FIGURE 43-2. Contrast-enhanced brain MRI. Fifty-two years old liver transplant recipient (R−) with unknown donor toxoplasma serostatus, showing multiple ring-enhancing lesions suggestive of central nervous system toxoplasmosis. Diagnosis of toxoplasma encephalitis (TE) was established by positive polymerase chain reaction (PCR) in the cerebral spinal fluid (CSF).

In the vast majority of patients, toxoplasmosis in the setting of HSCT is the result of reactivation of an infection acquired in the distant past. A pre-transplant seronegative HSCT patient has a very low risk of toxoplasmosis in the first 100 days of the post-transplant period [2, 87, 88]. Toxoplasmosis in allogeneic HSCT patients is most likely the result of reactivation of a previously acquired infection and occurs more frequently in those who have developed GVHD; in autologous HSCT-patients reactivation occurs rarely (see Chap. 42. Toxoplasmosis after Hematopoietic Stem Cell Transplantation).

Toxoplasmosis in heart transplant patients is most likely to occur in the setting of a D+R− mismatch. Most common clinical presentation of toxoplasmosis in heart transplant recipients includes fever, myocarditis, encephalitis, pneumonitis, and multi-organ dysfunction [8, 42, 44, 46, 89–91]. Toxoplasma retinitis, overwhelming sepsis, and asymptomatic seroconversion in heart transplant recipients have been reported [63, 90, 92]. In a large case-series that include non-cardiac SOT recipients (kidney, liver, pancreas, and multivisceral organ transplants), toxoplasmosis manifested most commonly with fever (77%), respiratory manifestations (29%), neurological dysfunction (26%), bone morrow suppression (26%), and chorioretinitis (10%) [9]. Of note, 85% cases developed disseminated disease, most commonly affecting lungs, brain, bone morrow, and central nervous system [9].

43.11 Laboratory Diagnosis

Available laboratory methods for the diagnosis of toxoplasmosis include direct visualization of the parasite by Wright–Giemsa or immunoperoxidase stains, serologic tests, polymerase chain reaction (PCR), and parasite isolation [93] (Table 43-2). In SOT-recipients with suspicion for disseminated *toxoplasma* disease, detection of *T. gondii* by microscopy and/or PCR, can be attempted in several body compartments such as peripheral blood, bronchoalveolar fluid (BAL), cerebrospinal fluid (CSF), vitreous fluid, ascitic fluid, pleural fluid, bone morrow aspirates, and histologic tissue sections. Of note, conventional stained tissue sections (e.g., hematoxylin and eosin stain) hardly demonstrate tachyzoites. This limitation is easily overcome by the use of immune-peroxidase stain, which uses antisera to *T. gondii*. The immune-peroxidase methods are highly sensitive and

TABLE 43-2. Laboratory diagnosis of toxoplasmosis in transplant patients

Identification of tachyzoites by microscopy
Wright–Giemsa and *T. gondii*-specific immunoperoxidase stains of any body fluid or a "touch" preparation slide of any tissue or biopsy specimen
Identification of tissue cysts in histopathology samples
Hematoxylin and eosin or *T. gondii*-specific immunoperoxidase stains of any tissue or biopsy specimen. Numerous cysts or an associated strong inflammatory response is highly suggestive of toxoplasmosis and not simply *T. gondii* infection
Polymerase chain reaction
T. gondii DNA amplification of the *B1* gene or REP-529 multicopy gene. PCR can be performed in any body fluid including peripheral blood, cerebrospinal fluid, bronchoalveolar lavage fluid, vitreous fluid, aqueous humor, and peritoneal, pleural, or ascitic fluids. PCR can also be performed in tissues, but this method has not been standardized
Serologic tests consistent with a recently acquired T. gondii infection
All transplant candidates and donors should undergo serologic testing for *T. gondii*-specific IgG and IgM antibody tests before transplantation. Positive IgM test results should be sent for confirmatory testing to a reference laboratory specialized in the diagnosis of toxoplasmosis (e.g., Palo Alto Medical Foundation Toxoplasma Serology Laboratory http://www.pamf.org/Serology/). Serologic test results, confirmed by a reference laboratory, that are consistent with a recently acquired infection (e.g., within 3 months of sera sampling) should trigger consideration for treatment of the donor or recipient or postponing the transplant procedure. Serologic tests performed post-transplant may not be accurate
Parasite isolation
Attempts to isolate *T. gondii* can be performed in tissue culture or the peritoneal cavity of animals. Establishing the strain of the parasite may have clinical and prognostic implications
Lymph-node histology
Demonstration of characteristic lymph-node histology can also be used for the diagnosis of toxoplasmosis

specific; and can be applicable to unfixed or formalin-fixed paraffin-embedded tissue sections [94].

The symptoms and/or conventional epidemiologic factors associated with acute *T. gondii* infection are often absent in patients who have been already infected. Thus, if it is clinically important to establish an exposure to *T. gondii*, routine serologic or other tests should be performed regardless of the present illness or epidemiologic history.

43.11.1 Diagnosis of Latent *T. gondii* Infection

Because toxoplasmosis is usually associated with high morbidity and mortality (particularly when diagnosed late), does not have pathognomonic clinical manifestations, and can be treated effectively if diagnosed early, each transplant candidate and donor should be tested before transplantation for *T. gondii*-specific IgG and IgM. Initial serologic testing for *T. gondii*-specific IgG and IgM antibodies can be performed at nonreference or commercial laboratories, but all positive or equivocal IgM test results should be sent to a reference laboratory (e.g., Palo Alto Medical Foundation *Toxoplasma* Serology Laboratory, PAMFTSL; Palo Alto, CA; http://www.pamf.org/serology/;+1-650-853-4828; Toxolab@pamf.org). Transplant candidates and donors that are *Toxoplasma* IgG and IgM negative do not have serologic evidence of prior exposure to *T. gondii* and should be considered to be at extremely low risk for developing toxoplasmosis. Transplant candidates and donors who are *Toxoplasma* IgG positive and IgM negative have been infected for at least 3 months and are at risk for *Toxoplasma* reactivation if they are liver, kidney, pancreas, multivisceral, or HSCT transplant recipients. Reactivation in heart, heart–lung, and lung transplant recipients occurs rarely. Donors who are IgG positive and IgM negative, however, pose a serious risk to their seronegative (*Toxoplasma* IgG and IgM negative) recipients (D+R− mismatch) in the setting of heart, heart–lung, liver, kidney, and kidney–pancreas transplants.

43.11.2 Diagnosis of Acute *T. gondii* Infection and Toxoplasmosis

Serologic test results consistent with a recently acquired infection are diagnostic of acute *T. gondii* infection and highly suggestive of toxoplasmosis in the symptomatic patient but are seldom found in the transplant population. However, an attempt to establish whether the transplant patient has a recently acquired infection should always be attempted by testing the patient's serum for *T. gondii*-specific IgG and IgM antibodies prior to transplantation. If serological testing is performed after transplant, results should be interpreted in light of the results obtained in the pre-transplant period. Acute infection or toxoplasmosis should be suspected in any patient with an equivocal or positive result in any IgM antibody test. A reference laboratory should confirm whether a positive IgM antibody test result is indicative of a recently

acquired infection. Specialized testing at PAMF-TSL includes IgA, IgE, AC/HS, or differential agglutination and IgG avidity assays [93]. Only 40% of positive IgM test results in the USA are confirmed at PAMFTSL to be consistent with a recently acquired infection. If the transplant candidate or donor is confirmed to have a recently acquired infection (e.g., within 3 months of sera sampling), anti-*Toxoplasma* treatment or postponing transplantation (or both) is strongly advised and should be seriously entertained.

The diagnosis of toxoplasmosis from reactivation of a latent infection in transplant patients is rarely established by serologic tests alone. In fact, increasing *T. gondii*-IgG titers and even IgM, can be observed in the absence of clinical manifestations for toxoplasma reactivation. Additional laboratory methods should be used, including stains to visualize the tachyzoite, techniques (e.g., PCR) to amplify *T. gondii* DNA, histological methods to identify characteristic pathological findings or tissue cysts, and parasite isolation.

Visualization of the tachyzoite in any body fluid or tissue is pathognomonic for the diagnosis of toxoplasmosis (in the setting of primary infection or reactivation of a latent infection) and should never be interpreted as a manifestation of latent *T. gondii* infection. In contrast, tissue cysts may simply represent a chronic infection, and in the case of an ill patient, toxoplasmosis may not be the etiology of the patient's syndrome despite the presence of cysts. However, in those cases, the presence of "numerous" cysts or a strong inflammatory response suggests that toxoplasmosis is responsible for the patient's symptoms.

