly, the reversed halo sign or "atoll sign"—a focal ground-glass attenuation surrounded by a ring of consolidation—has been shown to be often due to mucormycosis in hematology patients, but may also be observed in other infections, including aspergillosis [113]. Ground-glass opacities are very nonspecific and consistent with any infectious and many noninfectious processes such as pulmonary edema or hemorrhage. However, even with more characteristic lesions—such as the air crescent sign which is rare after HSCT but very evocative of mold infection—a CT scan does not replace the need for identification of the pathogen for diagnosis. Magnetic resonance imaging (MRI) usually does not provide more information than CT, except in the detection of lung abscesses [114]. The usefulness of PET scan is limited for diagnosis of acute pneumonia but may be better in nodular, subacute lesions [115], to identify extrapulmonary lesions or to follow the treatment efficacy [116–118]. Any workup using imaging should be completed rapidly, and it should lead quickly to a diagnostic procedure or, in most cases, to an empiric approach considering the most likely hypotheses.

16.5.2 Diagnostic Investigation

Blood cultures should be performed routinely, but they are of limited value in diagnosing pneumonia except for when the pathogen has a high propensity for the blood, such as *Streptococcus pneumoniae*, or in neutropenia. Special culture media are required when *Nocardia* or atypical mycobacteria are suspected. The blood should also be quickly sampled for CMV antigenemia or quantitative real-time PCR (qPCR) in patients at risk. The microbial documentation of any other site of infection, such as skin biopsy of cerebrospinal fluid, may be useful.

Blood biomarkers for the diagnosis of IFD include the detection of galactomannan by an enzyme-linked immunosorbent assay and of (1-3) β(beta)-D-glucan by a colorimetric assay. (1-3) β(beta)-D-glucan is a panfungal marker, while galactomannan is mainly associated with aspergillosis, although it may be positive in other mold infections, e.g., fusariosis. A meta-analysis of 27 studies showed that the galactomannan test has a sensitivity of 0.71 and a specificity of 0.89 for proven invasive aspergillosis [119]. The assay seems to be more useful for the prospective screening of neutropenic patients rather than for diagnosing pneumonia and also more useful in neutropenic than in non-neutropenic patients [120, 121]. The cutoff of positivity usually recommended is an index ≥0.5 in plasma or serum [121]. In an autopsy-based study, the sensitivity and specificity of the serum (1-3) β(beta)-D-glucan test for the detection of IFD were 95.1 % and 85.7 %, respectively [122]. Serum (1-3) β(beta)-D-glucan test is also very useful in the indirect diagnosis of PjP [63, 123]. Fungal NAT have also been widely investigated in HSCT recipient [124], but no consensus on their use in clinical practice currently exists. At this time, no noninvasive test that can replace the specificity of direct pulmonary investigation exists.

Although *sputum* may be analyzed to yield organisms colonizing the oropharynx, the clinical relevance of the results is not evidence based in the setting of HSCT. A positive culture may be valuable when agents that do not normally inhabit the oropharynx are isolated, especially *Legionella*, mycobacteria, and some fungi, or to document MDR colonization which may guide an empirical antibacterial treatment. In HSCT recipients with pneumonia, a positive sputum culture may be highly suspicious for pulmonary aspergillosis. Similarly, the presence of *M. tuberculosis* in the sputum may be considered the cause of the pneumonia when clinical and radiologic signs support this etiology. This assertion is to be considered with more caution for nontuberculous mycobacteria [125].

Nasopharyngeal aspirates or washings are useful to detect respiratory viruses in patients with URT infection [81, 84]. However, the correlation with the cause of the concomitant pneumonia is only presumptive as coinfections are frequent [84].

The standard for diagnosing pulmonary infection after HSCT is *bronchoscopic sampling with BAL* [126] (Table 16-1). Lavage is safe, minimally invasive, and reproducible. Its overall diagnostic yield is comparable to the one of lung biopsy, but with more infectious diagnostic and much less complications [126].

The clinician who consults with a pulmonary specialist for BAL should consider platelet transfusions if the patient is thrombocytopenic and should alert the microbiology laboratories to ensure that all potential organisms are sought. Oxygen saturation or arterial pressure should be assessed before the procedure. Fever, transient hypoxemia, and worsening of chest X-rays may be expected in as many as one half of patients during the few hours following the procedure [127]. When the patient is hypoxemic (paO2 < 70 mmHg spontaneously or with O2 supplementation) or tachypneic before BAL, he usually benefits from noninvasive ventilation immediately after the procedure. The overall diagnostic yield of BAL in infectious pneumonia occurring in hematologic patients varies between 27 and 55 % [2, 95, 128–131] depending on many parameters such as the following:

- The localization of the pulmonary lesions: whether they are accessible by BAL or not.

Table 16-1. Investigations on bronchoscopic samples in HSCT recipients

	Laboratory investigations	
Sample	Essential	Optional
Protected bacteriologic sample (brush or catheter)	Gram stain	Search for bacteria in neutrophils
	Quantitative cultures	
Aspiration	*Legionella*: immunofluorescence (IF), culture on BCYE medium or more selective media	India ink
	Mycobacteria and *Nocardia*: AFB stain, culture	
	Fungi: wet mount, culture	
Lavage fluid	Cytologic examination of lavage fluid on smear and after cytocentrifugation: direct examination, differential count, viral inclusions, pathogens	
	Stains	Stains
	–May-Grünwald-Giemsa	–Gomori methenamine silver (or alternative stain for *P. jirovecii*)
		–Papanicolaou
		–Periodic acid-Schiff
		–Perls' Prussian blue (hemosiderin-laden macrophages)
	Microbiologic processing	
	–Gram stain, bacterial culture	–Quantitative culture of BAL fluid
	–Legionella: culture on BCYE medium or more specific media	–PCR for *Legionella pneumophila*
	–Mycobacteria	–PCR for *Chlamydia pneumoniae*
	–Fungi: wet mount stain, culture	–PCR for *Mycoplasma pneumonia*
	–*P. jirovecii*: IF and/or qPCR	–PCR for *Mycobacterium tuberculosis*
		–Galactomannan antigen
	Virus	
	–All possible viruses, particularly the herpes family, adenovirus, and respiratory viruses: IF	–PCR for HSV, VZV, CMV, EBV, HHV-6
		–PCR for respiratory viruses and adenovirus
	Other	–Toxoplasmosis: IF, PCR
Transbronchial biopsy[a]	Histology	

[a]Transbronchial biopsy is essential for noninfectious processes and less contributive than BAL for infectious pneumonia. However, it is usually not proposed in the initial investigation of pneumonia, due to its possible complications (pneumothorax, bleeding).

BCYE buffered charcoal yeast extract, *AFB* acid-fast bacillus, *IF* immunofluorescence, *PCR* polymerase chain reaction.

- Whether the patient is neutropenic. The yield of the procedure is usually lower in neutropenic than in non-neutropenic patients [131].
- The type of the causal infection: for example, the diagnostic yield of BAL with conventional mycological techniques—without galactomannan tested in the BAL fluid—for aspergillus pneumonia is usually lower than 50 %, while it is higher than 90 % in PjP or CMV pneumonia, for which one rarely needs a lung biopsy [67].
- The laboratory exams performed on fibroscopic samples. The laboratory protocol should be established in advance in a multidisciplinary approach according to the expected, infectious and noninfectious, causes of pneumonia, eventually adapted to seasons for respiratory viruses.
- The criteria used to define specific entities. For example, it is generally believed that the presence of candida in a BAL fluid or bronchial aspiration does not necessary mean a candida pneumonia, while the presence of aspergillus in an HSCT recipient does [132]. However, for some causes of pneumonia, there are until now no consensus definition. The increasing availability of NAT for many pathogens should not replace, in many instances, more classical techniques, until the need for classical techniques is shown to be no longer useful in diagnosing a given infection.
- The delay elapsed between presentation and BAL and the number and duration of previous antibiotics before performing BAL [133]. The diagnostic yield of BAL has been shown to be better when it is performed early after the onset of pulmonary symptoms. In a series of 297 HSCT patients who underwent a BAL, the diagnostic yield of the procedure was 56.8 % in patients since less than 24 h versus 32.8 % in the others [131]. In another study, the diagnostic yield was 73 % in patients who underwent BAL within 4 days of presentation and 31 % thereafter [2]. This may be due to the effect of previous anti-infectives on the probability to identify a pathogen, but also to the fact that lung inflammatory lesions may persist some time after the

infection is controlled, so that delayed BAL may be performed in patients with a favorable outcome but still imaging and clinical signs. Therefore, it is recommended to do a BAL as soon as possible.
– Finally, although pneumonia is less frequent after autologous than after allogeneic HSCT, the diagnostic yield of BAL has been reported to be lower in pneumonia occurring after autologous rather than after allogeneic HSCT [133].

However, despite these variabilities, BAL, when well tolerated and correctly processed at the laboratory, represents the best diagnostic strategy for a minimum of complications. It should also be noticed that cytologic examination of BAL fluid will also document alveolar hemorrhage [96] or alveolar proteinosis [99].

A routine BAL protocol for HSCT recipients should include at least total and differential cell counts on cytocentrifuge preparations using May-Grünwald-Giemsa stains, as well as cytologic examination on cell pellets obtained by centrifugation and cytocentrifugation that are stained with the May-Grünwald-Giemsa stains and the Papanicolaou stain for viruses and the Gomori-Grocott method for *P. jirovecii* and fungi (Table 16-1). Other stains are necessary to identify alveolar proteinosis (PAS) [99], mycobacteria (Zielh), and siderophages (Perls' Prussian blue) [96].

A sample of fluid should be sent for bacteriologic and fungal cultures and viral tests. Galactomannan detection may be done in BAL fluid, especially in neutropenic patients with aspergillosis [128, 134], but with a higher cutoff (≥1) than in serum [121]. Aspiration and BAL fluids should be examined for *Legionella pneumophila* by cultures and eventually NAT and for *Nocardia* and mycobacteria. Due to the better sensitivity of qPCR over conventional stainings and IF assays [54, 55, 59], some laboratories already use qPCR exclusively. The viruses of interest in HSCT patients are the viruses of the herpes family, adenoviruses, and respiratory viruses (i.e., respiratory syncytial virus, influenza, and parainfluenza, rhinoviruses, metapneumoviruses, coronaviruses, enteroviruses, and bocavirus) which should be determined particularly in the setting of known exposures and during seasonal outbreaks [79].

A *protected bacteriologic sample* (*PBS*), done by a protected brush specimen or a plugged telescoping catheter, should be processed by quantitative culture techniques. Although determined from mechanically ventilated patients, the minimal threshold bacterial concentration required to usually consider the isolated pathogen as the cause of the pneumonia is 10^3 colony-forming units (CFUs)/mL for PBS and 10^4 to 10^5 CFUs/mL in the BAL fluid [135, 136].

Due to the increased risk it provides for bleeding and pneumothorax, *transbronchial biopsy* is not routine in acute pneumonia occurring in patients with HSCT and should not be proposed with the first bronchoscopy and BAL [137, 138]. Also, it does not add significant informations to concomitant BAL in most cases [133, 138, 139].

In cases in which noncontributory bronchoscopy, one should consider performing a second BAL and/or a transbronchial biopsy or better, a transthoracic needle aspiration when the lesion(s) is nodular and subpleural [126]. After HSCT, focal lesions that develop or persist despite antibiotics are mostly of fungal origin [140]. Successful fine needle aspiration, guided by either ultrasound or CT, has been reported, with a complication rate around 15 %, and is useful for documenting IFD when other procedures failed [140, 141]. The final decision between lung biopsy through open or video-assisted thoracoscopy or empirical treatment to cover the most likely organisms should be made by the transplant physician and the lung specialist after weighing the risks of surgery, empirical treatment, and failure to reach a diagnosis and the etiologies most likely at that time after transplantation. Lung biopsy is more helpful when the clinical course is prolonged and the pattern is nodular or cavitary.

16.5.3 Starting Treatment and Reevaluation of Efficacy

Because any pneumonia that occurs after HSCT may be life threatening, empirical antibiotics against the likely organisms must be started immediately. The best approach is to conduct bronchoscopic investigation with BAL as soon as possible; this should not, however, delay the initiation of treatment, especially when acute (likely bacterial) pneumonia is present or with patients who are neutropenic. Consideration should be given to the likelihood of fungus in patients with prolonged neutropenia and in those with GVHD on steroid therapy. Some empirical treatments may render subsequent testing negative, especially that for bacteria and viruses, yet they may be warranted. Some empirical treatments will not affect the chance of isolating the pathogen for at least several days after the empirical treatment is begun (e.g., TMP-SMX for *P. jirovecii*, antifungal agents for aspergillosis).

Daily clinical reevaluation should be performed, especially when no diagnosis is initially established and the patient does not improve. The use of noninvasive markers, when initially positive, is mostly useful to assess the treatment efficacy:

– Patients with initial positive blood cultures should be sampled for blood culture controls daily until negative.
– It has been shown in aspergillus infection with an initial positive serum or plasma galactomannan test that the quantitative evolution of the test correlates with the prognosis as soon as from the first week of therapy [142, 143].

Serial follow-up X-rays or, preferably, lung CT scans should be repeated according to the type and severity of the pneumonia. However, some infections, although favorably evolving, may be associated with a long persistence of image abnormalities, which may take several months to decrease or disappear. In the absence of new lesions, it should not be per

se a reason to reinvestigate the patient if the clinical outcome is favorable. In aspergillosis, it has been shown that a transient increase of the volume of the fungal lesions on CT scan may occur at the time of neutropenia recovery without any significance of treatment failure [112].

New investigations should be rapidly undertaken when the pneumonia does not respond to empirical treatment. Even when the cause of the pneumonia has been established, the occurrence of new infiltrates should be regarded as suspicious for treatment failure or new infections, as the association or succession of several causes of pneumonia is not uncommon in this setting. When a BAL has been initially done on accessible lesions, a second one should not be considered before most of the results of the laboratory be back, except if the BAL has been performed in poor conditions or in case of new lesions. Usually, a delay of 1 week before a first noncontributory BAL and a second BAL is minimal. If the initial lesion is peripheral and nodular and the BAL was noncontributive, a transthoracic fine needle biopsy should be considered. If the lesion is subacute or chronic and there is no response to targeted or empirical treatment, surgical biopsy may be contemplated for chronic nodular lesions.

16.6 Place of Intensive Care and Ventilatory Support

Pneumonia is the cause of the ICU transfer in roughly one third of the cases both in allogeneic [144] and autologous [145] HSCT recipients. Although the prognosis of HSCT patients transferred in the ICU has slightly increased over time [146], the decision of transfer remains difficult in terms of the emotional burden for the patient, family, and caregivers. The use of predictive scores—such as the sepsis-related organ failure assessment (SOFA) [147]—assessed at ICU transfer in HSCT recipients is debated [148]. Patients with acute respiratory failure benefit from ICU support and can be investigated by BAL, knowing that BAL does not increase the need for mechanical ventilation [149]. The prognosis of ICU support is usually better in autologous rather than in allogeneic HSCT recipients, and those with severe acute GVHD and under corticosteroids usually do not clearly benefit from ICU support [146]. Guidelines should be adapted to new data, but, in general, the clinician should consider the individual's chance of survival and of return to an acceptable life before transferring the patient to an ICU. The patient and the family should be provided with reasonable estimations of prognosis before transfer; in addition, the likelihood of continuing life support should be considered regularly during the course of treatment. Patients who respond to noninvasive mechanical ventilation have a better prognosis than those who required mechanical ventilation [150].

16.7 Summary

Pneumonia is a principal determinant of posttransplantation survival. Because of the predictable timing of some infections after most types of transplantations, some prophylactic regimens have been instituted with far-reaching benefits. However, any change in the transplant procedure, conditioning, or immunosuppressive regimen may affect the incidence and cause of infectious pneumonia. Additionally, new pathogens are emerging, and familiar pathogens are becoming more resistant. A high level of suspicion when pneumonia occurs in a transplant recipient and vigilance in diagnosing and treating will continue to be required to prevent an increase in mortality from pneumonia. The development of indirect diagnostic procedures is essential in the evaluation of pneumonia, but their clinical pertinence must be established in large prospective studies, and, until now, they do not replace direct investigation of the lung, mainly by BAL.

Pneumonia After Solid Organ Transplantation

Timothy Sullivan and Shirish Huprikar

Pneumonia in solid organ transplant (SOT) recipients encompasses a broad spectrum of disease caused by a diverse group of pathogens and may result in significant morbidity and mortality. The risk of pneumonia following SOT is influenced by many factors including the organ transplanted, the time from surgery, the net state of immunosuppression, and the presence of comorbid medical conditions. Pneumonia is particularly common following lung transplantation.

In this chapter we review the pathogenesis, risk factors, and epidemiology of pneumonia in SOT recipients with a focus on the major causative organisms and the specific risks associated with each SOT type. We also discuss the approach to the diagnosis and empiric treatment of SOT recipients with suspected pneumonia, examine strategies for preventing post-transplant lung infections, and highlight some of the future directions in the management of pneumonia in SOT recipients.

17.1 Pathogenesis

Host defenses against pulmonary infection include components of the innate immune system such as the airway epithelium and alveolar macrophages, as well as aspects of adaptive immunity such as T-cell and B-cell-associated responses to pulmonary pathogens. In SOT recipients, these defenses are affected by numerous pre-transplant, peri-transplant, and post-transplant risk factors for infection.

Prior to transplantation, SOT recipients may be chronically ill with multiple comorbid medical conditions, poor nutritional status, and the need for frequent hospitalization, which may all predispose to pulmonary infection. Pre-transplant pulmonary infections are particularly prevalent in patients being considered for lung transplantation, and colonization with certain bacteria may increase the risk of post-transplant pneumonia. For example, among patients with cystic fibrosis, prior pulmonary infection or colonization with *Pseudomonas* may be predictive of post-transplant infection [1], and pre-transplant colonization with certain species of *Burkholderia cepacia* complex may be associated with higher rates of postoperative infection and death [2–4]. In general, however, Gram stain of donor respiratory specimens correlates poorly with the development of post-transplant pneumonia in lung transplant recipients [5].

An important peri-transplant risk factor for pulmonary infection is the need for endotracheal intubation [6], which may be prolonged following complex surgeries. For example, one review of 546 liver transplant recipients in Germany reported that 11 % of patients required endotracheal intubation for more than 24 h after surgery [7]. Postoperative intubation may also be prolonged following lung and heart transplantation although strategies for early extubation in these patients are being investigated [8–10].

In the post-transplant setting, the risk of pneumonia is strongly influenced by the introduction of transplant immunosuppression. Although most lung infections in SOT recipients are due to common bacteria [11, 12], the impaired cell-mediated immunity resulting from combination immunosuppression also results in increased rates of infection with viruses, fungi, intracellular bacteria, and mycobacteria.

The calcineurin inhibitors (cyclosporine and tacrolimus) cause reduced levels of TNF-alpha, IL-2, and other inflammatory cytokines, resulting in impaired lymphocyte proliferation and defects in T-cell and B-cell immune responses. These drugs have been linked with increased rates of fungal pneumonia and infections due to cytomegalovirus (CMV), *Pneumocystis* and *Legionella*. The mTOR inhibitors (sirolimus and everolimus) interrupt T and B cell responses to inflammatory cytokines, similarly resulting in impaired lymphocyte proliferation. Sirolimus has been associated with higher rates of pulmonary infection when compared to the calcineurin inhibitors [13] although the rate of CMV infection is reportedly lower in those receiving sirolimus. Antimetabolite therapies such as azathioprine and mycophenolate mofetil (MMF) impair lymphocyte proliferation and immunoglobulin production by blocking

P. Ljungman et al. (eds.), *Transplant Infections*, DOI 10.1007/978-3-319-28797-3_17

purine synthesis. MMF has been associated with lymphopenia and high rates of viral infection although it may be protective against the development of *Pneumocystis* pneumonia (PCP) in SOT recipients. Corticosteroids, the other mainstay of transplant immunosuppression, are broadly immunosuppressive and may result in increased rates of bacterial, viral, and fungal pneumonia including PCP.

There are also several unique considerations in the pathogenesis of pneumonia in lung transplant recipients. Pulmonary infection in lung transplant recipients may be transmitted directly from the donor [14]. Allograft rejection resulting in bronchiolitis obliterans syndrome (BOS) may further predispose to infection [15]. Additionally, lung transplant recipients may have an impaired cough reflex and be unable to clear pathogens from the airway [16], and the lack of intact lymphatic drainage may further impair the immune response.

17.2 Epidemiology

The rates of pulmonary infection and the causative pathogens vary greatly depending on the organ transplanted, the time from transplant, and the use of prophylactic antimicrobials. Pneumonia is the most common infectious complication following heart and lung transplantation [17–20], and the second most common infection after liver transplantation [21], but it occurs less frequently among kidney transplant recipients [22].

17.2.1 Time from Transplant and the Role of Prophylaxis

The typical timing of the onset of infection in SOT recipients has been well described [23, 24]. The post-transplant timeline is classically divided into three periods of varying infectious risk: the first month, month two to six, and more than six months after SOT. This timeline, however, is not absolute, and rates of infection are affected by other factors including the use of antimicrobial prophylaxis and the need for increased immunosuppression in cases of graft rejection.

In the first month following SOT, patients are most at risk for pulmonary infection due to hospital acquired pathogens. Healthcare-associated bacterial pneumonia may occur in recipients of any SOT during this period; however, bacterial pneumonia is most common in lung transplant recipients in the first month following transplant [18, 25]. Donor-derived bacterial and fungal pneumonia in lung transplant recipients may also present during this time.

In months two through six after SOT, pulmonary infection due to respiratory viruses, herpes viruses, and PCP are more common although the risk of CMV pneumonitis and PCP is reduced with prophylaxis. Pulmonary tuberculosis, typically due to reactivation and less commonly due to donor-derived infection in lung transplant recipients, may also present during this period. The median time to development of active tuberculosis following SOT is about 6 months [26].

Beyond six months after SOT, the risk of pneumonia varies depending on the ongoing need for immunosuppression. In patients for whom immunosuppression can be reduced, the risk of opportunistic infection typically declines, but patients remain at risk for community-acquired bacterial or viral pneumonia. In patients that still require high doses of immunosuppression due to rejection, the risk for opportunistic infections persists. Fungal pneumonia and pulmonary tuberculosis may occur during this time, and late-onset CMV pneumonitis or PCP may develop during this period after the discontinuation of prophylaxis.

17.2.2 Lung Transplant

Pneumonia occurs frequently following lung transplantation: one large Spanish study reported an annual incidence of pneumonia of 72 % among lung transplant recipients. In the immediate post-transplant period, particularly during the first postoperative month, bacterial pneumonia predominates [18, 25]. Gram-negative rods are the most common causative agents including *Pseudomonas*, *Acinetobacter*, *Stenotrophomonas*, and the Enterobacteriaceae although Gram-positive organisms such as *Staphylococcus aureus* also cause pneumonia in this population [25]. The majority of early bacterial pneumonia in lung transplant recipients is thought to be due to either hospital-acquired or donor-derived infections although the risk of donor-derived infection can be reduced with the use of appropriate targeted perioperative antibacterial prophylaxis [14]. Postoperative bacterial pneumonia, especially due to *Pseudomonas*, is particularly common among patients who undergo lung transplantation for cystic fibrosis. The increased rate of bacterial pneumonia in these patients may be the result of pre-transplant colonization with resistant organisms [27] as well as ongoing chloride channel defects and mucus production in the native upper airways.

About six months after transplant, lung transplant recipients may develop pneumonia due to community-acquired bacteria including *Streptococcus pneumoniae*, *Haemophilus influenza*, and *Legionella*. Those who develop chronic allograft rejection and BOS remain at risk for infection with *Pseudomonas* although it is unclear if *Pseudomonas* infection in these patients is a cause or result of BOS [28, 29].

Lung transplant recipients are also at risk for viral pneumonia during the post-transplant period, and viral infections have also been associated with rejection and BOS. CMV is a frequent and potentially severe cause of pulmonary infections in this population. Before the era of routine CMV prophylaxis, the incidence of CMV infection in high-risk lung transplant recipients was reported as high as >90 %, and high rates of CMV pneumonitis and death due to CMV were also described [30, 31]. CMV infection and pneumonitis have

both been associated with the development of BOS [32, 33] and higher post-transplant-mortality [34]. The rates of CMV infection and pneumonitis have been reduced by the widespread use of valganciclovir prophylaxis in high-risk patients [30, 35], and it is postulated that CMV prophylaxis may also help reduce the incidence of BOS in these patients [36].

In addition to CMV, lung transplant recipients are at risk for pulmonary infection with other herpes viruses and with community-acquired respiratory viruses. Herpes simplex virus may cause severe pneumonitis in this population but has become infrequent in the era of routine antiviral prophylaxis. Epstein–Barr virus (EBV) infection may result in post-transplant lymphoproliferative disease (PTLD), which may involve the lung and mimic pneumonia. Human herpes virus 6 (HHV-6) has been described as a cause of pneumonitis in SOT recipients and has also been associated with the development of BOS in lung transplant recipients [37] although this association has not been uniformly demonstrated [38]. Community-acquired respiratory viruses including influenza, respiratory syncytial virus (RSV) and adenovirus account for more than half of the respiratory infections in symptomatic outpatient lung transplant recipients [39, 40] and have also been inconsistently linked to rejection [41, 42].

Invasive fungal infections, especially invasive aspergillosis, were historically common in lung transplant recipients but have become less frequent with the use of antifungal prophylaxis [43]. A 2003 review reported a 6.2 % median incidence of *Aspergillus* infections in lung transplant recipients, which occurred a median of 3.2 months after transplant and were associated with 52 % overall mortality [44]. *Aspergillus* may cause invasive pulmonary infection in lung transplant recipients, or infection may be limited to tracheobronchitis. Airway colonization with *Aspergillus* has been liked to chronic rejection [45]. Pulmonary infection with other fungi including the agents of mucormycosis *Cryptococcus*, *Fusarium*, and the endemic mycoses are less common but have also been reported in lung transplant recipients.

Prior to the routine use of prophylaxis, PCP was a common cause of pneumonia in lung transplant recipients. One series reported an incidence of 88 % in heart–lung recipients [46], while another review described a 33 % incidence following lung transplantation [47]. Prevention of PCP following SOT with trimethoprim-sulfamethoxazole (TMP-SMX) is effective and typically recommended lifelong after lung transplantation as late PCP infections may occur following discontinuation of prophylaxis [47, 48].

Pulmonary tuberculosis occurs rarely in lung transplant recipients and may be the result of donor-derived infection, reactivation of latent infection, or primary infection post-transplant. Lung transplant recipients have been found to have higher rates of post-transplant tuberculosis than other organ recipients although this incidence varies depending on geographic location and other donor and recipient risk factors. Other rare causes of pneumonia following lung transplant include non-tuberculous mycobacteria, *Nocardia*, and parasites such as *Strongyloides* and *Toxoplasma*.

17.2.3 Heart Transplant

The incidence of pneumonia following heart transplant has been reported as 17–21 % [20, 49]. Pneumonia is the most common infection and most common respiratory complication following heart transplantation [20, 50]. About half of all respiratory infections in heart transplant recipients are caused by bacteria [20, 50]. Similar to lung transplant recipients, heart transplant recipients are at risk for healthcare-associated bacterial pneumonia in the immediate post-transplant period. Community-acquired bacteria and respiratory viruses become more common in the following months.

CMV frequently causes disease, including pulmonary infection, in heart transplant recipients not receiving prophylaxis. In a 1998 Spanish study of pneumonia following heart transplantation, CMV was the second most common pathogen isolated following bacteria [49]. High rates of death have been reported in heart transplant recipients with CMV pneumonitis [51]; however, CMV prophylaxis with valganciclovir has been shown to be safe and effective in this population [52].

Fungal pneumonia is also common following heart transplantation. Invasive pulmonary aspergillosis has been reported in 3.3–14 % of heart transplant recipients and accounts for the majority of invasive fungal infections following heart transplantation [53].

Prior to the use of prophylaxis, PCP was reported in up to 41 % of heart transplant recipients [54], but PCP has been shown to be effectively prevented by TMP-SMX prophylaxis in this population [54].

Toxoplasmosis is of particular concern in heart transplant recipients given that up to 75 % of seronegative heart transplant recipients from seropositive donors may develop disease in the absence of prophylaxis [55]. Pulmonary manifestations including fever, cough, and diffuse infiltrates on chest imaging may be the only manifestation of *Toxoplasma* infection in transplant recipients [55]. Donor-derived *Toxoplasma* infection can be prevented by administering prophylaxis to high-risk patients.

17.2.4 Liver Transplant

Postoperative pneumonia has been reported in up to 23 % of liver transplant recipients [56, 57]. Similar to other organ recipients, the majority of pulmonary infections in this population are due to bacteria [58]. High rates of Gram-negative and *Legionella* pneumonia have been reported in liver transplant recipients [58, 59] although these may now be less common in the setting of TMP-SMX prophylaxis.

The risk of respiratory complications following liver transplantation is greater among patients with more advanced liver disease [60], possibly due to volume overload, encephalopathy resulting in aspiration, and hepatopulmonary syndrome [19]. In the immediate post-transplant period, diaphragm dysfunction, poor nutritional status, and the need for prolonged intubation may also cause higher rates of pneumonia [19].

Similar to other SOT recipients, liver transplant recipients may also develop pulmonary infections with opportunistic pathogens including *Aspergillus*, CMV, and *Pneumocystis* [61] although some of these infections are preventable with prophylaxis.

Cryptococcus neoformans is a notable cause of pulmonary infection both before and after liver transplantation. Cirrhosis has been identified as a major risk factor for cryptococcal infection. In some series, 6–21 % of patients with cryptococcosis had underlying cirrhosis [62]. Although pre- and post-liver transplant recipients may develop disseminated cryptococcosis [63, 64], disease is limited to the lungs in about one-third of SOT recipients with cryptococcal infection [64]. Among SOT recipients with cryptococcal infection, isolated pulmonary infection may be more common in those receiving calcineurin inhibitors [64]. Calcineurin inhibitor use in SOT recipients with cryptococcosis has also been associated with lower overall mortality [64].

17.2.5 Kidney Transplant

The incidence of post-transplant pneumonia following kidney transplantation is lower than that following lung, heart, or liver transplantation, possibly due to the less invasive nature of the surgery and lower acuity and severity of illness in kidney transplant recipients [65]. One large review found that hospitalization for pneumonia occurred 2.86 times per 100 person-years in kidney transplant recipients [66], while another found that 13 % of patients developed pneumonia in the first year following kidney transplantation [67]. Although postoperative pneumonia is less common among kidney transplant recipients, the specific pathogens involved and timing of infection are similar to other SOT recipients.

17.3 Noninfectious Conditions That May Mimic Pneumonia

Several noninfectious conditions with clinical or radiographic features similar to pneumonia may occur in SOT recipients. Diffuse pulmonary infiltrates may be due to pulmonary edema, transfusion-related lung injury, or acute respiratory distress syndrome. A focal pulmonary lesion may be caused by a pulmonary embolism, infarct, or malignancy.

In lung transplant recipients, graft rejection and BOS may result in respiratory symptoms and diffuse pulmonary infiltrates on chest imaging. Although BOS is often associated with infection, rejection may develop without concurrent infection.

Another noninfectious pulmonary complication that may occur in SOT recipients is the development of interstitial pneumonitis following treatment with the mTOR inhibitors sirolimus and everolimus. Patients with pneumonitis due to mTOR inhibitors may present with signs of pulmonary infection including cough, fever, and abnormal chest imaging. In one review of 217 patients who received sirolimus, 11 % developed pneumonitis [68], and in another review of 102 everolimus recipients, 12.7 % developed pulmonary toxicity [69]. Impaired renal function and a late switch to sirolimus as opposed to de novo use following transplant have been identified as risk factors for pulmonary toxicity in kidney transplant recipients [68, 70]. Symptoms typically resolve after mTOR inhibitor discontinuation [68, 69].

The incidence of lung cancer is higher among SOT recipients than the general population [71], particularly among former smokers and lung transplant recipients who undergo transplantation due to COPD [72]. Additionally, post-transplant lymphoproliferative disorder with pulmonary involvement may occur following any type of SOT transplantation and may be difficult to distinguish from an indolent infection without a tissue diagnosis.

17.4 Diagnosis

17.4.1 History and Physical Exam

The clinical manifestations of pneumonia in SOT recipients are variable due in part to the effects of immunosuppression and the wide range of pathogens that cause respiratory infections in this population. Some patients with pneumonia may present with fever, cough, and sputum production; however, typical symptoms may be absent in SOT recipients, particularly those infected with opportunistic pathogens.

The duration and severity of symptoms may be important clinical clues. Patients with bacterial pneumonia typically present with an acute onset illness, while fungal, mycobacterial or PCP may present with a more indolent or chronic onset illness. Chronic cough, persistent fever, or unexplained hypoxia may be the only clinical signs of infection in some patients. Hemoptysis may suggest an invasive fungal or mycobacterial infection. Extrapulmonary symptoms such as nausea, vomiting, diarrhea, rash, sore throat, or myalgia may suggest a viral etiology such as influenza or CMV.

The evaluation of SOT recipients with suspected pneumonia should also include a careful assessment of sick contacts, travel history, animal exposure, and tobacco and drug use.

Typical physical exam signs of pulmonary infection such as rales may also be lacking in SOT recipients. For example, pulmonary auscultation may be normal in patients with PCP. The initial examination should also include evaluation for signs of systemic infection including conjunctivitis, skin findings, lymphadenopathy, hepatosplenomegaly, or abdominal tenderness.

17.4.2 Imaging

Chest X-ray is the initial imaging test for most SOT patient with suspected pneumonia. Bacterial pneumonia including *Legionella* may manifest as a focal consolidation, while viral infections and PCP are typically more diffuse or not visualized

FIGURE 17-1. Chest X-ray of PCP in a liver transplant recipient.

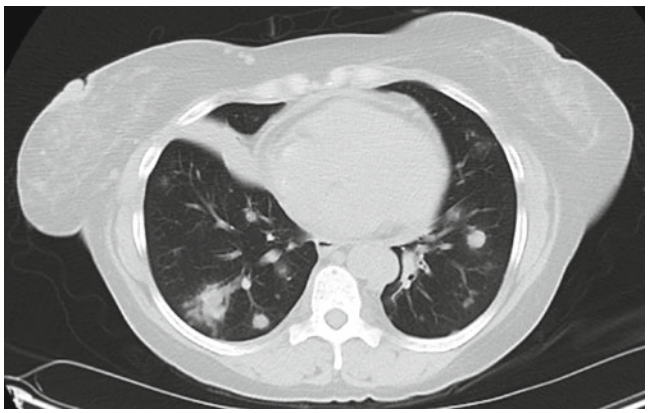

FIGURE 17-2. Chest CT of a kidney transplant recipient with invasive pulmonary aspergillosis.

at all (Figure 17-1). Although tuberculosis is classically described as producing bilateral apical infiltrates, chest X-ray findings may be variable among SOT recipients. The appearance of fungal pneumonia on X-ray imaging is also variable and includes nodular lesions, cavitary disease, or patchy infiltrates. Because invasive fungal infections may be poorly visualized with X-ray imaging, computed tomography (CT) imaging is the preferred modality to evaluate for fungal pneumonia in these patients.

CT imaging of the chest may provide important diagnostic information in the evaluation for pneumonia in SOT recipients. Bacterial pneumonia is usually readily visible on CT imaging. Invasive pulmonary aspergillosis in SOT recipients usually causes nodular or mass-like pulmonary lesions [44, 73] (Figure 17-2). The "halo sign" and the "air-crescent sign," which are classically described CT findings of invasive pulmonary aspergillosis in patients with hematologic malignancies, may be absent in the SOT population [44, 73]. Pulmonary mucormycosis may also be seen as a nodular or cavitary lesion on CT [74]. CT imaging may also reveal the diffuse infiltrates of a viral pneumonia or PCP (Figures 17-3 and 17-4). Additionally, CT may identify noninfectious causes of pulmonary disease such as malignancy or pulmonary emboli and may provide important information regarding the anatomic location of the suspected infection to help determine if the area is amenable to bronchoscopic evaluation.

FIGURE 17-3. Chest CT of a liver transplant recipient with CMV pneumonitis.

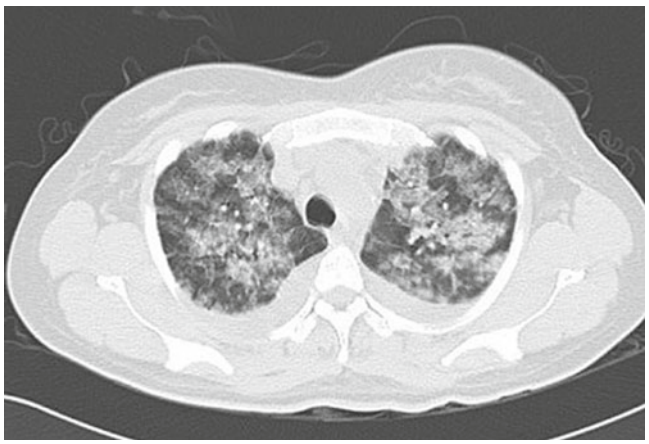

FIGURE 17-4. Chest CT of PCP in a liver transplant recipient.

17.4.3 Blood and Urine Testing

Blood and urine testing may provide valuable diagnostic information for SOT recipients with suspected pneumonia, and in some cases these tests may definitively establish a causative organism.

Blood cultures are positive in about 4–18 % of patients with community-acquired bacterial pneumonia [75]. For those with negative blood and sputum cultures, urine antigen testing for *Streptococcus pneumoniae* and *Legionella* may helpful. These tests have been shown to be insensitive, but highly specific [76, 77] although the *Legionella* urinary

antigen test is only able to diagnose infection with *Legionella pneumophila* serogroup 1. Urinary antigen excretion may be prolonged in immunocompromised patients with Legionnaire's disease [78].

In patients with suspected viral pneumonia, serum antigen or polymerase chain reaction (PCR) testing may provide diagnostic insight. Serum CMV DNA PCR testing is often performed in patients with suspected CMV pneumonia. Although serum CMV DNA viral loads do not strongly correlate with the existence of CMV pneumonia [79], this test may suggest the presence of invasive infection when levels are significantly elevated. Other viral causes of pneumonia in SOT recipients such as adenovirus and HSV may also be identified via serum PCR testing.

Serum testing is an important adjunct in the diagnosis of invasive fungal pneumonia. Serum galactomannan is specific but not sensitive for the detection of invasive aspergillosis in SOT recipients. One large meta-analysis reported that serum galactomannan was 89 % specific and 71 % sensitive for diagnosing proven aspergillosis, but the same study found a sensitivity of only 22 % in SOT recipients. False-positive galactomannan results may occur in patients receiving piperacillin-tazobactam or amoxicillin-clavulanic acid, those who consume foods contaminated with mold, and those with infections due to other fungi that may cross-react with the test. False-positive results are particularly common in the immediate post-transplant period and in lung transplant recipients [80, 81]. False-negative results may occur in patients receiving mold-active antifungal prophylaxis.

The 1,3-Beta-D-glucan assay is another serum test useful for the diagnosis of invasive fungal pneumonia. Unlike galactomannan, 1,3-Beta-D-glucan is not specific for aspergillosis, and elevated levels may also occur during infection with PCP, *Candida*, *Fusarium*, and *Histoplasma* but not *Cryptococcus* or mucormycosis. As a result, a positive 1,3-Beta-D-glucan does not establish a specific diagnosis but may provide useful information in the appropriate clinical context. In the diagnosis of PCP, 1,3-Beta-D-glucan has been found to be highly sensitive although data in SOT recipients is limited [82]. False-positive results may occur in patients on hemodialysis, those receiving intravenous immunoglobulin or albumin, and those with *Pseudomonas* bacteremia.

Antibody testing or serum and urinary antigen testing for endemic mycoses may also be useful in patients with risk factors and signs of pulmonary infection with these organisms. For example, in one large review of 152 cases of histoplasmosis in SOT recipients, 80 % of whom had pulmonary disease, serum antigen testing was positive in 86 %, and the urine antigen was positive in 93 % [83]. Another study of coccidioidomycosis in SOT recipients found that individual serologic tests were positive in 21–56 % of cases, but when multiple tests were used for the same patient, at least one was positive in 77 % of cases [84].

17.4.4 Expectorated Sputum and Nasopharyngeal Testing

Expectorated sputum is of limited value in the diagnosis of pneumonia following SOT particularly among lung transplant recipients, whose airways are frequently colonized with *Pseudomonas* and other bacteria. However, expectorated sputum stains and cultures may be useful when cultures reveal an organism compatible with the clinical syndrome such as *Streptococcus pneumoniae* or an organism that should typically be considered pathogenic such as *Mycobacterium tuberculosis* or *Pneumocystis*.

Nasopharyngeal swab collection for viral detection via culture, DFA or PCR may be useful for identifying upper respiratory viral pathogens although positive nasopharyngeal viral cultures could represent colonization as opposed to true infection, and these tests may fail to identify lower respiratory tract disease, which is better evaluated via bronchoscopy [85].

17.4.5 Bronchoscopy

Bronchoscopy with bronchoalveolar lavage (BAL) and in some cases transbronchial biopsy is a mainstay in the diagnostic evaluation of SOT recipients with pneumonia. Several studies have shown that bronchoscopy can be a safe and effective method for identifying the cause of pulmonary infection in the SOT population [86, 87]. Furthermore, in lung transplant recipients with suspected pneumonia, biopsy is essential to evaluate for BOS and rejection. Biopsy may also be necessary to demonstrate the presence of an invasive fungal infection and to diagnose a pulmonary malignancy.

BAL fluid can be analyzed for Gram stain and bacterial culture, mycobacterial studies, viral PCR and culture, *Pneumocystis* PCR and stains, fungal stains and culture, and stains for parasitic infection. Multiplex PCR testing has been shown to enhance the diagnosis of viral pneumonia in lung transplant recipients [88]. Galactomannan testing may be performed on BAL fluid and when used in conjunction with fungal cultures may improve the sensitivity and specificity of detecting invasive aspergillosis in SOT recipients [89]

Cytology may also be performed on cells collected during BAL for evidence of malignancy, PCP, or other fungal infections.

A frequent diagnostic dilemma following bronchoscopy is differentiating between airway colonization and active infection when an organism is identified. The airways of lung and other SOT recipients often become colonized with drug-resistant bacteria and fungi; however, the isolation of these organisms may not indicate infection. *Candida*, in particular, is frequently isolated from respiratory specimens but is rarely thought to be a cause of invasive disease with the exception of lung transplant patients with suspected anastomotic *Candida* tracheobronchitis [90]. Similarly, viral cul-

tures from BAL fluid may be positive in the absence of histologic evidence of tissue invasion. In these situations, the BAL findings must be interpreted in the context of other available clinical data.

17.5 Empiric Treatment

The most important aspect of treating pulmonary infections in SOT recipients is to establish the diagnosis. Determining the causative organism is ideal, but not always possible or timely, and therefore empiric therapy is usually initiated early in the diagnostic workup. The approach to treating specific pathogens is beyond the scope of this chapter and is detailed elsewhere in this book.

Empiric antibiotic choices for bacterial pneumonia in SOT should be based on national guidelines for community-acquired and healthcare-associated pneumonia [91, 92] but should also be guided by patient-specific respiratory culture data when possible. Choosing appropriate empiric therapy may be particularly challenging in lung transplant recipients who are more frequently colonized with multidrug-resistant Gram-negative organisms.

Empiric antiviral therapy may be initiated with oseltamivir for suspected influenza and with either ganciclovir or foscarnet for suspected CMV pneumonitis. Intravenous TMP-SMX (with corticosteroids when severe hypoxia is present) may be initiated while awaiting confirmation of PCP.

SOT recipients with presumed invasive fungal pneumonia may be treated with either a lipid amphotericin B formulation or voriconazole when there is a high suspicion for pulmonary aspergillosis. Of note, voriconazole is not effective for the treatment of mucormycosis and must be used with caution in SOT recipients due to the risk of serious drug interactions. Voriconazole is a potent inhibitor of several of the cytochrome P450 enzymes, which may result in decreased metabolism of the calcineurin inhibitors tacrolimus and cyclosporine. Calcineurin inhibitor doses need to be adjusted and levels monitored closely when co-administering voriconazole.

Empiric therapy for pulmonary infection in SOT recipients should be adjusted based on culture and imaging data, and the patients' clinical response to therapy. A lack of response to empiric treatment should prompt a re-evaluation of the treatment strategy and further investigation into the etiology of the infection.

17.6 Prevention

The epidemiology of pneumonia in SOT recipients is changing due to the evolution of preventive strategies, which primarily consist of vaccination and antimicrobial prophylaxis.

Vaccination for measles, mumps, rubella, diphtheria, and pertussis is recommended for all patients prior to SOT [93]. Live vaccines including the measles, mumps and rubella vaccine, varicella vaccine, and live attenuated influenza vaccine, are contraindicated following SOT, and should generally be given at least four weeks prior to transplantation.