The diagnosis of toxoplasmosis can also be made by PCR of any body fluid (e.g., peripheral blood, cerebrospinal fluid, bronchoalveolar lavage fluid, vitreous fluid, aqueous humor, and peritoneal, pleural, or ascitic fluids). PCR can also be performed in tissues, but this method has not been standardized. The most commonly used gene target is the multicopy B-1 gene. However, the REP-529 multicopy gene has been shown to be more sensitive that the B-1 gene [95]. Quantitative PCR to measure *T. gondii* burden in sequential body compartment samples (peripheral blood, CSF, and BAL) correlates well with favorable clinical response to anti-*toxoplasma* therapy and allows modulation of the immunosuppressive drug regimen [71, 96]. For maximum reliability, clinical samples should be sent to reference laboratories experienced in performing this assay.

Attempts to isolate the parasite from any body fluid or tissue, as clinically indicated, can be attempted at reference laboratories (e.g., PAMF-TSL). If positive, strain typing and genotyping can be used to further study the emerging concept that correlates certain strains with more aggressive disease. Characteristic lymph-node histology can also be used to diagnose toxoplasmosis [97].

43.12 Treatment

Asymptomatic or symptomatic acute *T. gondii* infection or reactivation of a latent infection should be treated immediately in the transplant patient. One hundred percent mortality is observed in SOT patients if toxoplasmosis is left untreated or if treatment is initiated too late. Treatment is also indicated for the transplant candidate and donor with asymptomatic or symptomatic acute infection if transplantation is scheduled to occur within 6 months of the primary infection. In general, higher doses are indicated for the post-transplant immunocompromised patients (Table 43-3). The drug regimen should always include at least two drugs. Pyrimethamine is probably the most active drug against *T. gondii* and is best when used in combination with sulfadiazine. However, studies of TE in AIDS patients reveal that trimethoprim/sulfamethoxazole (TMP/SMX) is equivalent to pyrimethamine/sulfadiazine [98, 99], and according to experienced clinicians, these findings, thus far, translate to the transplant population. Primary therapy should be extended for 6 weeks with longer treatment duration for patients with equivocal clinical or radiographic responses. Following primary toxoplasma therapy, secondary prophylaxis or chronic maintenance (at half-treatment doses) is recommended for SOT-recipients. Duration of secondary prophylaxis must be individualized according to the net-state of immunosuppression and tailored to the perceived risk of toxoplasma reactivation but should be given at least for 1 year.

43.13 Prevention

43.13.1 Primary Prophylaxis for D+/R− SOT-Patients

The (D+R−) SOT-recipients are ideal candidates for anti-*Toxoplasma* primary prophylaxis. TMP/SMX and atovaquone, primarily used by transplant physicians to prevent *P. jirovecii* pneumonia (PCP), have been successful in preventing toxoplasmosis. Effective regimens include one single-strength TMP/SMX tablet daily, one double-strength TMP/SMX tablet thrice a week, or 1500 mg atovaquone daily, with duration of therapy ranging from 3 months to lifelong [45, 48, 49, 51]. Other drug regimens used to prevent PCP (e.g., pentamidine or dapsone alone) are not effective in preventing toxoplasmosis. D+R− SOT-patients have developed toxoplasmosis when TMP/SMX has been discontinued or switched to pentamidine in the post-transplant period and when toxoplasmosis prophylaxis was not addressed [50, 60, 69, 96]. Pyrimethamine (25 mg/day) has also been reported to be effective for D+R− solid organ transplant patients [46]. In high-risk SOT-recipients

TABLE 43-3. Drugs used for the treatment of acute or reactivated toxoplasmosis in transplant donors, candidates, and recipients (primary therapy)[a]

	Transplant donors and candidates with asymptomatic or symptomatic acute infection including clinically active ocular disease, myocarditis, myositis, or hepatitis	Transplant recipients[b] with asymptomatic or symptomatic acute infection or reactivation of latent infection
Preferred regimen		
Pyrimethamine (PO)	50 mg every 12 h for 2 days followed by 25–50 mg daily	200 mg loading dose followed by 50 mg (<60 kg) to 75 mg (>60 kg)/day
Folinic acid[c] (PO)	10–20 mg daily (during and 1 week after therapy with pyrimethamine)	10–20 mg daily (up to 50 mg/day) (during and 1 week after therapy with pyrimethamine)
plus		
Sulfadiazine (PO)	75 mg/kg (first dose) followed by 50 mg/kg every 12 h maximum 4 g/day	1000 (<60 kg) to 1500 mg (>60 kg) every 6 h
or		
Clindamycin (PO or IV)	300 mg every 6 h	600 mg every 6 h (up to 1200 mg every 6 h)
or		
Atovaquone (PO)	1500 mg orally twice daily	1500 mg orally twice daily
Trimethoprim/sulfamethoxazole (PO or IV)	10 mg/kg/day (trimethoprim component) in two to three doses	10 mg/kg/day (trimethoprim component) divided in two to three doses (doses as high as 15–20 mg/kg/day have been used)
Alternative regimens		
Pyrimethamine/folinic acid	Same doses as above	Same doses as above
plus		
Clarithromycin (PO)	500 mg every 12 h	500 mg every 12 h
or		
Dapsone (PO)	100 mg/day	100 mg/day
or		
Azithromycin (PO)	900–1200 mg/day	900 to 1200 mg/day

Preferred regimens: pyrimethamine/sulfadiazine/folinic acid or trimethoprim/sulfamethoxazole.

[a]Assistance is available for the diagnosis and management of patients with toxoplasmosis at the Palo Alto Medical Foundation Toxoplasma Serology Laboratory; +1-650-853-4828; toxolab@pamf.org; http://www.pamf.org/serology/.

[b]After the successful use of a combination regimen during the acute/primary therapy phase, the same agents at half-doses are usually used for maintenance or secondary prophylaxis.

[c]Folic acid should not be used as a substitute for folinic acid (leucovorin).

(D+R−), prophylaxis with TMP-SMX should be extended beyond 6 months in patients that received antilymphocyte therapies, patients with chronic CMV infection, history of PCP or those who have undergone treatment for acute allograft rejection [100–102].

For patients in whom appropriate toxoplasma prophylaxis cannot be given, weekly screening using peripheral blood toxoplasma PCR for 100 days following transplantation, can be considered for D+R− heart transplant patients and R (+) non-cardiac SOT. PCR-positive patients should subsequently be offered effective toxoplasma treatment.

43.13.2 Primary Prevention for the Seronegative Transplant Candidate, Donor or Recipient

Transplant candidates and recipients who do not have serologic evidence of prior exposure to *T. gondii* should be aware of the known risk factors for acute infection. They should adopt basic measures to decrease their risk for exposure to *T. gondii* as much as possible (Table 43-4). Similarly, the same preventive measures apply to seronegative potential donors prior and during the transplant procedure.

TABLE 43-4. Preventive measures to decrease the risk of acute *T. gondii* infection

Reduction of risk of Toxoplasma infection from ingestion of food or water
Cook food to safe temperatures. Do not sample meat until it is cooked. Red meat should be cooked to 160 °F. Whole poultry should be cooked to 180 °F (measured in the thigh)
Peel or wash fruits and vegetables thoroughly before eating
Wash cutting boards, dishes, counters, utensils, and hands with hot soapy water after contact with raw meat, poultry, seafood, or unwashed fruits or vegetables
Freeze meat for several days before cooking to greatly reduce chance of infection
Avoid ingestion of dried, smoked, or cured meat
Avoid eating raw oysters, clams, and mussels
Refrain from skinning animals
Reduction of risk of Toxoplasma infection from the environment
Avoid drinking untreated drinking water
Wear gloves when gardening and during any contact with soil or sand because it might be contaminated with cat feces that contain *T. gondii*
Wash hands thoroughly after gardening or contact with soil or sand
Keep outdoor sandboxes covered
Feed cats only canned or dried commercial food or well-cooked table food, not raw or undercooked meats
Avoid changing cat litter if possible. If no one else can perform the task, wear disposable gloves and wash your hands thoroughly with soap and water afterwards
Litter box should be changed daily if you own a cat. *T. gondii* does not become infectious until 1–2 days after it is shed in the feces
Keep cats indoors
Avoid adopting or handling stray cats, especially kittens

Parasites After Hematopoietic Stem Cell or Solid Organ Transplantation

Marcelo Victor Radisic and Laura Linares

There are more than 300 parasitic species known to infect humans, but only 5 % have been reported to occur in transplant recipients [1]. Parasitic infections are, in general, neglected diseases, closely related to low socio-economic conditions and poor access to healthcare. World-developing areas suffer most of the burden of parasitic diseases; they also perform a limited number of transplants [2]. This may be one of the reasons to explain scarcity of information on parasitic infection in transplantation, which is mostly based on random case reports, small cohorts, and occasional case-control studies. However, parasitic infections—which may have a deep impact in transplantation outcomes—are increasingly recognized in the industrialized world, and its incidence is expected to grow due to multiple circumstances: Many geographic areas where parasitic infections are prevalent have now active organ transplantation programs; patients from endemic areas with subclinical infections are sometimes referred to transplantation centers in industrialized countries and some patients from developed countries undergo transplantation in highly endemic areas and return home infected; and immigrants from highly prevalent areas are accepted for blood and organ donation without a thorough search for endemic diseases. Also, the use of immunosuppressive regimens without cyclosporine (and without its antiparasitic effect) [3] may partially explain this situation. Lastly, increased levels of leisure travel may enhance risk of exposure when transplant recipients travel to endemic areas.

This chapter addresses the most relevant reported parasitic infections in the transplantation setting.

44.1 Tissue and Blood Protozoa

44.1.1 American Trypanosomiasis (Chagas Disease)

Chagas disease is caused by *Trypanosoma cruzi*, a hemoflagellate protozoan parasite. In 80 % of cases, transmission is vector-borne. However, the infection can also be acquired by contaminated/unscreened blood transfusion (5–20 %), by an infected mother to her fetus (0.5–8 %), by laboratory accidents, sporadically by oral transmission, and by organ transplantation [4, 5].

T. cruzi has a complex life cycle that includes mammals and insect vectors. The vector density and housing standards account for the prevalence of the disease, but immigration from rural to urban communities and also to non-endemic areas has led to an increased non-vector transmission-related risk.

In humans, the disease has an acute and a chronic phase. The acute stage can be asymptomatic or can present only mild clinical symptoms such as a malaise, fever, anorexia, and/or lymphadenopathies, which usually resolve spontaneously in ~8–12 weeks [6]. Acute Chagas disease mortality rate (usually related to acute myocarditis or meningoencephalitis) is 2–6 % [7].

In the acute phase, *T. cruzi* invades different host cells and tissues (e.g., macrophages, cardiomyocytes, fibroblasts, and neurons), producing severe inflammation, but the host's immune response usually leads to parasite control and resolution of this acute phase. However, without specific treatment, the immune response is ineffective to eradicate the infection, and patients become chronically infected with the parasite. The lifelong chronic phase has a long period of clinical latency—the so-called chronic stage without demonstrable pathology [8] (previously called indeterminate phase)—which can last 10–30 years or even lifelong. The infection is evident only by positive serology with intermittent and extremely low levels of parasitemia [9]. About 20–30 % of infected patients in the chronic stage, after several years without symptoms, may progress to symptomatic disease, developing Chagasic cardiomyopathy (90 %), and less frequently, gastrointestinal (15–20 %) [9] and peripheral nervous system disease (~10 %) [10]. The diagnosis of infection in the acute phase relies on the direct identification of the parasites, which are usually present in high titers in blood. Motile *Trypanosomas* can be detected using microscopic examination of the buffy coat, thin or thick blood films stained with Giemsa; or by a concentration method [7] (Strout method [11] or microhematocrit).

P. Ljungman et al. (eds.), *Transplant Infections*, DOI 10.1007/978-3-319-28797-3_44

In the chronic phases of the disease, the parasitemia level is low and intermittent, and tissue parasitism is scarce [12]. In this stage, although direct parasite detection can be achieved by blood cultures or xenodiagnosis, these are time-consuming, labor intensive methods, with a sensitivity of less than 50 % [6, 13] making their use impractical and of little or no clinical utility. Low level parasitemia in the chronic phase can be detected by blood polymerase chain reaction (PCR)-based assays, with sensitivity reaching 100 % with repeated sampling [13].

However, the method of choice for Chagas diagnosis in the chronic phase is the detection of circulating antibodies against *T. cruzi* [14]. The most commonly used methods are the enzyme-linked immunosorbent assay (ELISA), indirect hemagglutination (HA), and indirect fluorescent antibody (IFA) test. Sensitivity and specificity are best for ELISA (94–100 % and 96–100 %, respectively), IFA (98 %; 98 %), and particle agglutination (97–100 %; 97–99.5 %) assays, and they are the recommended methods for screening [15]. FDA-licensed screening test for blood or organ donors includes Ortho *T. cruzi* ELISA Test System [16] and ABBOTT PRISM Chagas chemiluminescent immunoassay (ChLIA) with sensitivities and specificities also close to 100 %.

However, in endemic countries, health agencies still recommend that at least two different methods of testing must be positive for a diagnosis of Chagas disease to be reached [7, 17]. Radio-immunoprecipitation (RIPA), Western Blot, immunoblot, and IFA have the highest specificity and sensitivity, and are considered confirmatory tests [7, 15].

During the 1960s and 1970s, two drugs were introduced for treatment: nifurtimox and benznidazole. When these are administered for 30–60 days, both achieve parasitic cure in 60–100 % of acute cases, but cure rates among adults when the disease is in the chronic phase are far lower, in the range from 15 % to 35 % [18].

The adverse side effects of these drugs include dermatitis, peripheral polyneuropathy, weight loss, gastrointestinal disease, hematologic disorders, and an increased incidence of lymphoma [19]. Benznidazole is considered as first-line treatment, because it is better tolerated than nifurtimox; however, some patients tolerate nifurtimox better than benznidazole [20]. Although neither drug is approved in the USA, both can be obtained from the Centers for Disease Control and Prevention (CDC) [21].

Posaconazole and ravuconazole show activity against *T. cruzi*, however, clinical trials investigating treatment of chronic indeterminate Chagas disease revealed their inferiority to the current standard-of-care benznidazole [18, 22].

Allopurinol has trypanocidal properties and may also have a role in Chagas treatment, alone [23] or combined with benznidazole [24].

44.1.1.1 Chagas in Solid Organ Transplantation (SOT)

Chagas endemic area extends from southern USA to northern Argentina in America. However, due to international migration from the endemic areas, Chagas is on its way of becoming a worldwide-health issue. An estimate of ~300,000 infected immigrants are living in the USA, 48,000–87,000 in Spain, and several thousand in other European countries, Australia, and Canada. These infected immigrants may transmit the infection acting as blood or organ donors [25].

Adventure travel is another way to acquire the infection for people from non-endemic areas.

Reactivation of chronic Chagas disease may occur with immunosuppression therapy. In endemic areas, pretransplant serological test for Chagas is routinely performed in transplantation donors and recipients. Awareness of Chagas transmission in non-endemic countries boosted considering or implementing routine serotesting in patients with increased risk, i.e., people from endemic areas, people whose mothers were born in endemic areas, or people who received blood transfusions in an endemic area [26–29].

Different clinical scenarios can be found in the setting of SOT: the patient that needs heart transplantation because of terminal Chagasic cardiomyopathy; the patient with chronic infection that needs a SOT (because of a disease different from Chagas), and the chronically infected donors.

44.1.1.2 The Chagas-Infected SOT Recipient

Since the 1980s, Chagas infected transplantation candidates in the chronic stage without demonstrable pathology have been accepted for kidney transplantation. More recently, liver and kidney–pancreas transplant has also been performed in chagasic recipients.

In most endemic countries, all transplantation candidates are routinely tested for Chagas seroreactivity during the pretransplantation evaluation. This routine should be considered for all candidates with epidemiological risk (recipients who were born, received a blood transfusion or lived for in an endemic area, or whose mother was born in an endemic area). When serotesting is positive, the patients are diagnosed as chronically infected. The following approaches can be considered in this situation: (1) proceed with transplantation; (2) start the patient on specific treatment, with the assumption that either cure or a decrease in the parasite load will be achieved; or (3) search for actual parasitemia with specific detection tests and treat only those with positive results before transplantation.

Failure to detect circulating parasites should be interpreted with caution because low levels of parasitemia and intermittent parasitemia do occur in the chronic stage of the disease;

hence, the direct methods of parasitic detection are usually negative. In addition, there is no documented evidence that pretransplantation treatment leads to better results and the adverse side effects of specific treatment in patients with terminal organ failure make their use almost impossible [30].

A strict protocol to search for reactivation evidence after transplantation is considered the best approach [30–32]. An adequate follow-up modality entails the sequential monitoring for early parasitemia detection with both direct parasitic methods [33] and real-time PCR methods. These new techniques have enabled early reactivation detection, preceding Strout test positivization and clinical signs [32, 34].

Reactivation has been reported in 22–50 % of **kidney transplant** recipients with Chagas disease; it generally occurs soon after transplantation (i.e., in the first 3 postoperative months) [33, 35] but it has also been found as late as 36 months, following immunosuppression intensification [36].