Yearly influenza vaccination with the inactivated vaccine is recommended following SOT [93]. Although the reported immunogenicity of the inactivated influenza vaccine in SOT recipients has been variable, influenza vaccination in this population has generally been found to be safe and effective [94, 95]. In one large review of 51,730 kidney transplant recipients of whom 9678 of whom received influenza vaccination, receipt of vaccine was associated with lower rates of graft loss and death [96]. Early reports of a possible association between influenza vaccination and rejection have not been supported by larger studies [94, 95]. Yearly influenza vaccination of household members of SOT recipients is also recommended [93]

Vaccination against *Streptococcus pneumoniae* is also recommended prior to SOT transplantation. The current recommendation is to administer the 13-valent protein-conjugated (PCV13) vaccine first, followed by the 23-valent polysaccharide vaccine (PPSV23) at least eight weeks later with an additional dose of PPSV23 given five years later and after age 65 [97]. Some experts recommend monitoring yearly pneumococcal antibody titers in SOT recipients given evidence of waning immunity in this population and the potential need for further PPSV23 doses [93, 98]. The PCV13 and PPSV23 vaccines have both been found to prevent invasive and noninvasive pneumococcal disease in the general population, but studies of pneumococcal vaccine efficacy in SOT recipients are limited. However, a study of the seven-valent protein-conjugated vaccine in HIV-infected adults showed that it was effective in this population [99], which suggests that protein-conjugated pneumococcal vaccination may be efficacious for other immunocompromised patients as well.

Antimicrobial prophylaxis strategies following SOT are typically designed to prevent PCP and CMV disease. PCP prophylaxis with TMP-SMX is usually given for 6–12 months following SOT, but should be considered for longer durations in all transplant recipients and particularly in patients with a history of PCP infection, small bowel or lung transplant recipients, and patients being treated for rejection [100]. TMP-SMX is highly effective for PCP prevention. In a Cochrane review of PCP prevention in non-HIV patients, TMP-SMX use was associated with an 85 % reduction in the incidence of PCP infection [101]. TMP-SMX is considered the drug of choice in SOT recipients not only because of its efficacy against PCP, but also because it may confer additional protection against *Toxoplasma*, *Legionella*, *Listeria*, *Nocardia*, and other bacteria. Alternative drugs for PCP prophylaxis such as atovaquone and dapsone are less protective against PCP and do not provide the same broad protection against other pathogens.

CMV prophylaxis is routinely administered to high-risk SOT recipients usually for 3–6 months and up to 12 months in lung transplant recipients. The major risk factor for CMV

disease is CMV IgG seronegative recipients and seropositive donor (D+/R−) status. CMV IgG seropositive recipients (D+/R+ and D−/R+) are also at risk for CMV disease. The incidence of post-transplant CMV in D−/R− SOT recipients is significantly lower, and prophylaxis is generally not indicated for these patients. Although valganciclovir prophylaxis is effective, CMV disease may still occur following the cessation of prophylaxis. For example, in a study of D+/R− kidney transplant recipients, CMV disease in the first two years following transplant occurred in 39 % of patients who received 100 days of valganciclovir prophylaxis and 21 % who received 200 days [102]. Due to high rates of late-onset CMV disease in lung transplant recipients, indefinite CMV prophylaxis for these patients has also been investigated, but high rates of valganciclovir discontinuation due to hematologic toxicity have been reported with indefinite use [103].

An alternative strategy for CMV disease prevention is preemptive therapy, which entails monitoring patients for CMV viremia with weekly blood tests following SOT and then initiating antiviral therapy in those with detectable viremia before symptomatic disease develops [104]. Although this approach has been shown to be as effective as routine prophylaxis for the prevention of CMV disease in patients at intermediate risk for CMV, the efficacy of preemptive therapy for the highest risk patients is still under investigation [104].

In addition to PCP and CMV prophylaxis, lung transplant recipients often receive postoperative antibacterial prophylaxis for 3–7 days. Many lung transplant centers also administer universal antifungal prophylaxis either with inhaled amphotericin or systemic voriconazole to prevent invasive aspergillosis [105].

Heart transplant recipients at risk for toxoplasmosis such as those who are seropositive for *Toxoplasma* and those who are seronegative and receive an organ from a seropositive donor should receive *Toxoplasma* prophylaxis [55]. TMP-SMX is also the recommended prophylactic medication for *Toxoplasma* although other regimens such as dapsone, atovaquone, or sulfadiazine, each with pyrimethamine, are also used at some centers [55].

17.7 Future Directions

Several aspects of the diagnosis, treatment and prevention of pneumonia in SOT recipients are currently under investigation. Innovations in diagnostics are aimed at more accurate, faster, and less invasive identification of bacterial, viral, and fungal infections. Novel antibiotics are being developed that may be effective for the treatment of multidrug-resistant Gram-negative pneumonia, particularly among cystic fibrosis patient who undergo lung transplantation. New azole antifungal agents are being investigated for the treatment of invasive aspergillosis and other fungal infections. Innovative preventive strategies, particularly for CMV and vaccine preventable illness, are also being evaluated in clinical trials.

17.8 Conclusion

Pulmonary infections in SOT recipients are caused by a wide range of pathogens and result in a broad spectrum of clinical disease. Some of the usual causes of pneumonia are effectively prevented with routine postoperative prophylaxis, but nonetheless, pneumonia is common in this population, particularly among lung transplant recipients. When pneumonia is suspected, a thorough investigation for the causative pathogen is essential. Diagnosis usually requires imaging, microbiologic testing, and often bronchoscopy. Although empiric therapy for pneumonia is often clinically appropriate, establishing the etiology of infection is essential to ensure appropriate treatment and effective cure. The investigation of novel diagnostic, therapeutic, and preventive strategies for pneumonia in SOT recipients is ongoing, and the management of these patients will continue to evolve as new data emerges.

Central Nervous System (CNS) Infections After Hematopoietic Stem Cell or Solid Organ Transplantation

Diana Averbuch and Dan Engelhard

18.1 Central Nervous System (CNS) Complications After Transplantation

CNS complications are frequent after stem cell transplantation (HSCT) and solid organ transplantation (SOT). Among HSCT patients, 10–59 % develop CNS complications [1–5]. The type of the HSCT influences the incidence. For example, in one study, the incidence of CNS complications was highest in unrelated allogeneic transplantations (39 %), followed by related allogeneic (21 %) and autologous transplantations (11 %) [1]. Differential diagnosis includes infectious, metabolic, bleeding, drug induced, posterior reversible encephalopathy syndrome (PRES), and other etiologies [6, 7]. In one study in HSCT patients with reduced intensity conditioning (RIC), the etiologies of 31 episodes of neurological complications (23 CNS), were due to nonfocal encephalopathies ($n=11$), meningoencephalitis ($n=5$), and stroke or hemorrhage ($n=4$ each). The majority of them appeared before day +100. Drug-related toxicity was responsible for 10/31 events (32 %) (eight caused by cyclosporine) [5]. In another study, 10/77 (13 %) patients following umbilical cord transplantation developed early (the median time of onset 19 days (range: 2–58 days) CNS complications presented as impaired consciousness; etiologies included cyclosporine ($n=5$) or tacrolimus encephalopathy ($n=2$), thrombocytic microangiopathy ($n=1$), and unknown ($n=3$) [8]).

The frequency of neurological complications after SOT varies: 8–80 % in liver, 7–60 % in heart, 22–33 % in lung, and 21–30 % in renal transplant patients [9–13]. The possible etiologies include infections, drug toxicity, cerebrovascular events, bleeding, pontine myelinolysis, PRES, and others [12–14]. In one study, 64/395 (16.2 %) liver transplant patients developed major neurological symptoms (37 within 30 days of transplant), including cerebrovascular in 15 patients (3.8 %), tacrolimus-related leukoencephalopathy in 3 (0.8 %), pontine myelinolysis in 2 patients (0.5 %); no clear cause was identified for 44 cases (11.1 %) [12]. Neurologic complications were found in 75/384 (19.5 %) heart transplant patients; 32 % of infectious and 68 % of noninfectious etiology, including stroke in 25/78 (32 %); more rare complications were seizures, episodes of transient ischemic attack, anoxic encephalopathy, metabolic encephalopathy, and others [14]. Among patients after intestinal transplantation, 46/54 (68 %) developed headaches (50 %), encephalopathy (43 %), seizures (17 %), opportunistic CNS infections (7 %), and ischemic stroke (4 %) [15].

Neurologic complications were reported in 68 % of 132 lung transplant recipients, mainly impairment of consciousness (25 %), headaches (20 %), and neuromuscular complications (21 %). The neurologic complications were commonly related to immunosuppressant neurotoxicity (17 %) and opportunistic infections (11 %). There was a trend for an increased frequency of seizures and headaches in recipients with cystic fibrosis ($p>0.05$) [16].

CNS complications affect the outcome in transplantation. In one neuropathological autopsy study in HSCT, the survival time was almost half in the group (37/180 patients) of "CNS as cause of death" as compared to the rest 143 patients whose cause of death was considered to be extracerebral (96 vs. 178 days; $p=0.0162$). Infectious disorders were one of the two main neuropathological findings [17]. In HSCT RIC patients with CNS involvement, 1-year non-relapse mortality was significantly worse (42 % vs. 20 %, $p=0.02$) and 4-year overall survival less (33 % vs. 45 %, $p=0.05$) [5]. 4/10 umbilical cord transplant patients with early CNS complications died within 30 days [8]. Mortality rate in heart transplant patients was 12/53 (22.6 %) with noninfectious and 12 % with infectious neurological complications (42.8 % if the CNS was involved) [14]. On the other hand, the presence of neurologic complications did not affect posttransplant survival in one study in lung transplant patients [16].

P. Ljungman et al. (eds.), *Transplant Infections*, DOI 10.1007/978-3-319-28797-3_18

18.1.1 Incidence for CNS Infections

The incidence of CNS infections varies between 2 and 15 % in HSCT [4, 6, 17–22], 0.6 and 10 % in liver [23–25], 4 and 13 % in renal [11, 26], 1 and 3 % in lung [9, 11], and 3 and 18 % in cardiac transplant recipients [10, 27]. The outcome is usually grave: mortality up to 36–67 % is reported in HSCT [2, 6]. In heart transplant recipients, CNS infection was found to be a strong predictor for mortality in multivariate analysis (HR, 4.39; 95 % CI, 1.72–11.18; $p = 0.002$) [28].

18.1.2 Risk Factors for CNS Infections

CNS infections occur in allogeneic, and they are very rare in autologous HSCT [6, 19]. In the early post-HSCT period, there is severe neutropenia as an important risk factor if it is prolonged. The early post-engraftment period (30–100 days) is characterized by acute GVHD and cellular immune deficiency. Later on, chronic GVHD and its immunosuppressive therapy are major risk factors [21, 29, 30]. Following SOT, intensive immunosuppressive therapy early after transplantation, or in later periods, especially following rejection or retransplantation, is a major risk factor [31, 32].

18.1.3 Etiology of CNS Infections

Fungal pathogens, mainly *Aspergillus*, are the most common, up to 70 %, causes of CNS infections in HSCT and SOT [10, 17, 18, 26–28, 33–35]. Bacteria, on the other hand, are infrequent causes of CNS infections in SOT and HSCT, it causes 0–10 % of them [18, 28, 36]. The etiology depends on geographical prevalence of certain pathogens. For example, in one study from Germany, the most common CNS infections post-HSCT was *Toxoplasma* encephalitis (74 %), while only 18 % had *Aspergillus* and 4 % had each *Candida* and viral encephalitis [6]. Toxoplasmosis was also found in 30 % of 180 HSCT recipients, in an autopsy study in Brazil [18].

Effective antimicrobial prophylactic strategies have led to a change in the epidemiology of opportunistic CNS infections transplant recipients. A third of CNS infections post-heart transplantation in two cohorts from 1968 to 1987 were due to *Listeria monocytogenes* or *Toxoplasma gondii*, while these pathogens were not found in the later cohort in 2007 after the implementation of trimethoprim-sulfamethoxazole (TMP-SMX) prophylaxis [28, 33, 34]. There is a trend toward less viral infection, especially CMV, due to the application of PCR monitoring and preemptive treatment [6].

Table 18-1. Main etiologies of focal lesions vs. meningoencephalitis in CNS infectious diseases

Focal lesions	Meningitis/meningoencephalitis
Aspergillosis	Cryptococcosis
Zygomycosis	Herpes viruses
Dematiaceous fungi	Polyomaviruses (JC)
Nocardiosis	Listeriosis
Toxoplasmasmosis	
EBV (PTLD)	

18.1.4 Clinical Manifestations of CNS Infections

The clinical manifestations include fever, headache, altered mental status, focal neurological signs, seizures, and other signs. These signs may develop rapidly, as in *Aspergillus* infections, or subacutely, as in cryptococcal meningitis [6, 24, 28, 32, 36–41]. The clinical presentation of different CNS infections is not specific.

Brain imaging helps to classify CNS infections into two main entities: those which present predominantly as focal lesions (brain abscess) and those presenting usually as meningitis or meningoencephalitis, as shown in the Table 18-1. MRI appeared to be more sensitive than CT in identifying the brain lesions.

18.2 Focal Lesions

18.2.1 Incidence

Brain abscesses may develop in 5 % of HSCT recipients, 0.3–0.6 % in liver; 0.2–0.4 % in kidney; 1.3 % lung; and in about 1 % in heart and heart–lung recipients [24, 37, 42].

18.2.1.1 Etiology

Fungi are the main pathogen causing brain abscess in all transplant recipients. Among 58 HSCT recipients with brain abscess a fungus was isolated in 92 % of cases [36]. *Aspergillus* species were the most prevalent fungi (58–65 %) [36, 37]. *Candida* species were reported in some series [18, 36], although other studies did not recognize it at all [24, 28, 37]. Other fungal pathogens include *Cladophialophura bantiana*, *Scedosporium apiospermium*, *Microascus cinereus*, *Rhizopus*, *Absidia*, *Scopulariopsis,* and *Pseudallescheria* species [36, 37]. Among the *Aspergillus* species, *Aspergillus fumigatus* is the most frequent [24, 32, 43, 44]. The fungal pathogens causing focal brain lesions are described in Table 18-2.

TABLE 18-2. Fungal pathogens which cause focal brain lesions in transplant patients

Hyalohyphomycosis [45, 46]	Mucormycosis [47, 48]	Phaeohyphomycosis [46, 49–51]
Aspergillus fumigatus	*Rhizopus*	*Cladophialophora bantiana*
Aspergillus flavus	*Mucor*	*Scedosporium prolificans*
Aspergillus terreus	*Rhizomucor*	*Exophiala jeanselmei,and E. dermatitidis*
Aspergillus niger	*Absidia*	*Pyrenochaeta romeroi*
Scedosporium apiospermum (*Pseudallescheria boydii*)	*Cunnighamella*	*Cladosporium species*
	Apophysomises	*Ochroconis gallopavum*
		Ramichloridium mackenziei
		Chaetomium strumarium and C.atrobrunneumy
		Scopulariopsis brumptii
		Fonsecaea pedrosoi
		Microascus cinereus

18.2.1.2 Diagnostic Criteria for CNS Invasive Fungal Disease (IFD) [52]

Proven CNS IFD is diagnosed when there is one of the following:

1. Microscopic analysis of brain tissue: histopathologic, cytopathologic, or direct microscopic examination of a brain tissue in which hyphae, melanized yeast-like forms or yeast cells are seen accompanied by evidence of associated tissue damage.
2. Culture of CSF or of brain tissue obtained from a radiologically abnormal site consistent with an infectious disease process, with recovery of a mold, "black yeast" or yeast.
3. Cryptococcal antigen in CSF.

Probable CNS IFD in transplant recipients requires a clinical criterion and a mycological criterion. Cases that meet the clinical criteria but not the mycological criteria are considered as **possible CNS IFD**.

Clinical criteria for CNS infection include one of the following two signs: focal lesions on imaging or meningeal enhancement on MRI or CT.

Mycological criteria for probable IFD include:

1. Direct test (cytology, direct microscopy, or culture) of mold in bronchoalveolar lavage fluid, bronchial brush, bronchial biopsy, or sinus aspirate samples, indicated by one of the following:
   - Presence of fungal elements indicating a mold
   - Recovery by culture of a mold
2. Indirect tests (detection of antigen or cell-wall constituents):
   - For aspergillosis—galactomannan (GM) antigen detected in plasma, serum, or CSF
   - For IFD other than cryptococcosis and mucormycosis—b-D-glucan detected in serum

18.2.1.3 Treatment

Generally, treatment modalities include drug therapy and surgical intervention. The drug therapy for each pathogen will be discussed later. In a retrospective analysis of 192 proven or provable fungal CNS infections *Aspergillus* spp. (63 %) and *Scedosporium* spp. (18 %), success rate in patients treated with voriconazole was 14 % in HSCT, 54 % in hematological malignancy patients, 40 % in SOT, 45 % in patients with other chronic immunosuppression, and 72 % in patients with other conditions ($p<0.001$). In this study, combination antifungal therapy showed a trend toward an improved response rate ($p=0.09$) and superior survival ($p=0.0149$), while patients receiving neurosurgical interventions showed superior responses ($p=0.0174$) and survival ($p=0.0399$). In all, 49 % of patients died, 71 % (67/94) due to fungal infection. The overall median survival was 297 days (range 3 to >2000). Pediatric ($p=0.014$) patients exhibited superior survival compared with adults [53].

18.2.2 *Aspergillus*

18.2.2.1 The Pathogen

The pathogen is described in Chap. 40, Mold Infections after hematopoietic stem cell transplantation, and Chap. 41, *Aspergillus* and other mold infections after SOT.

18.2.2.2 CNS Involvement

The primary site of infection with *Aspergillus* is the respiratory tract, and it can disseminate, involving mainly the CNS [54]. Dissemination to CNS was found in 16 % of SOT and HSCT recipients with pulmonary aspergillosis [55, 56]. Once *Aspergillus sp*. spread beyond the lung it can be found in very high proportion in brain of fatal cases, for example,

50 % in one study in HSCT patients, when examined both macroscopically and microscopically [57, 58]. In a retrospective analysis of 322 patients undergoing allogeneic HSCT, 55 % of patients with pulmonary disease developed CNS involvement [43]. Lungs were involved in the majority of cases with CNS aspergillosis [24, 58, 59], and only 10 % have isolated CNS involvement [32]. *Aspergillus* sinusitis is not frequent (8 %) in patients with CNS aspergillosis [60]. In SOT patients, dissemination was much more frequent in liver transplant recipients, 46–60 %, compared to 22 % in lung, 17 % in heart, and 10 % in renal transplantation (10 %) [31, 55, 60]. However, one study showed that in the current era of liver transplantation, invasive aspergillosis (IA) occurs later in the posttransplantation period, is less likely to be associated with CNS infection, and is associated with a lower mortality rate, compared with IA in the early 1990s [44].

18.2.2.3 Incidence

In HSCT recipients, 3 % developed *Aspergillus* brain abscess [39, 43]. In SOT recipients, incidence is less than 1 % [24, 37, 42].

18.2.2.4 Time After the Transplantation

Median time to the diagnosis of CNS aspergillosis was 110–124 days (range 18–395 days) post-HSCT [6, 37, 39].

Median time of development of CNS aspergillosis in SOT varies in different studies from 15 (range, 8–81 days) to 538 days (range 14–1260 days) [32, 37, 60]. There are two peaks of infection. The first one is during the early post-transplantation period. In one study in early 1990s in SOT recipients, 64 % of CNS aspergillosis developed in the initial 2 months after transplantation [32]. In the 1990s, several studies showed that liver transplant recipients tend to develop CNS aspergillosis earlier than other transplant patients (50–73 % of cases developed in the first month after transplantation [24, 32, 60]). In the current era, one study in liver transplantation showed that IA occurs later in the post-transplantation period [44]. Chronic rejection and/or retransplantation during a period of intense immunosuppression are associated with a second peak of incidence, after the first year [32]. In one study in heart transplant patients, CNS involvement was more common in patients with late aspergillosis (>3 months after transplant) as compared to early disease [61]

18.2.2.5 Risk factors

The risk factors for IA infections in HSCT and SOT can be divided to patient related, transplant related and environmental factors (see session???).

Table 18-3. Clinical presentation of CNS Aspergillosis [6, 24, 32, 36, 37, 39]

Clinical signs/symptoms	Percentage of patients with sign or symptoms
Fever (>38.0)	45–76 %
Altered mental status	35–82 %
Hemiplegia/paresis	27–50 %
Cranial nerve abnormalities	29 %
Seizures	21–40 %
Nausea/vomiting	18 %
Headache	12–60 %
Hemianopia	Reported
Meningismus	Reported

18.2.2.6 Clinical Manifestations

The common clinical manifestations of CNS aspergillosis, which are similar in SOT and HSCT recipients [37], are summarized in Table 18-3. The most common clinical manifestations of CNS aspergillosis are focal neurologic deficits and seizures, due to stroke or mass effect [62]. The neurological symptoms usually progressed quickly [32, 39].

18.2.2.7 Laboratory

The most common finding in CSF is a moderate increase in the protein concentration [39]; however, CSF findings are often nonspecific [62]. Laboratory diagnosis of IA includes blood testing of GM, PCR, and (1-3)-β-D-Glucan (BDG). In HSCT recipients with pulmonary IA serial GM blood test shows sensitivity of 50–90 %, specificity 89–98 %, PPV 46–90 %, and NPV 94–98 % [63–66]. There is also good correlation between GM and outcome from IA [67]. Serum GM measurement is less studied in SOT patients and shows lower sensitivity results for the diagnosis of pulmonary aspergillosis: 56 % in liver [68], 30 % in lung transplant recipients [69]. Blood PCR was used for the non-culture diagnosis of IA in HSCT recipients, showing variable sensitivity (63.6–100 %) and specificity 63.5–100 % [70–73]. Data on GM, BDG, or PCR in CSF are limited [74–77], but it may be positive in CNS aspergillosis, while they were found negative in small number of CSF samples of patients having CNS disease of other etiology [75]. The sensitivity and specificity of Platelia ELISA for the detection of galactomannan in CSF were 80 % and 100 %, respectively, in a study describing five patients with proven CNS aspergillosis [76]. Culture of CSF samples yielded negative results, but PCR yielded positive results for all patients. Galactomannan levels in CSF were significantly higher than in serum [77]; decreasing galactomannan CSF levels correlated with clinical improvement [74].

18.2.2.8 Imaging

CT and especially MRI are the imagings that detect easily the focal lesions suggestive of CNS aspergillosis [37, 59, 78]. Characteristically they show infarction and necrosis, some with hemorrhage, due to the angioinvasive nature of the fungus [39, 59, 79, 80]. Lesions of CNS aspergillosis are multiple in about 70 % of cases [24, 37, 39], with a mean of 2.8 lesions per patient (range, 1–8) [37]. The most common location for lesions is the frontoparietal region (54–82 %), followed by the basal ganglia or thalami (17–72 %), occipital lobe (13 %), temporal lobe (9 %), and cerebellum (7 %) [24, 37, 80]. Corticomedullary junction involvement is common [78, 81]. In one series, the corpus callosum was involved in 7/18 (40 %) patients [80]. As the corpus callosum is not commonly subject to pyogenic infection and thromboembolic infarction, callosal lesions strongly suggest the diagnosis of aspergillosis [78].

Progression of the size and number of lesions during the first 10 days of therapy was reported in one series, in all their 11 patients who underwent serial imaging studies [80]. Serial imaging performed in the patient who recovered showed regression of small lesions and calcifications in the large lesions [80].

18.2.2.9 Treatment and Outcome

In one series, death because of CNS aspergillosis contributed 8 % of all causes of death during the first year post-HSCT during 1989–2000 [39].

Mortality in CNS aspergillosis in HSCT and SOT patients treated with amphotericin B or its lipid formulations with or without combination with itraconazole or 5-fluorocytosine (5-FC) was 94–100 % [6, 37, 39, 55, 82, 83]. During 1989–2000, one series reported on median survival of only 7 days (range 0–27 days) from the onset of the neurological symptoms or signs, in 14 HSCT recipients suffering from CNS aspergillosis and treated with amphotericin B [39].

Management of CNS fungal infection is complicated by the poor CNS penetration of a lot of agents. Drugs with acceptable CSF penetration include 5-FC (drug penetration 74 % serum concentration), fluconazole (60 % serum concentration), and voriconazole (50 % serum concentration). Other antifungals with poor CSF penetration are amphotericin B dexochycolate (<4 % serum concentration), itraconazole (<5 % serum concentration) [84]. Caspofungin administration reveals brain tissue/plasma ratio of 0.2 in animal studies [85]. Data on posaconazole CSF concentration levels show conflicting results [86–88]. Voriconazole penetrates the CSF and brain tissue of animals and the penetration is not dependent on meningeal inflammation. In humans, 1–10 h after receipt of voriconazole, the CSF concentrations ranged from 0.08 to 3.93 mg/mL, and the ratio of CSF to plasma concentration ranged from 0.22 to 1.0 (median, 0.46). The moderate lipophilicity and large volume distribution of voriconazole may well contribute to the higher concentrations detected in brain tissue, compared with those detected in the CSF or blood [55, 89].

Initial therapy of IA, including those with CNS involvement, with voriconazole lead to better responses and improved survival—of 27 % (SOT) and 22 % (HSCT) in CNS aspergillosis [90], in another study 16 % showed partial response and 26 % showed stabilization with CNS aspergillosis [91] and also resulted in fewer severe side effects than with amphotericin B [92]. Neurosurgical intervention is associated with improved survival [90, 91, 93, 94]. Thus, voriconazole is currently the drug of choice for CNS aspergillosis. Although there are no formal guidelines regarding therapeutic drug monitoring in CNS aspergillosis, maintaining trough concentrations of 2–5 μg per milliliter in serum is recommended [95]. Itraconazole, posaconazole, or LFAB are recommended for patients who are intolerant or refractory to voriconazole [96]. Caspofungin is an alternative treatment. In one small series of proven or possible CNS aspergillosis, including those with disseminated infection, 2/6 of the patients had a favorable response with caspofungin therapy [97].

Local intracavitary treatment with amphotericin B in adjunction to systemic amphotericin B and surgical therapy was described in case reports in transplant patients [98].

Combination therapy may have benefit in the treatment of CNS aspergillosis. In an immune suppressed murine model, significant enhancement of efficacy for the prolongation of survival was attained with the ambizome-plus-voriconazole regimen as compared to each agent given alone ($p = 0.0001$) [99]. Combination therapy with voriconazole and caspofungin for IA showed a trend to lower mortality in transplant patients, although only minority suffered from CNS disease [100, 101]. Treatment of IA with the combination of voriconazole and anidulafungin was associated with a nonsignificant but clinically meaningful survival benefit in patients with HM or HSCT in a recent randomized double-blind, placebo-controlled multicenter trial [102].

Monitoring includes serial imaging every 1–2 weeks until stabilization of patient's condition [95].

18.2.3 Emerging Fungal Pathogens

Infections due to infrequently encountered fungi (e.g., dematiaceous fungi and zygomycetes) have become increasingly common in immunocompromised hosts. Non-*Aspergillus* molds were reported in 35–45 % of fungal brain abscesses in transplant patients [24, 37].

Transplant patients suffering from invasive infection due to non-*Aspergillus* molds (zygomycetes, phaeohyphomycetes, and hyalohyphomycetes) vs. *Aspergillus* have more frequent CNS involvement, 23 % vs. 5 % in one study in liver and heart transplant recipients. In this study, infections

limited to the CNS were not observed with infections due to *Aspergillus* species, as compared with 21.4 % with other mycelial fungi ($p=0.017$) [49].

18.2.4 *Scedosporium apiospermum*

18.2.4.1 Pathogen

S. apiospermum (sexual form, *Pseudallescheria boydii*) is an emerging pathogen which belongs to hyalohyphomycosis.

18.2.4.2 Incidence

The incidence of invasive *Scedosporium apiosrermium* infections was 0.2 % among 5589 HSCT patients [103]. In a series of 23 SOT patients with *Scedosporium apiospermum* infections, 11 had CNS disease, with overall incidence of 1 per 1000 patients and CNS involvement of 0.5 per 1000. There was a trend of higher incidence in patients receiving lung transplants compared with other transplant organs ($p=0.06$) [45].

18.2.4.3 Time After Transplantation

In HSCT, invasive infections with *Scedosporium* species occurred mainly in the first 30 days after transplantation [103]. In SOT, it was diagnosed at a median of 4 months (range, 0.4–156 months) after the transplantation [45]. In cystic fibrosis (CF) patients after lung transplantation, the median time from transplantation to the onset of infection was shorter—5 weeks (range, 2 weeks to 7.5 months), possibly explained by the colonization with *Scedosporium*/*Pseudallescheria* at the time of transplantation [104].

18.2.4.4 Clinical Manifestation

CNS involvement was mainly brain abscess ($n=10$) and occasionally meningitis ($n=1$). Half patients with brain abscess had a single brain lesion and the other half had multiple lesions [45].

18.2.4.5 Treatment and Outcome

Voriconazole is the current recommended therapeutic agent, with 43 % (9/21 patients) successful response in CNS infection in one report [46]. In another report, all four CF lung transplant patients with CNS *Scedosporium* infection died [104]. Combination of voriconazole and surgical drainage may be needed [45].

18.2.5 Phaeohyphomycosis

Agents of phaeohyphomycosis, which are called also dematiaceous fungi, are increasingly recognized as a cause of serious disease in patients with immunodeficiency. Most agents of phaeohyphomycosis are found in soil and are ubiquitous in the environment. These fungi have a high degree of neurotropism. Animal model showed that cortisone-treated mice intranasally inoculated with *Cladophialophura bantiana*, develop CNS disease following hematogenous dissemination from a primary pulmonary focus [105]

18.2.5.1 Pathogen

The characteristic feature of all these species is the presence of melanin in their cell walls, which imparts the dark color to their conidia or spores and hyphae [106]. Among 18 transplant patients with CNS phaeohyphomycosis, *Cladophialophura* was isolated in seven (40 %, five of them *C. bantiana*), four *Ochroconis gallopavum*; *Ramichloridium mackenzei* and *Chaetomium strumarium* (two each) and *Chaetomium atrobrunneum*, *Scopulariopsis brumptii* and *Fonsecaea pedrosoi* (one each) [50].

18.2.5.2 Incidence

CNS phaeohyphomycosis is a rare infection, which occurs mainly in immunocompetent young males but may occur also after transplantation [50]. In one series, the incidence of phaeohyphomycosis infection varied from 0.16 % among liver transplant patients to 3.6 % among kidney/pancreas transplant patients, with an overall incidence of 0.7 % [107]. Interestingly, male predominance is mentioned in all the series: 64–83 %, probably because of occupational or environmental exposure [45, 46, 50]. Only 1.8 % of 56 phaeohyphomycosis cases were in CNS [108].

18.2.5.3 Time After Transplantation

Infection with phaeohyphomycosis can appear 2–128 months after SOT [49, 107]. Median time was 20 months in one series [107]; it was 358 days in summary of 56 cases with proven and probable phaeohyphomycosis in transplant patients from the Transplant Associated Infection Surveillance Network (TRANSNET) (HSCT 100 days; SOT 685 days; $p=<0.001$) [108]. Median time after transplantation was 11–17 months for *Ochroconis gallopava* (range 2–44 months) [51, 109].

18.2.5.4 Clinical Presentation

Thirty to fifty percent of transplant patients with *Ochroconis gallopavum* infection had CNS involvement [51, 109].

All except one of 101 cases of CNS phaeohyphomycosis presented with brain abscess, usually single. Clinical signs on presentation included headache 59 %, neurological deficits 54 %, seizures 34 %, altered mental status 32 %, fever 32 %, and nausea and vomiting 19 %. Clinical presentations varied considerably, although one neuro-

logic sign or symptom was present in all cases. However, the classic triad of fever, headache, and focal neurologic deficits described in patients with brain abscess was rarely observed [50].

18.2.5.5 Treatment and Outcome

In one series, 4/6 transplant patients with *Ochroconis gallopavum* CNS infection died [51]. In another report, 12/18 (67 %) transplanted recipients with brain abscess caused by phaeohyphomycosis died [50]. The most frequently used drug was amphotericin B; voriconazole was not used at all [50]. In this review, combination of amphotericin B, 5-FC, and itraconazole was associated with improved survival, although there were relatively few cases in which this triple combination was used [50]. Overall mortality in transplant patients with phaeohyphomycosis was 25 % and was higher in HSCT than in SOT (42 % vs. 10 %; $p = <0.001$) [108]. In another summary, voriconazole (44.6 %) and amphotericin B preparations (37.5 %) were the most common antifungal therapies in patients with phaeohyphomycosis [108]. Itraconazole and voriconazole demonstrate the most consistent in vitro activity against phaeohyphomycosis, except *S. prolificans*, which is resistant to all azoles [106]. Complete excision of brain abscesses improves the outcome [50]. Amphotericin B may be used for severe infections in unstable patients; high doses of lipid formulations may have a role in the treatment of refractory cases or in patients intolerant of standard amphotericin B. Combination antifungal therapy with voriconazole and a lipid formulation of amphotericin B, pending the availability of in vitro susceptibility data, is recommended in conjunction with surgery [95]. Once the infection is under control, longer term therapy with a broad spectrum oral azole is a reasonable approach, until complete response is achieved [106].

18.2.6 Mucormycosis

18.2.6.1 Pathogen

Mucormycosis is an invasive mold infection with high morbidity and mortality (see Chaps. 40 and 41). Portals of entry include sinuses, lungs, gastrointestinal tract, and skin.

18.2.6.2 Incidence

Mucormycosis represents 2 and 8 % of invasive fungal infections in SOT and HSCT recipients [30].

18.2.6.3 Time After Transplantation

Mucormycosis may occur as early as 1 day and as late as several years after HSCT and SOT [47, 49].

18.2.6.4 Clinical Manifestation

Among HSCT recipients with mucormycosis, 10–15 % have involvement of the CNS, most frequently in the context of dissemination. Among 116 SOT patients with mucormycosis, in 19 % CNS was involved as a part of rhinocerebral or disseminated disease [47]. A half of patients after kidney transplantation with mucormycosis had rhinocerebral disease [110]. The initial symptoms of rhinocerebral mucormycosis are consistent with either sinusitis or periorbital cellulitis. The infection may rapidly extend into the neighboring tissues. Extension from the ethmoid sinus through the lamina papyracea involves the orbit, extraocular muscles, and optic nerve; extension from the maxillary sinus into the oral cavity may present as a painful black necrotic ulceration on the hard palate [111]. Among 90 SOT recipients with rhino-orbital-cerebral mucormycosis, the maxillary cavities and brain were involved in 80 % and 57 %, respectively [112]. Cranial nerve may be involved, including vision loss. A bloody nasal discharge may be the first sign that infection has invaded through the turbinates into the brain. When there is extensive CNS involvement, the angioinvasive nature of the fungus may result in cavernous sinus thrombosis and internal carotid artery encasement and thrombosis with extensive resulting cerebral infarctions [113]. Diplopia and ophthalmoplegia may be the earliest manifestations of cavernous sinus syndrome [111].

18.2.6.5 Treatment and Outcome

Patients with CNS mucormycosis had a very grave prognosis, with mortality above 90 %, even when combined amphotericin and surgery approach was applied in one study [47]. In another study, mortality however was 30.8 % in kidney SOT [110]. Doses of 10 mg/kg/day of liposomal amphotericin are suggested for infections involving the CNS [114]. For salvage treatment who need prolonged continuation or maintenance therapy posaconazole 4 × 200 mg/day is recommended [114, 115].

One study described 24 patients refractory or intolerant to previous therapy, the majority post-HSCT or SOT, 58 % with CNS involvement as a part of rhinocerebral or disseminated disease. Under treatment with posaconazole, 79 % achieved complete or partial response. Surgery, in addition to posaconazole, improved the prognosis 5.7 times [48]. Success was achieved in 73 % of patients with CNS mucormycosis in a retrospective summary of 91 patients (40 % transplant recipients) refractory or intolerant to prior antifungal treatment who participated in the compassionate-use posaconazole program [116]. Surgical debridement is recommended, it was associated with improved outcome in patients with rhino-orbito-cerebral mucormycosis [112, 114]. The use of a combination of a polyene and an echinocandin may be an option in salvage therapy after failure of appropriate first-line therapy [114]. Salvage therapy with isavuconazole was

reported [117]. Therapeutic drug monitoring is recommended where possible [114]. Using granulocyte colony-stimulating factor in patients with ongoing neutropenia is recommended [114, 115]. The duration of antifungal treatment should be determined on an individual basis, but therapy usually continues for at least 6–8 weeks [114]. Routine use of adjunctive iron chelator and hyperbaric oxygen therapy is not recommended [114].

18.2.7 *Candida*

Although *Candida* was reported in the past as causing CNS abscesses or meningoencephalitis [6, 10, 17, 34, 36], it is currently not considered as a significant pathogen for CNS disease [24, 28, 37].

18.2.8 *Nocardia*

18.2.8.1 Pathogen

The genus *Nocardia* consists of Gram-positive, variably acid fast, filamentous, branched cells [118]. *N. asteroides* is the most common species identified in nocardial brain abscesses [119]. Nocardial lesions frequently erode into blood vessels, causing dissemination.

18.2.8.2 Incidence

The incidence of invasive nocardiosis was 0.3–1.7 % in allogeneic and 0.2 % in autologous HSCT recipients [120, 121]. Organ transplantation is one of the predisposing conditions for nocardial infection, being reported as a risk factor in 22 % of patients with nocardiosis [118]. The incidence was 0.04–0.7 % of renal [122], 0.65–2.5 % heart [34], and 0.6–3.5 % of lung transplant recipients [123, 124]. Decrease in the incidence of nocardiosis has been observed [124, 125].

In a summary of 1050 patients, immunocompetent and immunocompromised, with systemic nocardiosis, CNS involvement was reported in 44 % [118]. CNS disease is the most common extrapulmonary site of disease, it occurred in 3/35 (9 %) SOT recipients and in 3/10 (30 %) of hematological patients with nocardiosis [123, 126]. Summary of 66 cases with nocardiosis in kidney transplant patients reported in the literature during 30 years revealed cerebral involvement in 27 cases (41 %), and in 75 % of disseminated infection [125].

18.2.8.3 Time After Transplantation

In the study on SOT patients, in 63 % nocardiosis occurred within 1 year after transplantation, and in 14 % >5 years after transplantation [123]. Infection in the first month after transplantation is rare, median time varied 1.25–48 months after SOT (34 months for kidney transplant patients [125]) and 6–10 months after HSCT [124].

18.2.8.4 Risk Factors

In HSCT, almost all infections occurred in allogeneic HSCT vs. autologous and GVHD was present in almost all patients [120, 121]. Eighty percent of hematological patients with nocardiosis were lymphopenic, and the same proportion were treated with steroids [126]. Four of six patients in one study had extensive exposure to soil or dust before nocardiosis developed [121]. Receipt of high-dose prednisone in preceding 6 months, ($p=0.003$), elevated median calcineurin inhibitor level in preceding 30 days ($p=0.012$) and CMV disease ($p=0.047$) were identified as risk factors in SOT recipients [123].

18.2.8.5 Clinical Manifestations

The clinical presentation of CNS infection by *Nocardia* spp. may be acute with rapid progression, but can be also insidious in onset [118]. Some patients present with focal deficits, headache or confusion, seizures, and psychological abnormalities [119, 125]; others have no fever or neurological signs at all [118]. Therefore, CNS imaging is advised in transplanted patient with the evidence of *Nocardia* infection [127].

18.2.8.6 Imaging

The most common clinical CNS manifestation is single or multiple (38 %) abscesses affecting any part of the brain. Radiological evidence of meningitis may be present [118, 119, 127].

18.2.8.7 Treatment and Outcome

Overall, 64 % of immunocompromised patients, 40 % of whom were transplanted patients, died of nocardial brain abscess. The mortality rates for single and multiple abscesses were 33 and 66 %, respectively ($p<0.0003$) [119]. Prophylaxis with TMP-SMZ, administered to prevent *Pneumocystis jirovecii* pneumonia, does not prevent nocardial infections [120, 121, 123]. Therapy of choice for nocardial brain abscess is TMP-SMX. Other treatment options include minocycline, imipenem, or a third-generation cephalosporin, like ceftriaxone [119, 123].

Three-drug regimen comprising trimethoprim-sulfamethoxazole, amikacin, and either ceftriaxone or imipenem can be initiated until susceptibility results available [124, 128]. Linezolid may be used due to high CNS penetration, evidence of high success rate (80 %), no resistance reported and oral availability [124, 129]

Regardless of the antibiotic regimen selected, it should be administered intravenously for at least 6 weeks, depending on clinical response, followed by oral antibiotics for at least 1 year [119].

Analysis based on 131 cases of nocardial brain abscess (13 % of them in transplant recipients) suggested that all abscesses larger than 2.5 cm should be aspirated, regardless of the immune status of the patient [119]. Contrast-enhanced CT scans or MRI should be obtained every 2 weeks or after any clinical deterioration. If any abscess enlarges after 2 weeks of antibiotic therapy or fails to shrink after 4 weeks of therapy, a craniotomy should be performed to excise the abscess. If the abscess is surgically inaccessible, aspiration/drainage may be repeated, although the likelihood of success is reduced [119]. Small abscesses may resolve with long-term medical treatment.

18.2.9 *Toxoplasma*

18.2.9.1 Pathogen

Toxoplasma gondii is an intracellular protozoan parasite [130]. *Toxoplasma* encephalitis occurs mainly from reactivation of latent microorganisms in seropositive recipients, but may be due to new infection.

18.2.9.2 Incidence

The incidences of toxoplasmosis after transplantations are detailed in Chaps. 43 and 44.

18.2.9.3 Time After Transplantation

Cerebral toxoplasmosis occurred from day 4 to day 689 after HSCT (median 64–84 days [6, 130–133]). The disease usually begins early after HSCT, 30 % within the first 30 days, 67–100 % developing in the first 100 days [6, 130, 132, 134, 135] and 95 % within 6 months after the HSCT [130, 136]. Toxoplasmosis was diagnosed within the first 6 months after transplantation in 64 % of SOT patients [137]. Among 64 noncardiac SOT recipients who developed toxoplasmosis, 65 % developed symptoms within the first month and 86 % within 3 months after the transplantation [138]. In high-risk patients (donor positive/recipient negative), toxoplasmosis developed earlier than in the others [138].

18.2.9.4 Clinical Manifestations

Neurological involvement is frequent in toxoplasmosis in HSCT recipients, with 66–80 % of patients presenting with neurological symptoms [134]. In HSCT who developed toxoplasmosis, brain or brain stem was involved in 74–89 % of patients, and in 94 % of autopsies [130, 131]. Isolated CNS involvement occurred in 44–50 % of patients; in another 25–56 % CNS was involved as a part of disseminated disease [131, 139]. Review of 53 *Toxoplasma* cases in noncardiac SOT recipients revealed a different picture: neurologic manifestations at onset were only in 26 % of patients; only 5.5 % had isolated CNS disease [138].

Among 22 SOT recipients, 22.7 % presented with brain abscess and 4.5 % with meningitis [137]. Presenting symptoms include seizures 45 %; neuropsychological signs, including somnolence and obtundation 35–50 %; focal signs, as hemiparesis, hemianopia, ataxia, dysarthria, 25 %; headaches 25 %; coma 20 % [6, 130]. High grade fever (>39 °C) is frequent (80–91 %) [130, 132], although in another series it was reported in 43 % of HSCT recipients [131]. Relapse was reported in 30 % of HSCT patients, 33–318 days after the first episode [135]. Concommitant severe infections were diagnosed in 27–40 % [130, 131, 137].

18.2.9.5 Diagnostic Criteria

Definite *Toxoplasma* disease is determined by histological or cytological demonstration of tachyzoites or isolation of the parasite by culture in brain tissue samples obtained by biopsy or at autopsy.

Probable *Toxoplasma* disease is determined by clinical and radiologic evidence suggestive of CNS involvement plus at least one positive PCR test from blood, CSF, or BAL.

Possible *Toxoplasma* disease is determined by CT or MRI highly suggestive of CNS toxoplasmosis (as considered by each hospital's neuroradiologists) and response to anti-*Toxoplasma* therapy and absence of another pathogen that may explain the findings [130].

18.2.9.6 Laboratory

Blood PCR can be used for the diagnosis of patients with CNS toxoplasmosis, although the rate of positive blood PCR was much lower in cerebral disease (13 %) vs. disseminated (78 %) disease in SOT and HSCT and other immunocompromised patients [140]. Routine PCR testing of peripheral blood specimens may be an appropriate tool for guiding preemptive therapy in patients at very high risk of developing invasive disease. The incidence of disease was 38 % in patients with positive *Toxoplasma* PCR in blood drawn prospectively during follow-up after 110 HSCT recipients, whereas it was 0 % in patients with negative PCR ($p < 0.0001$). Copy number of *Toxoplasma* ribosomal DNA in blood samples was higher in patients with invasive disease than in patients with *Toxoplasma* infection [135].

CSF PCR is positive in some patients [133, 141, 142]. The value of CSF PCR was checked in HIV-infected patients and showed the sensitivity, specificity, and positive and negative predictive values for detecting *T. gondii*

62.5 %, 100 %, 100 %, and 85.7 %, respectively [143]. The negative predictive value of PCR results from blood might also be dependent on the timing and the repetition of blood sampling [144].

CSF protein level may be slightly elevated, otherwise CSF was normal [133].

A seroconversion occurring early after transplant, with demonstration of IgM and IgG antibodies, and eventually IgA and IgE, is a strong indication of an acquired (and probably transmitted) infection with subsequent risk of disease. In some patients, positive IGM was early indicator of acute infection [145]. The majority of SOT patients with toxoplasmosis were diagnosed due to seroconversion [137]. However, the serological diagnosis of toxoplasmosis has important limitations in transplant patients, as the underlying immunosuppression alters antibody production and its kinetics [144].

In cases of profound immunosuppression, the antibody response might be lacking or atypical [139]. A reactivation should be suspected upon observation of a rise in specific antibody titers, usually IgG antibodies without IgM or IgA antibodies [144].