Most reactivated cases have parasitemia with positive Strout tests, but with no clinical manifestations of disease or increase in antibody levels. Severe disseminated disease is highly infrequent, but anecdotal cases of meningoencephalitis [37], tumor-like brain lesions [38], and acute myocarditis [39] have been described. The development of a febrile illness with painful solitary or multiple subcutaneous nodules has been the most frequently described clinical feature of the reactivated illness [33, 35, 36]. Lesions can take different forms—erythema nodosum–like, panniculitis, and ulcers (see Figure 44-1) and are predominantly located in the upper and lower extremities [40]. On histopathologic examination, nodules show nests of intracytoplasmic amastigote parasites that confirm the etiology of the disease. Subcutaneous nodules are not a frequent manifestation of Chagas disease in immunocompetent hosts, and their relatively high incidence in SOT patients could be interpreted as an indication that the reactivation is pathogenically dependent on the tissue pseudocyst reservoir activity [41]. Reports on Chagas disease in kidney transplant recipients lack extensive discussions on the relationship between reactivation and the immunosuppressive regimens, but reported patients received cyclosporine or tacrolimus-based triple therapy; polyclonal or anti-CD3 monoclonal antibodies have been used as induction treatment in many of these cases. The relationship with rejection treatment has not been analyzed in the published reports. Risk of reactivation may correlate with the net state of immunosuppression; therefore, keeping the immunosuppression to a minimum in SOT patients with Chagas disease would be beneficial. Benznidazole (10 mg/kg/day) or nifurtimox (15–20 mg/kg/day) has been administered for 30–60 days. Remission of skin lesions and the disappearance of parasitemia are usually obtained in <2 weeks, without further reactivations documented on long-term follow-up [33, 36].

FIGURE 44-1. Skin lesions caused by *T. cruzi* in a kidney transplanted patient.

The experience with **liver transplantation** in chronic Chagas disease is scant. Reactivation has been reported in fewer than 20 % of cases, and it seems to follow the same pattern as in kidney transplantations—parasitemia or subcutaneous nodules with a good response to treatment [42–44].

If liver transplantation is performed in patients with Chagas disease, careful monitoring for possible reactivation—which includes testing for parasitemia and performing biopsies of any subcutaneous lesion—should be implemented.

44.1.1.3 Chagas and Heart Transplantation

Chagas disease is an important cause of end-stage cardiomyopathy in endemic areas. Patients with chagasic cardiac disease are mostly young men who have a life expectancy of 6–13 months from the onset of heart failure [45]. Although Chagas disease was initially considered a relative contraindication for heart transplantation—because of the potential for reactivation in the setting of immunosuppression—it was later demonstrated that patients with chronic Chagasic cardiomyopathy with heart transplantation had higher survival rates than patients who were transplanted because of other heart conditions [45]. Heart transplantation is now routinely performed for this otherwise fatal condition.

Heart transplantation programs in Latin America—mainly in Brazil and in Argentina—have accepted patients with chronic Chagas disease for heart transplantation for the last 25 years [45, 46]. Cardiac chagasic disease is the underlying disease in 35 % of heart transplantations performed in Brazil [47] and 13 % of those performed in Argentina [31]. In the USA, a non-endemic country, seropositive rates in patients with non-ischemic dilated cardiomyopathy who were born or lived for more than a year in endemic area reach up to 19 % in certain areas [48, 49], and so far, 17 patients have been transplanted for Chagasic cardiac disease in the USA [50]. Patients who undergo heart transplantation for Chagasic cardiomyopathy should have a rigorous follow-up protocol, aimed at early detection of parasitemia, which may allow anticipation to clinical reactivation and damage to the heart graft or non-cardiac tissues.

Serial monitoring with microscopy of blood samples and PCR for *T. cruzi* may allow early parasitemia detection, before clinical disease development. PCR-based detection of parasitic DNA has revealed variable levels of sensitivity and specificity, and, among other factors, these variations may be related to parasite's high genetic variability, (which has been the basis to classify it into six Discrete Typing Units (DTUs), TcI to TcVI) [51]. Specificity and sensibility is improved combining 2 o 3 PCR with different genetic targets. A multicenter study for validation of PCR procedures for detection of *T. cruzi* in human blood samples described that the four best performing methods have a sensitivity of 83.3–94.4 % and a specificity of 85–95 % [52].

There is a growing amount of evidence supporting the value of PCR testing for early diagnosis of Chagas reactivation in heart transplanted patients, preceding Strout test positivization and clinical signs. Real-time PCR-based strategies allow measuring parasitic load growth, pre-emptive therapeutic management, and monitoring treatment efficacy [34, 46].

The main clinical features of Chagas reactivation are fever, myocarditis, subcutaneous infiltration with nodules, and rarely disseminated disease [46, 53, 54]. Chagas disease with myocarditis must be differentiated from rejection. On a preliminary observation of endomyocardial biopsy specimens, this may prove to be a difficult challenge [55] because the endomyocardial biopsy specimens show lymphocytic infiltrates with edema and areas of necrosis in both situations. Agent identification provides the diagnosis. Polyclonal antibodies against *T. cruzi* or its antigens (immunohistochemistry) and tissue-based PCRs have been used for diagnostic purposes [56]. PCR sensitivity may differ regarding whether they amplify nuclear (nPCR) or kinetoplast (kPCR) *T. cruzi* DNA. Negative tissue-PCR seems to have a high negative predictive value for Chagas myocarditis, while only nPCR (and not kPCR) may have a positive predictive value [57]. The risk of Chagas reactivation seems to be related to the amount of immunosuppression [53, 58]. Although the use of mycophenolate mofetil (MMF) for maintenance immunosuppression [54, 58], number of rejection episodes and neoplasms have been described as risk factors for reactivation [58], the significance of these findings has been questioned [59]. Patients with reactivated Chagas disease respond very well to benznidazole treatment (10 mg/kg/day for 60 days); nifurtimox could also be effective, but its side effects are considerable. Allopurinol may be considered for treatment because it has good in vitro activity against *T. cruzi* [60]; there is anecdotal experience of its use (dose 600–900 mg/day for 2–3 months) to treat reactivation following heart transplantation, apparently with good results and no side effects [61, 62]. Parasitemia clearance and remission of clinical manifestations are usually obtained in the first treatment week. Some patients may experience relapse—some even several times and many years after transplantation—after the first reactivation episode, with parasitemia or clinical manifestations; however, these individuals have had good responses to the new treatment courses [53, 63]. Mortality related to Chagas disease reactivation has been reported to be 0.3 %, and the survival rates are better than those observed patients who were transplanted because of non-Chagasic cardiac diseases [45].

44.1.1.4 Chagas and Hematopoietic Stem Cell Transplantation (HSCT)

Chagas disease in HSCT may occur due to reactivation of a latent infection [64] (previously acquired by vector-borne transmission, blood transfusion, or congenital transmission); by de novo infection transmitted by blood transfusion during HSCT, or by infection transmitted by the graft. Few patients with Chagas disease have ever undergone HSCT [65–67]. All HSCT candidates at risk for Chagas (Donors or recipients who were born, received a blood transfusion or lived in an endemic area, or donor or recipient whose mother was born in an endemic area) should be serologically screened before they start conditioning chemotherapy. Positive serology is not a contraindication for recipients, but positive donors are not accepted [68] or are accepted only in exceptional circumstances [69]. Patients at risk for Chagas reactivation should be systematically monitored for parasitemia (with PCR—as the most sensitive method—and/or direct methods) and clinical manifestations. Even in non-endemic countries, unknown *T. cruzi* carriers may serve as blood donors. Considering the number of immigrants from endemic countries, a definite possibility does exist that a blood donor may unknowingly be infected. It has been estimated that about 100 million people may be at risk of acquiring the infection this way [7]. Therefore, even outside endemic areas, Chagas disease should be considered in patients with HSCT and unexplained febrile illness [70]. In fact, the first report of Chagas disease in a bone marrow transplant recipient came from Spain; in that instance, the source might have been a blood donor [71]. In patients with chronic Chagas disease, reactivation has been described in 16.6 and 40 % of autologous and allogeneic hematopoietic transplants, respectively (after engraftment and, in sporadic cases, even before the bone marrow infusion during the neutropenia that results from myeloablative preparative regimens). The methodical search for parasitemia allows an early reactivation diagnosis, and prompt, specific treatment can then be initiated with excellent results [67].

44.1.1.5 Donors with Chagas Disease

In countries where the disease is endemic, transplantation teams often have to decide whether to accept a donor with Chagas disease or to postpone the transplantation. Almost ~5 % of all deceased donors in Argentina are chronically infected individuals that are diagnosed by serotesting at the

time of organ procuration [31]. The decision should be made balancing the risk of expected mortality in the waiting list against expected morbidity from eventual Chagas transmission. The likelihood of transmission appears to vary by organ type [72].

Transmission by infected donors to seronegative kidney recipients was reported to be from 0 % [73] to up to 18 % [33, 36]. In liver transplant recipients, infection from positive donors was 0 % (with prophylactic treatment with benznidazole) [74] and from 0 % to up to 20 % (without prophylaxis) [31, 75]. When patients were monitored for early transmission detection, treatment with benznidazole was highly effective, with no mortality attributable to Chagas disease. Based on this information, in Argentina, with appropriate informed consent, organs from infected deceased donors are considered acceptable (with exception of the heart) for non-infected or infected kidney recipients and, eventually, for uninfected lung and liver recipients in emergency situations. Infected living donors should receive trypanocidal treatment for 30 days prior to donation to allow clearance of parasitemia. Donation should take place as soon as possible after treatment completion [31].