18.2.9.7 Imaging

Multiple lesions in the basal ganglia and subcortically in supra- and infratentorial location are the most frequent imaging finding in HSCT patients [6, 133, 136]. Hemorrhage is more frequent finding in HSCT patients vs. others due to low platelet count [6, 136].

There are two patterns of MRI imaging in HSCT patients with CNS toxoplasmosis. Disease which manifests early (in the first 3 months) posttransplant is characterized by minimal space-occupying effects and enhancement. Oppositely, late disease shows typical MRI appearance of *Toxoplasma* encephalitis with multiple lesions and ring enhancement with perifocal edema, reflecting higher ability to cause inflammation.

18.2.9.8 Treatment and Outcome

High suspicion for toxoplasmosis is needed for every patient with unexplained neurological findings [134]. Presence of concomitant infection with overlapping clinical presentation and false negative laboratory tests makes diagnosis challenging in some cases [146]. The recommended treatment is pyrimethamine, sulfadiazine plus folinic acid [138], followed by suppressive doses of TMP-SMZ or an alternate regimen, as written below, for the duration of their immunosuppression [147].

The overall mortality from *Toxoplasma* encephalitis was 55–90 % in HSCT [6, 134], and 35 % in SOT patients [138]. Good prognostic factors include: cerebral disease vs. disseminated (42 % vs. 80 % mortality) because CNS toxoplasmosis is usually diagnosed earlier (80 % during life vs. 20 % in disseminated infection) and treated appropriately [131]; early diagnosis and treatment with anti-*Toxoplasma* antibiotics, especially with reduction of immunosuppression improved survival [130, 138]; toxoplasmosis that was discovered late (36 % mortality) after transplantation, vs. early (70 % mortality) [6, 130].

18.2.10 Posttransplantation Lymphoproliferative Disorder (PTLD)

PTLD is a serious complication of transplantation. 12–22 % of PTLD involve CNS [148–150].

18.2.10.1 Incidence of CNS PTLD

Retrospective analysis of the complete autopsy records and clinical histories of 500 adults who underwent SOT showed PTLD involving the brain in 2 % of the liver, 3 % of the heart, and 7 % of the heart–lung recipients [35]. Among 910 PTLD cases from the USA reported to the Israel Penn International Transplant Tumor Registry, CNS was involved in 136 (15 %) cases, 15 occurred in pediatric patients. Isolated CNS involvement occurred in almost half of patients in several series. By organ transplanted, the highest incidence of CNS involvement occurred in pancreas transplant recipients (27 %), followed by those with kidney (18 %), heart (13 %), liver (11 %), and lung transplants (13 %) [148, 150]. Others reported on increased frequency of CNS PTLD in kidney transplant patients 55–78 % of all PTLD cases [151, 152].

The 3-year cumulative incidence of EBV-associated CNS disease was 8.6 +/− 2.4 % in allogeneic [153] and 4.3 % in cord blood HSCT patients [154].

18.2.10.2 Time After Transplantation

PTLD occurs late after SOT (see Chap. 26). The median time to onset was 19–33 months (range, 3–131 months) in a summary on 45 patients, predominantly adult kidney transplants recipients with isolated CNS PTLD [148, 149, 155, 156]. Among 84 CNS PTLD patients in a multicenter, international analysis, median time of SOT-to-PTLD was 54 months, 83 % of PTLDs were late onset (>1 year post-SOT); among them 36 % occurred >10 years after SOT [151].

PTLD may appear earlier in HSCT patients. The median time to PTLD was 73 (36–812) days after cord blood [154] and to CNS manifestation onset ~48 (22–184) days post-allogeneic transplantation [153, 157].

18.2.10.3 Risk Factors

Several risk factors for developing PTLD have been identified (see Chap. 26 Epstein–Barr Virus Infection and Lymphoproliferative Disorders after Transplantation).

18.2.10.4 Clinical Manifestations

The main symptom, encountered in 75–84 % was focal deficits, such as hemiparesis or aphasia. This was the isolated manifestation in about a third of patients, or associated with seizures in another third or symptoms of increased intracranial pressure in 13–36 %. Mental changes occurred in 8–50 % [149, 155]. Fever was frequent [153]. The mean duration of symptoms before diagnosis was 36 days (range 5–98 days) [149, 155]. Nonspecific symptoms of headache and altered mental status may be the only complaint [158].

18.2.10.5 Diagnostic Criteria

Definitive diagnosis of PTLD is based on symptoms, signs, and imaging consistent with PTLD together with at least two and ideally three of the following histological features: (1) disruption of underlying cellular architecture by a lymphoproliferative process; (2) presence of monoclonal or oligoclonal cell populations as revealed by cellular and/or viral markers; (3) evidence of EBV infection in many of the cells, that is, DNA, RNA, or protein. Definitive diagnosis of EBV-PTLD requires biopsy and histological examination (including immunohistochemistry or flow cytometry for CD19+ and CD20+). Detection of EBV nucleic acid in blood is not sufficient for the diagnosis of EBV-related PTLD [149, 155, 159, 160].

Positive CSF EBV PCR should be interpreted with caution, and other treatable etiologies have to be excluded. In one study, in 15/32 (47 %) of the patients with positive EBV DNA in CSF (18 were transplant patients) the clinician had a strong suspicion of cause other than EBV for the patients' CNS symptoms/findings, in some of them alternative diagnosis was confirmed [161].

18.2.10.6 Laboratory

The most common finding is an increased protein concentration while pleocytosis in CSF was found in some patients. EBV PCR in CSF may be negative [149, 155]. The laboratory findings used to identify EBV infection in immunocompetent persons (atypical lymphocytosis, VCA-IgM, and heterophile antibodies) may or may not be present in immunosuppressed patients. The absence or loss of anti-EBNA may precede PTLD, and the lack of seroconversion following primary EBV infection may be a risk factor for mortality from PTLD [159]

Regular monitoring of EBV DNA blood levels in allogeneic HSCT patients revealed that DNA loads of blood increased 3–14 days before the clinical manifestations of EBV-associated PTLD. The EBV DNA loads of CSF were higher than that of blood in patients with EBV-associated CNS PTLD. Dynamics of CSF EBV DNA levels correlated with the disease course—they declined with the control of diseases, and increased in patients who did not respond to treatment [153]. Isolated CNS PTLD, with negative blood EBV DNA can occur [162].

18.2.10.7 Imaging

Radiological findings show multifocal bilateral lesions in 37–83 %, 77–100 % with ring enhancement. CNS parenchymal lesions are distributed in highest frequency in the cerebral hemispheres (81 %), brain stem (9–15 %), and cerebellum (4–9 %). In the cerebral hemispheres, lesions are most common in the cortex and white matter (33 % each), basal ganglia (13–40 %), and corpus callosum (2 %). The majority of lesions were periventricular (72 %) with predisposition to ependymal location [149, 151, 155, 156]. Isolated leptomeningeal and ependymal enhancement occurred in 10 % patients [152]. MRI can be normal at early stages of the disease [153].

18.2.10.8 Treatment and Outcome

The prognosis is poor. In one summary, survival at 3 years in adults and children was 9 % and 13 %, respectively, vs. 49 % and 56 % in those without CNS involvement ($p < 0.01$). In children, better survival was noted for isolated CNS disease compared with multiple-site involvement (29 % vs. 0 %); however, in adults, the difference was less pronounced (12 % vs. 6 %) [148]. Mortality was 58 % in allo-HSCT patients with CNS PTLD, 40 % died because of CNS PTLD [153]. Overall survival in another study in kidney transplant recipients was 40 %, all the patients had isolated CNS involvement. Surviving patients received multimodal therapy, including immunosuppression reduction, chemotherapy (systemic and intrathecal methotrexate, steroids, and other agents), radiation, anti-B cell antibodies and cytotoxic lymphocyte (CTL) infusion [155]. In another series of 198 SOT patients, 39 patients (20 %) had complete remission, although 17 died later of other causes, and 12 (6 %) were alive and still undergoing therapy [150]. Most of those who had remission got radiation therapy, which appeared to be associated with better outcome and longer survival in several other studies [148, 155]. 41 % of SOT patients were alive at the last follow-up of median 23 months in another study, age was the only predictor of survival [152].

The overall response rate among 84 SOT patients with CNS PTLD was 50/84 (60 %). Complete response was observed in 32/84 (38 %) and partial response in 18/84 (21 %), while 27/84 patients (32 %) had progressive disease with first-line therapy. The most important prognostic factor was response to initial therapy [151].

Reduction of immunosuppression, anti-CD20 antibodies (rituximab), donor lymphocyte infusion or adoptive immunotherapy with EBV-CTL are recommended as first-line therapy for PTLD. Chemotherapy is recommended as a second-line therapy and antiviral agents and IGIV are not recommended [160]. Radiation therapy is an important modality in CNS disease. In one report, outcome was significantly better in patients who received radiotherapy as compared to those who had not: 1 and 5 years survival rates were 71 % and 37 %, compared to 41 % and 28 %, respectively, for the control

group ($p<0.05$) [163]. Rituximab is usually recommended as a first-line therapy in PTLD, but it may be insufficient in CNS PTLD because its low penetration to CSF. After intravenous administration in patients with CNS lymphoma, rituximab is reproducibly detected in the CSF at concentrations that are at most 0.1 % that of matched serum. It is probable that the blood–brain barrier limits the potential efficacy of intravenous rituximab in the prophylaxis or treatment of CNS lymphoma or lymphomatous meningitis [164]. There is some favorable experience with intrathecal (IT) rituximub treatment in resistant cases [165–167]. Seven of eight HSCT patients recovered from CNS PTLD after IT rituximab therapy, five of them achieved complete remission [157]. Most clinical signs and symptoms resolved within 7–10 days after the first IT rituximab administration [157].

18.2.11 Other Causes of Brain Abscess

Pyogenic bacteria, such as *Streptococcus epidermidis*, *Staphylococcus aureus*, *Klebsiella pneumonia,* and *Listeria* were involved in fewer than 10 % of brain abscesses in some series in HSCT and SOT [17, 18, 28, 33, 36].

Tuberculosis is a rare cause of CNS lesions in transplant patients. It was reported in few case reports. It should be considered as a part of differential diagnosis in the endemic areas [168, 169].

Neurocysticercosis is a condition that must be included in the differential diagnosis of patients with CNS involvement and cystic lesions on neuroimaging investigations in transplant recipients, especially patients originating from or traveling to endemic areas [170].

18.3 Meningoencephalitis

Meningoencephalitis in transplant patients may be caused by fungi, bacteria, viruses, and parasites (Table 18-1).

18.3.1 *Cryptococcus neoformans*

18.3.1.1 Pathogen

Cryptococcus neoformans is a ubiquitous saprophytic fungus with worldwide distribution. The fungus is found in nature primarily in association with bird droppings [171].

18.3.1.2 Incidence

Cryptococcal disease, frequently involving the CNS, has an incidence of 2.8 % in SOT population [38]. *Cryptococcus neoformans* was the cause of all five CNS fungal infections that occurred in 51 simultaneous pancreas-kidney transplantations [40]. CNS was involved in 48–72 % of *C. neoformans* infection in SOT recipients; 55 % had *C. neoformans* infection at the CNS site only [38, 172]. The majority of cryptococcal infections (52–64 %) occurred in kidney transplant patients, followed by liver (23.1 %), lung (11.5 %), and heart (7.7 % of cases) recipients [172, 173] in two series in SOT patients. In another report, the incidence of cryptococcal meningitis was higher in heart (2.1–3.5 %) and small bowel (1.7 %) compared to lung, liver, and kidney (0.2–1.1 %) transplant recipients [41, 171]. It is rarely reported after HSCT [174].

18.3.1.3 Time After Transplantation

Cryptococcal CNS infections in SOT recipients occurred in 40 % in the first-year posttransplant. The time to onset varied significantly for different types of organ transplant recipients. The median time to onset after transplantation was 35 months for kidney, 25 months for heart, 8.8 months for liver, and 3 months for lung transplant recipients ($p=0.001$). Overall, cryptococcosis developed in 100 % of the lung, 75 % of the liver, 33 % of the heart, and 30 % of the kidney transplant recipients within 12 months of transplantation ($p=0.002$) [38]. The median time from transplantation to disease was 17.8 months (range 1 month to 15 years) in SOT patients with *Cryptococcus gattii* infection [173].

18.3.1.4 Risk Factors

Patients receiving tacrolimus were significantly less likely to have CNS involvement than patients receiving non-tacrolimus-based immunosuppression (78 % vs. 11 %, $p=0.013$). Furthermore, both tacrolimus and cyclosporine were less likely to be associated with CNS involvement and more likely to be associated with cutaneous infection than azathioprine [38].

18.3.1.5 Clinical Manifestations

Presenting features of transplanted patients with CNS cryptococcosis include headache in 46–62 %; confusion or lethargy in 48–64 %; nausea and vomiting in 50 %, fever/chills in 46 %, malaise in 32 %, meningismus in 14 %, visual loss in 7 %, seizures in 4 %, and coma in 1 % [28, 38, 40, 41]. Subacute meningitis is the usual presentation of cryptococcal infection which appears in 98 % of cases; others have space-occupying lesions [38, 41]. The mean length of symptoms before the diagnosis of meningitis was 17 ± 25d (range 2–30) [171]. The CSF may evidence minimal inflammation and a low cryptococcal antigen titer, leading to an underestimation of the severity of the infection [173].

18.3.1.6 Diagnostic Criteria

Detection of cryptococcal polysaccharide capsular antigen in blood or CSF is the best diagnostic tool. Positive cryptococcal antigen is found in 98–100 % in CSF, and in 86–97.5 % in serum. CSF culture is positive in 77–93 % and blood culture in 3.6–39 %. Positive India ink CSF smear was found in 50–80 % of patients [38, 41, 175]. In another report, serum or cerebrospinal fluid cryptococcal antigen assay was positive in 57.4 % of SOT recipients [172]. Patients with CNS disease had higher serum antigen titers and were more likely to be fungemic (35.6 % vs. 4.8 %, $p=0.0002$) than those without CNS disease [171, 175].

18.3.1.7 Imaging

CT scan and MRI may be normal or with nonspecific findings, including meningeal enhancement [41, 171]. In one study, leptomeningeal lesions was described in 8/55, parenchymal lesions in 6/55 and hydrocephalus 2/55 [175]. In another study, hydrocephalus was the most common finding, found in 7/12 (58 %) patients [176]. Space-occupying lesions (contrast enhancing mass lesions) due to *C. neoformans* were present in 3/125 SOT patients [38]. Immune reconstitution syndrome may contribute to the CNS findings that develop after initiation of the antifungal therapy [175]. Neuroimaging in SOT patients with *Cryptococcus gattii* infection, demonstrated leptomeningeal enhancement more frequent (70 % vs. 7 %) and brain mass was less frequent (0 % vs. 64 %, both $p<0.05$) as compared to normal hosts [173].

18.3.1.8 Treatment and Outcome

The following two options are strongly recommended currently for the treatment of cryptococcal meningitis [177–179]: (1) Amphotericin B, 0.7–1 mg/kg/day, plus 5FC, 100 mg/kg/day, for 2 w, then fluconazole, 400 mg/day for minimum 10 weeks; (2) Amphotericin B, 0.7–1 mg/kg/day plus 5FC, 100 mg/kg/day for 6–10 weeks.

Each of these regimens should be followed by 6–12 months of suppressive therapy with a lower dose of fluconazole (200 mg/day). For those patients receiving long-term prednisone therapy, reduction of the prednisone dosage to 10 mg/day (or its equivalent), if possible, may result in improved outcome to antifungal therapy [177].

Close monitoring for evidence of elevated intracranial pressure is crucial. For patients with elevated baseline opening pressure, lumbar drainage should remove enough CSF to reduce the opening pressure by 50 %, and daily lumbar punctures to maintain CSF opening pressure in the normal range is required. Among patients with normal baseline opening pressure (up to 200 mm H2O), a repeat lumbar puncture should be performed 2 weeks after initiation of therapy to exclude elevated pressure and to evaluate culture status [171, 177].

The use of intrathecal or intraventricular amphotericin B, via a reservoir, may be considered in refractory cases where systemic administration of antifungal therapy fails, i.e., persistence of clinical manifestations of meningitis and elevated cryptococcal antigen titers in CSF [41, 171]. In one study, it was done in 3/28 (11 %) of SOT patients [41].

The mortality is 25–72 % and death occurs at a median of 19 days (range, 5–53 days) after diagnosis [38, 41, 173, 175]. Factors associated with poor outcome are abnormal mental status, absence of headache, parenchymal lesion vs. leptomeningeal [175], renal failure on admission (in the series describing predominantly kidney transplant recipients), and liver allograft failure in liver transplant recipients. The outcome is not correlated with the presence of fever, CSF pleocytosis, positive blood cultures, CSF cryptococcal antigen titer, and different immune suppressive protocols [38, 41, 171]. SOT patients receiving a calcineurin-inhibitor agent have better outcome ($p=0.008$), probably due to antifungal activity of this agent seen in vitro [180]. Mortality did not differ in those who received amphotericin B alone (59 %) and who received amphotericin B plus 5FC (44 %) [38, 175].

18.3.2 Viral Encephalitis

Viruses that can cause posttransplant encephalitis include human herpesvirus 6 (HHV-6), JC virus (JCV), herpes simplex, and others. In one recent study, 32/2628 (1.2 %) allo-HSCT patients developed viral encephalitis. Development of viral encephalitis was associated with the use of OKT-3 or alemtuzumab for T-cell depletion ($p<0.001$). Detected viruses included HHV-6 (28 %), EBV (19 %), herpes simplex virus (HSV) (13 %), JCV (9 %), varicella zoster virus (VZV) (6 %), CMV (6 %), and adenovirus (3 %), more than one virus was identified in 16 % of the patients.

The median onset time was 106 days after HSCT, but onset times were shortest in those with HHV-6 encephalitis and longest in those with JCV-associated progressive multifocal leukoencephalopathy (PML). Alteration of consciousness was the most frequent symptom (81 %), followed by fever (59 %), seizures (34 %), psychiatric disorders such as confusion, psychosis or personality changes (28 %), paresis (25 %), and hypo- or dysesthesia (19 %). Neuroimaging detected abnormalities attributed to viral encephalitis in 53 % of these patients (in 36 % diffuse, in 13 % focal, 4 % both), in 37 % it was normal [181]. The probability of a sustained response to treatment was 63 % with a median survival of 94 days after onset, but significant variation was found between different causative viruses [181]. Mortality was significantly higher in HSCT patients who developed encephalitis as compared to those without encephalitis (66 % vs. 42 %, $p=0.011$).

The mortality rates attributed to viral encephalitis were as follows: 33 % for HHV-6, 33 % for EBV, 80 % for more than one detected virus, 0 % for HSV, and 67 % for JCV.

18.3.3 Human Herpesvirus 6 (HHV-6)

18.3.3.1 Pathogen

HHV-6 is an enveloped DNA virus; see Chaps. 28 and 29.

18.3.3.2 Incidence

In prospective studies, HHV-6 DNA PCR in blood was detected in 47–78 % of HSCT recipients, and 3–6.9 % developed CNS symptoms contributable to HHV-6 [182–188]. In another study, HHV-6 DNA was detected in CSF samples from 5/11 (45 %) HSCT patients with CNS symptoms of undefined origin. On the other hand, it was found in only one of 107 (0.9 %) immunocompromised patients without CNS symptoms and in none of the 11 HSCT patients for whom other causes for the CNS diseases were documented ($p=0.001$) [189].

Acute limbic encephalitis, which is may be associated with HHV-6, developed in 9/584 (1.5 %) HSCT patients, in six of them HHV-6 infection was diagnosed [190].

In SOT recipients, 38–55 % of renal, 22–54 % of liver, 36 % of heart, and up to 57 % of heart–lung transplant recipients have been shown to develop active HHV-6 infection [191, 192]. CNS complications of any etiology occurred in 29 % (9 of 31) of the patients with HHV-6 and 12 % (6 of 49) of the patients without HHV-6 infection ($p=0.06$). However, mental status changes of unknown etiology were significantly more likely to occur in patients with HHV-6 infection (29 %, 9 of 31), compared with those without HHV-6 (6 %, 3 of 49, $p=0.008$) [191]. There are additional sporadic reports on CNS dysfunction related to HHV-6 in other SOT recipients [193].

18.3.3.3 Time After the Transplantation

HHV-6 reactivation usually occur 2–9 weeks after HSCT, which corresponded to the time period when most cases of encephalitis occur [181, 183, 189, 194, 195]. Overall, 33 % of the cases occurred within 3 weeks, 50 % within 4 weeks, and 83 % within 12 weeks of HSCT transplantation [194]. Most HHV-6 infections occur between 2 and 4 weeks after SOT [192]. In liver transplant patients, symptoms of encephalitis occurred within 10 days after transplant in one study, and in another—71 % of the HHV-6 infections occurred within 4 weeks of transplantation [191, 196].

18.3.3.4 Risk Factors

GVHD is a risk factor: overall incidence of grade III and more GVHD was 80 % and 10.5 %, respectively, in those with and without HHV-6 encephalitis ($p=0.003$) [197]. Treatment with alemtuzumab and anti-CD3 monoclonal antibody (BC3) for prophylaxis of acute GVHD was associated with higher incidence of encephalitis [183, 197].

Acute GVHD grades II to IV and adult-mismatched donor were significant risk factors for HHV-6 limbic encephalitis in another report [198].

In addition, acyclovir was associated with a decreased risk of encephalitis after adjustment for receipt of BC3 (RR, 0.3; 95 % CI, 0.1–0.8) [183].

A meta-analysis of studies published during 10 years (2002–2012) demonstrated that prevalences of HHV-6 reactivation and HHV-6 encephalitis were significantly higher in patients receiving umbilical cord blood transplantation (UCBT) as the stem cell source than in patients receiving another stem cell source (72.0 % vs. 37.4 %, $p<0.0001$; 8.3 % vs. 0.50 %, $p<0.0001$, respectively). Monitoring for HHV-6 reactivation was recommended for HSCT patients [199]. Several later studies reported that prevalence of HHV-6 encephalitis and HHV-6 associated limbic encephalitis was significantly higher among patients receiving UCBT than in patients with other sources (7.9–15.7 % vs. 0.7–2.8 %) [104, 187, 198, 200] and in patients who underwent two or more HSCTs (11.9 %), compared to those who received only one HSCT (3.6 %, $p=0.018$) [104].

18.3.3.5 Clinical Manifestations

Clinical manifestations include confusion, somnolence, amnesia, headache, speech abnormalities, seizures, dysesthesia, and coma. Focal neurological findings are less common (17 %). Fever was documented in 25 % (4 of 12) of the patients. The electroencephalogram (EEG) showed mild or severe diffuse abnormalities in some cases and in the others it was nonspecific [185, 189, 194, 197].

HHV-6 infection is associated with acute limbic encephalitis. It is a distinct syndrome which clinical features include acute onset over 1–3 days with marked anterograde amnesia, patchy retrograde amnesia for up to 4 years, seizures, SIADH, and mild CSF pleocytosis. Focal abnormalities in EEG are seen over the temporal or frontotemporal leads in the majority of these patients [190].

Patients with HHV-6 reactivation after HSCT were more likely to develop delirium (adjusted odds ratio = 2.5) and demonstrate neurocognitive decline (adjusted odds ratio = 2.6) in the first 84 days after HCT [201].

18.3.3.6 Diagnostic Criteria

Diagnosing HHV-6 in HSCT patients may be challenging, since neurological complications after transplantation are frequent on the one hand and asymptomatic elevation of CSF HHV-6-PCR may occur [182–184]. Establishing a diagnosis of HHV-6 encephalitis therefore requires the triad of neurological manifestations, evidence of HHV-6 infection in CSF and absence of other pathogens or pathology [197].

18.3.3.7 Laboratory Examination

Examination of CSF may be normal [185], but usually the protein is elevated and sometimes CSF lymphocytosis is found. CSF PCR was positive in all patients at a median of 4700 copies/mL (range, 600–225,000 copies/mL) while HHV-6 PCR in plasma or PBL may be negative [184, 189, 194, 195, 197].

Higher thresholds of HHV-6 DNA were statistically significant predictors of subsequent CNS dysfunction [182]. The quantity of HHV-6 viremia over time was higher in those who developed encephalitis than in those who did not. Patients with levels of HHV-6 DNA 15,000 copies/mL appeared more likely to develop encephalitis than did those with lower levels: 7/29 (24 %) vs. 11/94 (12 %) [183]. Prospective, multicenter study of 230 allogeneic HCT recipients who had twice weekly plasma HHV-6 DNA load demonstrated that none of the 144 patients without high-level HHV-6 reactivation and 7 of 86 patients (8.1 %) with high-level HHV-6 reactivation (plasma HHV-6 DNA $\geq 10^4$ copies/mL) developed HHV-6 encephalitis ($p=0.0009$). For identifying HHV-6 encephalitis, plasma HHV-6 DNA $\geq 10^4$ copies/mL offered 100 % sensitivity and 64.6 % specificity, and plasma HHV-6 DNA $\geq 10^5$ copies/mL offered 57.1 % sensitivity and 90.6 % specificity [187]. In another study, elevated plasma IL-6 concentrations preceding HHV-6 infection in patients who developed CNS dysfunction.[202]

18.3.3.8 Imaging

CNS imaging shows abnormalities only in part of the patients. Abnormalities most commonly involving the temporal lobes and especially the medial temporal lobes may be seen in MRI. All HSCT patients with limbic encephalitis showed focal medial temporal abnormalities in MRI [183, 189, 190, 195, 197].

18.3.3.9 Treatment and Outcome

Treatment usually included foscarnet or ganciclovir [184, 185, 197]. In severe cases, the recovery is slow. In one HSCT study, the confusion improved after median of 11 days, followed by a reduction in seizure frequency and severity, and recovery of short-term memory loss was much slower, with frequent fluctuations in severity over the ensuing weeks [197]. Although some patients developed CNS symptoms on acyclovir prophylaxis [189], prophylaxis with acyclovir was associated with a decreased risk of encephalitis [183]. Breakthrough HHV-6 encephalitis was reported during foscarnet prophylaxis in HSCT patients [203].

Summary of 48 HSCT cases showed full recovery in 43 % patients, 25 % had a progressive course and died within 1–4 weeks of diagnosis and others had improvement, and the others remained with neurological sequella or died later due to other medical problems [195]. In another summary of 14 cases (13 HSCT, 1 liver transplant), the overall mortality was 58 %; in about a half of them the death was considered attributable to HHV-6 infection [194]. HHV-6 encephalitis was independently associated with decreased survival in patients with allo HSCT [200]. In another report, death from HHV-6-limbic encephalitis occurred in 50 % of affected patients undergoing UCBT and no recipients of adult-donor cells [198].

18.3.4 JC Virus

18.3.4.1 Pathogen

JCV is a neurotropic papovavirus virus. Primary infection occurs during childhood in 75 % of the population [204–206]. In immunocompromised patients JCV causes PML, a demyelinating infection.

BK virus known to cause urinary tract problems in transplant recipients was rarely documented as a cause of encephalitis [207, 208].

18.3.4.2 Incidence

Although JC DNAemia or viruria can occur after transplantation, reports on JCV encephalitis are not frequent. The overall JCV DNAemia rate was 5 % in one study in SOT patients, nobody developed PML picture [209]. The rate of JC viruria in kidney transplant patients is 3.8–40 % [210]. Cumulative incidence of PML, however, was 0.027 % following 32,757 renal transplantations or 8.8 cases/100,000 person-years at risk [211]. Sixty-nine cases of PML in SOT and HSCT recipients were summarized in 2011, of them 54 from review of literature from the period 1958–2010; 36 % of them following HSCT, 34 % kidney, and 30 % other SOT [212]; PML was reported in a few allo- and autologous HSCT patients [206, 213]. JCV reactivation occurred in a quarter of allo HSCT patients in one study, 2/20 patients with persistent reactivation developed PML [214]. The incidence of PML in the heart and/or lung posttransplantation population was three cases in 2428 total posttransplantation person-years or an incidence rate of 1.24 per 1000 posttransplantation person-years [212].

A few cases were described following liver transplantation [215].

18.3.4.3 Time After Transplantation

The median time of onset of PML following transplantation (SOT and HSCT) was 17 months and ranged from 1 week to 132 months. Overall, 71 % (17/24) of the cases of PML occurred within 24 months of transplantation.

In another review, the median time to development of first symptoms of PML following transplantation was longer in SOT vs. HSCT (27 vs. 11 months, $p=0.0005$, range of <1 to >240) [212]. Renal transplant recipients seemed to develop these lesions later after transplantation than did other trans-

plant recipients, some cases are reported to occur years after transplantation [204]. Median time was 334 (range 107–1340) days in HSCT patients [181].

18.3.4.4 Risk Factors

Factors associated with PML development were BK polyoma infection, blood transfusions, use of antirejection medications, and higher panel reactive antibody levels before transplant. BK polyoma infection developed in 22.2 % of PML patients vs. 1.1 % of other patients ($p=0.004$), probably reflecting higher level of immune suppression in these patients. Treatment with mycophenolate mofetil was suggested to be associated with PML [211]. Treatment with rituximub is suspected to be associated with JC viremia and cases of PML in SOT and HSCT patients [216, 217].

18.3.4.5 Clinical Manifestations

The clinical presentation of PML in transplant patients is subacute in 75 % of the patients and more abrupt in the others. The most common presenting symptoms are mono- or hemiparesis (50 %); some of them developed tetraparesis with bilateral pyramidal signs: cognitive deficits (47 %), apathy and behavioral changes (46 %), confusion (38 %), and pseudo bulbar changes.

The symptoms usually worsen gradually over a course of days to weeks, and new neurological manifestations may appear, usually resulting from a spread of the lesion or from new lesions at remote sites. Visual symptoms, including homonymous hemianopsia, occurr in 23–29 % of the patients. Sensory symptoms, ataxia, discoordination and memory impairment are described in 29 % of the patients. Other manifestations include speech disturbances (25 %), cerebellar symptoms (19 %), dysarthria (19 %), aphasia (15 %), frontal release signs (12.5 %), and seizures (10–21 %) usually occurring as the disease progressed, and most patients have focal motor seizures. Extrapyramidal signs are described in four patients (17 %). Alexia, dyscalculia, Gerstmann's syndrome, incontinence, dizziness, apraxia, and headache were described occasionally [204, 212].

18.3.4.6 Laboratory

The CSF content is normal in all patients, except for possible mild elevation in protein levels [204]. The sensitivity of PCR for detecting JCV DNA in CSF from HIV-infected patients with confirmed cases of PML was 74 %; the specificity was 96 %. The positive predictive value was 89.5 %, and the negative predictive value was 88.5 % [218].

18.3.4.7 Imaging

MRI is the preferred mode of imaging, showing lesions in all patients. CT scans in patients with PML characteristically reveal hypodense, non-enhancing lesions of the cerebral white matter and mass effect is distinctly unusual [204]. Parietal, occipital, and temporal lobes are the most common sites involved. Neuroimaging abnormalities are usually located in the subcortical white matter but some extend into the deeper white matter or the cortical ribbon. In another study, infratentorial lesions were found in two-thirds of patients [205]. MRI findings can be subtle in HSCT patients because of heavy immune suppression [213].

Imaging characteristics of PML are similar to immunosuppression (cyclosporine or tacrolimus)-associated leukoencephalopathy, and this diagnosis should be excluded.

18.3.4.8 Diagnostic Criteria

Consensus standards for diagnosis of PML have been divided into a "histologic-confirmed" diagnosis, requiring histology from brain tissue, a "laboratory-confirmed" diagnosis, requiring positive PCR from a CSF specimen, and the entity of a "suspected/possible" diagnosis, based upon clinical findings in the presence of characteristic radiologic abnormalities [219].

18.3.4.9 Treatment and Outcome

Mortality is high: 64–71 % of HSCT and SOT patients died, 53–84 % of them directly from PML [204, 212]. Survival rate reported in other studies was 29–41 % [205, 206]. Time from PML onset to death ranged from 2 to 7 months [206]. Median survival following symptom onset was 6.4 months in SOT vs. 19.5 months in HSCT ($p=0.068$) [212]. The majority of the survivors suffer from residual neurological damage, which includes hemiparesis, speech difficulties, dementia, partial incontinence, or myoclonic jerks. Improvement of their neurological symptoms, however, is described, with treatment and time [204]. There were no specific clinical manifestations that differentiate these patients from those who died.

In a summary of post-HSCT patients, 9/15 (60 %) of cases which reported an attempt at therapy reported positive clinical response including survival (median 19 months) at time of case report publication. This positive-reported response was associated with a median time from HCT to symptom onset of 13 months vs. 10 months for cases with reported lack of response (median survival from symptom onset 3.5 months) [213].

In all seven survivors described in one series, the immunosuppressive therapy was reduced to the minimum, and five of them received treatment for PML—cytarabine (three patients), IL-2 (one patient), and cidofovir (one patient). Treatment options used in other patients include cytarabine intrathecally, α-interferon, cytosine arabinoside, mefloquine, donor-derived JCV Ag-specific cytotoxic T lymphocytes [204, 206, 213, 220]. Reduction of immune suppression is important [215, 221].

18.3.5 West Nile Virus (WNV)

18.3.5.1 Pathogen

WNV is a mosquito-borne flavivirus that is transmitted primarily among birds; humans serve as incidental hosts [222]. The disease is endemic in Africa, the Middle East, and southwestern Asia. It has recently spread to Europe and North America [223].

18.3.5.2 Incidence

WNV disease is infrequent in transplant recipients. The seroprevalence of WNV IgM was 2/816 (0.25 %) in one seroprevalence study performed in SOT patients after WNV outbreak in 2002 in Canada [224]. Twenty cases of WNV disease following SOT from infected donor were reported, as well as another SOT and HSCT cases who acquired it from blood product transfusion [222, 225, 226].

18.3.5.3 Time After Transplantation

Patients developed clinical signs of WNV infection 5–37 days after transfusion of infected blood product or donation of infected organ [222, 225, 226]. WNF can occur any time after transplantation, after exposure to infected mosquito.

18.3.5.4 Risk Factors

Transplant recipients may acquire WNV by three mechanisms: (1) from exposure to mosquito (after median incubation time of 13.5 days); (2) from a blood product transfusion (within 4 weeks) and (3) from infected organ that is transplanted (within 4 weeks after the receipt of a component from a donor) [222, 225–227]. Outdoor recreational activity is a risk factor for community exposure to WNV infection [224].

In donor-derived WNV, donors usually reside in areas of increased WNV activity, they are usually asymptomatic [226]

18.3.5.5 Clinical Manifestations

Unlike healthy individuals, in whom the majority of infections are asymptomatic, transplant patients often develop a severe disease. Review of the 20 published cases of organ-derived WNV infection found that 70 % of infected recipients developed encephalitis [226]. The initial clinical symptoms include fever, weakness, myalgia, gastrointestinal complaints, and altered mental status. Neurological involvement appears within 0.5–7 days and the signs and symptoms progress rapidly, reaching a maximum within a few hours to 2 days. Three categories of serious neurological manifestations are described: meningitis, encephalitis, and acute flaccid paralysis. Meningoencephalitis develops in the majority of the patients [223, 225, 228]. Transient seizures occur in up to 30 % of cases. In one series on 11 HSCT and SOT recipients with WNV disease, four developed acute flaccid paralysis; all had severe quadriparesis or quadriplegia associated with hypotonia and areflexia with relatively preserved sensation [228]; four suffered from myoclonus, some had parkinsonian features. All patients who had EEGs manifested a diffuse slowing of variable severity consistent with generalized encephalopathy [228].

18.3.5.6 Diagnostic Criteria

Determination of WNV infection after transfusion requires at least one of the following [222]:

1. WNV-associated illness within 4 weeks after the receipt of a component from a donor with viremia and laboratory evidence of recent WNV infection.
2. Positive test for IgM antibody either without a history or with a possible history of illness compatible with WNV infection.

Determination of WNV-associated illness in a recipient required the following:

- New onset of unexplained fever, meningitis, encephalitis, or acute flaccid paralysis (alone or in combination).
- Laboratory criteria for confirmed recent WNV infection were as follows:
  - Isolation of WNV from tissue, blood, or cerebrospinal fluid.
  - Detection of WNV antigen by immunohistochemical staining or of WNV genomic sequences in tissue, blood, or CSF.
  - Detection of WNV IgM antibodies in a cerebrospinal fluid sample obtained during the acute phase of illness by IgM-capture ELISA.
  - Recent seroconversion, with detection of WNV IgM by IgM-capture ELISA.

18.3.5.7 Laboratory

Usually patients manifested an initial CSF pleocytosis. Positive serum and CSF IgM or PCR confirm diagnosis [223, 225, 226, 228].

18.3.5.8 Imaging

Abnormalities in cerebral white matter, thalami, basal ganglia, brain stem, and other areas are usually demonstrated in MRI [228].

18.3.5.9 Treatment and Outcome

The treatment include (1) reducing immunosuppression; (2) nonspecific antiviral therapy (interferon alfa-2b); (3) passive

immunization with anti-WNV antibody-containing IVIG when available; (4) intravenous immunoglobulin; and (5) ribavirin. The mortality rate was 17–30 %. Among survivors, 36–43 % had full recovery, while others had minor or major sequelae [223, 226–230].

18.3.5.10 Prevention

Transplant patients living in areas of high WNV activity should be advised of the risk of WNV and counseled on the use of protective measures as well as on potentially avoiding outdoor activity during dusk and dawn, when mosquitoes are most active. Testing of donors would be most reliable in areas with a high prevalence of WNV [226], but the screening is controversial, because of the rarity of the disease [228, 231].

18.3.6 *Listeria*

18.3.6.1 Pathogen

Listeria monocytogenes is a Gram-positive, facultative anaerobic non-spore-forming motile intracellular bacillus that is most often transmitted to humans via contaminated foods such as milk and cheese, undercooked meat, or uncooked vegetables [232, 233].

18.3.6.2 Incidence

The incidence of listeriosis during 13 years was 0.5 % (6/1315) allogeneic HSCT in one center, 2/6 cases developed meningoencephalitis [234]. In one review of the reported cases of brain abscess due to *Listeria*, 18 % of 39 patients were renal transplant recipients [235]. A report summarizing 820 cases of *Listeria* CNS infection showed that 21 % were in transplant recipients. It was mainly described in renal transplantation, where it was the most common cause of bacterial meningitis [233]. The great majority of the patients with CNS listeriosis (97 % of 820) had meningitis/meningoencephalitis and the rest had abscesses [233]. CNS involvement is reported from 30 % in HSCT and liver transplant recipients up to 70 % in renal transplant recipients with listeriosis [232, 234, 236].

18.3.6.3 Time After the Transplantation

The time of diagnosis of listerial infection ranged from 3 weeks to 6 years following SOT and HSCT [232, 234, 235].

18.3.6.4 Risk Factors

Graft rejection or transplant dysfunction, as well as CMV infection which cause immune dysfunction are supposed to be risk factors for listeriosis [234, 235].

18.3.6.5 Clinical Manifestations

Clinical symptoms include fever (in 92 %), headache, and irritability, altered mental status on presentation, headache, or obtundation [232]. Notably, meningeal signs are found in 70 % [233]. In patients with cranial neuropathies, the IIIrd, VIth, VIIth, XIth, and/or Xth nerves are most commonly affected [233].

18.3.6.6 Diagnostic Criteria

Isolation of the bacterial pathogen from the CSF or from a brain abscess is needed for diagnosis.

18.3.6.7 Laboratory

CSF is characterized by predominance of PMNs and elevated protein; hypoglycorrhachia may be found. Blood cultures are positive in the majority of cases [233, 234].

18.3.6.8 Imaging

Brain imaging can show signs of cerebritis, abscess, and hydrocephalus, but it can be normal [232–234].

18.3.6.9 Treatment and Outcome

A combination therapy of ampicillin with gentamicin, or with TMP-SMX, is recommended. In meningitis, the duration of therapy is 3 weeks, and for brain abscess or rhombencephalitis is at least 6 weeks. The mortality rate is 14–50 %, higher in patients with seizures [232, 233].

18.3.6.10 Prevention

Transplant recipients should be educated about the potential risks associated with consuming unpasteurized milk and soft cheese and should be encouraged to cook meat products thoroughly [233]. The use of TMP-SMX prophylaxis to prevent PCP may decrease the incidence of the infection in the transplant population.

18.3.7 Other Causes of Encephalitis Posttransplantation

18.3.7.1 **Measles inclusion bodies encephalitis** *(***MIBE***)* occurs typically in immunocompromised patients within 1 year of measles infection. Patients usually present with afebrile focal seizures and altered mentation. The seizures tend to be refractory to anticonvulsant therapy, and EEG often shows epilepsia partialis continua. Laboratory studies in MIBE are

nondiagnostic, as CSF parameters are often normal and CSF antibodies to measles are usually undetectable. Imaging studies such as brain MRI and computed tomography are often normal. Diagnosis requires a brain biopsy, confirming the diagnosis of MIBE by RT-PCR for measles virus RNA or by immunohistochemistry. The prognosis is poor, with a 76 % mortality rate, and all survivors manifesting significant neurologic sequelae. Possible treatment options include Ribavirin and Interferon-α [237].

18.3.7.2 **Parvovirus B19** is a rare cause of posttransplant encephalitis or CNS vasculitis as reported in two renal transplant recipients. One of them developed vasculitis with skin eruptions and recurrent episodes of encephalopathy with focal neurological deficits. B19 DNA was detected in blood, bone marrow, and skin biopsy specimens. Repeat cranial MRI during each episode of encephalopathy showed variable focal findings, and MR angiography revealed vasculitic changes with narrowing of the cerebral arteries. Specific IgM antibodies were positive in CSF [238]. The second one developed seizures and signs of encephalitis on MRI, with positive blood parvovirus B19 PCR, probably acquired from the donated organ [239] Intravenous immune globulin and reduction of immune suppression may help.

18.3.7.3 **VZV**. Although reactivation of VZV is a common event in patients undergoing HSCT occurring in 41 % of patients, CNS involvement is rare (2 %), probably because of an efficient antiviral chemoprophylaxis. Cases of meningoencephalitis and large- and small-vessel vasculopathy in HSCT and SOT recipients were described, some of them fatal [240–242].

Median time since transplantation until the onset of symptoms was 234 (range 207–261) days in HSCT patients [181].

Diagnosis is established by positive CSF PCR in patients with neurological manifestations, although interpretation of a positive VZV CSF PCR result is more problematic in patients with concomitant cutaneous zoster involvement, as some studies have reported VZV DNA in CSF of patients with uncomplicated zoster or with neurological disease likely caused by other pathogens [240]. Treatment with acyclovir should be initiated. Acyclovir-resistant VZV in the CSF was reported in HSCT patient, due to thymidine kinase mutation, while the virus remained sensitive in blood [243].

18.3.7.4 **CMV**. Although CMV is a very significant pathogen in transplant patients and CMV disease often involves a variety of organs, CMV CNS disease is uncommon. In one study, definite CMV encephalitis was diagnosed in only 11 of 552 (2 %) autopsies performed in HSCT and SOT recipients [244]. CMV ventriculoencephalitis was reported is four peripheral HSCT patients [245].

Eleven cases of CMV CNS disease, mainly encephalitis, were described. All were late-onset CMV disease, occurring median 210 (range 166–285) days after HSCT transplantation. CT or MRI of the brain commonly showed multiple foci of restricted diffusion or infarction. Three patients had concomitant retinitis; two patients had concomitant CMV disease outside the CNS, either pneumonia or colitis. All had ganciclovir (GCV)-resistant virus. Some developed CMV CNS disease despite clearing of their CMV viremia, thus the absence of viremia does not exclude CMV encephalitis [246]. Only one patient survived. Alternative treatments for CMV include foscarnet and cidofovir. Combination of increased dosage of GCV (7.5 mg/kg twice a day), foscarnet, and CTL was successful in one HSCT patient with CMV encephalitis [247].

18.3.7.5 **HSV-1/2**. Although HSV-1/2 can be responsible for the majority of nonendemic cases of viral encephalitis and is the most common cause of fatal sporadic encephalitis [248], it is rarely reported in transplant patients. In one report, five of 23 herpesvirus-associated CNS diseases in allo-HSCT patients were due to HSV-1. In another report, HSV was responsible for 5/23 (13 %) of all cases of viral encephalitis in allo-HSCT recipients, in two of them HSV was isolated together with other viruses [181]. The onset time of encephalitis was median 66 (range 42–189 days). Three patients in whom HSV was the only virus isolated in CSF survived; two other patients, with multiple viruses, died [181].

Other rare causes of CNS infections include:

1. **Adenovirus** [249, 250]. Meningoencephalitis without viremia was reported in HSCT patients [250].
2. **Rabies** encephalitis. Transmission via transplanted solid organs from infected donor was reported. Incubation period may be prolonged—18 months after transplantation [251, 252].
3. Five clusters of transmission of lymphocytic choriomeningitis virus (LCMV) and an LCMV like arenavirus via SOT have been described. Some cases may progress to meningitis, encephalitis, and other CNS manifestations, with high case fatality rate [253, 254].

18.3.8 Parasite

A few cases of *Acanthamoeba* infection has been reported in patients following HSCT and SOT. It presented mostly as encephalitis and rarely as cerebral abscess [255]. Presentation in both HSCT and SOT was fulminant manner and death occurred within 2 weeks after the onset of neurologic symptoms [256, 257].