Reports of transmission by unscreened deceased organ donors [76, 77] and unscreened blood transfusion [71] in non-endemic countries have also been published. Donor screening should be carefully considered in those areas that have a significant immigrant population from endemic areas.

In summary, patients with Chagas disease are acceptable candidates for SOT and HSCT because the incidence of disease reactivation does not seem to be a deterring factor and because its clinical presentation does not have a life-threatening pattern, furthermore, sequential monitoring may allow early parasitemia detection and pre-emptive treatment implementation. The recipients with Chagas infection must be monitored for parasitemia on a sequential schedule for early detection of reactivation (weekly or every 2 weeks for the first 6 months, monthly thereafter after transplantation, and weekly for 2 months after intensification of immunosuppression) [31]. Infected donors are unacceptable for heart transplantation; however, the use of the other organs is acceptable for infected recipients; for uninfected kidney recipients; and, eventually, for uninfected lung and liver recipients in the emergency list. These patients should not only be monitored for disease transmission, but also be fully informed and must provide written consent.

When transplantation is being performed to a non-infected patient who resides in or who moves to an endemic area, this individual has the possibility of being exposed to vector transmission, and acquire post-transplant Chagas infection. This situation has been reported [78]. Possibly, the best approach would be to search for parasitemia at regular intervals. Seroconversion is also diagnostic, but it may be delayed or may not occur at all in these patients.

44.1.2 Leishmaniasis

Leishmaniasis is caused by a heterogeneous group of protozoan parasites, and comprises a variety of clinical syndromes. This zoonotic infection is transmitted by infected sandflies in tropical and subtropical climates in the Mediterranean basin in Europe, Asia, Africa, and America [79].

Clinical forms of leishmaniasis include cutaneous leishmaniasis (CL); mucocutaneous leishmaniasis (MCL); and visceral leishmaniasis (VL). The most severe form is visceral leishmaniasis (VL), which is typically fatal if untreated.

An estimate of 350 million people are at risk of acquiring the infection [80], and approximately 0.2–0.4 million VL cases and 0.7–1.2 million CL cases occur each year [79].

Infection is usually asymptomatic in immunocompetent host. Viable parasites persist lifelong in the host [81], but derangement of cell-mediated immunity may allow reactivation of the disease, which may appear as late as 30 years after the initial infection [82]. As should be expected, disease incidence is higher among the low socioeconomic, immunosuppressed, or malnourished population.

With increased travel and access to advanced medical care in developing countries, the leishmaniasis burden in immunosuppressed individuals will probably continue to rise. The true incidence of the disease is underestimated, especially in hyperendemic regions [79]. Imported leishmaniasis is being increasingly reported in Europe [83–88].

44.1.2.1 Leishmaniasis in Transplantation

Transplanted patients may acquire leishmania infection as primary infection after transplantation takes place; they may have reactivation of latent infection after transplantation; or may acquire the disease from the graft [82, 89]. Clinical manifestations of leishmaniasis in transplant recipients appear similar to those observed in normal hosts, although some atypical features may be present.

44.1.2.2 Visceral Leishmaniasis

Visceral leishmaniasis (VL) is caused by *L. donovani* complex (*L. donovani, L. infantum*, and *L. chagasi*). Leishmaniasis should always be considered as differential diagnosis in patients with fever who live, have lived in endemic areas, or who have a history of travel to them, even in the remote past. Visceral leishmaniasis presents at a median time of ~30 days, but presentation as early as 7 days [82] and as late as 13 years [90] after transplantation has been observed. Reactivation of previously acquired infection is the most frequent disease mechanism in transplanted patients [91, 92]. Visceral leishmaniasis incidence in endemic areas has been described in 0.1–0.5 % of transplanted patients [93] occurring in all types

of transplantations: Kidney [94–96], kidney–pancreas [97, 98], liver [99–101], heart [99, 102], lung [93], and bone marrow [103–108].

The main clinical manifestations are fever, splenomegaly, and pancytopenia [109]. The presenting symptoms are often atypical because anemia and leukopenia may be absent and splenomegaly may develop late in the course of an unnoticed infection [94]. Fever of unknown origin, diarrhea, and malabsorption caused by infiltration of the gastrointestinal tract [110, 111]; interstitial pneumonitis with fever and pancytopenia [112]; and kidney graft's interstitial nephritis [113, 114] may also occur.

Immunosuppression is one of the most important risk factors for overt clinical disease, and can also alter disease presentation and treatment response [115]. High-dose prednisone in the preceding 6 months [93], cytomegalovirus infection after transplantation, and living with cats [93] have been reported as risk factors for VL.

Post–kala azar cutaneous disease may occur in a subset of patients after treatment of visceral leishmaniasis. This condition is characterized by macular, papular, or nodular lesions in the face, trunk, or limbs; amastigotes are present in macrophages within the lesions. Post–kala azar cutaneous disease with distinctive tongue involvement has been reported in two transplant recipients [99, 116].

44.1.2.3 Cutaneous and Mucocutaneous Leishmaniasis

Cutaneous and mucocutaneous presentations are rare in the transplant setting and a protracted time interval may occur between transplantation and disease manifestations [82, 117].

Diffuse cutaneous leishmaniasis and mucosal leishmaniasis (sometimes with exclusive tongue involvement) have been described [118–122].

44.1.2.4 Diagnosis

Even when leishmaniasis is actively sought using appropriate methods, the diagnosis can be elusive, and the examination of multiple samples may be needed [109].

Definitive diagnosis requires the identification of the parasite in a smear or tissue culture (usually bone marrow or spleen). Aspirated material should be inoculated into Novy-MacNeal-Nicolle or other parasitic growth media and the remainder should be used to prepare a Giemsa-stained smear. Culture sensitivity is 60–85 % [123]. Bone marrow microscopy sensibility in transplanted patients is ~98 % [82]. Serological studies (IFA, ELISA, and direct agglutination test) are usually positive in transplanted patients with leishmaniasis (92 %) [82]. However, positive serology does not distinguish past from present infection, and may have cross-reaction with Chagas disease, malaria, and other infections. The recombinant kinesin antigen (rK39) is a useful antigen in ELISA assays achieving high specificity [124] although sensitivity in transplant recipients is currently unknown. Serological results interpretation demands a context of clinical and epidemiological information.

When available, urinary antigen test and PCR techniques are extremely useful. Quantitative or semiquantitative PCR assays have shown a high diagnostic sensitivity in a limited number of patients, allowing measurement of blood parasitic load; therefore, these tests could be used as surrogate markers of disease activity and response to treatment [82].

Cutaneous and mucosal leishmaniasis is best diagnosed by histopathological examination and culture of a small wedge or punch biopsy specimen taken from the margin of the lesion at a site that is not ulcerated; touch preparations should also be performed because their diagnostic yield is often superior to that from the histopathological examination [80]. After a parasite has been identified in tissue samples or culture, speciation can be performed through isoenzyme analysis or species-specific monoclonal antibodies. Quantitative or semiquantitative PCR assays have high diagnostic sensitivity when applied to histopathological specimens [125].

44.1.2.5 Treatment

Visceral leishmaniasis can be treated with amphotericin B, pentavalent antimonial drugs, paromomycin, and miltefosine (the first oral drug for treatment of VL). Liposomal amphotericin has the highest therapeutic efficacy and the most favorable safety profile and should be used whenever possible [126]. Liposomal amphotericin B has been used as the first-line treatment in a small number of kidney transplant recipients (total dose administered was 20–40 mg/kg) with optimal results and no significant toxicity or relapses [127]. Acceptable second-line therapies include conventional amphotericin B deoxycholate or pentavalent antimonial drugs (with close monitoring for toxicity), miltefosine, and paromomycin.

The treatments have several drawbacks such as duration, administration, high costs, and adverse effects. Drug resistance has also been reported, so whether combination therapy could be an alternative needs to be evaluated [128, 129].

Immunosuppression may be temporarily reduced during the initial phase of treatment in severe cases. Bacterial superinfections are a common complication, and they are the important cause of death. Up to 36 % of patients may present bacterial or cytomegalovirus infections [93], and the mortality rate in transplant recipients is nearly 30 %. Patients should be closely monitored because relapse and recurrence may occur in approximately 30 %. Repeated spleen measurement has been proposed as both a marker of cure and a recurrence predictor [109].

Secondary prophylaxis with intermittent weekly amphotericin [130], daily fluconazol [100], and monthly

meglumine antimoniate [99] has been reported. It has also been suggested that allopurinol could be effective to prevent relapses [131].

For cutaneous or mucocutaneous leishmaniasis, pentavalent antimony compounds should be considered first-line therapy for most patients.