Skin lesions (multiple recurrent panniculitis-like subcutaneous nodules) may predate neurologic involvement and provide an opportunity for early diagnosis and treatment [256, 257]. The diagnosis was made by biopsy. There is no effective treatment for *Acanthamoeba*-related CNS infection. The outcome of 90 % of the patients has been fatal, despite various treatment regimens [255]. Survivors may develop disability, such as hearing loss, vision impairment [257]

18.4 Conclusion

CNS abnormalities are frequent after HSCT and SOT. A variety of pathogens may cause CNS infection which is an important and significant component of the differential diagnosis. The clinical manifestations are not specific and cannot distinguish between different infectious etiologies. Laboratory examination may be normal and biopsy is usually not feasible. Imaging can help to divide CNS pathology into two categories: brain abscess and meningoencephalitis, each has certain pathogens causing it. MRI is more informative than CT. Prompt appropriate workup for patients with neurological findings, attempting to identify the infectious cause followed by treatment targeted to the specific pathogen is critical for survival and for minimizing the neurological sequelae.

19 Gastrointestinal Infections After Solid Organ or Hematopoietic Cell Transplantation

Christopher J. Damman and George B. McDonald

19.1 Introduction

The gastrointestinal tract is a common site of infection in patients who are immunosuppressed following either solid organ (SOT) or hematopoietic cell transplantation (HCT). Patients undergoing these procedures have many immunosuppressive drugs in common, but hematopoietic cell recipients must also face the toxicity of myeloablative conditioning regimens, absence of cellular immunity pending engraftment, acute and chronic GVHD, and delayed immune reconstitution. Clinical presentations of intestinal infection can be subtle, and diagnosis of specific infections often requires endoscopic biopsy of intestinal mucosa. Noninfectious problems, for example, diverticular bleeding after kidney transplant or intestinal GVHD after allogeneic HCT, may mimic infections and may also coexist with infection.

19.2 Gastrointestinal Infections After Solid Organ Transplantation

The frequency of gastrointestinal complications after SOT is 20–35 %, encompassing graft dysfunction and side effects of immunosuppression including direct side effects, malignancy (often from viral transformation), and infection [1–3] (Tables 19-1 and 19-2). Despite screening measures and antimicrobial prophylaxis, infectious complications remain a major source of morbidity and mortality. Infections occurring in the first month of transplant are distinct from those occurring later. In the first month most infections are those present prior to transplant (e.g., urinary tract infection), those transmitted by the transplanted organ (e.g., CMV infection), and those related to technical complications of the procedure (e.g., ascending cholangitis). After 1 month, opportunistic infections from viruses, fungi, and parasites residing in gastrointestinal reservoirs, immunoprivileged sites, or latent states, along with community-acquired infection, are more likely to occur [4].

19.2.1 Kidney and Kidney–Pancreas Transplant

After renal grafts (KT), gastrointestinal complications, usually infections, are seen in up to 50 % of patients and correlate with long-term survival [47–49]. Intestinal ischemia is more common problem after KT than after other organ transplants, particularly in patients with polycystic kidney disease [50, 51]. A life-threatening infection can lead to discontinuation of immunosuppressive drugs and the renal graft sacrificed, as uremia is treatable by dialysis.

Biliary tract and pancreatic infections (cholecystitis, ascending cholangitis, infected pancreatitis) are common in KT recipients particularly among patients with diabetes [52], related to a high frequency of gallstones and to elevated blood triglycerides, secondary hyperparathyroidism, and medications, (cyclosporine, azathioprine, and prednisone), respectively [53, 54].

Cytomegalovirus (CMV) viremia and gastrointestinal disease are common in KT and KPT, with pancreas recipients at greater risk due to higher levels of immunosuppression [5, 55]. CMV disease is a risk factor for rejection of renal grafts [56]. Preemptive therapy for viremia reduces the frequency of CMV disease [57]; however, after surveillance has ceased, CMV can cause enteritis or pneumonia years after transplant [58]. The peak time for symptoms is about 8 weeks after transplant. In high-risk patients (donor seropositive and recipient seronegative), valganciclovir prophylaxis is now routinely practiced [5, 59]. In high-risk patients receiving prophylaxis kidney retransplant has been identified as a risk factor for developing CMV reactivation [60].

In historical KT recipients there was a 20 % incidence of gastrointestinal hemorrhage likely related to *Helicobacter pylori* infection [61, 62]. With treatment of *H. pylori* before transplant and use of proton pump inhibitors, ulcer formation and hemorrhage are now rare (<5 %) after KT [3].

Five to 10 % of kidney transplant patients require long-term immunosuppressive therapy because of chronic rejection increasing the risk of CMV, EBV, hepatitis viruses, papillomavirus, parasites, and fungi [63, 64]. Severe colitis

P. Ljungman et al. (eds.), *Transplant Infections*, DOI 10.1007/978-3-319-28797-3_19

Table 19-1. Microorganism causes of gastrointestinal infection after solid organ transplantation

Organism class	Epidemiology	Clinical presentation/diagnosis	Treatment/prophylaxis
CMV	Most common gastrointestinal infection resulting from reactivation of latent donor or recipient virus [5] Especially common in treatment for organ rejection [4] treatment with mycophenolate mofetil [6] CMV-negative recipients who receive a CMV-positive graft [7–9] and coinfection with immunomodulating viruses, bacteria, or fungi [4, 10] The peak incidence of CMV infection is 4–6 months after transplant once antiviral prophylaxis has been stopped [11]	Gastroenteritis accounts for 80 % of cases of organ-invasive disease [12] The presentation of CMV gastroenteritis varies widely depending on the affected gut segment and can include dysphagia, odynophagia, nausea, vomiting, abdominal pain, GI bleeding, perforation, or diarrhea CMV intestinal infection may also form intraluminal masses, masquerading as a neoplastic lesion [13]	Use of ganciclovir, foscarnet, valganciclovir prophylaxis has significantly reduced the risk [14–18] Prolonged CMV prophylaxis beyond the typical 6 months has also been evaluated in high risk patients to prevent late reactivation of CMV [19] Low risk patients can be placed on surveillance and treated only if positive for CMV DNA, but virologic surveillance can miss CMV gastroenteritis and hepatitis [20]
HSV	HSV1 and HSV2 are the second most common infection resulting from reactivation of latent recipient virus (not donor)	Gastrointestinal manifestation most commonly involves esophageal ulcers presenting as odynophagia, dysphagia, or nausea. Only rarely involves the intestines If left untreated, it can progress to gastrointestinal bleeding and/or perforation Disseminated HSV presenting with fever, leucopenia, and hepatitis can also rarely occur [21]	Prophylaxis with acyclovir, valacyclovir, valganciclovir, or famciclovir has reduced recurrence [22] If antiviral prophylaxis is not used, manifestations of HSV infection can develop in up to 70 % of transplant recipients [21]
EBV	Gastrointestinal manifestations of Epstein–Barr virus (EBV) less common than other herpes viruses	Primary EBV presents more commonly as mononucleosis with fever, pharyngitis, hepatitis, and enlarged lymph nodes in the early postoperative period [23] Secondary EBV presents more commonly in older patients as posttransplant lymphoproliferative disorder, an infiltrative lymphomatous process involving the viscera and central nervous system [24–27]	Reduction of immunosuppression, rituximab, surgery, and/or chemotherapy may be used for lymphoproliferative disorders
HHV-8	Gastrointestinal manifestations of human herpes viruses (HHV-8) less common than other herpes viruses	HHV-8 is oncogenic and can lead to Kaposi's sarcoma, Castleman's disease, and primary effusion lymphomas (a form of non-Hodgkin's lymphoma) involving the gastrointestinal tract and presenting as intestinal bleeding [28]	Reduction of immunosuppression, possibly surgical excision, radiation therapy, or chemotherapy
Enteropathic viruses	Adenovirus, norovirus, rotavirus, and astrovirus until recently have been an underrecognized cause of diarrhea in patients undergoing SOT [29] Shedding can pose an infectious risk to other immunocompromised patients especially in facilities specializing in transplant care [29] Routine testing with PCR for these viruses should be performed in immunosuppressed patients with diarrhea for the purpose of guiding therapy and infection control	Watery non-bloody diarrhea is usually proceeded by nausea, vomiting, and abdominal cramping Can cause both acute and chronic infections and can lead to prolonged symptomatic or asymptomatic viral shedding [29]	A live attenuated vaccine is available for adenovirus types 4 & 7 and rotavirus that can only be administered only prior to transplant [29] There are no vaccines available for norovirus (see Chap. 28) Alcohol disinfectants are not effective for enteric viruses and soap and water should be used Cidofovir or brincidofovir has shown efficacy against adenovirus [29, 30] Nitazoxanide may have activity against norovirus, although no controlled trials have been performed. No antiviral therapies exist for rotavirus or astrovirus

C. difficile	*C. difficile* infection (CDI) represents one of the most common causes of diarrhea in the SOT population and occurs in greater than 10 % of patients [31, 32] Antibiotics and other factors that decrease microbial diversity in the gut microbiota are thought to contribute to the disease by compromising colonization resistance to pathogenic strains of *C. difficile* [33, 34] A hypervirulent strain BI/NAP1/027 has been responsible for many of the outbreaks of CDI and for severe refractory CDI [35]	Watery non-bloody diarrhea often with elevated white count Pseudomembranous colitis on colonoscopy or flexible sigmoidoscopy Diagnosed most often by a positive PCR for DNA coding for *C. difficile* toxins A or B	Treatment usually consists of metronidazole, oral vancomycin, or fidaxomycin [36] Recurrent CDI can be treated with pulsed dose antibiotics [37] Fecal microbiota transplantation has been given in the immunosuppressed population, and in small cases series does not have increased incidence of infectious complications [38] First FMT has cure rates of 78 % in the immunocompromised population and approaches cure rates of 90 % after a second course of FMT [38, 39] Other therapies including investigational antibiotics, monoclonal antibody therapy, vaccine, and microbe-based approaches to treatment are also currently in clinical trials [40] Colonization with nonvirulent strains by administration of spores has been shown to be protective against recurrent CDI [41]
Fungi	Gastrointestinal infections with fungi are most commonly due to *Candida* spp. (*C. albicans*, *C. albicans*, *C. tropicalis*, and *C. krusei*) [42] and less commonly to *Aspergillus* spp Candidal yeast forms can traverse intact small intestinal mucosa into the portal circulation. Mortality from visceral fungal infection is high especially in patients located in the ICU	Gastrointestinal *Candida* infection can manifest as candidal esophagitis presenting most often with dysphagia or odynophagia, sometimes without oral thrush, thus, obviating the need for upper endoscopy for diagnosis Esophageal candidiasis can often present simultaneously with CMV or HSV especially in patients on high levels of immunosuppression In addition, intestinal reservoirs and swallowed yeast forms of *Candida* and aspergillus can translocate the gut leading to peritonitis, fungemia, intra-abdominal abscesses, and invasive mycoses of the liver or pancreas	Antifungal prophylaxis with fluconazole in SOT patients has not been universal due to side effects, emerging resistance, and lack of controlled trials [43] Instead prophylaxis depends on identifying patients that are at high risk for developing infections [44] Fluconazole is more routinely given in liver, lung, pancreas, and intestinal transplants due to the higher incidence of fungal infections [44] Treatment of Candidal infections depends on the specific species, susceptibilities, and nature of infection [44]
Microsporidia	Microsporidia infection is well appreciated in patients with HIV infection, but may be under diagnosed due to low suspicion and lack of detection with routine stool examination in the post-SOT population [45]	Chronic unexplained diarrhea, fatigue, and weight loss Detection of microsporidia requires the use of a modified trichrome stain	Treatment is most often with albendazole
Strongyloides	Pretransplant screening measures of patients that are from or have visited endemic areas (West Indies and Far East) has reduced the prevalence of disseminated strongyloidiasis in the SOT setting	*Strongyloides stercoralis* can lead to fever, abdominal pain, bloody diarrhea, abdominal distension, and nausea Rarely it presents with an acute respiratory illness caused by migration of *S. stercoralis* through the lungs or hyperinfection which is associated with high mortality [46]	Treatment is most often with ivermectin

Table 19-2. Noninfectious causes of gastrointestinal signs and symptoms after solid organ transplantation, by organs transplanted

Kidney and kidney–pancreas	Pancreas	Liver	Heart, lung, and heart–lung	Intestine and intestine–liver
Acute pancreatitis	Acute pancreatitis	Biliary leak	Choledocholithiasis	Anastomotic leak
Biliary leak	Biliary leak	Bowel perforation	Bowel perforation	Graft rejection
Bowel necrosis	Bowel necrosis	Bowel obstruction	Gastroparesis	
Bowel obstruction	Bowel obstruction	Gastrointestinal bleeding	GERD/Dyspepsia	
Choledocholithiasis	Duodenitis	Graft rejection	Pancreatitis	
Duodenitis	Enterocutaneous fistula	Hepatic artery stenosis	Peptic ulcer disease	
Enterocutaneous fistula	Graft vessel thrombosis	Hepatic artery thrombosis	Pseudoobstruction	
Gastrointestinal bleeding	Graft rejection			
Graft rejection	Internal hernias			
Graft vessel thrombosis				
Intestinal ischemia				

and enterocolitis caused by CMV, *C. difficile*, *C. septicum*, cryptosporidia, and enteric bacterial infections have been described in small numbers of KT patients, usually in case reports [65–68].

19.2.2 Pancreas Transplant

Pancreas transplant recipients develop all the infections common to SOT patients, but most of the abdominal problems that develop are related to the surgery and the grafted tissue [69, 70]. *C. difficile* and CMV are most common gastrointestinal infections [71]. Surgical complications are given in Table 19-2 [69] Pancreatitis may develop in the pancreatic portion of the graft, causing nausea and vomiting, bleeding, anastomotic leaks, perforation, and abscesses [69]. Hematuria may be one sign of bleeding of the graft, if bladder drainage is used.

19.2.3 Liver Transplant

Gastrointestinal complications unique to orthotopic liver transplant (OLT) are generally related to the surgery itself (Table 19-2) [72, 73] and recurrence of the underlying liver disease, both infectious (see Chap. 14) and noninfectious.

A higher incidence of bacterial (70 %), viral (20 %), and fungal (8 %) infections are seen in OLT than other solid organ transplants [74, 75], including enteritis, colitis, ascending cholangitis, peritonitis, and intra-abdominal abscess. This high rate of infections may be related to low albumin state (and ineffective opsonization capacity), decreased barrier function of the intestine, disruption of the luminal integrity with transection of the biliary tract, and iron overload [75, 76]. Viral infections are associated with increased bacterial infections [77] and increase the risk of allograft injury and rejection [74, 78].

Most bacterial infections occur within the first 2 months after transplant [75, 79–81]. A range of bacterial prophylactic regiments have met with mixed results in preventing surgical site and deep intra-abdominal infections [75, 82]. Unusual opportunistic infections (Listeria and Mycobacterium) are more prevalent beyond 2 months after transplant [75]. *Clostridium difficile* infects 2.7–15.8 % of OLT recipients leading to high rates of graft loss, total colectomy, and death [75]. OLT patients with hyperbilirubinemia and hypoalbuminemia are at increased risk for bacterial infections (particularly with *Pseudomonas*) in the setting of liver biopsy [83].

CMV infection in OLT recipients is the most problematic viral pathogen, associated with increased morbidity and mortality [84]. Prophylactic use of ganciclovir is associated with an increased incidence of delayed-onset primary CMV disease, associated with increased mortality. Alternatively, surveillance for CMV viremia or DNAemia and preemptive therapy can be effective. Primary CMV infections can occur in OLT patients who were seronegative at the time of transplant [85–87]. A finding of asymptomatic low-level CMV viremia after OLT does not require antiviral therapy, but patients with high-level viremia or CMV disease in the liver, gastrointestinal mucosa, or lungs are treated (see Chap. 25) [88, 89].

Herpes simplex virus, VZV, rotavirus, adenovirus, and norovirus are rarer causes of viral infections in OLT patients. EBV infections and lymphoproliferative syndromes may occur in chronically immunosuppressed OLT recipients. The incidence of adenovirus infection after OLT is 2–6 % and usually involves the transplanted liver, although other organs can be infected in the absence of liver involvement [90, 91]. The incidence of adenovirus infection is lower in isolated OLT than in combined liver and small intestinal transplant [92].

In the past, OLT recipients frequently developed invasive fungal infections with mortality rates ranging from 65 to 90 % [93], related to fungal overgrowth in the gut with translocation. Current rates of fungal infections are less than 10 % [94, 95]. Many risk factors for fungal infection have been identified including dialysis, rejection treatment, CMV infection, biliary tract disease, use of broad-spectrum antibiotics, indwelling Foley catheter, and iron overload [93, 96]. Fungal resistance to fluconazole has led to alternative antifungal regiments (e.g., micafungin and anidulafungin) [97, 98].

19.2.4 Heart, Lung, and Heart/Lung Transplant

Some 50 % of heart (HT), lung (LT), and heart–lung transplantation (HLT) recipients have gastrointestinal complications, with up to 20 % requiring surgery [99–101]. In the first 30 days the most common complications are pancreatitis, gastroduodenal ulcers, pseudoobstruction, and colonic perforation. In the ensuing months diarrhea, gastroesophageal reflux disease (GERD), gastroparesis, dyspepsia, nausea and vomiting, abdominal pain, pancreatitis, CMV, cholelithiasis, ulcers, and hepatobiliary disease are more common [100, 102, 103].

Symptomatic gastroparesis has been described in 25 % of LT recipients and up to 80 % in HLT recipients [104, 105]. The course is often waxing and waning, but in most patients, there is remission of symptoms [104, 106]. Recipients with GERD and/or gastroparesis are at risk for the development of obliterative bronchiolitis [102, 104]. Proton pump inhibitors are useful for reducing reflux; however, if reflux disease is unremitting, laparoscopic fundoplication may be successful [107, 108]. Giant gastric ulcers (>3 cm in diameter) have been described in LT recipients despite use of proton pump inhibitors. Risk factors include bilateral LT, high-dose NSAIDs, high-dose corticosteroids, and cyclosporine. The description of these ulcers suggests decreased mucosal blood flow from stress or CMV endovascular infection rather than NSAIDs as the cause [109, 110].

CMV disease is more frequent after LT and HT than other organ transplants, presenting most often as pneumonia but gastrointestinal CMV infection is also common [9]. LT and HLT recipients have the highest incidence of fungal infection in SOT. Aspergillus is more common than *Candida* species.

Adenovirus infections in LT and HLT patients affect primarily the transplanted organ rather than the gut and carry a high incidence and mortality [111]. HSV, VZV, and EBV cause the same spectrum of problems in cardiac as in other transplantation patients. The most serious complication is EBV-related lymphoproliferative disease. Although most cases are of B-cell origin, T-cell lymphomas have also been described [112].

Patients undergoing LT for cystic fibrosis experience a unique set of gastrointestinal complications [113] including pancreatic insufficiency and secondary biliary cirrhosis which can complicate absorption of immunosuppressive medications such as cyclosporine. Distal intestinal obstruction syndrome occurs in about 20 %. Cystic fibrosis patients may also experience cholecystitis, peptic ulcer disease, GERD, and gallstones. Biliary complications occur more frequently after HT than in the general population. Transplant patients can undergo elective prophylactic cholecystectomy as mortality of biliary disease post transplant is high [114].

19.2.5 Intestine and Intestine: Liver Transplant

Most of the complications of intestinal transplant are related to the underlying intestinal diseases leading to the transplant (usually short bowel syndrome following infarction or extensive Crohn's disease), rejection of the graft, and anastomotic leaks [115]. The level of immunosuppression to prevent rejection of the graft is high, along with the frequency of infection by herpesviruses, bacteria, and fungi. The most common causes of viral enteritis are rotavirus (high-volume watery diarrhea with prolonged viral shedding) [116]; adenovirus (mostly ileal involvement, with severe symptoms) [92, 117, 118]; norovirus (protracted, severe diarrhea) [119]; and CMV (now less common because of ganciclovir prophylaxis but potentially severe) [120]. The presentation of viral infection often overlaps with signs and symptoms of rejection. Hence differentiation between viral infection and rejection is crucial. Two types of malignancy related to immune suppression have been reported, EBV-lymphoproliferative disease and de novo cancers of non-lymphomatous origin [115, 121]. Surveillance for EBV DNA and preemptive treatment reduces the frequency of lymphoproliferative disease. Because the continuity of the intestinal neurons is disrupted by the surgery, intestinal dysmotility and anorexia can be problematic. Gastrointestinal symptoms secondary to de novo food allergy has been reported in three intestinal transplant recipients [122].

19.3 Gastrointestinal Infections Before and After Hematopoietic Cell Transplantation (HCT)

HCT recipients are prone to many of the same gastrointestinal infections as SOT recipients, but noninfectious intestinal complications are much more common after HCT (Table 19-2) [123]. The current approach to gastrointestinal infection after HCT emphasizes pretransplant screening for infection, prophylaxis, early recognition of infection using molecular methods, and preemptive therapy. Compared to past HCT experience, gut infections are now less common and only rarely cause death.

19.3.1 Gastrointestinal Infections Before the Start of Conditioning Therapy

Unlike SOT candidates, HCT candidates are often immunocompromised and have low platelets prior to transplant due to chemotherapy or the underlying disease process, for example, a hematologic malignancy or immune disorder. Pretransplant gastrointestinal problems can be infectious in origin and require evaluation prior to transplant [124].

In addition to the common causes of upper gastrointestinal bleeding (gastroduodenal ulcers related to *H. pylori* or NSAID use, Dieulafoy lesion, erosive esophagitis), upper sources of bleeding can be due to mucosal infection caused by CMV, HSV, VZV, or *Candida* spp. [124]. In addition to the usual causes of colonic bleeding (inflammatory bowel disease, colorectal cancer, telangiectasias, and diverticula),

bleeding can also be due to infection caused by CMV, *Entamoeba histolytica,* Clostridium *septicum* (typhlitis), and rarely *Clostridium difficile.* Ideally intestinal ulcerations should be healed prior to undergoing HCT as bleeding will likely worsen in the setting of more profound thrombocytopenia with conditioning therapy. Interestingly, *H. pylori* infection in one retrospective study inversely correlated with the development and severity of GVHD [125].

Patients with immune deficiency disorders and immunosuppression caused by hematologic malignancy or its treatment may also present with acute onset diarrhea. In addition to the common causes of diarrhea (irritable bowel syndrome, ulcerative colitis, and Crohn's Disease), infectious causes should be given special consideration including *E. histolytica*, *Strongyloides*, *Giardia lamblia*, cryptosporidia, *Clostridium difficile*, CMV, rotavirus, and adenovirus [126–129]. Some infections like Cryptosporidiosis may be resistant to therapy in an immunosuppressed patient [130], but restoration of normal immunity after allogeneic HCT can effect clearance of cryptosporidia [131]. Typhlitis is a syndrome of cecal edema, mucosal friability, and ulceration in neutropenic patients, often associated with polymicrobial sepsis and high mortality if left unrecognized and untreated; its cause is usually intestinal clostridia infection, particularly *C. septicum* [132, 133]. Typhlitis occurs in the setting of induction chemotherapy and is sometimes difficult to distinguish from the direct toxic effects of the chemotherapeutic agents. Typhlitis has become far less frequent since physicians began prescribing empiric antibiotics that cover clostridial organisms in patients with right lower quadrant pain.

Pain near the anal canal in a granulocytopenic patient is due to bacterial infection until proven otherwise. Administration of broad-spectrum antibiotics, including anaerobic coverage, is adequate treatment in most cases, with surgical incision and drainage reserved for progressive infections [134]. Extensive supralevator and intersphincteric abscesses may be present without being apparent on external examination but can be diagnosed by computed axial tomography (CT), magnetic resonance imaging (MRI) or transperineal sonography. Less commonly, perianal inflammation and ulcers may be due to HSV, CMV, and fungal infections [135].

19.3.2 Gastrointestinal Infections During the First Year After HCT

After HCT, gastrointestinal infections are now far less common than gut mucosal and liver injury caused by noninfectious diseases such as the effects of conditioning therapy, medication side effects, and GVHD [136]. This is largely due to prophylactic regimens. We also have a better understanding of some of the factors that predispose patients to GVHD and superimposed infections such as vitamin D deficiency [137]. When infections do occur, they usually develop in the background of these other gut diseases.

High-dose conditioning therapy damages the oropharyngeal and gastrointestinal mucosa, resulting in oral mucositis anorexia, and diarrhea. Oropharyngeal mucositis may extend into the esophagus, causing dysphagia and painful swallowing that mimics infectious esophagitis [138]. Esophageal infections have almost disappeared as problems after transplant because of prophylaxis against HSV, VZV, and *Candida* species and preemptive therapy in patients with CMV DNAemia.

Anorexia and nausea caused by conditioning therapy varies in its intensity (myeloablative regimens causing more severe and more protracted gut mucosal damage) and may persist beyond day 20. These symptoms are also common complications of transplant medications such as calcineurin inhibitors, sirolimus, mycophenolate mofetil, azole antifungal drugs, trimethoprim–sulfamethoxazole, nystatin, and rarely now, amphotericin B. In years past, herpesviruses were common causes of nausea, vomiting, and anorexia [139], but with the exception of sporadic cases of CMV disease, herpesvirus infections of the upper gut have largely disappeared.

Acute GVHD of the intestine and liver is an immunologic disorder that results from donor lymphoid cells reacting against host tissues and usually has its onset 15–40 days after transplant [136, 139–141]. Gut GVHD can occur earlier if prophylactic medications (e.g., methotrexate, cyclosporine, tacrolimus, mycophenolate mofetil) are not given, or later, following reduced-intensity conditioning regimens [142]. In most patients, acute GVHD diminishes by day 100, although in some it can be protracted. Intestinal manifestations of acute GVHD include nausea and vomiting, profuse watery diarrhea with protein loss, abdominal pain, bleeding, and ileus [123]. The diagnosis of acute GVHD can usually be made on clinical grounds and confirmed by biopsy of target organs. The syndrome of chronic GVHD occurs 3–9 months after transplantation. Intestinal problems of chronic GVHD include esophageal desquamation and stricture formation, bacterial overgrowth in the small intestine, and chronic cholestatic liver disease [143]. MMF can cause intestinal inflammation and ulcerations in a presentation that is difficult to distinguish from GVHD [144]. Oral potassium replacement among other medications can result in esophageal ulcers. Antibiotic use can lead to alterations in the intestinal flora and promote intestinal domination with certain fungi and gram-negative organisms [145]. This may predispose patients to antibiotic-associated diarrhea, *C. difficile* colitis, *C. septicum* typhlitis, and bacteremia (see Chap. 52).

The most common organisms causing gastrointestinal infection after HCT are viral (CMV, norovirus, adenovirus, rotavirus, and astrovirus) and bacterial (*C. difficile*) and they commonly develop in patients with GVHD [146]. Gut infections that were prevalent 30 years ago have largely disappeared because of changes in practice—low microbial foods during extreme immune suppression, prophylaxis of common infections, and microbial surveillance with preemptive therapies [147]. Before fluconazole prophylaxis, problems formerly caused by fungal infection (esophagitis, enteritis,

portal fungemia, bleeding ulcers, and hepatobiliary disease) were not uncommon [148, 149].

Before the advent of serological testing for CMV and preemptive treatment with ganciclovir, gastrointestinal CMV was the most problematic of the herpes viruses [150]. While valganciclovir prophylaxis showed no advantage over PCR-guided preemptive therapy [151], other next generation therapies with fewer side effects than currently used prophylactic antivirals are in Phase III clinical trials and are likely to be used widely as routine prophylaxis in the near future [30, 152]. CMV disease usually presents as nausea and vomiting between 40 and 60 days after transplantation. CMV may be recovered from ulcerations throughout the intestine even when molecular methods cannot identify CMV in the bloodstream [150]. CMV may also be associated with pancreatitis and infiltration of neural elements in the intestine [153].

Adenovirus usually causes a mild to moderately severe diarrheal illness, but severe disseminated disease, with fulminant hepatitis and necrotizing enteritis, has been reported with some serotypes of the virus [154–158]. Other enteric viruses that cause diarrhea include *astrovirus, norovirus,* and *rotavirus* [129, 141]. EBV-associated posttransplant lymphoproliferative disease (PTLD) has a frequency of about 3 % [159]. It can develop rapidly in HCT patients, infiltrating the stomach, intestine, mesentery, liver, and spleen [160]. Poor treatment response to rituximab is determined by age greater than 30 years, involvement of extralymphoid tissue, GVHD, poor response to immunosuppressive tapers, and unchanged EBV viremia [159].

The risk of parasitic diseases has decreased in the setting of pretransplantation screening and treatment. If patients are discharged to a less-controlled environment, they may acquire parasites such as *Giardia lamblia* and *Cryptosporidium* organisms, particularly from infected children and drinking water [126, 161, 162]. The diagnosis of cryptosporidial infection—often missed with standard microscopy—is best made by PCR of fecal specimens [128].

19.3.3 Gastrointestinal Infections in Long-Term Transplant Survivors

Intestinal and hepatobiliary complications after the first year are far less common than earlier post-transplant; most of these intestinal problems, however, are not related to infection (Table 19-2). Some patients with extensive chronic GVHD have esophageal desquamation, webs, submucosal fibrous rings, bullae, and long, narrow strictures in the upper and mid-esophagus [143, 163, 164]. The most common symptom is dysphagia; some patients present with insidious weight loss, retrosternal pain, and aspiration of gastric contents. Chronic GVHD may cause intractable esophageal disease if not diagnosed and treated promptly. Patients with protracted acute GVHD often have symptoms that wax and wane with intensity of immunosuppressive therapy for up to 15 years after HCT, with each exacerbation similar to the presenting signs of GVHD that occurred earlier after HCT (satiety, poor appetite, nausea, episodic diarrhea, and weight loss) [165, 166]. Sporadic cases of fungal and rarely viral esophagitis may occur in patients with chronic GVHD on immunosuppressive and antibiotic therapy. Esophageal strictures may be sequela of earlier herpes virus infection or mucositis. There are sporadic cases of gut infection with *C. difficile*, CMV, and rarely *G. lamblia*, *Cryptosporidia*, *rotavirus*, and *norovirus*, in long-term survivors [143, 161, 162, 167].

Squamous cell carcinoma of the esophagus has been reported in HCT survivors, usually with concomitant chronic GVHD of the oropharynx [168]. Myasthenia gravis may also complicate chronic GVHD, with dysphagia as its presenting complaint. Intestinal diseases in cell donors have been reported in their recipients, for example, inflammatory bowel disease and celiac sprue [169, 170]. Diarrhea, steatorrhea, and weight loss secondary to pancreatic insufficiency have developed in some HCT survivors [171].

19.4 Intestinal Microbiota in Transplant Patients

The gastrointestinal microbiota plays an important role in the development of infections after both SOT and HCT [172]. Much of our current understanding of the microbiota's role in SOT comes from work in patients who have undergone orthotopic liver transplantation [173, 174]. The microbiota may predispose patients to nonalcoholic steatohepatitis. In cirrhosis, the microbiota produces metabolites including ammonia that contribute to hepatic encephalopathy [175]. Administration of lactobacillus combined with a high fiber diet has been shown to prevent postoperative infections in liver transplantation [176]. A study evaluating the effect of pretransplant rifaximin on the incidence of post-liver transplant infections found no significant difference [82]. In kidney transplants, increased abundance of *Faecalibacterium prausnitzii* has been associated with escalation of tacrolimus levels [177]. The microbiota also influences the immune system's T cell subtypes and likely has direct impacts on transplant outcomes [178].

In HCT the microbiota is impoverished as a result of administration of systemic antibiotics [179, 180], gut inflammation caused by GVHD [179], and possibly other factors. The degree to which the diversity is decreased at the time of engraftment has been shown to predict all cause mortality after allogeneic HCT [181]. An impoverished microbiota may effect mortality by leading to worsened GVHD [179, 182], increased risk of enteric infections [183], and increased risk of bacteremia [145]. Certain probiotic species like *Lactobacillus* spp. have been shown to have an ameliorating effect on the severity of GVHD [182]. Patients with leukemia vs. other forms of hematological malignancy have been

shown to preferentially develop low diversity states with predominance of *Enterococcus,* but the reason is not known [145]. Increased risk of low diversity may also be associated with comorbid autoimmune conditions in which dysbiosis has been shown to be prevalent [184].

19.5 A Problem-Oriented Approach to Diagnosis of Gastrointestinal Infections After Transplant

19.5.1 Heartburn, Odynophagia, and Dysphagia

The organisms responsible for infectious esophagitis are fungi, viruses, and bacteria, but infections caused by multiple types of organisms are common in severely compromised, neutropenic patients [185]. In contrast, less compromised patients with indolent esophageal infections may present with chronic dyspepsia and dysphagia; these patients rarely have deep fungal infections involving the spleen or liver, probably because of adequate neutrophil function. Less well appreciated as symptoms of esophageal infection are nausea, vomiting, and anorexia, which are typical of infection with herpesviruses. With antimicrobial prophylaxis, preemptive therapy, and close monitoring, esophageal infections have become rare and noninfectious causes of esophageal disease relatively more common (Table 19-3).

19.5.1.1 Fungal Esophagitis

C. albicans is the most common infecting fungal organism, but other *Candida* species, other fungi (*Aspergillus, Histoplasma, Cryptococcus, Blastomyces*), and some plant molds may be found in severely immunosuppressed patients [185–187]. *Candida* esophagitis can be asymptomatic when few adherent plaques are present. Diagnosis is by stains of brushed or biopsied lesions at endoscopy; cultures cannot reliably differentiate among normal flora, colonization, and infection [188], but are useful if an unusual pathogen such as an azole-resistant *Candida* species, *Aspergillus* species, dematiaceous fungi, *Mycobacterium tuberculosis*, or bacterial esophagitis is suspected. Rapid viral cultures should be routine when viral esophagitis is in the differential, even when fungal esophagitis is obvious.

19.5.1.2 Viral Esophagitis

HSV, VZV, and CMV cause acute ulcerative esophagitis in the immunosuppressed patient, presenting with excruciating retrosternal pain in some and in others just nausea, anorexia, mild heartburn, or bleeding [185]. Reflux of acid-peptic juice contributes to the persistence of large ulcers. The diagnosis of HSV esophagitis is made by finding rounded 1–3 mm vesicles in the mid- to distal esophagus, the centers of which slough to form discrete, circumscribed ulcers with raised edges. The discrete ulcerations can coalesce into very large ulcers, presenting difficulty in diagnosis when there is near-total denudement of esophageal epithelium. The endoscopist must attempt to identify HSV-containing ulcer margins or islands of squamous mucosa from which to obtain samples. IHC, rapid viral diagnosis, and PCR are essential for diagnosis when routine histology is equivocal [185] especially in patients with gastric stasis, vomiting, or poor salivary flow (common problems after both HCT and heart–lung transplant). VZV causes typical vesicles and necrotizing panesophagitis in severely immunodeficient patients, with diagnosis by immunohistologic staining, rapid viral cultures, and PCR. The esophageal component of VZV infection may be overshadowed by varicella encephalitis, pneumonitis, and fulminant hepatitis. Immunohistochemical staining and PCR are helpful in differentiating VZV infection from HSV. VZV and HSV esophagitis are rare in patients receiving acyclovir

Table 19-3. Noninfectious causes of gastrointestinal signs and symptoms after hematopoietic cell transplantation, in descending order of frequency

Heartburn, odynophagia, dysphagia	Anorexia, nausea, vomiting	Diarrhea	Abdominal pain	Perianal pain	Gastrointestinal bleeding
Acid-peptic reflux	Mucosal injury from conditioning therapy	Mucosal injury from conditioning therapy	Intestinal pseudo-obstruction	Anal fissure	Acute and protracted acute GVHD
Oropharyngeal mucositis from conditioning therapy	Acute and protracted acute GVHD	Acute and protracted acute GVHD	Acute and protracted acute GVHD	Thrombosed external hemorrhoid	Mucosal injury from conditioning therapy
Chronic GVHD	Medications	Medications (see text)	Mucosal injury from conditioning therapy	Levator muscle spasm	Mallory–Weiss tear
Pill esophagitis	Rarely, brain disorders (neurotoxicity, hematomas)	Intestinal lactase, sucrose deficiency	Biliary pain (sludge, stones)		Bleeding from mucosal biopsy site
Peptic strictures			Hemorrhagic cystitis		Gastric antral vascular ectasia
Post-infection strictures			Acute pancreatitis		Bleeding from diverticula
Severe acute GVHD			Liver pain (SOS)		
Intramural hematomas			Intestinal perforation		
			Intestinal infarction		
			Intramural hematomas (intestine, abdominal wall)		

prophylaxis. In contrast, CMV never infects squamous epithelium but rather subepithelial esophageal cells leading to superficial erosions with serpiginous, non-raised borders in the mid- to distal esophagus. As CMV infection progresses, shallow ulcerations may deepen, extend for 10–15 cm, and even become strictured. Multiple biopsies should be obtained from the bases of the esophageal ulcers, as this is where CMV-infected sub-epithelial fibroblasts and endothelial cells reside [189]. Immunohistochemical staining for early, intermediate, and late antigens can confirm the diagnosis of CMV infection when infected cells are neither megaloid nor inclusion-bearing. These histologic and immunohistologic methods, however, are only about half as sensitive as rapid viral culture methods [189]. If a positive PCR result for CMV DNA is not concordant with viral culture, immunohistology, blood assays for CMV DNA, or endoscopic findings, antiviral therapy should be withheld.

19.5.1.3 Bacterial Esophagitis

Oropharyngeal bacteria may cause esophageal necrosis in patients who lack granulocytes following HCT [190]. Esophageal symptoms, fever, and bacteremia are the usual presenting symptoms; tissue Gram stain is needed for diagnosis. Mycobacterial esophagitis usually presents an extension of pulmonary and mediastinal infection caused by *Mycobacterium tuberculosis*; primary esophageal infection has also been described [185, 191].

19.5.1.4 Noninfectious Causes of Esophageal Symptoms

Infections must be differentiated from noninfectious esophageal disorders (Tables 19-2 and 19-3). It may be difficult to discern the dominant cause of esophageal mucosal injury when both infection and another cause of injury are present. Reflux of gastric contents is particularly problematic after lung or heart–lung transplant and in the presence of Roux-en-Y anastomosis in liver transplant patients. Less common causes of esophageal injury include pill esophagitis, intramural hematomas, and graft-vs-host disease after HCT.

19.5.2 Anorexia, Nausea, and Vomiting

Before effective antiviral prophylaxis and preemptive therapy after SOT and HCT, herpesvirus infections of the esophagus, stomach, or intestine commonly caused loss of appetite, nausea, and vomiting in addition to painful swallowing or diarrhea [189, 192, 193]. VZV and CMV infections may involve visceral neurons to produce a pseudo-obstruction picture with distention and vomiting [194]. Gastric ulcers caused by CMV may fail to heal on acid-reducing medications [195]. Nausea and vomiting are common manifestations of community-acquired viral gastroenteritis and intestinal parasitic infection, especially with *G lamblia* and *Cryptosporidium* organisms [161, 162]. In SOT recipients, *H. pylori* infections, particularly those that cause pyloric channel ulcerations, may cause anorexia, nausea, and poor oral intake, without ulcer pain (syndrome pylorique) [2]. Central nervous system infections such as aspergillus are another cause of nausea and vomiting after HCT; other neurologic signs and, symptoms usually dominate the clinical picture. Diagnosis of gastrointestinal infection as a cause of anorexia, nausea, and vomiting is a three step process: (1) Analysis of stool specimens if diarrhea or abdominal pain is part of the clinical presentation; (2) upper endoscopy for diagnosis of herpesvirus and *Helicobacter pylori* infections; and (3) directed examination of organs that declare themselves to be involved, for example, gallbladder ultrasound when right upper quadrant pain is present, serum lipase and pancreatic amylase when there is epigastric pain, and so on [100, 101, 136]. It is not uncommon to recover CMV from endoscopic biopsies of focal esophageal or gastroduodenal lesions, even when there is no detectable virus in the blood stream.

19.5.2.1 Noninfectious Causes of Upper Gut Symptoms

The differential diagnosis of anorexia, nausea, and vomiting encompasses a long list of noninfectious causes (Tables 19-2 and 19-3). Anorexia and nausea are such protean symptoms that medical judgment must dictate when to aggressively pursue their causes. The more immunosuppressed and the sicker the patient, the more aggressive should be the evaluation. In SOT recipients, anorexia and nausea may be due to organ rejection; gastroparesis (after lung transplant); failure of liver, renal, pulmonary, or cardiac function; visceral inflammation (for example, pancreatitis, cholecystitis, and cystitis). Acute GVHD may also develop after organ transplantation, usually presenting with fever, skin rash, and gastrointestinal symptoms [196–198]. After HCT, myeloablative conditioning therapy causes nausea, vomiting, and anorexia that lasts for 2–3 weeks [138]. After HCT day +20, the most common cause of upper intestinal symptoms is acute GVHD, which causes gastric mucosal edema and erythema [139, 199]. Lymphocytic gastritis resembling GVHD can also be seen in about 12 % of autologous graft recipients [200]. Less common causes of anorexia and nausea after day +20 include disorders of gastric emptying, medication intolerance, and central nervous system lesions [139, 201–204].

19.5.3 Diarrhea

The differential diagnosis of infectious diarrhea in a transplant patient encompasses the same pathogens as in the normal host, as well as some that are very uncommon under ordinary circumstances. However, in the acute care setting, exposure of patients to environmental pathogens is rare

except for *C. difficile* and thus, infection by common enteric pathogens is rare, particularly when patients are following dietary guidelines for safe foods. The exception to this rule is in countries where patients may arrive for transplant already infected by bacterial, viral, and parasitic organisms or be exposed to them after discharge [68, 126]. Infectious diarrhea is often accompanied by a constellation of symptoms (fever, abdominal pain, nausea, vomiting), particularly in SOT patients [68, 205].

19.5.3.1 Bacterial Causes

C. difficile is the most common bacterial cause of diarrhea in hospitalized transplant patients. Colitis caused by *C. difficile* in granulocytopenic patients may be paradoxically mild and lacking typical pseudomembranes perhaps because colitis is largely due to a granulocyte response to clostridial toxins [141, 206, 207]. A more typical clinical course and endoscopic appearance may be seen later after HCT and in SOT patients; severity of *C. difficile* colitis in SOT patients is similar to that in nontransplant patients [208]. With the emergence of more virulent strains of *C. difficile*, more severe colitis is being seen [209]. Available therapies include metronidazole, vancomycin, and fidaxomycin [40]. A proposed probiotic treatment for *C. difficile* colitis, *Saccharomyces boulardii*, may itself reach the bloodstream in patients with immune defects and should be avoided in transplant patients [210]. In refractory immunosuppressed cases, treatment with fecal transplantation has been as efficacious as in non-immunocompromised individuals without increase adverse outcomes [38, 39]. Strict infection control measures in the inpatient, outpatient, and home settings are essential to prevent the transmission of *C. difficile* [211, 212], Relapse is common in the presence of immunosuppression, especially with glucocorticoids [208]. *Recurrent C.* difficile colitis can be treated with pulsed antibiotics and in some cases fecal transplantation [37].

Cord colitis syndrome linked to infection with *Bradyrhizobium enterica* [213] and *Bacteroides fragilis* [214] presents clinically as non-bloody diarrhea 3–11 months after cord blood transplant, histologically characterized by epithelioid granulomas and responsive to metronidazole or fluoroquinolones [215, 216]. Infections with organisms such as such as *T. whipplei* may also be involved [217]. Cord colitis appears to be absent in some centers consistent with lack of exposure to these Z-specific gut pathogens [218].

Diarrhea (often bloody) is seen with neutropenic enterocolitis (typhlitis) caused by *C. septicum* [132, 219]. Mycobacteria, *Aeromonas* species, and enterohemorrhagic *E. coli* have been described as causes of diarrhea in immunosuppressed patients [220, 221]. Bacterial infections not obviously involving the intestine may also cause diarrhea, for example, *Legionella* pneumonia [222] and toxic shock syndrome associated with *Staphylococcus aureus* infection.

19.5.3.2 Viral Causes

Viral infections can result in both acute and chronic diarrhea in the compromised host. Of the herpesviruses, only CMV and rarely HSV infection [223] lead to enteritis and diarrhea. (1) CMV may cause profuse watery diarrhea with protein loss [224, 225]; (2) or an inflammatory colitis with bleeding and pain but less voluminous diarrhea [65, 226]. CMV enteritis does not always result in diarrhea—anorexia, nausea, vomiting, bleeding, and perforation may be the only symptoms [13, 185, 195, 227]. Later CMV infection, after discharge from the transplant center, remains an issue [228, 229]. Although CMV can be found by PCR or viral culture of stool, CMV enteritis is best diagnosed by IHC and rapid viral culture of biopsy specimens from involved tissue [189]. A positive PCR for CMV DNA may represent viral excretion without CMV disease.

Some serotypes of adenovirus cause rapidly progressive necrotizing enteritis associated with severe pulmonary, liver, or renal infection where prompt diagnosis and treatment is necessary to prevent death [2, 154, 156, 230, 231]. Other adenovirus isolates appear to cause less severe mucosal disease, leading to dilemmas about the optimal treatment strategy, particularly when immune suppressive drugs must be continued and the treatment has toxicity [154, 157, 158, 232]. Detection of adenovirus in stool by PCR may be useful in high risk patients [233].

Acquired enteric adenovirus infection with self limited diarrhea and transient fever has been reported in up to 18 % of children and 8 % of adults undergoing HCT [154]. Severe adenovirus enteritis and colitis may be associated with mucosal erosions, ulcerations or bleeding, and may cause abdominal pain and tenderness. Endoscopic diagnosis may be difficult when ileal disease predominates. Adenovirus may also cause pancreatitis in HCT (associated with abdominal pain) [154, 156, 234–237]. In SOT, the source and predominant site of adenovirus infection is the transplanted organ, particularly in children in the early posttransplant period, likely because of absent antibody immunity [90, 232, 237]. Early treatment of adenovirus disease with cidofovir in HCT may be associated with better outcomes, though criteria for early treatment are not fully established. Current criteria for treatment include multiorgan involvement (i.e., viral isolation, or histological documentation, from two or more sites), viremia with clinical signs of disease, or significant (endoscopic, histological, or clinical) enteritis, pneumonia, hemorrhagic cystitis or nephritis. Use of surveillance plasma adenovirus PCR, as well as stool and urine testing in patients with diarrhea or hematuria may be valuable in early diagnosis and preemptive therapy, especially in pediatric patients and patients undergoing T cell depleted transplants [238]. Most patients with isolated stool or urinary adenovirus recover spontaneously, but close monitoring for progressive disease may be prudent [234, 235]. Criteria for treatment in SOT are poorly defined because adenovirus viremia in SOT

commonly resolves spontaneously or with reduction of immunosuppressive therapy, especially in children [90, 117, 237, 239].

Other enteric viruses (astrovirus, rotavirus, norovirus, coxsackievirus), acquired through epidemic exposure or nosocomial transmission, may cause diarrhea in transplant patients [68, 141, 240]; this category is likely to increase in prominence as panels of molecular diagnostic tests become available. These viruses can be associated with prolonged viral shedding for weeks after cessation of symptoms [235, 236]. Astrovirus, a common cause of endemic as well as nosocomial diarrhea in children, has been reported after both HCT and SOT, with a frequency of <5 % of patients with diarrhea. In one prospective study, the most common viral cause of diarrhea after HCT was Astrovirus, which caused a self-limited form of diarrhea [141]. In HCT patients, symptoms may include nausea and anorexia in addition to diarrhea [141, 241, 242]. Rotavirus, a common cause of diarrhea-predominant viral gastroenteritis in children in winter months, causes diarrhea lasting 3–9 days. Prolonged and profuse watery diarrhea of 2 or more weeks' duration is the main symptom attributable to Rotavirus in transplant patients, where the frequency of infection varies widely from center to center (0–1.5 % in adults, higher in children) [116, 243–245]. Other symptoms reported in HCT patients include vomiting, abdominal pain, anorexia, fever, and abnormal liver tests, but without severe enteritis or mortality [244, 246, 247]. Fecal shedding can continue for three or more months after clinical illness. Nosocomial transmission likely accounts for many infections especially on pediatric units [244, 247]. Norovirus is the major cause of adult epidemic viral gastroenteritis [129]. Clues to diagnosis include epidemic exposure and rapid onset of transient vomiting followed by prolonged watery diarrhea [248, 249]. With the exception of CMV, some viruses for which there are no commercial diagnostic tests, rare cases of mycobacterial infection, and EBV-related lymphoproliferative disease involving the small intestine, almost all of the infectious causes of diarrhea can be discovered by analysis of stool specimens using bacterial and viral cultures, PCR (adenovirus, norovirus, cryptosporidia), ELISA (rotavirus, astrovirus, *G. lamblia*, *C. difficile* antigen), and microscopic examination (parasitic diseases, fungal overgrowth). If the lesion is out of the reach of an endoscope, the diagnosis of EBV-related lymphoproliferative disease can be based on finding EBV DNA in the bloodstream and a mass consistent with lymphoma on imaging.

19.5.3.3 Fungal Causes

In the minimally compromised patient, intestinal fungal overgrowth can be a cause of watery diarrhea [250]. In the absence of antifungal prophylaxis, patients with prolonged granulocytopenia may develop diarrhea caused by mucosally invasive fungal infections [251]. Wide use of azoles in the peritransplant period has eliminated gastrointestinal infections caused by *Candida albicans*, but mucosal infection by molds and other *Candida* species can now be seen [252].

19.5.3.4 Parasitic Causes

Parasitic infections have probably been under diagnosed as a cause of chronic diarrhea in transplant recipients because of insensitive tests [68]. Accurate tests for organisms such as *Giardia lamblia*, *Cryptosporidium*, *Enterocytozoon bieneusi*, *Isospora belli*, and *Strongyloides stercoralis* are now available [128, 130, 253–256]. Cryptosporidial infection may mimic GVHD after HCT [127]. Cryptosporidial infections can be eliminated if the underlying immune deficiency disappears [131]. *Strongyloides stercoralis* enteritis may become exacerbated during immunosuppressive therapy, causing diarrhea and hyperinfection syndrome [238]. *Blastocystis hominis* and *Enteromonas hominis*, long believed to be innocuous commensal parasites, have been blamed for persistent diarrhea in some immunodeficient patients.

19.5.3.5 Noninfectious Causes (Tables 19-2 and 19-3)

Noninfectious causes of diarrhea that are common to all transplant patients include magnesium salts to correct renal magnesium wasting; mucosal toxicity caused by mycophenolate mofetil [144] or brincidofovir, an investigational broad-spectrum antiviral agent [30]; the pro-motility side effects of the macrolides tacrolimus and sirolimus [257, 258]; and antibiotics that depress the colonic flora (removing the ability of these bacteria to salvage carbohydrate and thus, causing osmotic diarrhea after carbohydrate ingestion). The gut toxicity of mycophenolic acid delayed release tablets is considerably less than that of MMF [259]. After HCT, diarrhea is caused by mucosal injury from myeloablative conditioning regimens and from acute GVHD [141].

19.5.4 Abdominal Pain

Pain caused by some intestinal infections and intra-abdominal infection resulting from perforation may be a harbinger of a rapidly fatal illness in immune suppressed patients [47, 136, 260, 261]. Perforation is most common in the gastroduodenal region and the colon but can occur at any site in the intestine. Plain abdominal X-rays and helical CT will determine whether a perforation has occurred but the site of perforation can remain obscure. Causes of perforation include CMV infection, fungal infection, necrosis of transmural tumors, trauma, and diverticula [2, 47, 226, 261, 262]. Diverticular perforation is particularly common in renal transplant patients [263]. CMV and VZV can also involve neural plexi, causing ileus and abdominal distention [153, 194, 264]. Severe abdominal pain is often the first manifestation of disseminated VZV

infection, which may progress to fulminant hepatitis. PCR for VZV DNA in the bloodstream is the most useful diagnostic test for visceral VZV infection in the absence of skin lesions [265]. Early recognition and institution of acyclovir therapy result in improved survival [194].

Other focal infections of the intestinal tract that present with abdominal pain include phlegmonous gastritis, appendicitis, infections caused by clostridia organisms (*C. difficile, C. perfringens, C. septicum*), and *Aspergillus* vasculitis [266]. Most immunosuppressed patients with appendicitis have right lower quadrant pain, but in some the usual presentation is masked by corticosteroids and the lack of granulocytes. Typhlitis is a localized infection of the cecum and right colon, caused by clostridia toxins (usually *C. septicum*) and closely related to granulocytopenia [132]. Typhlitis has been rarely observed after solid organ transplantation, probably because of preserved granulocyte function [267]. Consideration of this diagnosis should prompt empiric use of antibiotics (imipenem, oral vancomycin) that cover both clostridia organisms and colonic flora that are translocating into pericolic tissues, and surgical consultation in the event of progression [268]. Cecal CMV ulcerations, fungal infection, and acute GVHD in HCT recipients may present similarly but do not have the same poor prognosis as clostridial typhlitis [269, 270].

A radiologic diagnosis of pneumatosis intestinalis (gaseous infiltration of the intestinal mucosa, usually the colon) is likely to be made in a patient with pain who undergoes abdominal plain film or computed tomography, and it does not necessarily represent a severe form of enteritis. In some cases, there may be air in the peritoneal cavity, mediastinum, and portal vein in addition to the intestinal mucosa. Pneumatosis intestinalis has been described in organ recipients and HCT patients. Disease associations have been with viral enteritis (particularly CMV) and GVHD. The abdominal examination and clinical course in many patients is surprisingly benign. There are, however, catastrophic processes that present with gas in intra-abdominal tissues (intestinal infarction, bowel obstruction, and clostridia infections) that must be differentiated on clinical, microbiologic, and occasionally surgical grounds from the more benign form of pneumatosis intestinalis [271].

EBV lymphoproliferative disease occurs in both solid-organ and HCT recipients on high-dose immunosuppressive therapy. Lymphoid infiltrates may present as abdominal pain, ileus, and bleeding. PCR for EBV DNA in the bloodstream may allow preemptive reduction of immunosuppressive drugs and use of rituxan to forestall development of tissue invasion with transformed immunoblasts.

19.5.4.1 Noninfectious Causes (Tables 19-2 and 19-3)

Many episodes of abdominal pain after SOT or HCT are not caused by infection but instead by conditions such as intestinal pseudo-obstruction (caused by mu-opioid and anticholinergic drugs), pancreatitis, cystitis, biliary stone disease, and in HCT patients, the toxicity of myeloablative conditioning therapy, acute GVHD, liver pain caused by sinusoidal obstruction syndrome, and intramural hematomas involving the gut or abdomen. The initial approach to diagnosis of the cause of abdominal pain in an immunosuppressed patient must be tempered by the knowledge that intra-abdominal catastrophes may occur without extreme signs and symptoms and that the time from presentation to death can be very short. Paradoxically, there is also a danger of physicians overreacting to severe abdominal pain from a cause that seldom results in morbidity, for example, intestinal pseudo-obstruction related to mu-agonist opioids, an intramural hematoma of the sheath of the rectus abdominus muscle, or narcotic bowel syndrome.

19.5.5 Perianal Pain

Perianal pain in a granulocytopenic patient is assumed to be caused by bacterial infection of perianal tissues until proven otherwise, and thus, this is a more a problem for HCT patients than after SOT. Infections can be a difficult problem to recognize because there may be little in the way of pus but instead only a painful cellulitis. These infections are usually polymicrobial (aerobic and anaerobic bacteria), arising either from anal crypts or from tears in the anal canal [272]. Extensive supralevator and intersphincteric abscesses may also occur without being apparent on external examination. Early antimicrobial treatment has led to a marked decrease in the need for surgery. If an obvious abscess is present, antibiotics, incision, and drainage usually result in relief of pain and resolution of the abscess [273]. If there is evidence of tissue necrosis, a more aggressive surgical approach may be needed to prevent a fatal outcome. Perineal examinations may be limited by severe pain and by a risk of bacteremia if the patient is granulocytopenic. CT, MRI, and rectal endoscopic ultrasound give accurate views of the anatomy involved if there is a true abscess; the predictive value of a negative imaging test for an abscess is high.(302) However, if an imaging test suggests an abscess or clinical examination suggests infection in a perirectal space, an experienced colorectal surgeon should examine the patient under conscious sedation or anesthesia, with an eye toward surgical drainage if a significant abscess is discovered.

HSV causes painful chronic mucocutaneous ulcerations in patients with immunodeficiency syndromes, especially those with T-lymphocyte defects [274]. In the perianal area, the appearance is of multiple superficial ulcers with raised borders. When these ulcers coalesce and become macerated and secondarily infected, it is often difficult to identify them as viral. In contrast to decubiti, HSV perianal ulcers are painful, have scalloped borders, and occur away from pressure points. The diagnosis is best made by rapid viral culture. Acyclovir treatment is effective, but secondary bacterial or fungal infection may delay healing. Recurrence is common unless acyclovir is continued or immunosuppressive therapy decreased.

19.5.5.1 Noninfectious Causes (Tables 19-2 and 19-3)

There are few noninfectious causes of pain in the perianal area in transplant patients aside from anal fissures, a thrombosed external hemorrhoid, and unusual disorders of smooth muscle (levator muscle spasm, proctalgia fugax). Persistent diarrhea may lead to painful maceration of perianal skin and secondary infection by bacteria and fungi.

19.5.6 Gastrointestinal Bleeding

In the era before effective antimicrobial prophylaxis, viral ulcerations were the most common cause of bleeding in both HCT and organ transplant patients, but in the current era, bleeding from viral ulcers has become uncommon [5, 275]. CMV ulcers in the esophagus are usually shallow, but those in the gastroduodenal, small bowel, and colonic mucosa are deeper and capable of eroding into large vessels [65, 84]. CMV may also cause diffuse gastritis or enteritis similar to that seen in inflammatory bowel disease [58, 223, 276, 277] and rarely present as mass lesions [13]. Duodenal or gastric ulcers that appear to be typical peptic lesions may harbor CMV in the ulcer base and may fail to heal on standard ulcer therapy [195, 278]. If ulcers are in the midgut, a radionuclide blood pool scan or capsule endoscopy can localize the bleeding site, allowing angiographic control or surgical resection if the ulcer is truly solitary and continues to bleed. Endoscopic hemostasis of bleeding CMV ulcers can occasionally be achieved, but this must be accompanied by antiviral therapy; CMV ulcers often require 2–3 weeks for mucosal lesions to heal following effective therapy [193].

HSV may present as bleeding from coalescent herpetic esophageal ulcers without symptoms referable to the esophagus [279]. HSV causes gastric and intestinal necrosis only rarely, usually in patients on high-dose immunosuppressive therapy [223]. VZV causes esophagitis similar to that caused by HSV and occasionally gastric ulcers, but not intestinal mucosal necrosis. EBV does not cause direct ulceration, but in transplant patients, it may lead to a lymphoma-like immunoproliferative disease may present with bleeding submucosal nodules as well as diffuse mucosal infiltration with immunoblasts [223, 280, 281]. Some serotypes of adenovirus cause extensive intestinal mucosal necrosis as well as fulminant hepatitis and multiorgan failure in HCT patients; prompt treatment can be effective [154–158].

Esophageal and intestinal fungal infections are now very uncommon causes of serious bleeding in transplant patients [251, 275]. Exceptions are patients with prolonged granulocytopenia in whom deeper penetration of fungal organisms, particularly molds, can erode into large submucosal blood vessels, leading to massive bleeding [252].

Aside from *H. pylori*-associated ulcers in SOT recipients [3], bacterial gut infection as a cause of severe bleeding is rare. Pseudomembranous colitis caused by *C. difficile* may also present as bleeding, especially in patients with a low platelet count [141, 206]. Bloody diarrhea also occurs with typhlitis (*C. septicum* infection), especially if platelet counts are low [282].

19.5.6.1 Noninfectious Causes (Tables 19-2 and 19-3)

Both SOT and HCT recipients may come to their respective transplant procedures with gut lesions that may bleed after transplant. Minor bleeding after HCT usually disappears when platelet counts stabilize [283]. The current frequency of severe bleeding after HCT is less than 2 %, almost all of which is due to noninfectious causes (GVHD, gastric antral vascular ectasia, mucosal biopsy sites) [275, 283, 284]. Bleeding after SOT is more likely to be caused by infection, especially CMV- and *H. pylori*-related ulcers [72]. Noninfectious causes of severe bleeding include diverticular bleeding (particularly after renal transplant), portal hypertension-related lesions after liver transplant [72], and bleeding from anastomoses (choledochojejunostomy after liver transplant, intestinal anastomoses after pancreatic or intestinal transplant), and ischemic colitis.

Severe intestinal bleeding, defined as enough bleeding to lead to hemorrhagic shock or a fall in hematocrit by >10 % or transfusion requirement of 2 units of blood per day, leads to two imperatives—one is to stop the bleeding and the other to make a diagnosis of the lesion that is bleeding—particularly if the cause is an infection that is not being treated. In practice, this means endoscopic evaluation of the upper intestinal tract, or the colon, or both, and blood-pool radionuclide scans, angiographic studies, or capsule endoscopy when endoscopy cannot localize the bleeding lesion.

Bacterial Infections

20 Gram-Positive Bacterial Infections After Haematopoietic Stem Cell or Solid Organ Transplantation

Malgorzata Mikulska and Claudio Viscoli

20.1 Introduction

Bacteria are the most frequent pathogens causing infection after transplant of haematopoietic stem cells, and Gram-positives cocci have been for decades more frequently isolated than Gram-negative rods. Although in this chapter we have chosen to focus mainly on bloodstream infections (BSI) and pneumonia, other types of infection can be observed in these patients, such as gastrointestinal infections, in particular neutropenic typhlitis, urinary tract infections, usually associated with the presence urinary catheters, skin and soft tissue infections (perianal cellulitis, central venous catheter insertion site infections, fasciitis) and meningitis (*Listeria*). In these patients, bacterial infections are usually correlated to neutropenia and graft vs. host disease (GvHD).

Similarly, in solid organ transplant (SOT) recipients, bacterial infections are the most frequent complications as well, including infections related to the surgical procedure and ICU-related infections. Each type of organ transplant is associated with specific infections, such as cholangitis in liver transplant, mediastinitis in heart transplant, tracheal infections and pneumonia in lung transplant and urinary tract infections in kidney transplant recipients. In all these patients there is a large use of central venous catheters (CVC) which play an important role in healthcare associated bacterial infections.

In the HSCT setting, reliable data on the aetiology of bacterial infections come mainly from the results of blood cultures, since bacteraemia is the most frequent bacterial infection. Microbiological documentation is missing in clinically documented infections such as pneumonia or typhlitis. In SOT recipients, bacteraemia is less frequent, and invasive procedures, such as bronchoalveolar lavage with biopsy in case of lung transplant or bile or fluid cultures from biliary stents or abdominal drainages in liver and pancreas transplants are often required to obtain a microbiological documentation of localised infections.

General epidemiology and risk factors for infections after transplant have been described in Section II. This chapter will first report on the epidemiology of infections caused by Gram-positive bacteria, separately for HSCT and SOT. In the HSCT section we will mainly focus on bloodstream infections and pneumonia, in both cases focusing on the most important pathogens, while in the SOT section we have chosen to describe the general situation, and then to focus on specific types of transplants. Less common localisations and unusual pathogens will be dealt with in a single paragraph for both HSCT and SOT. Therapeutic aspects will be discussed by pathogen and antibiotic, and not by type of transplant.

20.2 Epidemiology of Gram-Positive Infections After HSCT

20.2.1 Bloodstream Infections

BSI affect approximately 5–10 % of autologous and 20–30 % of allogeneic HSCT recipients, with significant variations among centres and among patients in the same centre, depending on different transplantation procedures, such as type of conditioning regimen or prophylaxis of GvHD and antibiotic prophylaxis. The incidence of BSI is the highest during the pre-engraftment neutropenic period, mainly in correlation with oral and enteric mucositis and the presence of a CVC. Staphylococci, Enterobacteriaceae and viridans streptococci predominate in this phase. Later on, after engraftment, BSI are more frequent in case of GvHD, hypoglobulineamia or, again, in association with a CVC. Among Gram-positive bacteria, staphylococci and pneumococci are the most typical. The main risk factors associated with BSI due to single Gram-positive bacterial species are reported in Table 20-1. Trends in the epidemiology of BSI after HSCT reflect changes in prophylaxis and treatment regimens (e.g. antibiotic selection during fluoroquinolone prophylaxis), in transplant protocols (impacting on severity of mucositis), and in the incidence of certain pathogens in the general population (e.g. a decline in infections due to *H. influenzae* and *S. pneumoniae* in countries with high vaccination rates).

The predominant aetiology of bacterial BSI during neutropenia, including the pre-engraftment phase of HSCT, has

Table 20-1. Main risk factors associated with infections due to Gram-positive bacteria in haematopoietic stem cell transplant recipients

Risk factor	Bacterial species
Oral mucositis	Viridans streptococci Coagulase-negative staphylococci
Enteric mucositis	Enterococci Coagulase-negative staphylococci
Use of central venous catheters	Coagulase-negative staphylococci *Staphylococcus aureus* Corynebacteria
Low performance status Comorbidities	Enterococci
Hypogammaglobulinemia Impaired humoral activity Hyposplenism GvHD	Pneumococci
Fluoroquinolone prophylaxis	Staphylococci Enterococci Viridans streptococci
Use of cephalosporins	Enterococci, viridans streptococci (in case of ceftazidime)
Treatment with beta-lactams	Beta-lactam resistant viridans streptococci
Nasal colonisation with MRSA	MRSA
Colonisation with VRE	VRE

GvHD graft-versus-host disease, *MRSA* methicillin-resistant *Staphylococcus aureus*, *VRE* vancomycin-resistant enterococci.

changed several times over the last 5 decades. While in the 1960s and 1970s Gram-negative rods were predominant, a global shift toward Gram-positives was observed in most transplant centres during the next 2 decades [1, 2]. Reasons for an increase in the Gram-positive to Gram-negative ratio included chemotherapy regimens associated with more oral mucositis, universal use of implantable long term CVCs, and selective antibiotic pressure of third-generation cephalosporins or fluoroquinolones, which are more active against Gram-negatives than Gram-positives [1, 3, 4]. However, in the early 2000 the etiological pattern of pathogens causing BSI started to reverse again, with an increase in Gram-negative bacteraemias, both during the early and late post-transplant phases [5–9]. A similar trend was thereafter reported in numerous centres [10–13]. In more recent years, similarly to what reported for other populations, also in HSCT recipients there has been a significant increase in the proportion of infections caused by multidrug resistant (MDR) bacteria, especially ESBL-producing Gram-negative rods, carbapenem-resistant *P. aeruginosa*, or vancomycin resistant enterococci (VRE) [14–16]. Interestingly, an increase in MDR strains has been seen in some [17], but not all countries [18, 19].

In order to investigate the latest epidemiological trends, in 2011, within the 4th European Conference on Infections in Leukaemia (ECIL-4), we performed a literature review on the aetiology of bacterial BSI in haematology and oncology settings. In addition, a questionnaire was sent to participating centres focusing on the current epidemiology, resistant patterns and recommended empirical therapy [19]. The literature review yielded 29 reports from 13 countries published after 2005, with data from autologous and allogeneic HSCT reported in 14 and 19 papers, respectively [19]. The median year of observation was 2001, and the Gram-positive to Gram-negative ratio was 60 % vs. 40 %, with centres reporting ratios ranging from 85 % vs. 15 %, to 26 % vs. 74 %. Coagulase-negative staphylococci and *Enterobacteriaceae*, mostly *Escherichia coli*, were the most frequent pathogens (approximately 25 % of BSI each, although with great variability from study to study: 5–60 and 6–54 %, respectively), followed by *P. aeruginosa* (10 %, range: 0–30 %), *S. aureus* (6 %, 0–20 %), viridans streptococci (5 %, 0–16 %) and enterococci (5 %, 0–38 %) [19].

The ECIL-4 survey questionnaire obtained answers from 33 centres in 18 countries, mostly reporting data from HSCT recipients (autologous in 32 and allogeneic in 30). The median year of observation was 2008, and the results indicated a further decrease in the Gram-positive to Gram-negative ratio (55 % vs. 45 %), again with important differences by-centre (from 85 % vs. 15 % to 30 % vs. 70 %) [19]. In these 33 centres, the *Enterobacteriaceae* were the most frequent pathogens isolated (median 30 %, range 8–56 %), followed by coagulase-negative staphylococci (24 %, 7–51 %), enterococci (8 %, 0–30 %), viridans streptococci (6 %, 0–22 %) and *P. aeruginosa* (5 %, 0–28 %) [19]. Compared to published data, in the ECIl-4 questionnaire the incidence of *P. aeruginosa* was lower, but the incidence of enterococci was higher [19]. Results of literature review and questionnaire are shown in Figure 20-1. One of the most important characteristics of the epidemiology of bacterial infections in transplant patients is the geographical and inter-centre variability in aetiology and resistance patterns. While there are centres where over 70 % of BSI are caused by Gram-negative rods, there are still other hospitals where 90 % of the isolated bacteria are Gram-positive cocci [11, 12, 18–20].

20.2.1.1 Staphylococci

Staphylococci are the most frequent pathogens causing BSI in HSCT recipients. In this setting, coagulase-negative staphylococci cause approximately 25 % of all BSI, while *S. aureus*, a significantly more virulent species, is isolated in only about 5 % of cases [19]. Variations in the incidence of coagulase-negative staphylococci might be in part explained by the fact that not all studies and centres regarded coagulase-negative staphylococci as the true cause of BSI only if isolated in two consecutive blood cultures [21]. Given their low virulence, coagulase-negative staphylococci are associated with very low attributable mortality, although their treatment is frequently complicated by high rates of resistance to methicillin. In fact, in ECIL centres more than half of the isolated coagulase-negative staphylococci were resistant to methicillin, while the rate of methicillin resistance in *S. aureus* was lower [19]. Similarly, in the ECIL literature review, methicillin

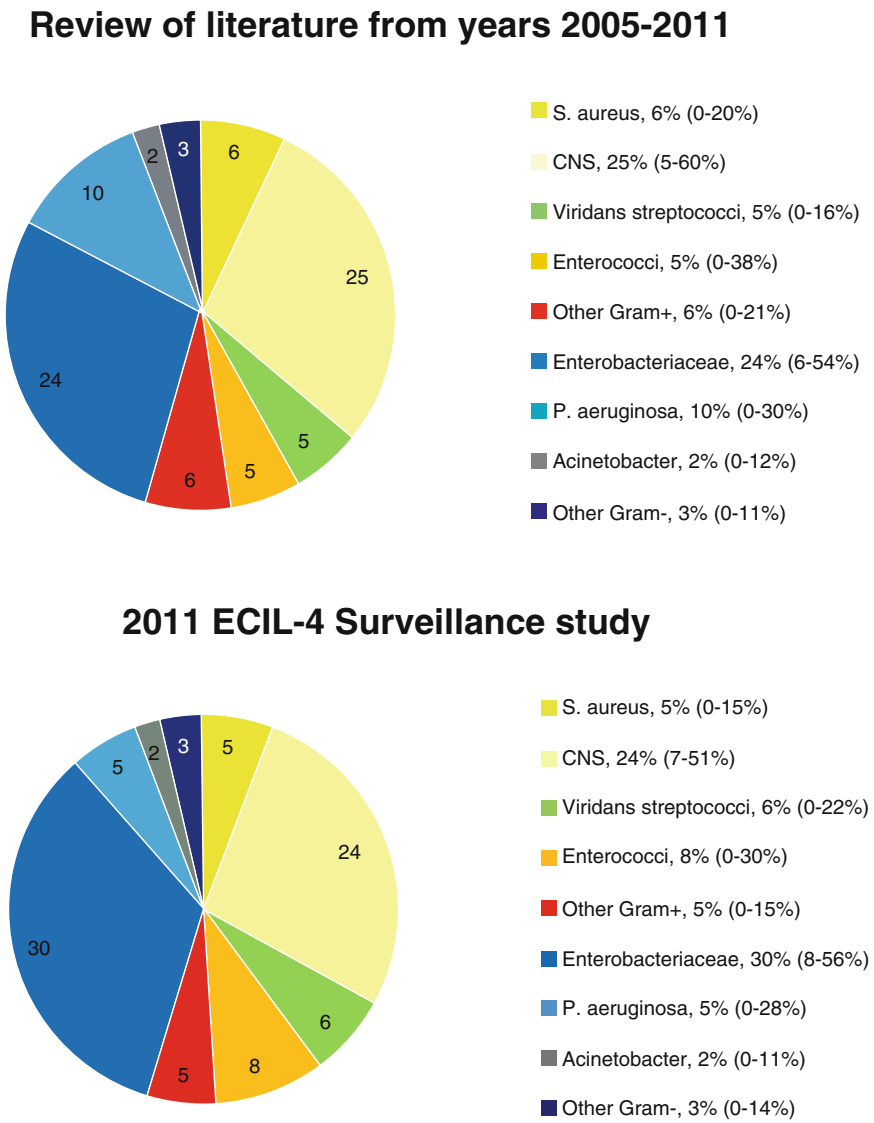

FIGURE 20-1. The aetiology of bloodstream infections according to (**a**) literature review and (**b**) questionnaire survey performed by the European Conference on Infections in Leukaemia reported as median rate (with range) [19]. Reproduced with permission from Mandell, Douglas, and Bennett's Principles and Practice of Infectious Disease 8th ed., by J. E. Bennett, R. Dolin, M. J. Blaser, MD; vol 2; Chapter 309: Prophylaxis and Empirical Therapy of Infection in Cancer Patients, E. Castagnola, M. Mikulska, C. Viscoli, Copyright Elsevier (2014).

resistance was more frequent among coagulase-negative staphylococci than in *S. aureus*, with respective median resistance rates of 80 and 56% [19]. Of note, resistance to methicillin has been reported to be lower in paediatric than adult populations.

Although the overall incidence of methicillin-resistant *S. aureus* (MRSA) bacteraemia is low in HSCT recipients, concerns about high mortality have been raised. In particular, in two MRSA outbreaks, the attributable mortality was very high [22, 23]. In a UK transplant centre, 22 patients became infected and the attributable mortality was 40% in case of early post-transplant infection (2 out of 5 patients) and over 20% in case of late infections [22]. Interestingly, pre-HSCT MRSA colonisation was associated with an increase in morbidity and mortality, even in case of successful mupirocin decolonisation (4 of 11 successfully decolonised patients developed later an MRSA infection) [22]. Hopefully, outside outbreak settings, the outcome of MRSA infections is more favourable, particularly in centres where methicillin-resistant staphylococci are regularly seen and glycopeptides are frequently used in empirical therapy. Infection control measures effective against MRSA and currently recommended by international guidelines include alcohol-based hand hygiene, nasal screening, universal or selective decolonisation, improvement in CVC management and reduction in the use of fluoroquinolones [24, 25]. A reassuring fact about MRSA infections is that, for reasons which remain to be fully understood, since 2004 a steady

worldwide decline in MRSA has been noted in the USA and in several European and Far East countries, despite different infection-control approaches undertaken [26, 27]. Finally, several new therapeutic options against MRSA have been introduced in the last 5 years, including anti-MRSA cephalosporins such as ceftaroline or ceftobiprole, lipoglycopeptides such as telavancin, dalbavancin or oritavancin, or new oxazolidinones, such as tedizolid [28]. Although none of these drugs has been approved for empirical or targeted treatment of infections in neutropenic or transplant patients, they offer a much appreciated alternative for better management of methicillin-resistant infections. Among them, cephalosporins might be particularly attractive due to their historically known efficacy and safety, while some novel lipoglycopeptides might revolutionise outpatient treatment allowing for once weekly administration.

20.2.1.2 Enterococci

Enterococci have emerged as the third most frequent group of bacterial pathogens causing BSI after HSCT, affecting up to 10–12 % of all transplant patients [6, 16, 29–31]. Prophylaxis with fluoroquinolones has been associated with an increased rate of enterococci [32]. However, in our centre, where levofloxacin prophylaxis is routinely used, other independent risk factors for early enterococcal bacteraemia were found, including mismatched related donor or cord blood transplant, low performance score, severe mucositis, pharyngeal enterococcal colonisation and previous empirical therapy with cephalosporins [29]. Interestingly, unrelated donor, cord blood transplant and higher comorbidity scores (together with a diagnosis of acute lymphoblastic leukaemia) were also identified as risk factors for VRE bacteraemia [31]. Compared to other pathogens, enterococcal bacteraemia occurs usually later after transplant. For example the median time to infection from the day of transplant was +4 for viridans streptococci and +11 for enterococci [33]. In many centres, *E. faecium* almost completely replaced *E. faecalis*, with important therapeutic consequences since *E. faecium* is frequently resistant to ampicillin [13, 30, 34]. In some centres, the shift from *E. faecalis* to *E. faecium* has been also accompanied by an important increase in the rate of resistance to vancomycin: in a multicentre Australian study VRE increased from 8 % in 2001–2004 to 64 % in 2007–2010 [30]. The problem of vancomycin resistance is important in HSCT recipients with enterococcal infections, since few therapeutic options are available and high mortality in patients infected with VRE has been reported [35, 36]. In general, the incidence of VRE in Europe is lower than in the USA [6, 13, 19, 26, 33, 34, 37]. In the ECIL-4 survey, 67 % of the interviewed haematological centres reported an incidence of VRE lower than 5 % among all enterococci [19]. On the contrary, in the USA, up to 80 % of *E. faecium* isolates are reported to be VRE and the overall 30-days mortality is very high [16, 31, 35]. It remains controversial whether or not the resistance to vancomycin is the main factor responsible for such a high mortality. In fact, enterococci are poorly virulent pathogens and usually develop in patients with several concomitant clinical problems that are able to affect survival [38]. Therefore, attributing the excess mortality only to the VRE infection in patients with multiple clinical problems might be arbitrary and might simply indicate that VRE are markers of clinical severity [16, 31, 34, 35, 39]. This was clearly suggested by one of the earlier reports, in which all 12 patients with early (average onset day +15) VRE bacteraemia died within less than 3 months from the infection, half of them had blasts at transplant, 80 % had concomitant infections and none achieved platelet engraftment [35]. In larger studies conducted in 76 and 68 patients with VRE bacteraemia, the attributable mortality was, respectively, 6 and 9 % [16, 31]. The view that enterococcal and VRE bacteraemias might be a marker of comorbidities and poor general condition, and as such associated with high overall mortality, is supported by other clinical experiences. In a recent Korean study, for example, a delayed use of adequate antibiotics in case of VRE infection resulted in no difference in 30-day mortality compared to infections caused by vancomycin-susceptible strains in neutropenic patients, and the severity of the underlying disease was the only predictor of poor outcome [40]. In another study in Brazil, the authors found that empirical treatment of neutropenic fever with linezolid had no effect on survival (54 % vs. 42 %) in 100 haematology patients who were colonised with VRE, while predictors of mortality were persistence of neutropenia and GvHD [41]. Finally, in our experience in a cohort of 67 adult allogeneic HSCT recipients with enterococcal BSI, of whom only 13 % had VRE infection, the 30-day mortality for vancomycin-susceptible strains was higher compared to VRE (respectively, 26 and 11 %), whereas the 1-year overall survival was the same in both groups, and significantly lower than in patients with no enterococcal BSI (24 and 65 %, respectively) [42]. These results were compared with an experience of a US transplant centre, where 66 % of patients with enterococcal BSI had VRE. In these patients the 30-day mortality was 38 % for both vancomycin-susceptible and resistant enterococci, while the 1-year overall survival was 48 % for vancomycin-susceptible enterococci, 23 % for VRE and 63 % for patients with no enterococcal BSI [43]. Although enterococcal colonisation (both with VRE and not) has been found significantly associated with enterococcal BSI, its negative predictive value is not very high since only 57 % of VRE-BSI were preceded by VRE colonisation, confirming that this aetiology could not be excluded in non-colonised patients [16, 29]. Screening for rectal carriage of VRE might help to identify patients at highest risk for this infection, yet the positive predictive value for subsequent infection in VRE colonised patients is limited since many of them will not develop a VRE infection. For example in a cohort of HSCT recipients with high prevalence of VRE colonisation (40 %), VRE bacteraemia occurred significantly more frequently in

patients colonised (13/37, 34 %), compared to those with no colonisation, (1/55, 1.8 %, $p < 0.01$), with the positive predictive value of 34 % [44]. As with other MDR bacteria, in order to limit nosocomial spread, patients colonised or infected with VRE should be isolated and contact precautions should be applied.

Treatment of VRE is based on the use of linezolid, for which efficacy data in this setting have been reported. Data on the use of daptomycin have also been reported, although the use of daptomycin in VRE remains investigational [45–48]. Other options are quinopristin–dalfopristin, which is active only against *E. faecium*, and not *E. faecalis* and tigecycline [49]. The new anti-staphylococcal cephalosporins remain inactive against enterococci, while novel glycolipopetides such as telavancin and dalbavancin seem active only against some strains (VanB). For the data supporting the choice between linezolid and daptomycin for VRE infection, see the paragraph on daptomycin in this chapter.

20.2.1.3 Viridans Streptococci

Infections with viridans streptococci have been traditionally associated with oral mucositis in course of chemotherapy (Table 20-1) [especially cytarabine (Ara-C)] and with younger age. Other risk factors were fluoroquinolone prophylaxis, the use of trimethoprim–sulfamethoxazole, antiacid medications and proton-pump inhibitors [50]. A unique aspect of viridans streptococcal bacteraemia during neutropenia consists of the high risk of complicating with septic shock and acute distress respiratory syndrome (ARDS), which usually develops 2–3 days after the onset of bacteraemia [50]. The incidence of these serious complications has been approximately 10 %, varying from 7 to 39 % in different cohorts [50, 51]. Considering that ARDS might be an immunologically mediated phenomenon, early administration of high dose corticosteroids has been studied and reported effective in small single-centre studies in the last 20 years [52, 53]. At present, viridans streptococci are responsible for approximately 5 % of all bacteraemias in transplant recipients. Streptococci are usually susceptible to penicillin and other beta-lactams. However, *Streptococcus mitis*, the species most frequently isolated in neutropenia, is frequently associated with resistance to penicillin and fluoroquinolones [54], making vancomycin the drug of choice for this indication. In fact, in a study which analysed 909 episodes of bacteraemia from 10 randomised clinical trials of antibiotic therapy for infection in patients with cancer and neutropenia in the years 1980–1993, the mortality associated with *S. mitis* bacteraemia was higher if vancomycin was not included in the first line empirical treatment [55]. In that analysis, better survival in patients with Gram-positive bacteraemia who received upfront vancomycin, compared to those in whom vancomycin was added later, was driven exclusively by the benefit observed in 117 cases of viridans streptococcal bacteraemia (mortality 0 % vs. 14 %, respectively, $p < 0.0001$) [55]. Another argument that supported the idea that viridans streptococci might benefit from empirical vancomycin therapy comes from a randomised trial in paediatric patients, in whom vancomycin was added to ticarcillin–clavulanate and amikacin [56]. Higher rates of breakthrough bacteraemia, including 1 case of fatal viridans streptococcal bacteraemia was observed in the non-vancomycin group.

On the other hand, most of the beta-lactams used in empirical therapy today (piperacillin–tazobactam, cefepime or carbapenems) have good activity against viridans streptococci, which is not the case with ceftazidime. In a recent study, only clinical strains with minimum inhibitory concentration (MIC) to penicillin ≥2 μg/mL were found resistant to other beta-lactams [57]. In particular, all isolates with a penicillin MIC=2 were generally susceptible to cefepime, ceftriaxone and piperacillin–tazobactam, while 4 among 17 isolates were resistant to meropenem according to CLSI breakpoints (susceptible according to EUCAST breakpoints). Few strains testing resistant to penicillin according to CLSI (MIC ≥4 μg/mL) were generally non-susceptible to ceftriaxone, cefepime and meropenem, but susceptible to piperacillin–tazobactam. In this study, 17 % of 732 patients were infected with viridans streptococci with a penicillin MIC ≥2 μg/mL, and 98 % of them had at least 1 of the following risk factors: current or past (previous 30 days) use of a beta-lactam as antimicrobial prophylaxis or nosocomial onset of bacteraemia. These might be the subjects who may benefit currently from an empirical treatment with vancomycin. The results of the aforementioned study illustrate well why the newest IDSA guidelines for treating infections in neutropenia do not any longer recommend the use of vancomycin if viridans streptococci are suspected [58]. The association between high penicillin MIC values, clinical outcome and the need for vancomycin treatment have been elegantly discussed in a recent editorial [51].

20.2.1.4 Pneumococci

Pneumococci are an important cause of morbidity and mortality in HSCT patients and the incidence of pneumococcal invasive disease is higher than in the general population, particularly in those with chronic GvHD [59–61]. Nevertheless, the absolute numbers remain low. For example, in a prospective 10-year observational study in Canada, only 14 cases of pneumococcal infection were diagnosed in 1238 adult HSCT recipients (100 % bacteraemia, 71 % with concomitant pneumonia) [61]. This translated into an incidence of 347/100.000 transplanted patients/year, which was higher for allogeneic than autologous HSCT (590 and 199/100.000 transplanted patients/year, respectively), and over 30 times higher than in the general population (11.5 cases/100.000 population/year ($p < 0.00001$). Two HSCT recipients died because of pneumococcal infection, which is similar to the mortality observed in the non-transplant population (14 % vs. 19.5 %). Another recent, more than 10 year-long, retrospective observational

study from Australia identified 23 allogeneic HSCT recipients with invasive pneumococcal disease [62]. The cumulative incidence was 2.3 %, and the incidence density was 956/100,000 transplant/year of follow-up. Of note, *Pneumocystis jirovecii* prophylaxis with trimethoprim–sulfamethoxazole was associated with lower odds of pneumococcal infection. Finally, pneumococcal bacteraemia remains usually limited to the post-engraftment period, accounting for 13 % of all bloodstream infections during this phase, compared to 1 % during pre-engraftment neutropenia [63]. Reasons for an increased risk of pneumococcal infection include long lasting deficit in immunoglobulin production, poor spleen function, and possibly, lack of protection from vaccination. Oral penicillin prophylaxis has been recommended for patients with chronic GvHD or low IgG levels with a grade or recommendation of A III, i.e. a strong recommendation for use, although just based on expert opinions and observational studies [64]. This recommendation might be an extrapolation from the paediatric post-splenectomy literature [65]. However, limitations of long term prophylaxis include suboptimal efficacy, particularly in areas where many pneumococci are penicillin-resistant, poor patient compliance and the risk of developing resistance. Therefore, since the introduction of the conjugated anti-pneumococcal vaccine (PCV), early 4-dose vaccination remains the most widely accepted preventive strategy [64]. The epidemiology of pneumococcal infections has changed after the introduction of conjugated vaccines in the general population, both due to a decrease in the circulation of pneumococci in the community and an increased response to vaccination in HSCT recipients.

20.2.2 Pneumonia

Pneumonia is a frequent infectious complication in HSCT recipients, with an incidence reported in retrospectives studies ranging between 15 and 25 % [66–70]. In a recent prospective observational study, 50 of 169 transplant recipients developed pneumonia. However, in this study, Gram-positive cocci were considered the cause of infection in only five cases, all occurring within 6 months from transplant (2 pneumococci, 2 enterococci and 1 *Nocardia*) [71].

CT scan is the technique of choice for diagnosing pneumonia in the immunocompromised host, Although most CT lesions are not typical for any single bacterial pathogen, cavitary lesions developing during neutropenia are highly suggestive for *S. aureus* pneumonia.. Among rare causes, *Rhodococcus equi* can also be the cause of cavitary and granulomatous lesions in these patients [72].

Numerous acute pulmonary complications may occur in transplant patients, including both infectious and non-infectious causes and it is difficult to obtain an etiological diagnosis. The clinical setting and microbiological analyses, such as cultures of blood samples, sputum and BAL fluid, can be used to provide clues for interpreting abnormal CT findings, although polymicrobial or mixed infections and coexistence of infectious and non-infectious processes (e.g. viral and immunological) further hamper the precise description of epidemiology in this setting [73, 74].

The results of a nationwide prospective study referring to data collected through the Spanish Research Network of Transplant (RESITRA) give insight into these complications [75]. From July 2003 to April 2005, 427 HSCT recipients were followed with a standardised diagnostic protocol for pneumonia. There were 112 episodes of pneumonia and 72 (64.3 %) of them were microbiologically defined. Bacterial pneumonia ($n=32$, 44 %) accounted for more cases than fungal ($n=21$, 29 %) and viral pneumonia ($n=14$, 19 %). The most frequent pathogens isolated in each group were: *E. coli* ($n=7$, 9 %), CMV ($n=12$, 15 %), and *Aspergillus spp* ($n=12$, 15 %). Among bacteria, the most common aetiologies were *E. coli* and *P. aeruginosa*, as previously reported in other studies [66, 76], whereas *S. pneumoniae* was involved in only 5 % of the cases. This low incidence might the result of the routine use of immunisation and prophylaxis. Median time to the diagnosis of pneumonia after transplantation was 66.5 days. The global mortality rate in allogeneic HSCT recipients that had at least one pneumonia episode was 46 % ($n=44$) compared to 13 % ($n=43$) in those without any pneumonia episode ($p<0.01$; relative risk 3.37; 95 % CI: 2.43–4.68). Clinical factors increasing the mortality rate in HSCT recipients developing a pulmonary complication were invasive fungal infection, acute or chronic GvHD, developing pneumonia in the first 100 days after transplantation, acute respiratory failure and septic shock.

In conclusion, bacterial pneumonia is a frequent complication after HSCT procedures, although the aetiological diagnosis is obtained only in a minority of cases. This is due to many causes, including lack of possibility of collecting appropriate respiratory specimens, low yield of blood cultures and an early empirical therapy. Gram-positive bacteria play a significantly less important role than Gram-negatives, with staphylococci and enterococci being most frequently reported.