44.1.2.6 Prevention

In endemic areas, serological studies of the donor and recipient may allow transmission/reactivation recognition and close monitoring implementation for signs and symptoms of infection. Primary prophylaxis for VL in asymptomatically infected individuals is currently not recommended [132]. A Brazilian study showed that none of the liver transplant recipients who were found to be *Leishmania*-PCR positive at the time of transplantation or received a PCR-positive organ developed VL over a median follow-up of 24 months, without any prophylaxis being given [133]. Protective measures to prevent sandfly bites are recommended for immunosuppressed individuals living in or traveling to *Leishmania*-endemic regions [83].

44.1.3 Malaria

Malaria is an acute febrile disease caused by *Plasmodium falciparum*, *P. ovale, P. vivax*, *or P. malariae*. Recently, *P. knowlesi* was also recognized as a human pathogen [134]. It is the most prevalent vector-borne disease in the world, and endemic in many tropical regions of Asia, Africa, and Central-South America [135]. Estimates of infections ranging between 130 and 390 million, and 2.6 billion individuals at risk of infection [136]. In Europe, an autochthonous malaria outbreak was reported in Greece in 2009 [137].

44.1.3.1 Malaria in Solid Organ Transplantation

Malaria in transplanted patients—a rare event in spite of the disease's high worldwide prevalence—has been related to: blood transfusions, either during the course of the terminal organ failure or in the immediate pretransplantation or post-transplantation period; transmission by the donated organ; reactivation of an old infection, and eventually, *Anopheles* mosquito inoculation. In developed countries, the disease is seldom seen, but it should be considered when looking after transplant recipients who present with an unexplained febrile picture and have resided in or have visited areas where the disease is endemic or have received an organ from a donor living in or originally from such areas. Careful malaria past history investigation is recommended due to the possibility of persistent disease, that can reach many years for *P. falciparum*, *P. vivax*, and *P. ovale* [138] and as long as 44 years for *P. malariae* [139].

Few cases of post-transplantation malaria have been published. It may be speculated that not all diagnosed cases get reported and that the number of post-transplantation malaria cases might grow because of increasing tourism; refugee and immigration movements; and living, unrelated organ donation in countries where the disease is endemic [140]. Transmission from the graft seems to be the main form of acquiring the disease in solid organ transplant recipients [141], although some cases have been traced to blood or blood products transfused to the recipient, even those occurring well before transplantation [142]. In some other cases, the source of malaria has not been clearly established. All of *Plasmodium* species (*P. knowlesi* excepted) have been implicated as the causes of infection in the transplantation setting [140]. Depending on the infecting species, speculation on the pathogenesis of transmission may arise. *P. malariae* infection may persist in the bloodstream for long periods, enabling transmission from an asymptomatic blood or organ donor. *P. vivax* and *P. ovale* hypnozoites may persist in the liver; the infection might be transmitted by a graft liver and a "relapse" of malaria would be seen in the recipient [143]. In addition, if procuration of organs other than the liver occurred during a subclinical relapse of the infection, infected erythrocytes might remain in the allograft despite perfusion and these may be the cause of disease in the recipient [141]. *P. falciparum*-infected erythrocytes have been demonstrated to remain in the capillaries, and reports have indicated that this cytoadherence is resistant to removal by flushing and irrigation at the time of organ preparation for engraftment, thus providing a possible route of infection transmission [144].

Clinical manifestations of the disease have occurred in the early post-transplantation period and have been described in kidney, liver, and heart recipients [141, 143]. In endemic areas, post-transplantation malaria may occur, but the incidence of the disease in transplant recipients is similar to the incidence in the general population [145].

Fever has been reported as the most frequent presenting symptom, but it did not always have the typical paroxysmal or cyclic pattern [146, 147]. Malaria may cause high creatinine levels—that revert with antimalaria treatment—in kidney transplant recipients [147]; and high transaminase levels in liver recipients, making differentiation from rejection critical [143].

Early diagnosis and the specific standard treatment administration are essential for a good outcome [141, 148]. However, serious disease may be observed in *P. falciparum* infection, and when drug toxicities or other infections complicate the clinical course. Special attention may be needed when quinine is used for treatment because it may interfere with cyclosporine, decreasing its blood levels [149].

44.1.3.2 Malaria in Hematopoietic Stem Cell Transplantation

The few reported cases of malaria after HSCT include both autologous [150] and allogeneic transplants [151–157]. The information is anecdotal, originating from case reports only. Although pretransplant screening for malaria does not avoid

the need for clinical surveillance, it could decrease the incidence of transplant-related malaria. Reported cases include patients with geographic exposure and no history of disease [149, 150]; patients and donors with a history of treated disease [155]; patients with no history of disease but with a large number of blood transfusions performed in endemic areas [152]; patients with remote geographic exposure and donors living in an endemic area with negative smears before procuration [153]; and unrelated bone marrow transplants from volunteer donors with a disease history that was undisclosed at the time of donation [151]. Reactivation of infection in bone marrow transplant recipients has also been reported. The diagnosis can be difficult in this particular setting when the aplasia caused by conditioning therapy has not yet reverted. As the number of circulating red blood cells is still low, parasitemia detection by blood smears is more troublesomet. The disease is much more severe in splenectomized patients because the spleen is responsible for removing parasitized cells from circulation.

44.1.3.3 Donor-Derived Malaria

Donor-derived malaria to multiple SOT recipients from a single donor has been reported [158, 159]. Recognition of transmission to one recipient usually raises the alarm to investigate transmission to the others [160]. Donor-derived malaria also may occur in HSCT [154]. When the risk of transmission from an infected donor is acknowledged, recipients should be studied for transmission with the most sensitive technique for parasitemia detection (PCR, and/or blood smears when PCR is not available). Prophylactic treatment is recommended to avoid transmission, or, if asymptomatic donor-derived infection is documented, pre-emptive treatment should be administered [159, 160].

Living donors diagnosed with malaria should be treated before donation to avoid transmission. Deceased donors with malaria should not be accepted.

44.1.3.4 Diagnosis

Malaria diagnosis in transplanted patients is usually made by identifying the parasite in thin or thick blood smears in patients with fever, unexplained hemolysis, and thrombocytopenia [145]. Quantification parasitemia level, expressed as the percentage of infected erythrocytes, is important as a direct correlation exists between parasitic load and disease severity [161]. *Plasmodium* species identification (based on parasite's morphology) is important for choosing specific treatment.

Parasitemia detection by microscopic observation of thick or thin blood smears has been recommended to rule out malaria infection in donors, but false-negative results do occur in asymptomatic patients [162]. Plasmodia antigen detection based on immunochromatography may be negative when parasitic burden is low. DNA detection by PCR is highly sensitive, detecting as few as one parasite per microliter, and allows species identification [163]. Specific antibodies can be investigated by latex agglutination and enzyme-linked and indirect fluorescent antibody assays. Positive antibody titers >1/64 are indicative of current or past infection [139].

44.1.3.5 Treatment

Plasmodium species identification and knowledge of their geographic distribution and sensitivity patterns are essential for decision making. Treatment should be initiated as soon as possible as the disease may be lethal in a transplanted patient. Treatment of choice for severe *P. falciparum* cases is intravenous artesunate, or if not available, intravenous quinine or quinidine administered in conjunction with clindamycin, doxycycline, or tetracycline [164]. *P. vivax, P. malariae, P. ovale*, and uncomplicated *P. falciparum* infection in chloroquine-susceptible regions should be treated with chloroquine. In areas of chloroquine resistance, therapeutic options include atovaquone–proguanil, a quinine-based regimen, or mefloquine [148].

44.1.3.6 Prevention

Routine screening with PCR, serology, or blood smear examination should be implemented for all patients and donors with epidemiological risk. In the absence of laboratory infrastructure, prophylactic treatment might be indicated to reduce the risk of infection [165].

Patients from non-endemic areas traveling to endemic areas should have pre-travel consultation and appropriate chemoprophylaxis to lessen the risk of acquiring malaria [166].

44.1.4 Babesiosis

Babesiosis is a zoonotic disease caused by *Plasmodium*-like protozoans (*Babesia microti, B. divergens, B. duncani,* and *B. MO-1*). Humans are accidental hosts, and transmission may occasionally occur via a tick vector or by blood transfusions. Babesiosis hallmarks are fever and hemolytic anemia. It is usually a mild disease in healthy people, but it can be fatal in asplenic and immunocompromised patients. *B. microti* infection is endemic in some regions of the USA, while *B. divergens* is endemic in Europe. Diagnosis is made through parasitemia detection by PCR or intraerythrocytic parasite identification in thin blood smears, and through serology by indirect immunofluorescent antibody testing [167]. High azithromycin doses (600–1000 mg) combined with atovaquone (750 mg twice daily) may be used for the treatment of immunocompromised patients [168]. Clindamycin and quinine are also effective. Partial or complete exchange transfusion is recommended in case of high

parasitemia (>10%), severe anemia (hemoglobin <10 g/dL), pulmonary, kidney, or hepatic failure [167]. In immunocompromised patients, therapy should be >6 weeks, including 2 weeks after parasites are no longer detected on blood smear [167]. Cases reported in transplant recipients have been traced back to pretransplant blood transfusion in an HSCT recipient [169]; to post-transplant blood transfusion in a kidney recipient [170], and to tick bite in both an SCT recipient [171] and in a splenectomized kidney transplant recipient, years after transplantation [172].

44.2 Worms

44.2.1 Strongyloidiasis

Strongyloides stercoralis is a human parasite, although dogs, cats, and apes can also be infected [173]. An estimate of 80–100 million persons are infected worldwide [174, 175]. The parasite is endemic to the tropics and subtropics, and it has also been reported worldwide excluding only the far north and south [175]. *S. stercoralis* is a nematode with a complex life cycle. Filariform (infective) larvae penetrate human skin and are carried to the lungs through the bloodstream. They reach the bronchial tree and are carried by respiratory secretions to the pharynx and swallowed, entering the small intestine where they can develop into adult worms. *Strongyloides* has the unique ability to complete the entire cycle within one host, thereby leading to autoinfection. In autoinfection, adult female worms within the intestine produce eggs that hatch into non-infective rhabditiform larvae which may subsequently molt into infective filariform larvae. These can then penetrate intestinal mucosa or perianal skin, migrate to the lungs and begin the cycle again. As a consequence, lifelong-parasite persistence in the host can occur despite the absence of external sources of infection [176].

Asymptomatic patients who acquired the infection decades before may develop life-threatening disease in the setting of immunosuppression or immunosuppressive medication.

According to the immunologic response of the host, the clinical spectrum of strongyloidiasis can vary from asymptomatic or mild disease to an amplification of the normal life cycle of the parasite known as ***Strongyloides* hyperinfection syndrome**. The molting of non-infective (rhabditiform) into infective (filariform) larvae is accelerated under immunosuppression, and a massive number of larvae from the intestinal lumen or the perianal skin autoinfect the host, traveling through the venous system to the lung and back to the small bowel. Clinical manifestations of this process are gastrointestinal (abdominal pain, diarrhea, ileus, obstruction, and gastrointestinal bleeding) and respiratory symptoms (cough, dyspnea, wheezing, and respiratory distress syndrome).

Disseminated strongyloidiasis occurs when larvae spread through the venous system to other organs (such as the urinary tract, liver, brain [177], and skin [178]). Complications of disseminated *Strongyloides* include bacteremia and meningitis, usually due to enteric Gram-negative bacteria which are thought to be carried to the lymphatic or mesenteric circulation by their attachment to the infecting larvae [179] or by passing through the disrupted mucosal barriers [176].

44.2.1.1 Strongyloidiasis in Transplantation

Strongyloidiasis has been described in solid organ [179, 180] and stem cell transplant recipients [181, 182] and has been attributed in most cases to reactivation of an old dormant infection. However, donor-derived strongyloidiasis has also been described in kidney, kidney–pancreas, liver, heart, lung, and intestine recipients. High-dose corticosteroid preconditioning of deceased donors may have a role increasing the risk of transmission [183].

Almost all of reported patients with reactivation have had a history of travel to or residence in endemic areas. Many of them had neither eosinophilia nor gastrointestinal symptoms before transplantation [179, 180]. Immunosuppression can transform a chronic, asymptomatic infection into hyperinfection syndrome, and disseminated strongyloidiasis. This transformation usually occurs in the initial months after transplantation when immunosuppression is most intense.

In the reported cases of strongyloidiasis in kidney [180, 184–187], liver [188, 189], and heart transplant recipients [190–192], it was found that most patients had hyperinfection syndrome or disseminated disease, being intestinal strongyloidiasis far less frequent. Systemic polymicrobial bacterial infections were observed in approximately 60 % of the patients [179].

Only a few cases of strongyloidiasis have been described in autologous and allogeneic stem cell transplantation patients [181, 182, 193], but they have been associated with a poor prognosis, especially when they evolve into a hyperinfection syndrome [193]. The onset of symptoms of *Strongyloides* infection in allogeneic HSCT patients seems to be earlier than in solid organ transplant recipients (median time 21 days) perhaps as a consequence of the more intense immunosuppression regimens [193].

Strongyloides hyperinfection syndrome is infrequent, and diagnosis is often delayed. However, it should be considered in the presence of diarrhea, abdominal pain, and fleeting pulmonary infiltrates with or without polymicrobial bacteremia. Because of the large parasitic load, filariform larvae can be easily observed in stool and respiratory samples (such as sputum, bronchoalveolar lavage fluid, and brushings). In disseminated disease, larvae can be observed in blood, cerebrospinal fluid, pleural fluid, urine, or biopsies of affected tissues. Duodenum biopsies may demonstrate rhabditiform larvae in patients who undergo upper gastrointestinal endoscopy [194].

44.2.1.2 Treatment

Ivermectin is considered the treatment of choice for uncomplicated strongyloidiasis as two single oral 200 mcg/kg doses of ivermectin administered either on 2 consecutive days or 2 weeks apart [195, 196]. Adverse effects, such as diarrhea, pruritus, anorexia, and increased transaminases levels, are infrequent and usually mild. Albendazole (400 mg twice daily for 3 days) has a primary cure rate of only 45–75 % [197] making it a second-line therapy. Thiabendazole is the agent with the most extensive clinical experience, but is also the least satisfactory of all available drugs due to frequent relapses and toxicities [176, 177].

The experience with ivermectin for the treatment of hyperinfection or disseminated disease in transplant recipients is still scarce, and reports describing clinical failure have been published [198]. Daily doses should be administered until larvae eradication from clinical samples with additional doses for 7–14 days to reduce the risk of relapse [194]. Retreatment is indicated if significant symptoms or eosinophilia return [148]. In many cases, combination or sequential ivermectin and albendazole treatment was used [199–203]. Severe strongyloidiasis may preclude oral treatment due to intolerance or malabsorption. In these cases, as in those refractory to oral therapy, use of subcutaneous (off label) veterinary formulation of ivermectin (200 μg/kg, daily, divided doses, each arm, until negative stool exam persists for 2 weeks) [204] should be considered [188, 197, 202]. Despite anecdotal success with rectal ivermectin treatment [205], absorption from the rectum may be insufficient to achieve therapeutic levels [206, 207].

S. stercoralis and HTLV-1 co-infection is a special situation that requires protracted therapy because no treatment reliably cures strongyloidiasis in this setting [208].

44.2.1.3 Pretransplant Screening and Prevention

Recipients and living donors residing or with a history of residence in areas where *S. stercoralis* is endemic need to be screened and treated before transplantation. Deceased donors with epidemiological risk should also be tested and prophylactic treatment (ivermectin, two oral 200 mcg/kg doses 2 weeks apart) [184] should be administered to recipients to avert donor-derived transmission, as strongyloidiasis may be transmitted via the graft [183].

Serological assays, when available, are the method of choice for screening. ELISA methods to detect IgG antibodies directed against antigens of *S. stercoralis* are highly sensitive (97 %) and specific (close to 100 %) [209]. False-positive results may occur, related to cross reactivity with other helminthic infections. The sensitivity and specificity of serologic tests in immunocompromised patients are unknown [176] and false-negative tests have been reported [210, 211]. Positive serologic tests may be positive because of a resolved or unresolved previous *Strongyloides* infection. Thus, ideally, examination of fecal samples should follow a positive serologic test [212]. Direct parasitological detection in stools varies in sensitivity because of low numbers and intermittent release of larvae. A single stool examination may not identify more than 70 % of positive cases [213]. The diagnostic sensitivity increases if serial stool samples are studied [176, 177], and the use of specialized methods can improve the diagnostic yield to close to 100 %. The agar plate culture is the method of choice for strongyloidiasis diagnosis because its sensitivity can be greater than 90 %, but multiple stool samples are needed to confirm negative results [214]. Although it is not widely available, reported sensitivity of real-time PCR in fecal samples is 100 % [215]. Parasites may also be sought for in duodenal fluid aspirated by duodenoscopy or obtained with the string test (enterotest capsules) [216].

Empiric treatment may be considered for transplantation candidates with unexplained eosinophilia and who reside in or have traveled to—even in the remote past—endemic areas and in those in whom strongyloidiasis is suspected on clinical grounds before the initiation of immunosuppressive therapy [148, 179]. Transplant recipients from endemic areas should be advised against walking barefoot, and they should be warned about the possibility of acquiring strongyloidiasis from endemic environments.

44.2.2 Schistosomiasis

Schistosomiasis is a parasitic disease caused by worms of the genus *Schistosoma*, affecting at least 260 million people worldwide [217].