20.3 Gram-Positive Infections After Solid Organ Transplant

There are several reasons why a solid organ transplant (SOT) recipient can develop infectious complications after the transplant procedure. First of all, the transplant recipient is usually affected by a severe underlying disease, like liver cirrhosis in the liver transplant setting or severe lung and/or heart insufficiency in the heart and lung setting. Other pre-transplant predisposing conditions include diabetes in pancreatic transplant recipients and long-term dialysis before kidney transplants. Given the fact that SOT recipients are

TABLE 20-2. Main risk factors associated with infections due to Gram-positive bacteria in solid organ transplant recipients

Risk factor	Bacterial species
Biliary leakage or intestinal perforation after liver or pancreas transplant	Enterococci
Sternotomy	Staphylococci (mediastinitis)
Length of surgery in any transplant, number of blood units transfused during liver transplant	Staphylococci Enterococci
Surgical technique of liver transplant resulting in intestinal contamination	Enterococci (cholangitis, bacteremia)
Use of central venous catheters	Coagulase-negative staphylococci *Staphylococcus aureus* Corynebacteria
T-cell immunosuppression, lymphopenia after any transplant	*Rhodococcus, Nocardia*
Hypogammaglobulinemia Impaired humoral activity	Pneumococci
Previous treatment with cephalosporins	Enterococci
In kidney transplant, strictures and stents	Enterococci
Colonisation with MRSA	MRSA
Colonisation with VRE	VRE

MRSA methicillin-resistant *Staphylococcus aureus*, *VRE* vancomycin-resistant enterococci.

usually affected by a chronic disease, they are often exposed to hospital pathogens during pre-transplant hospital admissions and might have received numerous courses of antibiotics and immunosuppressive agents, especially corticosteroids. At this point, during transplantation, the patient undergoes a long and usually very invasive surgical procedure, which may last hours and can be complicate by severe bleeding and contamination with intestinal flora (mainly in liver and pancreas transplant). Subsequently, with the incidence depending on the type of transplant, the patient remains in the ICU for a variable number of days, sometimes supported by mechanical ventilation and vasoactive therapy and always receiving artificial nutrition. Urinary catheters and biliary stents might be left in place for several days. Additionally, the patient usually receives an organ from a cadaveric donor and is therefore exposed to the risk of donor-derived infections. Last but not least, immunosuppressive therapy is started immediately after the surgical procedure, with the consequent risk of infections due to opportunistic pathogens and of reactivation of latent endogenous infections. Specific risk factors for infections due to Gram-positive bacteria in SOT recipients are outlined in Table 20-2.

Gram-positive bacteria obviously play an important role in infections in these patients, although an exact evaluation of their impact with respect to other types of pathogens may be difficult. MRSA can colonise the patient before transplant and then cause invasive infections afterwards. Gram-positive cocci are frequent pathogens in surgery- and ICU-related infections, with staphylococci being responsible for healthcare-associated bacteraemia (usually associated with the use of CVC) and pneumonia, and enterococci causing cholangitis and abdominal abscesses, especially in the liver transplant setting [77, 78]. In general, bacteria are the most common pathogens, and the rate of bacterial infections ranges from 5 to 25 % depending on the predisposing factors and type of transplant [79]. The highest incidence of infectious complications is reported for lung and kidney-pancreas transplants, closely followed by liver and heart transplants, while renal transplants are usually associated with a much lower risk [80]. As far as time from transplant is concerned, the risk of nosocomial and opportunistic infections is considered the highest during the first 6 months. In the first month, donor-derived infections as well as those related to the surgical procedure and ICU stay predominate, while in the following 5 months opportunistic infections and infectious reactivations become more frequent, due to the ongoing immunosuppression. Late infections are defined as occurring more than 6 months after SOT and are significantly less frequent than early ones, and are usually caused by the same pathogens that in other patients receiving similar chronic, long-term immunosuppression. However, in a multicentre Spanish study, only slight differences in the aetiology of infectious complications were detected comparing early and late period [80]. Even though late infections were significantly less frequent than early ones, the mortality rate was similar [80].

As already mentioned, Gram-positive infections occur mainly during the early period, accounting for 38 % of pathogens isolated during the first month after transplant, compared to 18 % during the late period [80]. Staphylococcal infections are the most frequent, usually caused by nosocomial methicillin-resistant strains. For example in a recent retrospective study of *S. aureus* bacteraemias in SOT recipients, 70 cases were identified, resulting in an attack rate of 22.9/1000 transplant patients [81]. Early-onset bacteraemia (≤90 days) was more frequent in liver transplant recipients (79 %), when compared with kidney transplants (17 %). All-cause 30-day mortality was 6 %, and was significantly higher in case of pneumonia as the source of bacteraemia (18 % vs. 2 %). Comparing to non-transplant recipients, resistance to methicillin was more frequent (86 % vs. 52 %), and the persistence of positive blood cultures was longer (mean 3.8 vs. 1.6 days); however, quite surprisingly, the 30-day mortality rate was lower [81].

As far as pneumonia is concerned, the Gram-positives are important pathogens, with *S. aureus* being more frequent in the early transplant period, and pneumococci in the late one [61, 82]. Although lower than in case of HSCT, the risk of invasive pneumococcal infections in SOT recipients was nevertheless found to be more than 12-fold higher than in the general population [61]. An interesting study from 90 Turkish SOT recipients who underwent bronchoscopy between 2000 and 2012 reported 46 % of microbiological yield [83]. In these 32 patients, *Mycobacterium tuberculosis*

was the most common pathogen ($n=6$, 7 %), followed by *S. aureus* in 4 (4 %) and *S. pneumoniae* in 2 (2 %) [83].

Enterococci are the second most common Gram-positive bacteria isolated after SOT. In a Swiss cohort, the highest rates of enterococcal infection were found early after liver transplantation (0.24/person-year) [78].

As mentioned, colonisation with resistant Gram-positives is a well-known risk factor for subsequent infection. A recent meta-analysis of 23 studies, mostly (17 %) performed in liver transplant recipients reported that pre-transplant and post-transplant MRSA colonisation significantly increased the risk for MRSA infections with a pooled risk ratio of 5.5 and 10.6, respectively. Similarly, pre-transplant and post-transplant VRE colonisation increased the risk of enterococcal infections almost seven and eightfold, respectively [84]. Thus, preventive strategies should be implemented in order to reduce the risk of resistant infection.

While many infections are common across all SOT receipts, some organ-specific bacterial complications deserve a separate discussion.

In orthotopic *liver transplant* recipients, bacterial, fungál and viral infections are the most frequent complications, affecting up to 68 % of the patients. Bacterial complications present usually early in the post-transplant course, typically occurring within the first 14 days after transplantation [77]. The main reasons for such a high incidence of early infections are prolonged intubation and surgical procedure, with the need to perform several biliary and vascular anastomoses, sometimes positioning intrabiliary devices (Kehr tube, stents). Some of these devices may create a direct communication between the external and the internal (duodenum) environment, with a consequent risk of both endogenous (intestinal flora) and exogenous infections.

For the above mentioned reasons, typical infections after liver transplant involve the biliary tract, and are related to stenosis or bile leakage. Although cholangitis is most frequently caused by Gram-negatives such as Enterobacteriaceae or *P. aeruginosa*, enterococci are not infrequent [85]. In fact, high rates of abdominal infections with any bacteria early after liver transplantation have been reported, but enterococci (in particular ampicillin-resistant *E. faecium*) were the most common pathogens [85, 86].

As far as other Gram-positive infections are concerned, a single-centre experience in 275 liver recipients showed that 7.3 % of them developed *S. aureus* bacteraemia, in median 6 days after transplant [82]. Of note, lungs were the most common primary site of infection, followed by abdomen and biliary tract. Resistance to methicillin was very high (80 %) and a 45 % mortality rate was reported [82]. In another recent experience in 412 adult liver transplants, 71 cases of surgical site infections were diagnosed (17 %) and MRSA was the most frequent single agent isolated, while 25 % of the cases were polymicrobial infections, with high prevalence of enterococci [87]. Half of the surgical site infections were associated with bacteraemia and 23 % with pneumonia; and the reported mortality rate was 14 % [87].

After *lung transplant*, the most important Gram-positive infection is *S. aureus* pneumonia and tracheobronchitis. In fact, Gram-positive infections in this setting are caused almost exclusively by staphylococci. *S. aureus* is particularly frequent and in a recent retrospective single-centre analysis of 596 lung transplant recipients, 18 % ($n=109$) developed *S. aureus* infection [88]. The most common infections were pneumonia (48 %), tracheobronchitis (26 %), bacteraemia (12 %), intrathoracic infections (7 %) and skin and soft tissue infections (7 %). Risk factors included mechanical ventilation for more than 5 days and *S. aureus* colonisation both in the recipient and the donor. The 30- and 90-day mortality rates from the onset of infection were 7 and 12 %, respectively, but there was a significantly higher risk of an acute or chronic rejection in patients with infection [88]. Similarly, in a prospective Spanish multicentre study on pneumonia in 236 lung transplant recipients, its incidence was high, with 72 episodes/100,000 transplants/year, and bacterial aetiology was documented in 83 % of the cases. Pneumonia was caused mainly by Gram-negatives (72 %), with *P. aeruginosa* being the most frequent species (14 cases), followed by *S. aureus* (8 cases); *Nocardia*, isolated in 1 patient, was the only other Gram-positive reported in this cohort [89].

In *heart transplant recipients*, mediastinitis and sternal wound infections are complications unique to this type of transplant. The pathogens are similar to those observed in other patients undergoing cardiothoracic surgery, with the predominance of *S. aureus* and coagulase negative staphylococci [90].

Urinary tract infections are particularly frequent after *kidney transplantation*, as 78 % of all urinary tract infections after SOT develop in renal transplant patients [91]. *E. faecalis* was the second most common isolated pathogen (the first being *E. coli*), and this infection was associated with previous antibiotic therapy or urinary tract instrumentation [92, 93]. *Corynebacterium urealyticum* is an underdiagnosed pathogen in kidney transplant recipients which is associated with encrusting cystitis and pyelitis, with consequent graft dysfunction [94]. When long term incubation and special media providing better diagnostic yield were used in 163 patients, 10 % had *C. urealyticum* bacteriuria, which was related to obstructive uropathy [94]. Similarly to other transplants, wound and CVC-associated infections are frequently caused by staphylococci [92].

Pancreas and small bowel transplant recipients have one of the highest rates of infections after SOT. They are either systemic or localised (intra-abdominal) infections caused by bacteria of enteric origin (for example abscesses in case of enteric drainage of pancreatic secretions or mucosal injury leading to breakdown of bowel-blood barrier with subsequent septic syndromes after small bower transplant). Enterococci are the main Gram-positive pathogens in these settings.

20.4 Other Infections in HSCT and SOT Recipients

20.5 Skin and soft tissue infections in transplant recipients are usually associated either with surgical procedures (particularly in case of SOT) or with the presence of CVC. Gram-positives are the most frequent pathogens, with the predominance of staphylococci. However, the possibility of CVC-associated infection caused by Gram-negatives, in particular *Pseudomonas aeruginosa*, should be always considered in transplant recipients. CVC-related infections include bacteraemia or localised (exit site or tunnel) infections. The exact role of indwelling catheters as a source of fever during neutropenia is difficult to establish since most of blood cultures are drawn only from CVC and not from a peripheral vein. Therefore, the role of CVC should be suspected in case of persistently positive blood cultures, presence of local signs of infection or fever developing precisely after CVC is used. CVC should be promptly removed in case of CVC-associated infection caused by *S. aureus, P. aeruginosa* or fungi. The benefit of CVC removal in case of other CVC-related infections is less clear. In some cases, systemic therapy of CVC-related BSI might be accompanied by local antibiotic intra-CVC therapy, i.e. high concentration of antibiotic solution is left for 8–24 h in each CVC lumen and the catheter is not used (antibiotic lock therapy, ALT). For Gram-positives, clinical experiences with vancomycin, daptomycin and gentamycin have been reported. Prevention and management of CVC-associated infections, including ALT have been recently reviewed elsewhere [95, 96].

20.6 Less Common Gram-Positive Pathogens

Numerous other Gram-positive bacteria may cause infections in immunocompromised patients. In general, in case of low virulence common skin contaminants such as micrococci, corynebacteria or *Rothia* (and similarly to what is done for coagulase negative staphylococci), at least two consecutive positive blood cultures are required in order to consider the case as true bacteraemia, at least in epidemiological studies. In particular, corynebacteria, which are part of skin flora, may occasionally cause bacteraemia, particularly in neutropenic patients with a CVC. Among them, *Corynebacterium jeikeium* is an important species, with a mortality rate in neutropenic patients as high as 34 % (but <5 % in case of bone marrow recovery) [97]. Risk factors for *C. jeikeium* include prolonged neutropenia, the presence of central venous catheter and previous antibiotic therapies [98]. Additionally, *C. jeikeium* is typically resistant to many antibiotics and vancomycin is the most reliable treatment [99]. In the absence of local infection, the removal of CVC does not seem to offer additional benefit to vancomycin therapy [100]. Resistance to new agents such as daptomycin has been occasionally reported [101].

Rothia mucilaginosa, formerly known as *Stomatococcus mucilaginosus or Micrococcus mucilaginosus,* is a Gram-positive coccus which can be easily mistaken for a coagulase-negative staphylococcus on initial culture results. It resides in the oral cavity and upper respiratory tract. It has recently emerged as a cause of life threatening infections in patients with a CVC, with prolonged neutropenia, and mucositis [102, 103]. In addition to disseminated infections and pneumonia, meningitis has been also reported [102, 103].

Bacterial foodborne infections seem infrequent during the first year after HSCT, affecting only 0.3 % of 4069 patients [104]. Listeria was only the fourth most common pathogen, after *Campylobacter, Yersinia* and *Salmonella,* with only two patients developing listeriosis. Also in another cohort, listeriosis was infrequent, with a 13-year incidence of systemic *Listeria* infections of 0.47 % in both HSCT and SOT recipients [105]. Interestingly, only two among six patients had meningoencephalitis, while all had positive blood cultures.

Nocardiosis is a rare bacterial infection occurring in patients with deficient cell-mediated immunity. As such, transplant recipients are at risk, and routine prophylaxis with trimethoprim–sulfamethoxazole prescribed for prevention of pneumocystosis is not effective in preventing nocardiosis. Clinical sites of nocardiosis include lungs, brain or skin, but disseminated infection might also occur. A review on Nocardia infection dedicated exclusively to transplant recipients has been recently published [106].

20.7 Treatment of Gram-Positive Infections in Transplant Recipients

20.7.1 Empirical Therapy for Febrile Neutropenia Targeting Gram-Positive Bacteria

Empirical antibiotic therapy for patients with febrile neutropenia has been one of the main advances in reducing mortality in this setting. The antibiotic regimen must include antibiotics active against Enterobacteriaceae and *P. aeruginosa* since even a short delay in starting treatment might have fatal consequences in these infections [58]. As shown by several clinical trials performed long time ago mainly, but not only, by the IATCG of the EORTC, ceftazidime, cefepime, piperacillin–tazobactam and the carbapenems are all listed as suitable options [58]. A recent trial performed by the Italian GIMEMA group suggested that tigecycline might

be beneficial for better coverage of Gram-negative rods when combined with piperacillin–tazobactam [21].

In the 1970s and 1980s, with an increase in the rate of Gram-positive bacteria causing infections during neutropenia and a rising proportion of methicillin-resistant staphylococci, the inclusion of a glycopeptide antibiotic in the empirical regimen has been proposed with the aim of reducing morbidity and mortality [107–109]. The issue has long been debated. Early data from case-control or historically controlled studies suggested that early initiation of vancomycin in some patients with Gram-positive bacteraemia might have resulted in improved outcome. For example, a survival benefit was reported for patients with viridans streptococcal bacteraemia who received immediately empirical therapy with vancomycin [55]. As a consequence, upfront vancomycin has been recommended in patients with the suspicion of this infection, since severe complications are not infrequent and standard treatment options can be inactive against *S. mitis* [55, 110]. The other side of the coin to consider before recommending upfront glycopeptides because of fear of streptococci is that only a small proportion of febrile and neutropenic patients actually has a viridans streptococcal bacteraemia, and, among them, an even smaller proportion is infected with a penicillin-resistant strain. Cefepime, piperacillin–tazobactam or carbapenems have all satisfactory activity against most viridans streptococci (see the dedicated paragraph).

Strategies for covering resistant Gram-positives include either starting upfront an empirical regimen that contain a glycopeptide or adding a glycopeptide in patients who remain febrile with a standard empirical treatment.

Two studies were performed in order to resolve the doubts about the benefit of including a glycopeptide in the initial empirical therapy. In a large retrospective cohort study, neutropenic patients with Gram-positive infections who did not receive vancomycin before identification of the pathogen did not have worse outcomes [107]. The second study was an IATCG-EORTC prospective randomised clinical trial in 747 patients with fever during neutropenia. The results showed no benefit of adding vancomycin to initial empirical therapy with ceftazidime and amikacin, neither on the length of fever nor on mortality [111].

The second strategy, i.e. adding a glycopeptide in patients not responding to the first line therapy, has been studied in two large placebo-controlled trials. In the first one, a single-centre study, 114 patients were randomised to receive either teicoplanin or placebo after 72–96 h of imipenem monotherapy [112]. The number of patients who became afebrile within 72 h after randomisation was similar in both groups (44.6 % in teicoplanin group vs. 46.6 % in placebo group), but the time to defervescence was not reported. In the second study, an IATCG-EORTC trial, vancomycin (or placebo) was added after 48–60 h of empirical therapy with piperacillin–tazobactam in 165 neutropenic patients with persistent fever of unknown origin or with Gram-positive bacteraemia due to a strain susceptible to piperacillin–tazobactam [113]. Defervescence occurred in 82 of 86 patients (95 %) in the vancomycin group and 73 of 79 (92 %) in the placebo group ($p=0.52$). The difference in the median time to defervescence (the primary endpoint) was not statistically significant [3.5 days (95 % CI 2.7–4.4) in the vancomycin group and 4.3 days (95 % CI 3.5–5.1) in the placebo group ($p=0.75$)]. Gram-positive bacteraemias and the rate of addition of amphotericin B were also similar in both groups. Therefore, these two studies suggested that the empiric addition of a glycopeptide antibiotic is of no benefit in persistently febrile neutropenic patients, in the absence of lung infiltrates, septic shock, or clinically documented infections likely caused by a Gram-positive (such as catheter-related or skin and soft tissue infections).

In fact, when empirical therapy apparently fails and a patient remains febrile, numerous possibilities other than infection with a resistant Gram-positive exist. They include: (1) slow response to initial empirical regimen (time to becoming afebrile might be longer 96 h in patients with a severe infection); (2) infectious but not bacterial cause of fever (usually fungal or viral); or (3) a non-infectious cause of fever such as engraftment syndrome, drug reactions, reaction to infusion of blood products, the underlying malignancy, etc.

The conclusions from the aforementioned studies were confirmed by two large meta-analyses published in 2005 [109, 114]. The first one included 13 studies with 2392 patients and reported no survival benefit for the practice of including vancomycin in the initial regimes, with the disadvantage of more frequent adverse events [109]. The second one, based on data from 14 randomised trials which studied 2413 patients, admitted that slightly higher (odds ratio between 1.6 and 2.2) treatment success without modification of the initial regimen was accomplished if a glycopeptide was included in the empirical therapy [114]. However, no effect on mortality or length of fever was found. Furthermore, adding a glycopeptide to the antimicrobial regimen in the case of persistence of fever for 72 or more hours after the start of the empirical treatment resulted in no increase in treatment success (odds ratio 1.02, 95 % CI 0.68–1.52) [114]. In consideration of the higher rate of adverse effects (odds ratio almost 5), including nephrotoxicity, also this meta-analysis concluded that glycopeptides should not be routinely used as part of the initial empirical treatment of febrile neutropenic patients [114].

Over 10 years later, clinicians are faced with the dilemma if these results still apply in centres with very high incidence of methicillin-resistant staphylococci and ampicillin resistant enterococci. It has been suggested that in centres with high rate of MRSA or other resistant Gram-positive, empirical therapy might be tailored accordingly [115, 116]. However, the benefit of early treatment of VRE infections has been debated. Preliminary single-centre experiences indicate that early use of adequate antibiotics in case of VRE infection might not have any significant impact on survival (see the paragraph on enterococci) [40, 41]. Therefore,

numerous guidelines agree that routine use of vancomycin should be avoided and indications for empirical therapy directed against Gram-positives remain in patients with presentation suggestive of a possible Gram-positive infection, such as presence of skin or soft tissue infection, pneumonia, or preliminary result of cultures positive for Gram-positive cocci [58, 115–118].

20.7.2 Targeted Therapy of Gram-Positive Infections

As a general rule, antibiotic-resistant pathogens are more difficult to treat than susceptible ones. This is true for any kind of pathogen, including Gram-positive cocci. However, for the time being, antibiotic resistance, shortage of new drugs and drug-related toxicity concern primarily multidrug resistant Gram-negative rods. For the Gram-positives, luckily, several drugs already exist or are being developed and approved for the treatment of methicillin-resistant staphylococci, such as linezolid, daptomycin, tigecycline, quinopristin–dalfopristin, telavancin, ceftaroline, ceftobiprole, tedizolid or dalbavancin. However, none of these drugs has been approved, or even properly studied in transplant recipients or in empirical therapy of febrile neutropenia. This is actually an indication which is not considered any more by regulatory agencies, and, therefore, is not searched any more by drug companies. Fewer treatment options are available against VRE, since cephalosporins are intrinsically not active against these pathogens and the only options remain oxazolidinones and daptomycin (see dedicated paragraphs).

A detailed description of all older and newer agents is beyond the aim of this chapter, and several reviews have been published on this issue [49, 119, 120]. In the following lines we try to discuss the main indications and limitation of each agent, focusing in particular, when possible, on transplant setting. The standard doses of anti-Gram-positive agents and main characteristics are reported in Table 20-3. Treatment of infections due to Gram-positive bacteria in transplant recipients is reported in Table 20-4.

20.7.2.1 Vancomycin

Vancomycin is the mainstay of therapy against penicillin- or methicillin-resistant Gram-positive cocci, but its efficacy even in vancomycin in vitro-susceptible organisms has been challenged in the following situations: (1) infections due to enterococci and staphylococci displaying increased minimum inhibitory concentration (MIC ≥2 for MRSA and ≥4 for coagulase-negative staphylococci and enterococci); (2) poor penetration into biofilm which may result in suboptimal outcomes in CVC-associated infections; (3) low and sometimes insufficient lung penetration, with suboptimal response in case of pneumonia. Additionally, nephrotoxicity and ototoxicity might represent other pitfalls for vancomycin, thus giving good reasons for choosing other agents.

The phenomenon of the low-level vancomycin resistance is one of the most common forms of decreased activity of glycopeptides and is thought to be a part of the so-called "MIC creep" phenomenon. Heteroresistant vancomycin-intermediate *S. aureus* (hVISA) strains have been identified, although vancomycin-resistant *S. aureus* (VRSA) remains very rare.

The question is whether or not pathogens expressing increased MICs to vancomycin still respond to vancomycin therapy in the real life. The issue is controversial. Increased treatment failures with higher MIC values have been reported in many, but not all studies [121–124]. A response has been to increase dosages, targeting high vancomycin trough concentrations (e.g. 15–20 μg/mL) through therapeutic drug monitoring. This strategy has been associated with modest improvements in clinical outcomes of selected patients, and is probably insufficient for achieving a desired PK/PD target (i.e. area under concentration-time curve AUC/MIC ratios ≥400 if MIC is 2 μg/mL) in severe MRSA infections. In addition, keeping through concentrations around 20 μg/ml has been associated with higher rates of nephrotoxicity, which may affect up to 20–30 % of the patients [125–127]. Last but not least, clinical outcomes in MRSA infections might depend heavily on the bacterial load at the site of infection, which appears to be worse in case of pneumonia [81, 128]. Therefore, although a number of questions remain unanswered, treatment alternative to vancomycin should be considered for infections with an MRSA isolate with vancomycin MIC ≥2 μg/mL [124] and in staphylococcal pneumonia. Other limitations of vancomycin include a large gap existing between inhibitory and bactericidal concentrations in vitro, its slow bactericidal activity and its insufficient activity in case of methicillin-susceptible staphylococci, in which oxacillin, nafcillin or cefazolin remain the drugs of choice [129].

20.7.2.2 Daptomycin

Daptomycin is a lipopeptide with a concentration-dependent bactericidal activity. The drug can be administered once-daily as a rapid (30 min) intravenous infusion. As expected for a drug with a concentration-dependent antibacterial activity, dosages higher than the approved 4–6 mg/kg/day have been associated with improved outcomes and a decreased risk of selecting for resistant strains. Therefore, in a setting with a high bacterial burden or with sequestered foci of infection, where it might be difficult to achieve adequate local antibiotic concentrations, as it might happen in valve vegetations and abscesses, higher doses might be considered [130]. In addition, in patients with a sepsis syndrome the volume of distribution is usually much higher and renal clearance increased, both good reasons for using higher doses of daptomycin. In fact, even IDSA guidelines for MRSA infections state that high-dose daptomycin, 8–10 mg/

TABLE 20-3. Dosage and main characteristics of antibiotics used in infections due to Gram-positive bacteria

Drug	Route of administration	Usual daily adult dosage	Number of daily doses	Dosing adjustment	Advantages	Disadvantages
Amoxicillin–clavulanate or ampicillin–sulbactam	i.v. or oral	i.v. 8000–12,000 mg (as amoxicillin/ampicillin)	3	Renal	Inexpensive; bactericidal; oral formulation with good bioavailability	Inactive against MRSA; diarrhoea as frequent adverse effect in case of oral administration; possible mild hepatotoxicity linked to clavulanate
Cefazolin	i.v.	6000 mg	3	Renal	Inexpensive; bactericidal; no significant interactions	Inactive against MRSA and enterococci
Ceftaroline	i.v.	1200 mg	2	Renal	Active against MRSA; bactericidal; in vitro activity against VISA, hVISA and VRSA; approved for skin infections due to MRSA	Limited clinical experience; expensive; not approved for nosocomial pneumonia; cross-allergenicity with other cephalosporins
Ceftobiprole	i.v.	1500 mg	3	Renal	Active against MRSA; bactericidal; approved for CAP and HAP caused by Gram-positive pathogens such as penicillin-resistant, *Streptococcus pneumoniae* and MRSA	Limited clinical experience; in 2015 approved only in Europe; expensive; not approved for VAP; gastrointestinal side-effects as the most frequent adverse events; cross-allergenicity with other cephalosporins
Dalbavancin	i.v.	1000 mg once followed 1 week after by 500 mg	–	Renal hepatic	Active against MRSA; long-acting antimicrobial activity; does not prolong QT interval	In 2015 approved only in the USA; approved only for acute skin and skin structure infections; impossible to rapidly discontinue treatment in case of toxicity
Daptomycin	i.v.	8 mg/kg (probably higher in case of VRE)	1	Renal	Rapidly bactericidal; active against MRSA and VRE	Inactivated by pulmonary surfactant; increases in serum CPK, rarely rhabdomyolysis; reports of drug-induced eosinophilic pneumonia; expensive
Linezolid	i.v. or oral	1200 mg	2	None	Highly bioavailable oral formulation (100%); good lung penetration; active against MRSA and VRE	Bacteriostatic; possible duration-dependent severe adverse events (thrombocytopenia, anaemia, lactic acidosis, optic and peripheral neuropathy); possible serotoninergic syndrome if co-administered with SSRI
Oritavancin	i.v.	1000 mg	1	None	Active against MRSA and VRE; extensive tissue distribution; bactericidal; once-daily dosing; no reported nephrotoxicity	In 2015 approved only in the USA; approved only for skin and skin structure infections; limited clinical experience
Oxacillin	i.v.	12000 mg	6	In the case of severe hepatic or renal failure	Inexpensive; bactericidal; no significant interactions	Inactive against MRSA and enterococci; high number of daily doses; possible cutaneous adverse events

Teicoplanin	i.v. or i.m.	600–1200 mg (a loading dose of 600 mg bid on first day of treatment)	1 (2 on the first day of treatment)	Renal	Inexpensive; red neck syndrome less common than with vancomycin	Frequently underdosed for severe infections; nephrotoxicity in case of correct dosing; possible thrombocytopenia; not available in the USA
Tedizolid	i.v. or oral	200 mg	1	None	Highly bioavailable oral formulation (100 %); good lung penetration; active against MRSA and VRE; enhanced in vitro activity compared with linezolid, and possibly less toxicity	In 2015 approved only in the USA; bacteriostatic; limited clinical experience; expensive
Telavancin	i.v.	750 mg (10 mg/kg/die)	1	Renal	Active against MRSA; approved for the treatment of HAP and VAP due to MSSA and MRSA	Inactive against VRE; Nephrotoxicity; potentially teratogenic; administered with cyclodextrin that may accumulate in the case of renal dysfunction; possible QTc prolongation, interference with laboratory coagulation tests; dysgeusia and nausea as frequent adverse events
Tigecycline	i.v.	100 mg loading dose, then 50 mg bid	2	In the case of severe hepatic failure	Active against VRE and MRSA; reported activity against *Clostridium difficile*; high volume of distribution	Bacteriostatic; low serum and lung concentrations; nausea and vomiting as frequent adverse events; FDA safety warning of higher risk of mortality than comparator agents in meta-analyses; expensive
Trimethoprim–sulfamethoxazole	i.v. or oral	15 mg/kg (dosing based on the trimethoprim component)	3–4	Renal	Inexpensive; oral formulation with good bioavailability (85 %)	Possible dermatologic and haematologic adverse effects; rarely drug-induced hepatitis; possible nephrotoxicity; interactions with ACE inhibitors or angiotensin receptor blockade possibly leading to adverse cardiac effects
Vancomycin	i.v.	2000 (30 mg/kg/die)	2	Renal	Large worldwide clinical experience; inexpensive	Nephrotoxicity; “slow” bactericidal activity; inactive against VISA, hVISA, and VRSA; increased MIC values within the susceptibility range associated with poor outcomes; possible red neck syndrome

HAP hospital-acquired pneumonia, *MRSA* methicillin-resistant *Staphylococcus aureus*, *MSSA* methicillin-susceptible *Staphylococcus aureus*, *VRE* vancomycin-resistant CAP, community-acquired pneumonia; HAP, hospital-acquired pneumonia; hVISA, heterogenous vancomycin-intermediate Staphylococcus aureus; MIC, minimum inhibitory concentration; MRSA, methicillin-resistant Staphylococcus aureus; MSSA, methicillin-susceptible Staphylococcus aureus; SSRI, selective serotonine reuptake inhibitor; VAP, ventilator-associated pneumonia; VISA, vancomycin-intermediate Staphylococcus aureus; VRE, vancomycin-resistant enterococci.

TABLE 20-4. Treatment of infections due to Gram-positive bacteria in transplant recipients

Pathogen	First line	Alternative	Comments
Corynebacterium urealyticum	Vancomycin	Linezolid, daptomycin	Aminoglycoside might be added to vancomycin for better efficacy, but high risk of nephrotoxicity
Corynebacterium urealyticum	Vancomycin	Linezolid, daptomycin	
Enterococci			
Ampicillin-susceptible	Ampicillin	Ampicillin + ceftriaxone in case of gentamycin resistant endocarditis Linezolid Daptomycin	If susceptible gentamycin can be associated for bactericidal activity; if susceptible nitrofurantoin may be used for urinary tract infections only
Ampicillin-resistant	Vancomycin	Daptomycin Linezolid	If susceptible gentamycin can be associated for bactericidal activity, but high risk of nephrotoxicity; if susceptible nitrofurantoin may be used for urinary tract infections only
VRE	Daptomycin Linezolid		
Listeria monocytogenes	Ampicillin	Meropenem Trimethoprim–sulfamethoxazole Linezolid	Gentamycin should be added in case of meningoencephalitis
Nocardia	TMP–SMX + meropenem–imipenem	Meropenem Linezolid ± meropenem Imipenem + amikacin	Prolonged treatment recommended
Pneumococci	Penicillin Ampicillin Ceftriaxone	Vancomycin	
Rhodococcus equi	2 of the following: levofloxacin/ciprofloxacin or rifampicin or azithromycin	Imipenem or vancomycin + one of first line drugs	Prolonged treatment recommended
Staphylococci			
Methicillin-susceptible staphylococci	Oxacillin Nafcillin Cefazolin	Amoxicillin–clavulanate Ceftriaxone Daptomycin	Outcomes with vancomycin has been reported inferior to anti-staphylococcal penicillin
Methicillin-resistant staphylococci	Vancomycin	Daptomycin Linezolid Telavancin Anti-MRSA cephalosporin	Vancomycin should be avoided in case of high MIC values No data for new cephalosporins
Viridans streptococci	Penicillin Ampicillin	Vancomycin Piperacillin–tazobactam Meropenem Cefepime	

TMP–SMX trimethoprim–sulfamethoxazole.

kg/day, might be used for complicated bacteraemia or endocarditis [24].

Concerns that higher dosages of daptomycin may be associated with muscular toxicity have been raised. A reassuring answer has been provided by the EU-CORE study, which is a retrospective, multicentre, non-interventional, manufacturer-funded patient registry designed to collect real-world data on the use of daptomycin in 18 countries worldwide between 2006 and 2012 [131]. In this database, 6075 patients were included and 1097 received high dose daptomycin (>6 mg/kg), mainly for osteomyelitis, foreign body prosthetic infections, and endocarditis. Increasing the dose of daptomycin was not related to any increase in toxicity, including muscle toxicity and creatine phosphokinase elevation [130, 131]. Rapid bactericidal activity and good biofilm penetration make daptomycin a valid choice in case bacteraemia and CVC-associated infection. Once-daily administration is particularly suitable for outpatient administration, which in turn might allow early hospital discharge. The main limitation of daptomycin, both in general and in the transplant population, is its lack of activity in pneumonia. Indeed, in the lungs the drug is inactivated by alveolar surfactant. In this case the safety and efficacy of daptomycin plus linezolid combination has been suggested.

Data from the aforementioned retrospective observational study (EU-CORE) obtained from neutropenic patients

showed it was a useful and well tolerated treatment [132]. Daptomycin was administered mainly in case of bacteraemia (78 %), and VRE infection (47 %), and discontinuation due to a possible adverse event occurred in 6 % of patients [132].

20.7.2.3 *Daptomycin in VRE Infections*

The optimal therapeutic choice in VRE infections remain to be established. At present, linezolid is the only drug approved for this indication, although clinical experience with the use of daptomycin is growing. Three recent meta-analyses addressed the comparison of outcomes of VRE BSI treated with linezolid and daptomycin [45–47]. All of them concluded that the quality of the analysed data was poor, since most of the data were coming from single-centre retrospective experiences. With the evident limit of the low quality of data, the mortality rates were found slightly higher in case of daptomycin, compared to linezolid [45–47]. On the contrary, a recent retrospective cohort study comparing linezolid and daptomycin for the treatment of VRE-BSI in 644 patients admitted during years 2004–2013 concluded the opposite, i.e. that linezolid was associated with slight but significantly higher risk of failure compared to daptomycin (adjusted risk ratio, 1.15; 95 % CI 1.02–1.30; $p = 0.026$) [48]. Additionally, linezolid was also associated with increased 30-day mortality and a higher rate of microbiologic failure. Indeed, the reason for the discrepancy between the above mentioned studies might be at least partially ascribed to the dosing of daptomycin, which remains problematic in enterococcal infections. According to in vitro data, the optimal dose of daptomycin against enterococci should be 10–12 mg/kg/day, which is almost twofold higher than approved dose, in order to improve efficacy and prevent the emergence of resistance [133]. In our opinion, neither linezolid nor daptomycin is an ideal treatment option in this setting. Linezolid is bacteriostatic, may offer suboptimal activity in deep-seated infections, and, in case of prolonged use, may be associated with significant haematological toxicity. The limitations of daptomycin in VRE infections include emergence of resistance during therapy, the presence of mutations associated with resistance even in isolates that are reported as susceptible in vitro but with higher MIC values, the lack of data on the optimal dose and its lack of activity in pneumonia [134].

In conclusion, enterococci are increasingly frequent in HSCT and SOT settings. *E. faecium* is growing in incidence, but resistance to vancomycin varies significantly by geographical regions. Enterococcal infections, both due to VRE and vancomycin-susceptible *E. faecium*, could be regarded as a marker of poor clinical status and important comorbidities [34]. Optimal treatment options remain yet to be defined.

20.7.2.4 *Oxazolidinones (Linezolid and Tedizolid)*

Linezolid is the first oxazolidinone approved in 2000 in the USA and a year later in Europe for both intravenous and oral use. It is bacteriostatic, with good activity against many Gram-positive aerobic bacteria, including resistant strains of several species, such as MRSA, penicillin-resistant pneumococci and VRE. It is also active against less frequently isolated strains, like *Corynebacterium* spp., *Listeria monocytogenes, Bacillus* spp., *Rhodococcus equi, Nocardia* spp. and *Lactobacillus* spp [120]. It exerts activity against resistant strains of *M. tuberculosis*. Its main features are good tissue and organ penetration, including lung epithelial lining fluid, central nervous system and eyes; and its excellent oral bioavailability. No dose adjustment is necessary in renal impairment, which makes it a suitable treatment option in patients with renal failure and if other nephrotoxic medications are being used.

Adverse events are unfortunately a pitfall for this drug, because of its myelotoxocity, which affects mostly red cell and platelets lineages, risk of lactic acidosis, and peripheral or optic neuropathy. All these side effects are seen also after relatively short treatment periods (as short as 14 days). Fortunately, all side effects, except for neuropathy which can be irreversible, subside shortly after drug discontinuation [120]. Transplant recipients frequently receive multiple other concomitant therapies, including anti-depressive medications. Therefore, it is worth mentioning that linezolid is a mild monoamine oxidase inhibitor and serotonin syndrome has been reported in patients taking selective serotonin reuptake inhibitors (SSRI). Data from retrospective studies suggest that co-administration is not contraindicated as long as such patients are closely monitored for the development of the serotonin syndrome [135].

Some experiences on the use of linezolid in HSCT and neutropenic patients have been published. A randomised double-blind study compared linezolid to vancomycin in over 600 febrile neutropenic patients. This trial was performed, despite previous trials (namely the EORTC study) had shown that vancomycin was not useful for this indication. Although the study design was erroneous (it should have been a placebo-controlled trial of linezolid vs. nothing) a similar efficacy rate was reported for both groups. However, a delayed recovery of absolute neutrophil counts was present in the modified intention to treat population receiving linezolid, while no difference in time to platelet engraftment was observed [136]. On the contrary, in a small single-centre experience, haematologic side effects, which are particularly important in HSCT recipients, have not been reported significantly more frequently in patients treated with linezolid during the pre-engraftment phase [137]. In particular, time to neutrophil and platelet engraftment were not different in 33 cases who received more than 7 days of linezolid treatment compared to controls [137]. Additionally, linezolid was reported safe and effective in 46 adult liver transplant recipi-

ents, with no cases of thrombocytopenia occurred during treatment for over 2 weeks [138].

After 15 years of use, resistance to linezolid has been rarely seen [120]. Resistance mechanisms were first described for *E. faecium* and *S. aureus*, and later also for *E. faecalis*, but they affect less than 1 % of strains, as documented in a surveillance study, which reported non-susceptibility rates between 0.03 and 1.83 % when tested against more than 42,419 clinical isolates of staphylococci and enterococci across nine consecutive surveillance years (2004–2012) in the USA [139]. Cases of linezolid-resistant isolates of staphylococci are described especially after prolonged therapy (>21 days) [140]. Resistance of enterococci to linezolid has been associated with previous linezolid therapy, although nosocomial acquisition of resistant enterococci has been also reported [120, 141, 142]. Coagulase-negative staphylococcal isolates, mainly *S. epidermidis*, currently account for the majority of Gram-positive organisms displaying elevated MIC to linezolid [139].

Tedizolid, a new oxazolidinone, has been recently approved for skin and soft tissue infections [143]. While sharing linezolid's excellent bioavailability and tissue penetration, its advantages include once daily dosing (200 mg/die) and fewer side effects, mostly gastrointestinal and haematological, together with the lack of interactions with SSRIs.

20.7.2.5 Tigecycline

Tigecycline is the first in a new class of glycylcyclines (similar to tetracyclines), that has been approved for the treatment of complicated skin and skin structure and intra-abdominal infections in adults. Although it is active against MRSA, it is not recommended for this indication mainly because of the 2010 FDA's warning, based on the observation from pooled efficacy data of an increased overall mortality among patients treated with tigecycline for serious infections. This increased mortality was probably the effect of study designs which did not take into adequate consideration the lack of activity of tigecycline against *P. aeruginosa.* Two meta-analyses confirmed subsequently the data [24, 144, 145]. In addition, tigecycline should not be used in patients with MRSA bacteraemia due to low plasma concentrations and bacteriostatic activity. At present, tigecycline is mainly used in combination regimens for the treatment carbapenemase-producing *Klebsiella pneumoniae* or for intra-abdominal infections.

20.7.2.6 New Anti-MRSA Cephalosporins

New anti-MRSA cephalosporins such as ceftaroline or ceftobiprole are active against methicillin-resistant staphylococci and share common characteristics of beta-lactams, namely bactericidal activity, excellent safety profile and possible paediatric administration. Although developed as anti-MRSA drug, ceftaroline in not recommended for treatment of MRSA pneumonia due to the lack of data because, surprisingly, few or no patient with this infection were included in the registration trial. Their drawbacks include lack of oral formulation, need to administer two to three times daily, no meaningful activity against enterococci and, last but not least, lack of data in immunocompromised and transplant patients.

20.7.2.7 New Lipoglycopeptides

New lipoglycopeptides such as telavancin, dalbavancin and oritavancin are now available to treat MRSA infections. They are all approved for immunocompetent patients, and dalbavancin and oritavancin offer an advantage for outpatient therapy due to their long half-life and thus the possibility of being administered up to every 7–10 days. Their role in transplant recipients remains yet to be established.

20.8 Conclusion

In conclusion, Gram-positive micro-organisms remain dangerous pathogens, both for HSCT and SOT recipients. They are observed relatively early after transplant in both cases, although they are related to different predisposing conditions, such as neutropenia in HSCT and mechanical defence impairment related to surgery and ICU stay in SOT. They can cause either bacteraemias or localised infections in both cases, even though bacteraemias and pneumonia are more frequent in HSCT recipients while abscesses and intra-abdominal infections, particularly enterococcal, are prevalent in the SOT population (especially in case of liver or pancreas transplants). Staphylococcal pneumonia can be an issue in thoracic organ transplantation. The mortality rate is variable, and usually lower than in Gram-negative or fungal infections. Enterococcal infections, especially VRE, can be a marker of disease severity. In late post-transplant phases, characterised by the risk of infections due to encapsulated organisms, pneumococci are the most important and vaccination seems the most effective strategy. Although widely used, an empiric anti-Gram positive coverage should not be the rule in febrile neutropenic patients undergoing transplantation, unless specific risk factors are present. Antibiotic resistance is not infrequent in Gram-positive bacteria, with high rate of methicillin resistance. VRE are still relatively rare in Europe and more common in the USA, and their treatment remains challenging. Fortunately, and contrary to Gram-negative rods, new drugs are available for treating resistant Gram-positive infections. Although no drug can be defined as ideal, several treatment options exist.

21 Gram-Negative Bacterial Infections After Hematopoietic Stem Cell or Solid Organ Transplantation

Diana Averbuch and Dan Engelhard

21.1 Introduction

21.1.1 Epidemiology of Gram-Negative Rods Infections

Gram-negative rods (GNR) cause significant morbidity and mortality in hematopoietic stem cell (HSCT) and solid organ transplant recipients (SOTR) [1–7]. These patients are prone to infection with GNR as a result of neutropenia, mucositis, the use of invasive devices and due to operation in SOTR [8]. Invasive GNR infections usually arise from abdomen (including infections of the hepatobiliary system in liver transplant recipients) [9], the urinary tract (especially occurring in renal transplant recipients) and lungs (occurring in all transplant groups, but notably in lung transplant recipients). In SOTR, complications (for example, portal vein thrombosis in liver transplant recipients) and prolonged mechanical ventilation represent significant risks. Risk factors for invasive GNR infection in neutropenic patients include age >45 years, recent administration of beta-lactams, chills, urinary symptoms, absence of gut decontamination with both colimycin and aminoglycosides [10] and previous colonization [11]. In the early years of transplantation, GNR were the leading cause of serious bacterial infection in both bone marrow and SOT recipients [12]. Later, gram-positive pathogens have become more frequent [13, 14]. Reemergence of GNR is reported in recent years [15–18]. A recent review of studies published during 2005–2011, on bacterial infections in patients with hematological malignancies or post HSCT, reported gram-positive to GNR ratios in adults 60 %:40 %, with a huge variation between centers, from 85 %:15 % to 26 %:74 % [17]. The corresponding numbers in children were: 58 %:42 %, ranging from 86 %:14 % to 32 %:68 % in individual studies. The main GN pathogens causing bacteremia in HSCT recipients (expressed as median prevalence, with range) were *Enterobacteriaceae* (24 %, 6–54 %), followed by *Pseudomonas aeruginosa* (10 %, 0–30 %) [17]. An ECIL-4 survey performed in 2011 on surveillance of bacteremia in hematology and HSCT patients summarized recent data from 39 European centers. As compared to published data, it showed a slight reduction of the gram-positive to GNR ratio (55 %:45 % vs. 60 %:40 %) and an increased rates of Enterobacteriaceae (30 % vs. 24 %), and decreased rate of *Pseudomonas aeruginosa* (5 % vs. 10 %) [17].

GNR are important cause of infections in SOTR [19]. 15.4 % of 956 SOTR developed GNR infection in one study [20]. The unadjusted overall incidence of gram-negative BSI was 15.8/1000 person-years following SOT [21]. In a recent multicenter Italian study, recipients of either heart or lung graft were at the highest risk to develop GNR bacteremia [20]. In another study, however, the rate of GNR infections was highest in simultaneous kidney–pancreas (40/1000 person/years) and lowest in liver and heart (12/1000 person years) recipients [21]. Others reported that 50–60 % of all BSI in liver Tx patients were due to GNR [7, 22]. The majority of infections with the GNR in transplant recipients occur in the early posttransplant period, especially in the first month post transplantation [9, 15, 16, 20, 21, 23].

21.1.2 Clinical Manifestations and Outcome

GNR infections may present with diverse clinical pictures: bacteremia with or without concomitant local site infections. One study reported pulmonary infections in 28.4 %, urinary tract infections in 14.8 %, and skin or soft tissue infections in 9.7 % [24]. Other studies have reported that septic shock was specifically associated with infection with GNR [25] or with drug-resistant GNR infections [26].

Infection with GNR is associated with worse prognosis. Mortality rate in HSCT patients experiencing GNR BSI was 59 % in one study [27]. In other studies, 7-and 30-day mortality after BSI onset was 17–22 % and 24–31 % [23, 28]. In one study, among aerobic gram-negative pathogens, *Pseudomonas aeruginosa* had the highest associated mortality rate (40 %) followed by the *Enterobacter, Citrobacter, Serratia* group with 25 % mortality and *E. coli* or *Klebsiella* with 3 % mortality within a 7-day period [15]. The overall unadjusted 28-day all-cause mortality of GNR BSI was

P. Ljungman et al. (eds.), *Transplant Infections*, DOI 10.1007/978-3-319-28797-3_21

4.9 % in SOTR and was lower in kidney than in liver recipients (1.6 % vs. 13.2 %, $p < 0.001$) [21]. However, another study reported lower mortality 2/70 (3 %) patients [29].

21.1.3 Antimicrobial Resistance

21.1.3.1 Definitions

The isolate is considered multidrug-resistant (MDR) if it is non-susceptible to at least one agent in ≥3 therapeutically relevant antimicrobial categories; extensively drug-resistant (XDR) was defined as non-susceptibility to at least one agent in all but two or fewer antimicrobial categories (i.e., bacterial isolates remain susceptible to only one or two categories); and pandrug-resistant (PDR) was defined as non-susceptibility to all agents in all antimicrobial categories [30].

21.1.3.2 Mechanisms of Resistance

The major mechanism of resistance to cephalosporins is beta-lactamase production. The most important beta-lactamases are the plasmid-mediated extended-spectrum beta-lactamases (ESBLs), including CTX-M, TEM and SHV and inducible group 1 AmpC cephalosporinases, which are resistant to beta-lactamase inhibitors [31–39]. Class B beta-lactamases (metallo beta lactamases, MBLs) hydrolyze all penicillins, cephalosporins, and carbapenems, with the exception of monobactam aztreonam. The most common types of MBL are IMP and VIM groups [40].

The usual mechanism of resistance to quinolones is mutation of the genes that encode the target enzymes (DNA gyrase and topoisomerase IV) for quinolones.

21.1.3.3 Epidemiology of Resistance

There is a growing problem of increasing resistance to antibiotics all over the world, including in oncological and transplant patients. There is a significant site-to-site variation in the epidemiology of resistance. Prevalence of resistance is influenced by the local policy of antibiotic use for prophylaxis and treatment, infectious control measures, as well as prevalence of resistance in the whole hospital and country.

Recent literature review of studies which report on the epidemiology of BSI in HSCT patients reported that 41 % (range 18–74 %) of GNR bacteria are resistant to fluoroquinolones, 28 % (6–41 %) to aminoglycosides, 43 % (17–45 %) to ceftazidime and 20 % (11–72 %) to carbapenems [17].

According to the ECIL-4 questionnaire assessing the recent situation in HSCT centers in Europe, median rates of ESBL-producers among *Enterobacteriaceae* was 15–24 %, aminoglycoside-resistant GNRs 5–14 % and carbapenem-resistant *Pseudomonas aeruginosa* 5–14 %. Resistance rates were significantly higher in South-East vs. North-West European HSCT centers [17]. The resistant pathogens causing most clinical problems were reported to be ESBL-producing *Enterobacteriaceae* in 28 (76 %) of centers, whilst the next-most frequent concerns were fluoroquinolone-resistant GNRs, ($n = 17$, 46 %), carbapenem-resistant *Pseudomonas aeruginosa* ($n = 15$, 41 %) and much less multidrug-resistant (MDR) *Acinetobacter baumannii* ($n = 5$, 14 %).

Several studies report on increase in MDR GNR rods in HSCT patients, including ESBL-producing *Enterobacteriaceae*, AmpC cephalosporinase hyperproducing *Enterobacteriaceae*, MDR *P. aeruginosa, Stenotrophomonas maltophilia*, and *Acinetobacter baumannii* [18, 41–43].

21.1.3.4 Risk Factors for Resistance

The most important risk factor for infection with resistant pathogens is prior colonization or infection by resistant organisms such as ESBL- and carbapenemase-producing Enterobacteriaceae, colistin-resistant *Klebsiella pneumoniae*; resistant *Acinetobacter baumannii*, *Pseudomonas aeruginosa*, and *Stenotrophomonas maltophilia* [44–56].

Another important risk factor for infection with resistant GN in transplant patients is previous exposure to broad spectrum antibiotics for treatment or prophylaxis [18, 40, 42, 57–66]. Especially important in this context is the potential role of fluoroquinolone prophylaxis in HSCT recipients [16, 60, 67–72].

Treatment with third-generation cephalosporins was associated with infection due to MDR GNR pathogens [73].

Other risk factors for resistant GNR pathogens in HSCT patients include serious illness (e.g., end-stage disease, sepsis, pneumonia), nosocomial infection, prolonged hospital stay and/or repeated hospitalizations, intensive care unit (ICU) stay, urinary catheters, and older age [18, 42, 45, 46, 48–55, 60, 61, 70–75].

In SOTR, risk factors for infection with resistant GNR include nosocomial acquisition, longer hospital stay, admission to hospital for more than 48 h before transplantation, previous transplantation, prior ICU admission, septic shock, age greater than 50 years, HCV infection, devices, increased severity of the underlying disease, renal failure with or without dialysis [20, 26, 62, 64, 66, 76–78].

In renal Tx recipients, risk factors for resistant GNR infections were double kidney–pancreas transplantation, requirement for posttransplant hemodialysis, surgical reoperation, posttransplant urinary obstruction, and requirement for nephrostomy [64, 77]. Lung transplant recipients had a higher risk for isolation of carbapenem-resistant bacteria in one study [20].

21.1.3.5 Impact of Resistance

Infections caused by resistant GNR, including ESBL-producing Enterobacteriaceae, MDR NFGNR, carbapenem-resistant GN, are associated with increased mortality in both HSCT and SOT patients [7, 22, 41, 42, 61, 64, 79–85].

Many of these studies show that failure to cover GNR pathogens, particularly ESBL producers, MDR *P. aeruginosa*, and CRE in empiric treatments significantly and independently impairs outcomes patients, increasing mortality and prolonging hospitalization [43, 60, 61, 71, 72, 80, 86–89]. Infection with multiresistant bacteria was associated with graft loss in kidney transplant recipients [64].

21.1.4 Treatment

Serious infections due to the GNR rods in transplant recipients should be managed with a beta-lactam or quinolone antibiotic, active in vitro against the infecting organism.

Several studies demonstrate that onco-hematological and transplant patients infected with resistant and MDR GNR are significantly more likely to receive an inadequate initial empiric antibiotic therapy than those with a susceptible strain [18, 26, 42, 60, 61, 71]. These studies also show that the time to appropriate therapy is much longer where the pathogen is resistant.

21.2 Enterobacteriaceae

21.2.1 Epidemiology

The members of the *Enterobacteriaceae* are GNR bacilli which are usually resident in the gastrointestinal tract. Examples of such organisms include *Escherichia coli*, *Klebsiella pneumoniae*, *Enterobacter cloacae, Proteus mirabilis*, and *Citrobacter freundii*. The majority of infections are caused by *E. coli*, followed by *Klebsiella* spp. and *Enterobacter*/*Citrobacter*/*Serratia* spp. [15, 21].

The majority of BSI in SOTR are due to *Enterobacteriaceae* [7, 20–22], they mainly occur during the first month after SOT [7, 22]. The risk is highest in transplant recipients whose peritoneal cavity has been breached (liver, intestinal, and pancreatic transplant recipients). Spillage of enteric organisms into the peritoneal cavity in such patients may lead to intra-abdominal abscess formation and manipulation of the biliary tree may lead to cholangitis.

Pneumonia occurring early after lung transplantation and urinary tract infections in renal transplant recipients may be more likely to be due to the *Enterobacteriaceae* [90, 91].

21.2.2 Clinical Manifestations and Outcome

Infections with the *Enterobacteriaceae* in transplant recipients have a multitude of clinical presentations. The sites of infection have been diverse and have included the urinary tract, lower respiratory tract, intra-abdominal, bloodstream, and wounds.

All transplant recipients, by virtue of prolonged hospitalization, may develop skin and upper respiratory tract colonization with gastrointestinal tract flora. Therefore, central venous line related infections and ventilator-associated pneumonia may occur due to the *Enterobacteriaceae*. Liver transplant recipients are prone to development of intra-abdominal infections with the *Enterobacteriaceae*. These may be mixed infections with anaerobes and enterococci. Examples of such infections include peritonitis, intra-abdominal abscess, cholangitis, and infected bilomas. Renal transplant recipients may develop complicated urinary tract infections or develop secondary infections within urinary leaks. The most common infections with the *Enterobacteriaceae* in lung and heart transplant recipients are pulmonary infections, which occur in all other SOT [92].

Death in neutropenic or other heavily immunosuppressed patients may occur within hours of onset of signs of infection, in the absence of appropriate supportive and antibiotic treatment. *Enterobacter* bacteremia was associated with 63 % mortality rate in one SOTR study [12].

21.2.3 Antimicrobial Resistance

21.2.3.1 Mechanisms of Resistance

The increasing resistance to carbapenems in *Enterobacteriaceae*, especially but not limited to *K. pneumoniae*, is a major concern. Resistance to carbapenems may be mediated by several mechanisms, including production of carbapenemases, efflux pump, decreased membrane permeability, and combination of these mechanisms [93]. Combination of plasmid-encoded AmpC or ESBL expression together with decreased cell membrane permeability may be also responsible for resistance to carbapenems [94]. The main mechanism of carbapenem resistance in *Enterobacteriaceae* in most parts in the world is hydrolysis by the serine class A β-lactamase *Klebsiella pneumoniae* carbapenemase (KPC). This mechanism also conferred resistance to all cephalosporins, aztreonam, and beta-lactamase inhibitors such as clavulanic acid and tazobactam. The gene encoding this enzyme *bla*KPC is located on plasmids and can be transferred between different species [94, 95]. Specifically, KPC-producing *Klebsiella pneumoniae* clone, sequence type ST258, has emerged and disseminated worldwide, being responsible for several outbreaks, including in HSCT patients [96–99].

Since 2009, a novel plasmid-encoded enzyme, New Delhi MBL (NDM), has spread through India, Pakistan, and the UK, and was reported also in transplant patients [100, 101]. These strains typically also have 16S rRNA methylases, conferring complete aminoglycoside resistance [102].

Carbapenem- resistant *Enterobacteriacea* (CRE) are frequently resistant to other antibiotics, including those considered as a “last resource,” as colistin, tigecycline, fosfomycin, and aminoglycosides.

21.2.3.2 Epidemiology of Resistance

Two to 44 % of *Enterobacteriaceae* in HSCT patients are ESBL producers [15, 16, 41, 73, 79, 81, 83, 103]. There is significant increase in carbapenem-resistant GNRs, especially *Klebsiella pneumoniae* (CRKp), in some HSCT centers [104].

In one study, CRKp infection was independently associated with recent stem-cell transplantation or organ, and it found to be associated with numerous health care-related risk factors and with high mortality [105].

In a recent retrospective Italian survey, more than a half of 52 centers reported on CRKp infections, and the incidence is growing, especially in allogeneic HSCT patients [43]. The incidence of CRKp infections was 0.4 % (from 0.1 % in 2010 to 0.7 % in 2013) in auto-SCT and 2 % (from 0.4 % in 2010 to 2.9 % in 2013) in allo-SCT populations [43].

ESBL producing organisms frequently colonize the gastrointestinal tract of SOTR.

The rate of ESBL-producers among Enterobacteriaceae in SOTR is 8–77 % [21, 22, 29, 77, 106–111]. 42.3 % of 80 MDR GNR strains isolated from 350 SOT recipients were ESBL-positive (mainly *Enterobacteriaceae*) [39].

There is increasing quinolones resistance of GNR bacteria in SOT [21, 112]. One study reported on increasing resistance among *Escherichia coli* isolates to fluoroquinolone antibiotics from 0 to 44 % ($p=0.002$) throughout the study period (1996–2007) [21].

Several studies reported on infections caused by carbapenem-resistant *Enterobacteriaceae* (CRE) in SOT patients. In one cohort study, organ transplant recipients appeared to be at increased risk for CRKp bacteremia [113]. Incidence of CRE infections was 1.3–12.9 % in liver, 9.4–26.3 % in kidney, 0.4–6.6 % lung, 7.5–16.7 % in heart transplant patients [100, 114]. In one recent multicenter Italian study, 26 % of all GNR bacteria and half of all *Klebsiella pneumoniae* in SOT patients were carbapenem-resistant [20]. SOTR were involved in hospital outbreak with CRE [115]. The median time since SOT to infection was 12–90 days, late infection 218 days after lung transplant was reported however [116]. The site of infection was bacteremia in 17–100 %. The other sites were pneumonia 25–50 % in liver, lung, and heart SOT; UTI in 60–100 % in renal transplants, intraabdominal (mainly in liver transplants) and soft tissue infections.

Colonization with CRKp endangers patients with subsequent infection. Generally, patient colonized with CRKp has 7.8–16 % chance to develop CRKp BSI [117, 118]. In transplant patients this risk is higher. The rates of BSI among rectal CRKp carriers was 39 % in hematological and allo-HSCT patients, 26 % in auto-HSCT, 18.8 % in SOTR, 18.5 % in ICU and 16 % in general ward patients [43, 117–119]. Patients with documented CRKp infection before allogeneic HSCT with had high chance of relapse—45.4 %; 90 % of them died despite early targeted therapy [43].

In liver transplant patients, CRKp infection rates among patients non-colonized, colonized at the time of transplantation, and colonized after transplantation were 2, 18.2, and 46.7 % in one study ($p<0.001$) [120]. In another study in liver Tx, 8/9 patients known to be colonized with KPC-2 CRKp developed infection, and five (56 %) were confirmed to have BSI with KPC-2-KP [84].

Certain factors predispose CRKp colonized patients to develop infection, such as number of colonization sites, admission to the ICU, abdominal invasive procedure, chemotherapy/radiation therapy, diabetes mellitus, solid tumor, tracheostomy, urinary catheterization, having a central venous catheter, receipt of antibiotics, renal replacement therapy; mechanical ventilation >48 h; hepatitis C virus (HCV) recurrence [117, 118, 120]. Some of these factors are routinely present in transplant patients, which can explain higher risks of invasive infection following colonization. In patients with health care-associated bacteremia, prior use of carbapenems may be only second to cephalosporins as the most significant antibiotic exposure associated with the involvement of ESBL-producing organisms [48].

21.2.3.3 Impact of Resistance

Mortality rate in infections caused by ESBL-producing bacteria was 38–52 % as compared to 5.5–29 % in infections caused by non-ESBL producing bacteria in HSCT recipients [41, 61, 79–81].

Mortality in infections caused by CRE was significantly higher as compared to non-CRE bacteria (33–72 % vs. 9–22 %) in several studies, including in transplant patients [43, 82, 104, 105, 121–123]. The infection-related mortality rates were 16 and 64.4 % in autologous and allogeneic HSCT recipients, respectively. Almost all patients died because of CRKp infection in one recent study [43]. The high rate of mortality in allo-HSCT patients was comparable or higher than that reported in previous series of intensive care unit (32–41 %), some solid organ transplant (40 %) and hematologic malignancies (65 %) patients [43, 100, 124]. The infection-related mortality rate was 48 % in patient who received CRKp- targeted 1st line therapy as compared with 73 % in those who received a not CRKp-targeted first-line antibiotic therapy ($p=0.002$) [43].

CRE bacteremia in SOTR caused septic shock in 18 % of patients, and was recurrent and persistent in 29 % each, in one study [116]. Summary of several studies in SOTR infected with CRE reported on 37 % mortality [100], in one study it reached 78 % [84]. SOTR with at least one positive culture for carbapenem-resistant GNR had a 10.23-fold higher mortality rate than those who did not [20]. Bacteremic or non-bacteremic infections due to CRKp resulted in a five-fold increased risk of death after liver transplantation [125]. Retrospective cohort study comparing SOTR with a first episode of UTI due to CRKp, ESBL-producing *Klebsiella*

pneumoniae, or susceptible *Klebsiella pneumoniae* demonstrated that CRKP is associated with long length of stay, and microbiological failure [78]. Six of 13 (46 %) kidney transplant recipients with CRKp infection, and none of the patients with carbapenem-sensitive *Klebsiella pneumoniae* infection, died within 6.5 months of infection onset [126]. Resistance to colistin has been independently associated with worse outcomes in patients infected with CRKp [127].

21.2.4 Treatment

An important caveat is that ESBL-producing organisms may appear susceptible in vitro to third generation cephalosporins (ceftazidime, cefotaxime or ceftriaxone) or cefepime, yet be functionally resistant to these agents [128]. 8–20 % of patients receiving broad-spectrum cephalosporins for *Enterobacter* infection had resistant isolates under treatment due to induction of AmpC [129–132].

ESBL producers in vitro are inhibited by beta-lactamase inhibitors (sulbactam, clavulanate, tazobactam). However, MIC to these agents rises with increasing inoculum [133]. Quinolones are usually inappropriate for treatment, as resistance to quinolone is frequent in ESBL producing bacteria: 20–90 % ESBL producers were resistant to quinolones, as compared to 2–42 % of non-ESBL-producers [61, 79, 134]. Carbapenems should be regarded as the drugs of choice for serious infections with β-lactamases-producing organisms [35, 37, 38, 121, 135].

Treatment of carbapenem-resistant GNR is discussed below. Resistance to agents active against carbapenem-resistant GNR has been reported. For example, among KPC-Kp isolates in HSCT patients, 80.8 % were susceptible to colistin, 69.2 % to tigecycline, and 65.4 % to gentamicin in one study [104].

Appropriate treatment for resistant bacteria is frequently delayed. Inadequate empirical therapy was most common in SOTR infected with ESBL bacteria [56]. CRKp-targeted therapy was provided with more than 2 days delay in one study in patients with hematological malignancies [124].

21.3 Non-fermentative Gram-Negative Rods (NFGNR)

21.3.1 Epidemiology

The NFGNR include *Pseudomonas aeruginosa, Acinetobacter* spp., *Burkholderia cepacia, Stenotrophomonas maltophilia*, and some other more rare bacteria. Non-fermentative refers to their inability to ferment glucose (instead, most species degrade glucose oxidatively). Non-fermentatives are less frequent causes of BSI than *Enterobacteriaceae* in transplant patients [7, 12, 15, 17, 20–22]. However, these are more frequent causes of pneumonia [20].

Pseudomonas aeruginosa is the most frequent of the NFGNR, causing about 5–15 % of bacteremias [7, 17, 20, 21]. *Acinetobacter* spp, *Burkholderia cepacia*, and *Stenotrophomonas maltophilia* are considerably less frequent—responsible for about 2 % (0–12 %) of bacteremia in HSCT [18, 27, 136–145] and 2–10 % of GNR bacteremia in SOTR [7, 20].

Pseudomonas aeruginosa is responsible for 8–25 % of cases of pneumonia occurring in SOTR [92, 146]. Lung transplant recipients are at greatest risk [90, 147, 148].

Between 2 and 13 % of patients with cystic fibrosis (CF) are colonized with *Burkholderia cepacia* [149–151]. Increasing age and advanced lung disease are risk factors for *Burkholderia cepacia* colonization implying that candidates for lung transplantation may also be at the highest risk of *Burkholderia cepacia*.

21.3.2 Clinical Manifestations and Outcome

In one study on NFGNR bacteremia in cancer patients (including HSCT), the risk of complications was high (47 %), including 35 % with septic syndrome, 19 % pneumonia, 3.5 % enterocolitis, and 3.5 % soft-tissue infections [139]. There are few clinical characteristics which distinguish transplant recipients with infection with NFGNR from patients with infection with the *Enterobacteriaceae*.

Pseudomonas aeruginosa bacteremia may be associated with ecthyma gangrenosum. The skin lesions of ecthyma ganrenosum may be multiple, with rapid evolution through stages of macules, nodules, vesicles, and ulcerative eschars. The lesions contain little, if any, pus. In children the lesions tend to occur on the perineum and buttocks, but they may appear anywhere. Although ecthyma gangrenosum is regarded by some as pathognomonic for *Pseudomonas aeruginosa* bacteremia, similar lesions have been reported with other etiologies of bacteremia, such as *Stenotrophomonas maltophilia* [152].

In SOT patients, *Pseudomonas* can cause pneumonia, UTI (mainly in renal Tx) and bacteremia [64, 106]. *Pseudomonas aeruginosa* may be associated with cholangitis in liver transplant recipients. De novo colonization of the lung allograft by *Pseudomonas* is associated with the subsequent development of bronchiolitis obliterans [153].

Mortality is especially high in *Pseudomonas aeruginosa* bacteremia in both HSCT and SOTR: 39–67 % [12, 15, 16, 23, 28, 62, 154]; the majority of patients died within 7 days from the onset of infection. Mortality is especially high if caused by multidrug resistant (MDR) bacteria [83, 155]. Onset of *Pseudomonas aeruginosa* blood stream infections in ICU is an independent predictor of mortality after HSCT and SOT patients [62].

Acinetobacter spp, *Stenotrophomonas maltophilia*, and other NFGNR were responsible for catheter related bacteremia, severe sepsis, severe hemorrhagic pneumonia and soft

tissue infection in HSCT patients [18, 27, 136–145] and 2–10 % of GNR bacteremia in SOTR [7, 20, 156]. The most frequent clinical manifestation of *Stenotrophomonas maltophilia* is pneumonia and the second most frequent is CVC-related bacteremia [144, 156–158]. It must be recognized that not every isolate from the respiratory system is a true cause of pneumonia, but may represent colonization of respiratory tract.

Stenotrophomonas maltophilia emerges particularly in patients with prior broad-spectrum antimicrobial therapy.

Acinetobacter spp. can cause suppurative infections in virtually every organ system; mainly they cause nosocomial infections [9]. Lung transplant recipients infected with *Acinetobacter* were less likely to clear infection as compared to non-transplant patients, and more likely to die because of *Acinetobacter* infection [85]. Infections with *Acinetobacter* can be severe, a third of them were associated with septic shock and 47.1 % deaths in liver Tx recipients [9].

Burkholderia cepacia infection in lung transplant recipients may produce a rapidly progressive pneumonia, sometimes accompanied by septicemia. Occasional patients have lung abscess or empyema [159]. Both lung transplant recipients and lung transplant candidates may have simple colonization with *Burkholderia cepacia* however. Some lung transplant candidates have a gradual but progressive decline in their clinical condition after they become colonized with *Burkholderia cepacia*. These patients may have repeated hospital admissions with fever, declining respiratory function and weight loss. In contrast, some lung transplant candidates have a rapidly progressive syndrome known as the "cepacia syndrome" [160]. These patients present with high fever and respiratory failure. Laboratory testing reveals leukocytosis and a markedly elevated erythrocyte sedimentation rate (ESR). Person to person transmission of *Burkholderia cepacia* has been reported, most likely through direct contact with respiratory secretions [161]. Transplant patients with CF and chronic granulomatous disease are vulnerable to *Burkholderia cepacia* pneumonia, and bacteremia with this pathogen may also occur.

Specific comment should be made regarding colonization and lung infection due to *Burkholderia cepacia*. Some, but not all, studies of *Burkholderia cepacia* pneumonia in lung transplant recipients have shown elevated mortality compared to patients who were never colonized with this organism. There is a report on mortality of close to 50 % in *Burkholderia cepacia* colonized CF patients undergoing lung transplantation [159]. Others found that 1-year survival of *Burkholderia cepacia* colonized patients was 67 % compared to 92 % for patients not colonized with this organism [162]. Lung SOTR with CF who were infected with *Burkholderia cepacia* had poorer outcomes and represented the majority of those who had a septic death [163]. In contrast, a number of small studies have not shown significant difference in survival of *Burkholderia cepacia* colonized versus non-colonized patients [164, 165]. It appears that a subset of *Burkholderia cepacia*, genomovar III, is linked to inferior outcome [166, 167]. Patients colonized with *B. cenocepacia* before lung transplant were six times more likely to die within one year of transplant than those infected with other *Burkholderia cepacia* complex (Bcc) species ($p = 0.04$) and eight times than noninfected patients ($p < 0.00005$) [168]. 9/12 patients with *B. cenocepacia* infection died following lung transplantation, as compared to significantly better outcomes of recipients infected with other Bcc species, comparable to other recipients with CF [169]. Therefore, colonization with *B. cenocepacia* is considered as a contraindication for lung transplantation in some centers [169].

Following lung transplantation, infection with Bcc species other than *B. cenocepacia* does not significantly impact 5-year survival whereas infection with *B. cenocepacia* pre-transplant is associated with decreased survival [168].

21.3.3 Antimicrobial Resistance

21.3.3.1 Mechanisms of Resistance

Pseudomonas aeruginosa displays a diverse array of antibiotic resistance mechanisms [170]. Resistance to beta-lactam antibiotics is usually, but not exclusively, mediated by beta-lactamases. A frightening arrival has been the IMP and VIM type beta-lactamases which can hydrolyze carbapenems, and all other beta-lactams with the exception of aztreonam [171]. However the coexistence of other beta-lactamases usually results in resistance to aztreonam. Metallo beta-lactamase production was the main mechanism of resistance in NFGNR found in one study [39].

Imipenem resistance can be mediated by loss of OprD, a porin or outer membrane protein. Loss of OprD results in resistance to imipenem and reduced susceptibility (but usually not frank resistance) to meropenem. OprD may be co-regulated with an efflux pump called MexEF-OprN [170, 172]. Use of imipenem can select for loss of OprD, but not for upregulation of the efflux pump. In contrast, use of quinolones can select for upregulation of the efflux pump and also reduced OprD (resulting in resistance to both quinolones and imipenem). Frank resistance to meropenem usually requires both loss of OprD and upregulation of an efflux pump known as MexAB-OprM [172].

The efflux pumps are an important mechanism of multidrug resistance, since they may confer resistance to quinolones, antipseudomonal penicillins, cephalosporins, and sometimes also aminoglycosides. Quinolone resistance may also be mediated by mutations to the chromosomally mediated topoisomerases II and IV. Aminoglycoside resistance may be mediated by outer membrane impermeability or by aminoglycoside modifying enzymes.

Stenotrophomonas maltophilia is intrinsically resistant to carbapenems because of the production of carbapenem hydrolyzing beta-lactamases. *S. maltophilia* usually harbors

two types of beta-lactamases: L1, a metallo-beta-lactamase that hydrolyzes all beta-lactams except aztreonam and is not inhibited by clavulanic acid and L2, an inducible class A beta-lactamase that hydrolyzes aztreonam but is inhibited by clavulanic acid. Strains harboring these beta-lactamases hydrolyze almost all beta-lactams and beta-lactam–beta-lactamase inhibitor combinations. The majority of strains are susceptible to ticarcillin–clavulanate, but not to ampicillin–sulbactam or piperacillin–tazobactam. *Stenotrophomonas maltophilia* is frequently resistant to all aminoglycosides, probably due to impermeability of the outer membrane.

A variety of beta-lactamases have been reportedly produced by *Burkholderia cepacia* [173–179]. Resistance may also be mediated by membrane impermeability.

Acinetobacter spp. may be capable of virtually complete antibiotic resistance. Some authors have used the abbreviations CRAB (carbapenem-resistant *Acinetobacter baumannii*) or PDRAB (pandrug-resistant *Acinetobacter baumannii*) [180]. As is the case with *Pseudomonas aeruginosa*, resistance of *Acinetobacter* spp. may be mediated by a combination of beta-lactamases and outer membrane protein deficiencies. A clinically useful observation has been the in-vitro efficacy of ampicillin–sulbactam in the face of resistance to almost all other drug classes. Sulbactam is able to bind to penicillin binding protein 2 (PBP-2) and therefore can impart direct antimicrobial activity against *Acinetobacter* spp [181].

21.3.3.2 Epidemiology of Resistance

Transplant recipients (HSCT and SOT) are at greater risk of MDR *Pseudomonas aeruginosa* BSI, with an appreciable mortality. In a large study, resistance to all antibiotic classes was significantly greater in *Pseudomonas* BSI isolates from transplant compared with non-transplant patients ($p<0.001$). Of isolates from transplant recipients ($n=207$), 43 % were MDR, compared with 18 % of isolates from non-transplant patients ($n=391$) ($p<0.001$) [62].

In HSCT patients *Pseudomonas aeruginosa* is frequently resistant to several antibiotic classes. 18–72 % are resistant to fluoroquinolones, 11–50 % to aminoglycosides, 15–50 % to third-generation cephalosporins, 10–28 % to piperacillin tazobactam and 8–60 % to carbapenems [15, 16, 23, 24, 72, 182]; 25–71 % are MDR [16, 62, 72, 73, 143]. Outbreaks of multidrug resistant GNR rods (*Stenotrophomonas, Pseudomonas*) were reported in HSCT units [183–185].

In SOT patients NFGNR are frequently resistant to antibiotics; 31–74 % of them are MDR in some reports [26, 29, 62, 76, 83, 186, 187]; others report on XDR *Pseudomonas* and *Acinetobacter* [76, 83]. 37 % of 49 cases of *Acinetobacter baumannii* infection in kidney and liver transplant recipients were caused by carbapenem-resistant isolates in one study [89], while in another study in liver transplant patients, 75 % were carbapenem-resistant [9]. Infection with CRAB manifested mainly as pneumonia (83 %) in one study in SOTR, half of these patients subsequently developed CRAB BSI; 5/6 patients died [188]. CRAB caused 42.9 % of all *Acinetobacter* infections in abdominal SOTR as compared to 13.7 % among non-transplant ($p<0.01$) [188]. XDR *Acinetobacter baumannii* in infections were significantly more common among cardiothoracic than abdominal transplant recipients ($p=0.0004$). Ninety-eight percent (40/41) of patients had respiratory tract infections, most commonly ventilator-associated pneumonia (VAP); 88 % [36/41]) [189].

CF patients undergoing lung transplantation are frequently infected with MDR and PDR NFGNR, such as *Pseudomonas, Burkholderia*, and others. In some centers, 44–55 % of patients harbored PDR NFGNR, mostly *Pseudomonas* [106, 190, 191]. *Burkholderia cepacia* is frequently MDR [192, 193].

Contact with other patients colonized with resistant *Pseudomonas aeruginosa* may be risk factor for acquisition of resistant strain [194].

21.3.3.3 Impact of Resistance

Mortality in MDR *Pseudomonas* infections was 36 % vs. 12.5 % in non-MDR infections in HSCT patients [182].

MDR and XDR *Acinetobacter* infections is associated with high mortality rate of 49–95 % in HSCT and SOTR [136, 188, 189, 195]. Polymyxin-resistant *Acinetobacter* colonization or infection after liver transplantation was independently associated with mortality [196].

Some studies reported on decreased survival in CF patients infected with PDR bacteria [190], others however reported that their survival is similar to patients without PDR colonization [163, 191]. Inappropriate therapy was associated with increased mortality in SOTR patients infected with *Acinetobacter* spp. and MDR GNR [39, 89].

21.3.4 Treatment

21.3.4.1 Pseudomonas aeruginosa

There has been long-standing debate over the value of combination therapy in the treatment of serious *Pseudomonas aeruginosa* infections. Combination therapy had been considered the mainstay of therapy for many years, but recently proponents of monotherapy have emerged. Much of the support for combination therapy emanated from the prospective observational study of 200 consecutive patients with *Pseudomonas aeruginosa* bacteremia, showing that combination therapy was found to be significantly better than monotherapy in improving outcome. Mortality was significantly higher in patients given monotherapy (47 %) than in patients given combination therapy (27 %) [197]. It should be noted that the most common combination used was piperacillin or ticarcillin combined with tobramycin or gentamicin. The monotherapy group was dominated by patients

given an aminoglycoside alone. Few patients received cephalosporins, aztreonam, carbapenems, or quinolones [197]. In the contrary, there are two studies, including *Pseudomonas aeruginosa*, on GNR bacteremia, that did not find statistically significant differences in mortality between those receiving beta-lactam monotherapy versus beta-lactam-aminoglycoside combination therapy [198, 199]. No difference in mortality between monotherapy with beta-lactam and combination of beta-lactam with aminoglycoside or fluoroquinolone was demonstrated in the recent review of randomized and non-randomized studies [200].

To definitively show that combination therapy is superior to monotherapy would require a randomized controlled trial of several hundred patients. It is not likely that such a study will be ever performed. The demonstration of in-vitro synergy between antipseudomonal beta-lactam antibiotics and aminoglycosides, and the development of resistance with monotherapy, prompts us to continue to recommend combination antibiotic therapy for serious *Pseudomonas* infections. It is not clear whether the combination of two antibiotics needs to be continued for the entire treatment course or whether combination therapy in the first 3–5 days of treatment is sufficient. A combination of antipseudomonal beta-lactam plus aminoglycoside is the gold standard of therapy. Minimization of the aminoglycoside component of this regimen to 3–5 days should minimize risk of toxicity [201]. Combinations of beta-lactams and quinolones are sometimes used but the clinical data to support such combinations is sparse. We do not recommend combinations of two beta-lactams. Double beta-lactam therapy has proved inferior to the beta-lactam-aminoglycoside combination in animal models [202]. One study in humans showed emergence of resistance in 40 % (two of five) of cases in one series of *Pseudomonas aeruginosa* infection treated with double beta-lactams [203].

High doses of quinolones for therapy of serious *Pseudomonas* infections are recommended. For ciprofloxacin, an intravenous dose of 400 mg every 8 h is recommended instead of standard 400 mg every 12 h. Likewise we recommend levofloxacin at 750 mg per day, rather than 500 mg per day, for serious pseudomonal infections. For beta-lactams, the rate of bactericidal activity of beta-lactams does not increase substantially once concentrations exceed four times the MIC. Beta-lactams do not exhibit a postantibiotic effect against *Pseudomonas aeruginosa* with the notable exception of the carbapenems. Thus, high drug concentrations do not kill *Pseudomonas aeruginosa* any faster than low concentrations, and bacterial regrowth will begin very soon after serum and tissue levels fall below the MIC. The duration of time that serum levels exceed the MIC is the pharmacokinetic parameter that best correlates with in vivo efficacy of the beta-lactams. Continuous infusion of antipseudomonal beta-lactams is therefore theoretically attractive. At this time, this approach remains to be validated in large clinical studies. Aminoglycosides, even when in combination therapy, should be dosed once daily. Aminoglycosides exhibit concentration-dependent bactericidal activity, and also produce prolonged postantibiotic effects. This supports the practice of once daily aminoglycoside dosing.

21.3.4.2 Other NFGNR

There are no randomized controlled trials which can guide therapy of *Stenotrophomonas maltophilia*. Trimethoprim–sulfamethoxazole should be considered the primary therapeutic agent. Resistance may arise and the sulfonamide component is poorly tolerated by some patients [204–206]. However, it must be recognized that *Stenotrophomonas maltophilia* may be a colonizer of the airways, in which case not treatment is needed. Alternative agents against *Stenotrophomonas maltophilia* proposed by some authors include the beta-lactams, ticarcillin–clavulanate, and ceftazidime; fluoroquinolones, with moxifloxacin reportedly active in-vitro against some ciprofloxacin-resistant isolates from hematological patients [207]; minocycline and chloramphenicol. Combination therapy with either ticarcillin–clavulanate or with a third-generation cephalosporin (mainly ceftazidime) should be considered in a neutropenic or severely ill patients [204, 208, 209]. Published cases series on treatment regimens other than trimethoprim–sulfamethoxazole are small with variable success and drugs used often in combination [50, 204–206].

Burkholderia cepacia can be extremely resistant, but ceftazidime, carbapenems (imipenem and meropenem), ciprofloxacin, piperacillin, chloramphenicol, and trimethoprim–sulfamethoxazole have the greatest likelihood of in vitro activity. It is important to note that combination therapy is highly desirable because of the probability of emergence of more resistant isolates during therapy. *Burkholderia cepacia* is resistant to commonly used inhaled antibiotics (tobramycin and colistin) [106].

Carbapenems (for example, imipenem or meropenem) have traditionally been regarded as extremely potent agents in the treatment of severe infections due to *Acinetobacter* spp. This has been borne out in studies of *Acinetobacter* bacteremia [210]. Carbapenem-resistant *Acinetobacter baumannii* may remain susceptible to sulbactam [2, 168, 211] a beta-lactamase inhibitor that also has clinically relevant intrinsic antimicrobial activity against the organism. In patients with strains resistant to virtually all currently available antibiotics, colistin may be the only viable option [212]. In-vitro studies show potential advantages of combinations of rifampin with colistin [213]. A new antibiotic, tigecycline, shows usefulness against multiresistant *Acinetobacter* organisms [65, 214]. *A. baumannii* can develop resistance to tigecycline by mutation, with the trait sometimes selected in therapy [215–217]; moreover some regionally prevalent MDR strains are non-susceptible to tigecycline [218].

21.4 Treatment Options for Carbapenem-Resistant GNR

Treatment of carbapenem-resistant GNR is challenging. In some cases, the only treatment options include old antibiotics (polymyxins and fosfomycin), tigecycline, and aminoglycosides [50, 135, 219–221]. All these options have efficacy, resistance, and/or toxicity issues.

Summary on current treatment options for carbapenem-resistant GNR is presented in Table 21-1.

21.4.1 Polymyxins

The polymyxins were originally isolated from *Bacillus* spp—polymyxin B from *B. polymyxa* in 1947 and colistin (also known as polymyxin E) from *B. colistinus* in 1950. The polymyxins act primarily on the bacterial cell wall, leading to rapid permeability changes in the cytoplasmic membrane. Entry into the cell is not necessary. The polymyxins may also have antiendotoxin activity. Carbapenem-resistant GN can remain sensitive to colistin. Increasing number of reports on successful systemic polymyxins use, including in transplant patients [222–224]. Other usages of colistin reported were: as aerosols, in adjunction to systemic therapy in patients with pneumonia [225], intraventricular use for CNS infections [226] and endotoxin removal using polymyxin-B-based hemoperfusion [227]. Inhaled colistin in lung transplant patients may delay colonization with *Pseudomonas aeruginosa* [228]. The use of colistin raises several issues of concern:

1. Efficacy. Treatment with colistin was associated with increased mortality as compared with other appropriate regimens in several studies; some of them included onco-hematological patients [229, 230]. Others, however, reported on considerable effectiveness, depending on the daily dosage and infection site [222, 223, 231].
2. Toxicity, mainly nephrological and neurological. Nephrotoxicity, which was reported in up to 50 % of patients receiving colistin–polymyxin B in older studies,

Table 21-1. Main characteristics of the new or revisited antibacterial drugs for treatment of infections due to MDR GNR bacteria

	Colistin/polymyxin B [115, 220, 221, 232, 235, 236, 305]	Tigecycline [216, 220, 244, 306]	Fosfomycin [204, 231, 307, 308]
Class	Polymyxin	Tetracyclines	Phosphonic acid derivative
Mechanism of action, hydro/lipophilic	Disrupts bacterial membranes, hydrophilic	Protein synthesis inhibition, lipophilic	Inhibits peptidoglycan synthesis, Hydrophilic
Bactericidal/-static; concentration/time dependent activity	Bactericidal, concentration dependent	Bacteriostatic, time dependent	Bactericidal, variable concentration-dependent or time-dependent
Spectrum	Enterobacteriaceae, *P. aeruginosa*, *A. baumannii*, *S. maltophilia*, not *Proteus, Serratia, Providencia* spp	Enterobacteriaceae, *A. baumannii, S. maltophilia,* not *P. aeruginosa, Proteus, Morganella*, and *Providencia* spp	Enterobacteriaceae (esp. *E. coli*), some *P. aeruginosa,* not *A. baumannii*
Half life	5.9 ± 2.6 h (Following administration of two million international units of colistin methanesulphonate)	37 ± 12 h	5.7 ± 2.8 h
Route of elimination	Renal	Biliary/fecal and renal	Renal and fecal
Dose and route	Wide dose range used (3–9 × 10^6 IU/day) Loading dose nine million IU and maintenance dose 4.5 million IU every 12 h preferred, IV	100 mg loading dose followed by 50 mg twice daily, IV	Range 2 g three times daily up to 4 g four times daily, IV
Main side effects	Nephrotoxicity, neurotoxicity	Nausea, vomiting and headache	Gastrointestinal (rare)
Warnings	Increased mortality as compared to other appropriate regimens in some retrospective studies Low colistin concentration after the first few doses in the routine dose regimen	Low blood levels Increased risk of death compared to other antibiotics used to treat severe infections	No clinical experience in this patient population Readily selects resistance
European Medicines Agency (EMA) labeled indications	Serious infections caused by GNR bacteria, including those of the lower respiratory tract and urinary tract where sensitivity testing suggests that they are caused by susceptible bacteria	Complicated skin and soft tissue infections, complicated intra-abdominal infections	No EMA license; individual country licenses include infections of lung, urinary tract, and bone, with associated bacteremia

Adapted from Averbuch D, Cordonnier C, Livermore DM, Mikulska M, Orasch C, Viscoli C et al. Targeted therapy against multi-resistant bacteria in leukemic and hematopoietic stem cell transplant recipients: guidelines of the 4th European Conference on Infections in Leukemia (ECIL-4, 2011). *Haematologica* 2013; 98(12): 1836–47.

is much less frequent in newer studies, including HSCT patients, with rates ranging from 10 to 30 % [221–224, 232].

3. Appropriate dose. The recommended dose in adults is nine million IU daily in two or three divided doses as a slow intravenous infusion; in critically ill patients a loading dose of nine million IU should be given. Doses should be reduced according to creatinine clearance in patients with renal impairment. In children, the suggested dose is 75,000 to 150,000 IU/kg daily, in three divided doses [233]. Loading dose and high daily dosages of colistin may help to overcome the problem of low blood levels that may have been responsible for the suboptimal efficacy of polymyxins, as well as to the selection of resistant strain variants [219, 234–237].
4. Emergence of colistin-resistant GN after previous exposure to colistin was reported [196, 234]. Susceptibility decreased during therapy with colistin in 40 % of SOTR infected with XDR *Acinetobacter baumannii* [195].

21.4.2 Tigecycline

Tigecycline has a broad spectrum of in vitro activity against MDR GNR bacteria, excluding *Pseudomonas aeruginosa, Proteus* spp., *Providencia* spp., *and Morganella* spp. [205, 238–240]. Standard dosage tigecycline, in combination with an anti-pseudomonal drug (ß-lactams, quinolones, aminoglycosides) achieved clinical response in 56 % of HSCT recipients [241]. Patients with pneumonia had lower response and higher mortality rates than those with bacteremia (51 % vs. 79 %, 44 % vs. 16 % respectively, both $p < 0.05$) [241]. In another study, standard dosage tigecycline used alone or combined with other antibiotics, showed clinical response (defined as partial or complete improvement of signs/symptoms of infection) in 16/23 (70 %) of bacteremia cases, 18/29 (67 %) of pneumonia and in 7/12 (58 %) where it was used for empirical treatment of febrile neutropenia [242],. The microbiologic response rate 70 % was achieved during treatment of CRKp infections after liver transplantation in the intensive care unit (ICU) with tigecycline, but 30 % died due to CRKp [243].

Higher-dosage tigecycline regimens potentially may be advantageous in severe infections. A recent randomized study in patients with hospital-acquired pneumonia showed that clinical cure with tigecycline 100 mg twice daily after a loading dose of 200 mg (17/20, 85.0 %) was numerically higher than with tigecycline 75 mg twice daily after a loading dose of 150 mg (16/23, 69.6 %) and imipenem–cilastatin (18/24, 75.0 %) [154]. However, evidence of increased mortality, compared to other antibiotic therapies, especially in VAP [244] leads to caution in its use. Moreover, a serious drawback, at least for monotherapy in bacteremia, is the low serum level obtained [216]. Superinfections with pathogens inherently resistant to tigecycline (*Pseudomonas aeruginosa*, *Proteus* spp., *Providencia* spp., and *Morganella* spp.) are another concern [215, 236, 243]. Breakthrough CRE bacteremia during tigecycline therapy was reported due to susceptible strains [113]. Increased MIC during treatment with tigecycline was reported in kidney Tx patient [245].

21.4.3 Fosfomycin

Fosfomycin is another old, but increasingly revisited, antibiotic with broad-spectrum in vitro activity against GNR bacteria, excluding *Acinetobacter* spp. Several studies estimate 80–90 % of Enterobacteriaceae with extended-spectrum beta-lactamases (ESBLs) and carbapenemases to be susceptible to fosfomycin [204, 219], but other studies report that only 50 % of *Klebsiella* spp. and fewer than 30 % of MDR *Pseudomonas aeruginosa* to be susceptible [135, 221]. Due to the possibility of resistance developing during therapy, fosfomycin should be used in combination with other agents, selected according to the susceptibility results [204, 246]. Data on the efficacy of intravenous fosfomycin are limited to case reports and small case series [204] and there is no published experience of treating invasive infections in oncohematological and HSCT patients. A retrospective study in HSCT patients showed, that in a multivariate analysis, exposure to fosfomycin (route of administration not specified) was associated with a significantly decreased incidence of veno-occlusive liver disease [247]. Fourteen cases of UTI in kidney Tx recipients were treated with fosfomycin, mostly due to *E.coli*, 50 % resistant to carbapenems. The overall clearance rate of UTI at 3 months was 31 %; recurrence occurred in 54 % and persistence occurred in 21 % of cases, no adverse drug reactions were reported [248]. In another report, 30 % microbiological cure was achieved when MDR GNR UTI was treated with fosfomycin in 15 SOTR; in 3 of them resistance to fosfomycin developed during treatment, and another one had superinfection due to fosfomycin-resistant bacteria [249].

21.4.4 Combination Therapy in Infections Due to Resistant GNR

21.4.4.1 In-Vitro Data

Some in vitro data suggest synergy in combining two agents (polymyxin B and either rifampin or doxycycline; fosfomycin with meropenem or colistin) against carbapenemase-producing *Klebsiella pneumoniae*, even when the pathogen is resistant to one of these agents [250, 251]. An ertapenem–doripenem combination may be of potential usefulness against KPC-producing *Klebsiella pneumoniae* based on a study in an immunocompetent murine thigh infection model based on the notion that the high affinity of KPC for ertapenem would “trap” the enzyme thus enhancing the activity of doripenem [252].

A recent meta-analysis of studies examining in vitro interactions of antibiotic combinations consisting of any carbapenem with colistin or polymyxin B against GNR reported that combination therapy showed synergy rates of 77 % for *Acinetobacter baumannii*, 44 % for *Klebsiella pneumoniae*, and 50 % for *Pseudomonas aeruginosa*, with low antagonism rates for all. Doripenem showed high synergy rates for all three bacteria. The use of combination therapy led to less resistance development in vitro [253].

Various combinations of rifampin, beta-lactams, aminoglycosides, quinolones, colistin–polymyxin B, fosfomycin, or other agents are synergistic in vitro, or in animal models, against MDR *Pseudomonas* or *Acinetobacter* spp. [135, 211, 254–258].

21.4.4.2 Clinical Data

In the era of increasing resistance, combination therapy is increasingly used for treatment of carbapenem-resistant and MDR GNR [221].

Several meta-analyses of randomized controlled studies, some of them done before the present era of increasing resistance, concluded that there was similar all-cause mortality in febrile neutropenic patients treated with a beta-lactam vs. the same beta-lactam plus an aminoglycoside as empirical or definitive therapy [148, 259, 260]. However, owing to the small numbers of cases of infection due to resistant bacteria, a benefit of combination therapy could not be ruled out for those patients who were critically ill or were infected with *Pseudomonas aeruginosa* or some other resistant pathogen [148, 259, 260].

In a recently published prospective multicenter study which compared empirical therapy with piperacillin–tazobactam with or without tigecycline in high-risk neutropenic patients with hematologic malignancies, the combination therapy proved to be more effective, including in patients with bacteremia and clinically documented infections [261].

A retrospective study reviewed patients with hematological malignancies or post-HSCT, who were infected by ESBL- or AmpC-producing Enterobacteriaceae or resistant *Pseudomonas*, most of whom were empirically treated with combination of a beta-lactam and an aminoglycoside. Mortality was lower among those patients whose pathogen was sensitive in vitro to either the beta-lactam or the aminoglycoside, compared with those whose pathogen was resistant to both (OR, 1.8; 95 % CI, 1.3 to 2.5) [87].

Carbapenem-containing combinations were associated with significantly reduced mortality compared to non-carbapenem-containing regimens in a retrospective analysis of 138 patients who received treatment for infections due to carbapenemase producing *Klebsiella pneumoniae* when the carbapenem MIC for the infecting organism was ≤4 mg/L [122]. Patients infected with CRKp who received combination therapy, especially with a combination of tigecycline, colistin, and meropenem, had lower mortality as compared to monotherapy treated group [262]. Combination antibiotic therapy improves the likelihood that at least one component agent is active in patients with severe sepsis or septic shock associated with GNR bacteremia [263].

The combination of a carbapenem and colistin was successfully used in SOT patients infected with CRKp and XDR *Acinetobacter baumannii* [116, 189, 195]. This combination was associated with improved survival in XDR *Acinetobacter baumannii* infections and decreased chance of development resistance to colistin as compared to other combinations [189]. In a recently published case-control study in critical patients in ICU infected with carbapenem resistant GNR, mainly *Pseudomonas aeruginosa*, combination therapy had been used significantly more often in survivors compared with non-survivors (32.1 % vs. 7.8 %, $p < 0.01$) [264].

Rifampin was considered for addition to other active antibiotics in the treatment of uncontrolled infection due to MDR bacteria [211, 240, 250, 265–267]. However, a randomized, open-label clinical trial, which enrolled 210 patients with life-threatening infections due *Acinetobacter baumannii* that were susceptible only to colistin showed that 30-day mortality was not reduced by addition of rifampicin [268]. Similarly, another randomized controlled study comparing colistin to combination of colistin and rifampin for VAP caused by *Acinetobacter* did not show significant differences in mortality [269]. Other problems with rifampin include its toxic potential and drug interactions, a main concern especially in transplant patients who receive a lot of other drugs concomitantly (such as cyclosporine, mycophenolate mofetil, antifungals, antivirals) [268].

Although several studies reported on the improved outcome in patients who received combination therapy, mainly including colistin, a summary of the studies (12 retrospective cohort studies or case series, two prospective observational studies and two randomized controlled studies) did not demonstrate difference in mortality between colistin alone and colistin–carbapenem combination therapy for the treatment of carbapenemase-producing GNB or carbapenem-resistant GNR [270].

Two randomized controlled studies are currently recruiting patients, comparing colistin–carbapenem combination therapy versus colistin monotherapy for invasive infections caused by MDR and XDR-GNB, will clarify this issue (NCT01732250, NCT01597973).

Aerosolized colistin can be considered as an adjunctive therapy for MDR infections causing pneumonia. A successful use of 100–150 mg colistin, administered via a Respirgard II nebulizer, as part of combination therapy for nosocomial pneumonia caused by MDR *Pseudomonas aeruginosa* was described [271]. Potential concerns over aerosolized colistin include development of resistance to the antibiotic [272]. In a retrospective study which compared treatment of colistin-only susceptible GNR bacteria with intravenous (IV) colistin vs. aerosolized colistin in adjunction to IV colistin, patients who received the adjunction therapy had a higher clinical cure rate required fewer days of mechanical ventilation after VAP onset [225].

21.5 Prevention

A meta-analysis of 109 trials performed during 1973–2010 reported that antibiotic prophylaxis, especially with quinolones, in afebrile neutropenic patients significantly reduced all-cause mortality [273]. Antibacterial prophylaxis with a fluoroquinolone (levofloxacin or ciprofloxacin) to prevent bacterial infections was recommended for adult SCT patients with anticipated neutropenic periods of 7 days or more. Antibacterial prophylaxis is generally started at the time of stem cell infusion and continued until recovery from neutropenia or initiation of empirical antibacterial therapy for fever during neutropenia. The prophylaxis should not be continued after recovery from neutropenia. Quinolone prophylaxis, however, has to be reconsidered in the situation of growing resistance. Local epidemiological data should be carefully considered before applying fluoroquinolone prophylaxis and once it is applied, the emergence of resistance in bacterial pathogens should be monitored closely because of increasing quinolone resistance worldwide [54]. Prophylaxis efficacy may be reduced when the prevalence of fluoroquinolone GNR bacillary resistance exceeds 20 % [274, 275]. Although a meta-analysis of 27 studies, published at 2007, reported on nonsignificant increase in colonization by quinolone-resistant bacteria under quinolone prophylaxis [276], later studies reported that infections which emerge under quinolone prophylaxis can be caused by MDR bacteria, necessitating use of broader spectrum antibiotics for treatment [277, 278]. Possible benefit of quinolone prophylaxis has to be considered based on local epidemiology and resistant data and if prophylaxis is discontinued—outcome of bacterial infections has to be closely monitored.

21.5.1 Prevention of Resistance

Efforts to reduce antibiotic resistance among transplant patients must address two directions: limitation of use of broad spectrum antibiotics and disruption of spread of resistant bacteria.

Heavy antibiotic use has been constantly reported as one of the main factors for development of resistant bacteria. Limitation of unnecessary use of broad spectrum antibiotics is important to reduce the spread of resistance.

The ECIL group has proposed guidelines for empirical antibiotic therapy in the era of growing resistance [279]. Initial antibiotic regimen has to be targeted on the most prevalent bacteria at the center, unless the patient is seriously ill at presentation or is known to be colonized or previously infected with resistant bacteria. Differential approaches should be implemented for febrile neutropenic patients based on their presentation, knowledge on colonization/previous infection with resistant bacteria and local epidemiology in each center. An escalation strategy is recommended for patients with uncomplicated presentation, who are unknown to be colonized or previously infected with resistant bacteria, in centers where infections due to resistant pathogens are rarely seen at the onset of febrile neutropenia. Such patients should be treated empirically with either anti-pseudomonal cephalosporins (cefepime, ceftazidime), or beta lactam-beta lactamase inhibitors (piperacillin–tazobactam, ticarcillin–clavulanate, cefoperazone–sulbactam) or combination of piperacillin and gentamicin. Usage of carbapenems and combinations should be avoided in such patients. Modifications of the initial regimen at 72–96 h should be based on the patient's clinical course and the microbiological results. The ECIL guidelines defined situations in which use of carbapenems and combination therapy is justified (de-escalation approach), specifically in seriously ill patients, e.g., presentation with septic shock; those known to be colonized or previously infected with resistant bacteria or in centers with a high prevalence of infections due to resistant bacteria at the onset of febrile neutropenia. This de-escalation approach has to be followed by discontinuation of combination therapy or switch to a narrower-spectrum regimen in patients who were stable since presentation and in whom resistant bacteria was not isolated, especially if fever normalized.

The empirical antibacterial treatment can be discontinued at ≥72 h irrespective of neutrophil count or expected duration of neutropenia in patients without evidence of clinically or microbiologically documented infections, who are hemodynamically stable since presentation and afebrile ≥48 h [280]. The patient should be kept hospitalized for at least 24–48 h under close observation if he is still neutropenic when antibiotic therapy is stopped. If fever recurs, antibiotics should be restarted urgently. This strategy aims to limit exposure to broad spectrum antibiotics and combinations, and also duration of antibiotic treatment, minimizing the collateral damage associated with antibiotic overuse, and the further selection of resistance.

Promising new diagnostic techniques enabling rapid (within few hours) identification of ESBL and carbapenemase-producing bacteria, with high sensitivity and specificity, may contribute to avoid of overuse of carbapenems [281–283]. The problem is that these tests should be applied on positive blood cultures, meaning that still ~24 h (ideally) will pass from the onset of infection until the result of these tests will be available. These tests can miss some carbapenemases in some bacteria (e.g., OXA-48, *Pseudomonas aeruginosa*) and they do not detect carbapenem-resistant bacteria due to mechanisms other than carbapenemases (e.g., reduced permeability of the outer membrane associated with overexpression of chromosomal or acquired AmpC and/or ESBL [284–286].

Antibiotic stewardship is crucial to use antimicrobials in such a way that each and every patient receives the most efficacious and safe antimicrobials to treat their infections, while at the same time minimizing the ecologic impact of

antimicrobials used [287]. Five main principles of antibiotic stewardship in HSCT patients were defined [288]:

1. Local surveillance of antibiotic resistance, antibiotic consumption and patient outcomes, including monitoring reports;
2. Multidisciplinary protocols and algorithms on the diagnosis, prevention and treatment of infections should be developed in collaboration of oncologists, infectious disease specialists, and medical microbiologists and updated to reflect changes in bacterial antimicrobial susceptibilities in the unit;
3. Swift reporting of positive clinical cultures and implementation of rapid techniques for bacterial identification and resistance patterns by the microbiology laboratory to control the duration of treatment and to facilitate reassessment of the antibiotic therapy;
4. Optimization of dosing regimens using pharmacodynamic principles;
5. Frequent multidisciplinary rounds including discussion of patient histories and interactive, bedside education on antimicrobial drug use and infection control.

Infectious control is crucial to prevent spread of resistant bacteria between patients within department, as well as between departments in the hospital and between hospitals. Antimicrobial resistance is a worldwide problem. Transportation of patients between departments in the same hospital, as ICU, surgery and transplant ward, between different hospitals, as well as medical tourism, contributes to the spread of resistant bacteria across the borders. Horizontal transmission of ESBL-producing *Klebsiella*, from patient to patient, via the hands of staff members has been very well documented [289–291]. Interventions to prevent and control the spread of MDR bacteria include hand-hygiene measures; active screening of patients with cultures; contact barrier precautions; enforcement of isolation criteria for patients colonized or infected with multidrug-resistant organisms; the use of single rooms for HSCT recipients; cohorting of infected patients; environmental cleaning and anti-infective stewardship [288, 292, 293]. Bundles including combination of multiple interventions were efficient for containment of carbapenem-resistant Enterobacteriaceae [99, 291]. Avoidance of contact with resistant *Pseudomonas* infected patients is important to prevent MDR *Pseudomonas* acquisition in lung transplant recipients [194].

Rapid detection and isolation of patients colonized with resistant bacteria can limit its spread. Novel molecular-based diagnostic screening tests enable simultaneous detection of several resistant bacteria directly from swab samples with high sensitivity, specificity, positive predictive value, and negative predictive value and results available in 24 h [294, 295].

Decolonization of patients colonized with CRE with oral aminoglycoside or colistin was successful in 37–68 % of patients, although the appropriate dose has to be determined and there is concern that those who remained colonized will be colonized with resistant bacteria after de-colonization [296–301].

Transmission of microorganisms from an infected brain-dead donor can cause severe, sometimes fatal infection in the SOT recipient, even if appropriate therapy is provided [115, 302, 303]. On the other hand, the donor pool is limited and increasing numbers of donors have underlying diseases, and may be infected with MDR bacteria. Investigation of donors for CRE carriage by suitable approaches (e.g., rectal swabbing) would seem mandatory, especially in areas where CRE are endemic [302]. A systematic approach for the acceptability of organs from donors infected with MDR bacteria was suggested, based on expert opinion [304]. The algorithm includes screening for MDR GNR in potential donors, who are at risk for MDR infection. If a donor was found to be colonized/infected with MDR bacteria, prophylactic antibiotic treatment should be initiated to donor and to recipient, with the appropriate agent according to susceptibility testing. Two conditions are contraindication to SOT: (1) if the donor has MDR bacteremia (2) lung transplantation from donor infected/colonized with MDR bacteria for which no adequate antibiotic treatment for pneumonia exists [304].

21.6 Summary

Infections caused by GNR are increasingly common in transplant recipients; they can cause severe, life-threatening diseases. Prevention approaches, early diagnosis, appropriate empiric therapy based on local epidemiology and proper targeted therapy are crucial for patients survival. There is a global problem of growing resistance among GNR and it compromises prophylaxis and treatment options. Previous colonization and exposure to antibiotics are the most important risk factors for the development of resistance. Treatment of carbapenem-resistant GNR is challenging; in some cases, the only treatment options include old antibiotics (polymyxins and fosfomycin), tigecycline, and aminoglycosides. All these options have efficacy, resistance, and/or toxicity issues. Development of new treatment modalities is an important goal. Continuous monitoring of the local epidemiology and antimicrobial stewardship is mandatory for optimization therapy with the currently available drugs. Infectious control is crucial to limit the spread of resistance.

Typical and Atypical Mycobacterium Infections After Hematopoietic Stem Cell or Solid Organ Transplantation

Jo-Anne H. Young and Daniel J. Weisdorf

22.1 Bacteriology

Mycobacteria share the staining characteristic referred to as *acid fastness* [1]. These include the organisms causing tuberculosis (*Mycobacterium tuberculosis* and *Mycobacterium bovis*) and a variety of other mycobacterial species of varying pathogenicity and clinical importance. The term *acid-fast bacilli* is, practically speaking, the identifying feature of mycobacteria, although some other non-mycobacterial microbes, notably *Nocardia*, are variably acid fast.

From a clinical standpoint, mycobacteria can be divided into the following four broad classes: *Mycobacterium tuberculosis* complex (*M. tuberculosis*, *M. bovis*, *M. bovis-BCG*, *M. africanum*, *M. microti*, and *M. canetti*), *Mycobacterium avium* complex (*M. avium* and *M. intracellulare*), Hansen's disease (leprosy, *M. leprae*), and the rest. The last class is also referred to as nontuberculous mycobacteria (NTM), atypical mycobacteria, or anonymous mycobacteria [2]. The organisms of *M. tuberculosis* complex can be differentiated from other mycobacteria by their in vitro culture characteristics, including slower growth (typically >10 days); lack of pigment; niacin production; and, most often, sensitivity to isoniazid (INH). The atypical mycobacteria grow more rapidly, usually lack niacin production, produce heat-resistant catalase in large amounts and are highly resistant to INH. In stained preparations, *M. tuberculosis* demonstrates serpentine cord formation, whereas nontuberculous atypical mycobacteria orient randomly. Using the culture characteristics of NTM, Timpe and Runyon [1, 3] proposed a useful method of classification based on colony characteristics, the rate of growth in culture, and pigment production. The four major groups are referred to as photochromogens, scotochromogens, nonchromogens, and rapidly growing mycobacteria. More sophisticated methods have been used to speciate mycobacteria in culture. These include DNA hybridization methods that use highly specific DNA probes, polymerase chain reaction (PCR)-based sequencing, computer-assisted gas liquid chromatography, or matrix assisted laser desorption-time of flight mass spectrometry (MALDI-TOF MS) [4–7]. These techniques can readily speciate mycobacteria, but they are time and labor intensive, they require pure cultures, and they generally have been available only in specialized laboratories. However, their clinical application, especially MALDI-TOF MS, is becoming more widespread, thus allowing the rapid early identification of mycobacterial species growing in vitro.

22.2 Epidemiology and Pathogenesis

M. tuberculosis is an aerobic, nonspore-forming, nonmotile, and slow-growing bacillus with a lipid-rich cell wall. Humans are the only known reservoir of this organism. Almost all infections are caused by the inhalation of infectious particles aerosolized by coughing, sneezing or talking. *M. tuberculosis* can survive only for extremely short periods outside the human body. Fomites, therefore, are rarely responsible for transmitting infection. *M. tuberculosis* rarely, if ever, has a commensal presence. The isolation of *M. tuberculosis* from pathologic specimens should therefore always be considered evidence of infection.

Atypical mycobacteria are free-living organisms that are ubiquitous in nature. They have been found in soil, water, domestic and wild animals, milk, and fruit products. They have been known to colonize body surfaces and secretions and they frequently can contaminate clinical specimens from the environment [8–11]. Therefore, unlike *M. tuberculosis*, in which the isolation of even a single colony is considered evidence of infection and is always viewed as clinically significant, atypical mycobacterial species may colonize body surfaces and secretions for prolonged periods without causing disease. Differentiation between contamination, colonization, and disease is often difficult. Guidelines have been proposed to facilitate making such decisions [12, 13]. Characteristics of a clinically significant atypical mycobacterial infection include a clinical presentation compatible with atypical mycobacterial infection; the culture of the pathogen from a normally sterile site, such as cerebrospinal or pleural fluid or a liver biopsy specimen; and/or repeated isolation of potential mycobacterial pathogens from nonsterile

P. Ljungman et al. (eds.), *Transplant Infections*, DOI 10.1007/978-3-319-28797-3_22

sites. The isolation of a species not known to cause human disease should be considered of clinical importance, because the clinical site sampled had some signs or symptoms of infection, particularly in an immunocompromised host.

Atypical mycobacterial infections may occur more often in the compromised host because immune deficiency contributes to the pathogenesis of mycobacterial infections. In the presence of normal host immune function, the organization of lymphocytes, macrophages, and Langerhans giant cells results in granuloma formation and the containment of infection [14]. When host immunity is compromised, the tissue reaction can be minimal or nonexistent, and uncontrolled proliferation of mycobacteria can continue without granuloma formation [15] or any effective means to control infection. Patients undergoing blood and bone marrow or solid organ transplantation require potent, and often prolonged, immunosuppressive therapy. These patients, therefore, have an increased risk of a variety of infections, including mycobacteria [16]. Furthermore, because the host response to these infections is limited, these patients may often present with atypical features, making the diagnosis difficult and the response to therapy suboptimal [16].

22.3 Immune Defects in Transplant Recipients That Are Permissive for Mycobacterial Infection

The incidence of mycobacterial infections is higher in transplant recipients than that observed in the general population. However, the rate in hematopoietic stem cell transplantation (HCT) recipients is not as high as that seen in solid organ transplant recipients. This may be due, at least in part, to the prolonged and often lifetime duration of immunosuppression in the solid organ recipients compared with that for the usual HCT recipient. Marrow allograft recipients typically recover adequate immune function in 9–12 months, unlike organ transplant recipients who experience immunosuppression for several years or throughout their lives. Therefore, the transient immune compromise experienced by HCT recipients may induce only a limited risk period of infection compared with that of organ allograft recipients.

Therapeutic immunosuppression to prevent graft rejection creates a permissive milieu for mycobacterial replication. The ideal immunosuppressive agent, which would prevent graft rejection while preserving antimicrobial immunity, is unavailable. Although agents differ in their mechanism of action and the aspects of immune function that they affect, all agents have increased infection risk as one of their major side effects.

Corticosteroids are commonly included in most immunosuppressive regimens to prevent graft rejection. The spectrum of host defense defects induced by corticosteroids includes the suppression of macrophage function; the blunting of acute inflammation; the inhibition of the T-cell activation cascade yielding impaired cellular immunity; and impaired antibody production [17–19]. Corticosteroid effects appear to be dose dependent, although a threshold dose below which immune function is unaffected is not apparent [20, 21].

Azathioprine, a purine analogue, has been a common component of immunosuppressive regimens for preventing organ allograft rejection, although less often used in recent years. After its in vivo conversion to 6-mercaptopurine, it inhibits purine nucleotide synthesis, thereby preventing antigen-induced lymphocyte proliferation and leading to impairments in natural killer cell activity, generation of cytotoxic T-cells and antibody production by B-cells [22]. In addition, azathioprine is myelosuppressive, and the resulting leukopenia further adds to infection risk.

Cyclosporine A, which was introduced in the early 1980s, has had a major impact on the prevention of graft rejection and improvement in graft survival rates. Unlike corticosteroids and cytotoxic agents, cyclosporine has a narrowly focused effect on T helper cells, while sparing cytotoxic T-cell function [23]. Its major action is to block the antigen-induced T-cell expression of lymphokines, including interleukin (IL)-2, IL-3, IL-4, interferon gamma, and tumor necrosis factor-α [24, 25]. Natural killer cells and macrophages are probably unaffected by cyclosporine. Unlike azathioprine and other cytotoxic agents, cyclosporine does not result in bone marrow suppression.

Patients on immunosuppressive regimens containing cyclosporine are at a lower risk of infection than those on non-cyclosporine immunosuppressive regimens [26, 27]. The risk of mycobacterial infections in cyclosporine-treated patients also appears to be less than in noncyclosporine-treated patients [28], although randomized comparative studies reporting the risks of mycobacterial infections are not available. Tacrolimus is nearly ten times more potent than is cyclosporine, and it has a similar, but distinct mechanism of action. The risk of infection in tacrolimus-treated patients is expected to be similar to that observed in cyclosporine-treated patients.

Other agents have been broadly applied for prevention of rejection in solid organ transplantation and graft-versus-host disease (GVHD) prophylaxis after HCT. Mycophenolate mofetil is a prodrug of mycophenolic acid with potent immunosuppressive capacity. It selectively and reversibly inhibits inosine monophosphate dehydrogenase and thereby blocks the de novo pathway of purine synthesis in lymphocytes. It has recognized additive and synergistic immunosuppressive activity with calcineurin inhibitors (cyclosporine and tacrolimus). Due to its lesser myelosuppressive activity it has frequently replaced methotrexate in GVHD prophylaxis for reduced intensity conditioning HCT and is widely used following umbilical cord blood grafting. Its broad T-cell immunosuppressive effects augment risks of infection, but no specific relationship to mycobacterial infection has been recognized.

Sirolimus is now broadly applied to prevent kidney and liver rejection and has promising activity in GVHD prophylaxis. It is a naturally occurring compound from a soil fungus and in addition to its immunosuppressive properties, sirolimus has antifungal, antiviral and antineoplastic properties, although limited in potency. Similar in mechanism of action to calcineurin inhibitors, sirolimus additionally binds to FK-binding protein 12 and then complexes with mammalian target of rapamycin (MTOR) to blunt T cell activation and proliferation. It inhibits IL-2 driven signaling from the T cell receptor and has activity limiting dendritic cell activation through reduced antigen uptake, cellular maturation, intracellular signaling, and apoptosis. Its side effects include modest impairment of renal function, but it induces hyperlipidemia and in combination with calcineurin inhibitors, increases risks of thrombotic microangiopathy. Although its broadly immunosuppressive capacity could augment infection, no specific reports of its relation to mycobacterial infection are available.

Antilymphocyte globulin, antithymocyte globulin, alemtuzumab, and monoclonal anti-T-cell antibodies (OKT3) have long been used for the treatment of graft rejection. Reports indicate a significant increase in the incidence of bacterial and viral infections with the use of these agents. One report suggests that OKT3 use led to a mycobacterial infection [29]. However, specific data on the effect of these agents on mycobacterial infections are not available [30–32].

22.4 Screening and Secondary Chemoprophylaxis

Screening for latent tuberculosis infection is recommended prior to organ transplantation [33, 34]. Transplant candidates at risk for reactivation of latent tuberculosis can be readily identified during the pretransplantation evaluation based on residence in endemic areas or a history of exposure to tuberculosis. These transplant candidates should undergo tuberculin skin testing (TST) or testing with an ex vivo interferon-gamma release assay (IFGRA) such as T-spot or QuantiFERON-TB Gold [35–38]. TST alone is an imperfect identifier of high-risk patients, because as many as 80 % of transplant candidates may be skin test anergic [39, 40]. For example, the QuantiFERON-TB Gold IFGRA test measures the release of interferon-gamma in fresh heparinized whole blood in response to stimulation of synthetic peptides representing two proteins present in *M. tuberculosis*: early secretory antigenic target-6 and culture filtrate protein-10 [41, 42]. It distinguishes between active pulmonary tuberculosis and nontuberculous mycobacterial infections [43].

In the general population, QuantiFERON-TB Gold has 96–99 % specificity that is unaffected by prior bacille Calmette-Guérin vaccination [44, 45]. In a study of 153 patients with chronic liver disease awaiting transplantation, 37 (24 %) had a positive TST and 34 (22 %) had a positive QuantiFERON-TB Gold assay, with overall agreement between the tests of 85 % [46]. Discordant test results were noted in both directions: 12 TST positive patients had negative QuantiFERON-TB Gold assays, whereas nine patients with positive QuantiFERON-TB Gold assays had negative TST. Indeterminate QuantiFERON-TB Gold assays were found among patients with low lymphocyte counts and high model for end-stage liver disease (MELD) scores. There is a need for caution when interpreting a negative QuantiFERON-TB Gold test in an endemic country, as illustrated by a case of tuberculosis that developed in a liver transplant recipient in Italy [47].

Positive QuantiFERON-TB Gold testing, in the setting of negative TST, frequently anticipates the booster phenomenon, helping to explain the discordance between the two tests [48]. In the setting of a pretransplant evaluation, which may occur over several days and is not amenable to serial TST testing, performing both TST and QuantiFERON-TB Gold testing may be helpful in finding most cases of latent tuberculosis infection.

Previous bacille Calmette-Guérin immunotherapy has been reported to result in reactivation after transplantation [49–51]. INH chemoprophylaxis has been suggested for patients with previous bacille Calmette-Guérin vaccination, but definitive data to quantify the risk posed by previous bacille Calmette-Guérin vaccination or the benefit of INH chemoprophylaxis are scant. INH chemoprophylaxis can be withheld if there is negative QuantiFERON-TB Gold assay for a transplant candidate with previous vaccination [45].

Chemoprophylaxis with INH should be given prior to transplant for all TST-positive or Quantiferon-positive candidates. In randomized trials in transplant recipients from India and Pakistan, INH prophylaxis effectively prevented tuberculosis [52–54]. One report from Turkey indicated that none of the 77 HCT patients treated with INH developed active tubercular infection, while five of the 274 other patients studied developed active peritransplantation mycobacterial infection [55]. Programs in Pakistan [53] and in Turkey [55] give INH to all TST-negative HCT recipients for 6 months, with a reduction in the development of active tuberculosis. Specifically, in liver transplant candidates at risk for infection after transplantation, INH chemoprophylaxis used during candidacy does not adversely affect hepatic function [56, 57].

INH chemoprophylaxis that starts before transplantation is continued to complete 6–12 total months continuous therapy [58]. The course can be completed prior to transplant if possible, but it is not a contraindication to proceed with transplantation while completing therapy [49, 59]. It is more practical to complete this course before the transplantation period for renal transplant candidates on renal replacement therapy [60], where there are prolonged wait list times. INH prophylaxis is safe for renal, lung and liver transplant candidates, and it would probably be effective prior to heart transplantation as well [52, 56, 61, 62].

Potential problems with INH therapy include liver toxicity (drug-induced hepatitis, especially in older individuals), neuropathy, drug interactions with medications such as cyclosporine, and the possibility of selecting out INH-resistant organisms. INH does not affect the bioavailability of cyclosporine in renal transplant recipients such that dosing changes are necessary [63]. INH therapy may be interrupted in transplant recipients who develop liver function abnormalities, a particularly common problem in the HCT and liver transplant settings. Tuberculosis prophylaxis with levofloxacin in liver transplant patients is associated with tenosynovitis [64].

Donor screening is performed in countries where tuberculosis is endemic. A report from Turkey found a 23 % rate of TST reactivity among both HCT donors and intended recipients [49]. A report from a Mexican program notes screening of all potential donors [65].

Transmission of tuberculosis by the transplanted organ, although rare, has also been documented [66–69]. Two separate cases of multidrug-resistant tuberculosis occurred in lung transplant recipients who probably acquired the disease from the donor [66, 67]; one of these cases required pulmonary resection for control of the infection [67]. Quinibi et al. suggest INH prophylaxis for TST-negative recipients of organs from TST-positive donors [40].

One report of tuberculous meningitis following travel to an endemic area 4 years after transplant suggests prophylaxis during travel [70]. This cannot be substantiated by other cases.

22.5 Hematopoietic Stem Cell Transplants

22.5.1 Epidemiology

Patients receiving allogeneic or autologous HCT are severely immunocompromised because of their underlying condition, the pretransplantation chemotherapy and radiation therapy and by the later development of GVHD and its prolonged, intensive immunosuppressive therapy. A variety of typical and atypical mycobacterial infections have been described in these patients [71–85]. However, even though the literature describing mycobacterial infections in HCT recipients is small, studies have not shown a high incidence of mycobacterial infections (summarized in Table 22-1). There is no information regarding the relative impact of stem cell source and conditioning regimen on risk.

Navari et al. reported seven mycobacterial infections (approximately 1 %) in their series of 682 patients with acute leukemia who received allogeneic bone marrow grafts [74]. Four pulmonary and three extrapulmonary infections with *M. tuberculosis* or atypical mycobacteria were observed. In a report from the M. D. Anderson Hospital that was published in 1984, Kurzrock et al. reported three patients (3.3 %) with mycobacterial infections in a series of 90 allogeneic bone marrow transplantations for hematologic malignancies or aplastic anemia [83]. Two infections were with *M. tuberculosis*, and one was with *Mycobacterium avium-intracellulare* complex. The two patients with *M. tuberculosis* infections were from Latin America, a high prevalence area for tuberculosis. The authors of this report emphasized the difficulties in making a specific diagnosis due to the unusual presentations, which often involved more than one pathogen.

A study from the University of Minnesota reviewed the experience with mycobacterial infections after bone marrow transplantation over a 20-year period [73]. Eleven mycobacterial infections (0.49 %) were diagnosed in 2241 recipients of allogeneic (9 of 1486) or autologous (2 of 755) HCTs. Two patients with *M. tuberculosis*, two with *M. avium-intracellulare complex*, and seven with infections caused by rapidly growing, atypical mycobacteria (e.g., *Mycobacterium fortuitum* or *Mycobacterium chelonae*) were described.

Other reports describing tuberculosis in allotransplant recipients from areas where the infection is more endemic have been reported. Tuberculosis develops in 1.4–3.5 % of allograft recipients, both pulmonary and extrapulmonary [77–79, 85]. In China, tuberculosis infections were diagnosed in 9 (3.1 %) of the 295 transplant recipients, from 45 to 165 days after transplantation [78]. Multivariate analysis revealed that a previous history of tuberculosis and total body irradiation increased the risk of tuberculosis in HCT patients (relative risk, 4.8 and 12.5, respectively) [78]. In Taiwan, while 1.9 % of HCT recipients developed newly diagnosed TB, the 10-year cumulative incidence was 3.5 %, and those with TB had a higher mortality rate than recipients without TB [85]. Independent risk factors for TB included adult age and GVHD [85].

Several additional case reports of both typical and atypical mycobacterial infections in HCT recipients have been published [15, 51, 55, 72, 76, 79, 82, 84, 86–90]. These reports emphasize the low incidence and the variety of unusual presentations of mycobacterial infection in HCT recipients and the generally successful treatment outcome with appropriate therapy. Even in Turkey, where the prevalence of tuberculosis is much higher, HCT recipients have relatively few active infections, especially with the judicious use of INH prophylaxis [55].

Atypical mycobacterial infection prior to transplant is not necessarily a contraindication to transplant [91]. A patient with chronic myeloid leukemia who developed a disseminated infection involving the liver with *Mycobacterium avium* complex was successfully treated 2 years prior to transplant. The patient underwent allogeneic bone marrow transplantation from a human leukocyte antigen (HLA)-matched sibling donor. The antimycobacterial prophylaxis given during transplant included ciprofloxacin and clarithromycin to day 100.

22.5.2 Clinical Manifestations and Diagnosis

Atypical presentations make the recognition of mycobacterial infections in HCT recipients difficult. These patients are severely immunocompromised and often neutropenic, which

can mask a febrile response and can obscure a granulomatous reaction. The presenting features are nonspecific, and they are related to the site of infection. In a review of mycobacterial infections in 2241 transplant recipients over a 20-year period, the clinical manifestations of mycobacterial infection included unexplained fever, pulmonary infiltrates, osteomyelitis, and central venous catheter tunnel inflammation [73]. The most common manifestation of mycobacterial infection in these patients was central venous catheter-related infection, which occurred in 6 of 11 patients. Atypical, rapidly growing mycobacteria caused all of the central venous catheter–related infections. Reports from other blood and marrow transplantation centers have described a similar spectrum of mycobacterial infectious syndromes [15, 55, 72, 76, 79, 83, 84, 86, 88, 92]. A large series from Seattle indicated that less than 1 % of patients were infected with atypical mycobacteria, with nearly all (21 of 23) experiencing catheter-related infections that resolved with therapy and removal of the catheter [72].

Invasive procedures may be required to obtain diagnostic material for culture or histopathology. Because the laboratory diagnosis of mycobacterial infection requires specific cultures that are often held for prolonged periods [4, 5], a high index of suspicion is required to request the appropriate diagnostic studies specifically to identify these infections. HCT recipients often have multiple coexisting infectious pathogens that can mask the existence or the significance of mycobacterial isolates. Although mycobacterial infections are uncommon in HCT recipients, they should be considered in all apparently affected HCT recipients, particularly those at high risk because of previous tuberculosis exposure, a positive TST or QuantiFERON-TB Gold test, residence in endemic area, or ethnic background.

22.6 Solid Organ Transplants

22.6.1 Immune Defects in Solid Organ Transplant Recipients

Several factors contribute to the incidence of infection in solid organ transplant recipients [93–124]. These patients are often immunosuppressed because of their underlying condition (e.g., uremia, liver failure, or malnutrition). In addition, therapeutic immunosuppression to prevent graft rejection is lifelong and is probably the most important factor contributing to infection in transplant recipients. The risk is likely exaggerated in those requiring boosted immunosuppression for episodes of rejection.

22.6.2 Epidemiology

Mycobacterial infections are more common in recipients of solid organ transplant than stem cell transplant (Table 22-2). In contrast to HCT recipients, solid organ transplant recipients typically remain immunosuppressed for long periods or for life. Consistent with this is the observation that mycobacterial infections generally occur later and more frequently in organ transplant recipients compared with patients who receive HCTs. Infections were diagnosed a mean of 48 months following transplantation, with rare infections being reported as late as 269 months after transplantation [108, 109]. In some, but not all, reports from heart transplant recipients, early infections have been noted [104, 110]. This contrasts with the experience in HCT recipients, in whom many infections occur early in the course of the transplantation [73]. A higher incidence of *M. tuberculosis* and nontubercular mycobacterial infections has been reported in renal transplant recipients than in the general population [125]. Three US renal transplantation centers [105, 106, 120] reported a 0.5–0.7 % incidence of tuberculosis, compared with that of 0.01 % in the general population [126]. In contrast, centers in areas endemic for tuberculosis report much higher incidences that range from 3.5 to 11.8 % [40, 93, 98, 100, 107]. Patients undergoing liver or heart transplantation also have higher rates of mycobacterial infections than do the general population; the reported incidences varied between 0.5 and 2.7 % [28, 39, 104, 127–129].

Nontuberculous mycobacterial infections after solid organ transplantation have been published mainly as case reports, which prevent a reliable estimation of the incidence of such infections in these patients. These are usually caused by *M. avium-intracellulare* complex [102, 103, 112], *Mycobacterium kansasii* [94, 102], *M. abscessus* [130], *M. chelonae* [103], and *M. fortuitum* [94, 131] and, rarely, by other species [116, 130, 132–134]. Their diagnosis is most frequent within the first year after transplantation [135], but it can be as late as 11 years after transplantation (mean of 3.5 years) [121, 136]. Patients present with isolated pulmonary infections, cutaneous lesions, tenosynovitis, joint infections, empyema, enteritis, or surgical wound infection.

22.6.3 Clinical Manifestations and Diagnosis

Tuberculosis and atypical mycobacterial infections often demonstrate unusual features in immunocompromised patients. Patients often present with nonlocalized, systemic symptoms. Studies of tuberculosis in organ transplant recipients consistently show a high proportion of patients—as many as 63 %—with nonpulmonary or disseminated tuberculosis [16, 40]. Extrapulmonary presentations include meningitis [39, 98, 99], peritonitis [114], lymphadenopathy [99], liver abscess [39, 111], disseminated intravascular coagulation [39], pericarditis [137], cutaneous abscesses [138], and renal tuberculosis. In one study, 20 % of renal transplant recipients had a fever of unknown origin [100]. Some patients may be asymptomatic, and the infection may be diagnosed incidentally or, rarely, at the postmortem examination [107].

Because of nonspecific clinical manifestations, the diagnosis of mycobacterial infections in organ transplant recipients can be difficult. Patients receiving immunosuppressive therapy

[a]Report from an area of high prevalence of tuberculosis.

[b]*M. tuberculosis* only reported.

[c]Not speciated.

have a blunted inflammatory response, so the characteristic granulomatous reaction to mycobacteria may not be seen. Patients may often have coexistent infectious and noninfectious complications that can add to the difficulty in diagnosis [40, 104]. A high index of suspicion is therefore crucial to performing an appropriate diagnostic workup and requesting mycobacterial cultures. Invasive procedures may often be necessary to obtain diagnostic material [98, 108, 139].

Patients who develop liver failure from INH may go on to orthotopic liver transplantation, and will require the remainder of their antituberculous treatment course in the months immediately following transplantation. In three cases, liver transplantation performed for progressive hepatic failure was successful [140, 141]. Even multidrug resistance was not a contraindication to liver transplant [141]. A modified antituberculous drug regimen was used while taking standard doses of immunosuppressive drugs.

22.6.4 Treatment

As in the general population, the treatment of tuberculosis in transplant recipients involves therapy with combination antimycobacterial agents [142]. Most centers use a combination of INH with or without rifampin for at least 12 months. One or two additional drugs, such as ethambutol or pyrazinamide, are often included in the treatment program for the first 2–3 months. Despite continuing immunosuppression, reports indicate that HCT recipients with tuberculosis respond to standard antimycobacterial therapy, but extensive data on the clinical and bacteriologic responses are not available.

The optimal duration of antituberculous therapy in these patients is controversial. Therapy is usually given for 12–18 months [142]. Limited experience suggests that a shorter treatment duration, similar to therapy in immunocompetent hosts, may be adequate. Successful outcomes with a 9-months regimen have been recorded in renal transplant recipients with localized pulmonary tuberculosis [100, 102, 123, 143].

Some drugs used to treat tuberculosis can have important side effects and drug interactions in HCT recipients. INH may cause transplant-related liver toxicity, and it must often be discontinued in the immediate posttransplantation period. Rifampin, a hepatic cytochrome P-450 enzyme inducer, can accelerate cyclosporine metabolism, resulting in subtherapeutic drug levels and increasing the risk of GVHD or graft rejection [144]. In posttransplant patients, rifampin-containing regimens are often avoided. Comparative efficacy data on which recommendations regarding the choice of therapy of tuberculosis in organ graft recipients to base are unavailable. The clinical setting, the frequency of drug resistance in the community, and in vitro sensitivities should guide therapy, but nonrifampin-containing regimens generally need to be administered for longer periods [119].

Multidrug-resistant tuberculosis occurs in several endemic areas around the world, including the USA and Europe. A case of multidrug-resistant tuberculosis in a Chinese double-lung transplant recipient was probably acquired from the donor [66]. Tenosynovitis was noted in a heart transplant recipient in France [145]. Reactivation of pulmonary tuberculosis acquired 10 years prior to heart transplant, while the patient was incarcerated [146], was resistant to both INH and rifampin during susceptibility testing. A report of drug-resistant tuberculosis in a bone marrow transplant recipient had a good result to second line therapy [147]. A renal transplantation center in India reported a high incidence of primary drug-resistant tuberculosis [148]. INH resistance was seen in 7 of 23 and rifampin resistance in 5 of 23 M. *tuberculosis* isolates from 727 renal allograft recipients [148]. This suggests that multidrug-resistant infections are likely in patients who come from communities harboring a large reservoir of drug-resistant *M. tuberculosis*. Patients residing in areas where drug-resistant tuberculosis rates are high should begin treatment with four antituberculous drugs, such as INH, rifampin, ethambutol, and pyrazinamide, until antimicrobial susceptibility results are available. The duration of therapy should be prolonged for 18–24 months in patients with drug-resistant tuberculosis.

Treatment of atypical mycobacterial infections is dictated by the identified species. Coverage with a macrolide and a fluoroquinolone is used until susceptibilities are ready. Remembering that atypical mycobacteria are often not susceptible to the agents typically used to treat tuberculosis is important. Furthermore, the drug susceptibilities of atypical mycobacteria are often unpredictable. Therefore, in vitro drug sensitivity assays should always be performed, and treatment should be revised if resistance to any of the drugs being used is demonstrated.

In general, antituberculous therapy in transplant recipients is effective despite continuing immunosuppression. However, mortality from tuberculous infections in transplant recipients has been reported. The role of temporarily reducing immunosuppression to facilitate antituberculous response has been discussed in the literature without achieving a consensus. Some authors recommend routinely decreasing immunosuppression until febrile illness resolves [110], yet this is rarely done in heart or lung transplant recipients who need higher immunosuppressive drug dosing, particularly in the early posttransplant period. Several investigators, however, report successful treatment of tuberculosis despite continuing immunosuppression.

22.6.5 Secondary Prophylaxis

Because of the lifelong immunosuppression in solid organ transplant recipients, posttreatment prophylaxis with INH has been proposed by some investigators [98]. However, reports of successful treatment in most patients, without a significant incidence of late recurrence, argue against the need for posttreatment prophylaxis. In the liver transplant population, a history

of tuberculosis treated prior to transplant did not lead to reactivation among the 6 of 1116 liver transplant recipients, who were observed for a median of 25.5 months (range 12–82). This study found no rationale for INH prophylaxis in liver transplant recipients with past diagnosis of tuberculosis, when the disease was considered to be inactive [149].

22.7 Conclusion

A clinical strategy of aggressive surveillance in high-risk patients, maintenance of a high index of suspicion, early diagnosis, and prompt treatment is most likely to be effective in limiting morbidity and mortality from mycobacterial infections in transplant recipients.

23
Other Bacterial Infections After Hematopoietic Stem Cell or Solid Organ Transplantation

Lynne Strasfeld and Stephen Dummer

23.1 Introduction

This chapter describes the epidemiology, clinical presentation, diagnosis, and management of infections caused by a diverse group of bacterial pathogens. These include classic opportunistic infections and also infections that are common in immunocompetent patients, but particularly prevalent or morbid in transplant populations. Some uncommon bacterial pathogens that have a predilection for patients with impaired immunity are discussed. Finally, the chapter touches on some miscellaneous bacterial infections that are important because they may be unanticipated in transplant recipients or present diagnostic or therapeutic challenges.

23.2 Gram-Positive Organisms

23.2.1 Listeria Monocytogenes

Listeria are small gram-positive bacilli that produce weak beta hemolysis on blood agar and have characteristic tumbling motility when observed by light microscopy [1]. Isolation from mixed specimens such as stool requires special media or a process called "cold enrichment" that capitalizes on the ability of *Listeria* to grow well at refrigerator temperatures. In clinical specimens, the organisms may appear gram-variable or resemble diphtheroids. Indeed, isolation of a "diptheroid" from the blood or CSF should raise concern for laboratory misidentification of *Listeria*.

Of the seven species of *Listeria*, only one, *L. monocytogenes,* is responsible for almost all cases of listeriosis. This organism is widespread in nature and has been isolated from tap water, sewage, several animals, and multiple foodstuffs including dairy products, fruits, vegetables, fish, and meats [1]. Human exposure to *Listeria* appears to be universal. Gastrointestinal carriage has been documented in about 5% of healthy adults and asymptomatic kidney transplant recipients [1–3].