The life cycle of the parasite is complex, requiring intermediate and definitive hosts. The infection is acquired through the skin when in contact with contaminated fresh water. The parasite reaches through venous circulation the liver or the bladder, maturing into adult worms which shed eggs that reach the stools or the urine.

Most human infections are caused by *Schistosoma mansoni* (Africa and South America), *S. japonicum* (East Asia), and *S. haematobium* (Africa and the Middle East).

S. mansoni and *S. japonicum* can lead to intestinal and hepatic complications, while *S. haematobium* predominantly leads to kidney and bladder sequelae. Less common, *S. mekongi* and *S. intercalatum* can lead to intestinal and/or liver disease.

Chronic schistosomiasis is the consequence of the granulomatous immune response to retained parasite eggs, and, in the long-term, it may result in permanent and progressive tissue damage.

End-stage liver or kidney failure may be caused by schistosomiasis. Therefore, patients from endemic areas waiting for liver or kidney transplantation should be thoroughly tested for schistosomiasis and treated before transplantation.

44.2.2.1 Schistosomiasis and Kidney Transplantation

Chronic *S. haematobium* infection may lead to urinary tract fibrosis, with obstruction and eventually end-stage kidney failure, whereas *S. mansoni* infection can induce terminal glomerular disease by the deposition of immune complexes [218]. More than 150 infected patients, some of whom had mixed infections, have undergone kidney transplantation [218, 219]. Patients transplanted for schistosomiasis have long-term outcomes similar to those observed in patients who underwent kidney transplantation for other diseases [219]. Urinary tract complications occur in 15 % (e.g., urinary anastomotic or ureteral obstruction, ureteral necrosis, urinary tract infection) of these patients. This may be related to poor tissue healing related to inflammatory changes in the setting of chronic urinary tract schistosomal infection [219]. Reactivation is infrequent [220, 221]; this has been attributed to specific pretransplantation treatment and to the possible antiparasitic effect exerted by cyclosporine or its non-immunosuppressive metabolites [222]; this potential effect [223, 224] could also explain the low level of re-infection in transplant recipients. Lack of treatment in the pretransplantation period seems to be associated to *Schistosoma* disease recurrence [219], although this association is not universal [225].

44.2.2.2 Schistosomiasis and Liver Transplantation

S. mansoni, S. japonicum, and *S. mekongi* infection may lead to chronic liver disease by way of immune-mediated damage and parasite eggs direct liver toxicity, causing pipe-stem fibrosis (pipe-shaped fibrosis around the hepatic portal veins, associated with large numbers of schistosome eggs) [226].

Liver transplantation has been performed mainly in patients co-infected with hepatitis C virus (HCV). Whether co-infection with HCV may increase the risk of end-stage liver disease is still uncertain [227]. Reactivation of schistosomiasis after liver transplantation (with intestinal tract and graft involvement) although infrequent, may occur, but praziquantel achieved cure in published cases [228]. Close post-transplant monitoring is recommended.

44.2.2.3 Infected Donors

Schistosoma infections are often subclinical, and patients may be unaware of the infection. While schistosomes can be transmitted by the graft, adult schistosomes do not replicate within the host so only transmission of nonreplicating adult worms occurs [149]. Liver grafts infected with *S. mansoni* (from deceased and living donors with undiagnosed infection) have been incidentally transplanted [228–230].

Intentional use of infected grafts has also been reported [231]. Praziquantel treatment after transplantation eradicated the parasite disease in recipient and living donors without further consequences.

Kidneys without anatomical damage from infected living donors have been accepted for donation [232]. Treatment should be given to all infected donors before surgery. Kidney function and morphology are not affected by nephrectomy in infected donors on long-term follow-up [233].

44.2.2.4 Diagnosis

The diagnosis is made by detection of eggs in stool or urine samples, or bladder and rectal mucosa biopsy specimens. False negative may occur in low-burden or initial infection.

Serological assays have limited usefulness, as they do not correlate with parasitic load, and seroconversion may occur several months after primary infection.

44.2.2.5 Treatment

Praziquantel is effective against the five *Schistosoma* species that infect humans. Dosing for *S. haematobium, S. mansoni,* or *S. intercalatum* is 40 mg/kg (in one or two divided doses). Higher doses should be used for *S. japonicum* or *S. mekongi* (60 mg/kg in two divided doses) [234]. Cure is achieved with the first course of treatment, even in chronic disease, in more than 60 % of patients. In those who remain infected, cure is usually achieved with a second course. Oxamniquine may also be effective. Praziquantel is a substrate of CYP3A4 [235] which is also a cyclosporine metabolic pathway. Close monitoring is warranted when cyclosporine and praziquantel are concurrently used. Potential interactions with other immunosuppressive agents have not been noted [148].

44.2.2.6 Prevention

Disease prevention involves avoiding contact with fresh water in endemic regions and screening and treating positive donors and recipients.

44.2.3 Echinococcosis

Echinococcosis, a parasitic disease for which domestic or wild canids are definitive host, is caused in humans by accidental ingestion of eggs of the cestodes *E. granulosus, E. multilocularis*, or *E. vogeli*.

E. granulosus causes cystic echinococcosis (CE), or hydatid or unilocular cyst disease, while *E. multilocularis* and *E. vogeli* cause alveolar echinococcosis (AE) cyst disease.

The clinical manifestations of cystic echinococcosis are determined by the site, size, and condition of the cysts. The slowly growing echinococcal cyst often is tolerated well until it causes dysfunction because of its size (mass effect of the enlarging cyst) or from the leakage, rupture, or bacterial infection of the cyst [236]. Although the mechanism of infection with *E. multilocularis/vogeli* is the same as that encountered in hydatid disease, its natural course is completely different because larvae proliferate making alveolar

cysts grow indefinitely, and they always behave as slow-growing cancers that in all cases require wide surgical resections to avoid recurrence. Alveolar echinococcosis is a fatal disease without treatment (>90 % mortality at 10 years).

44.2.3.1 Diagnosis

Diagnosis of CE and AE is based on typical imaging findings combined with positive serology. Serologic tests are more reliable for diagnosis of *E. multilocularis* infection than for *E. granulosus* infection. A negative serology does not rule out CE [237].

44.2.4 Cystic Echinococcosis (CE)

44.2.4.1 The Infected Recipient in Waiting List

Whenever possible, CE should be recognized and treated with the surgical removal of the fertile cysts and albendazole before transplantation [238]. Successful "delayed" management after HSCT has been described [239]. Uncomplicated, sterile WHO cysts (CE4 and CE5) do not need intervention [240]. Terminal organ failure due to CE has successfully been treated with liver [241–244] and kidney transplantation [245]. Although albendazole treatment before and after transplantation seems the logical approach [246], no recurrence of CE was observed even in absence of specific antiparasitic treatment [243].

44.2.4.2 Post-transplant CE

Management of CE acquired after transplantation (reported in kidney recipients) is similar to management in immunocompetent host. Surgical resection [246] and prolonged albendazole treatment are indicated [247, 248]. The role of immunosuppression with CE development in SOT patients is still uncertain, although unusual courses have been observed in immunosuppressed patients [240, 248–250].

44.2.4.3 Donors Infected with CE

Donors from endemic areas may have unrecognized hydatid cysts found at the time of organ procurement. Livers with inactive, calcified hydatid cysts have successfully been used, after complete [251, 252] or partial cystectomy of the graft [253].

44.2.5 Alveolar Cyst Disease (AE)

Alveolar echinococcosis is similar to a slowly growing hepatobiliary cancer in its clinical behavior.

Liver transplantation may be indicated in cases with extensive liver involvement or complications. Patients should be evaluated for extrahepatic involvement before transplantation, as the disease may spread to lungs and brain. Only CNS involvement should be considered as exclusion criteria for the procedure.

Survival rates are similar to those observed in patients transplanted for other liver diseases [254]. Immunosuppression can enhance the parasitic growth and the risk of recurrence; therefore, it should be reduced to a minimum as early as possible. Treatment with albendazole (15 mg/kg/day) is recommended for a minimum of 2 years after transplantation even in cases of apparently curative surgery. ELISA measuring anti-*E. granulosus* immunoglobulin G titers is considered useful for predicting recurrence.

44.3 Free-Living Amebas

44.3.1 ***Balamuthia mandrillaris*** and ***Acanthamoeba*** Species

B. mandrillaris has been isolated from soil, dust, and water. *Acanthamoebae* species are also ubiquitous in the environment. Both microorganisms are acquired through inhalation or damaged skin and causes granulomatous amoebic encephalitis (GAE), a sub-acute life-threatening encephalitis. *Balamuthia* infection is rare (<200 cases reported worldwide), and seems to be associated with contact with soil or stagnant water [255]. *Acanthamoebae* species are the most common causes of GAE in immunocompromised hosts. GAE may be sometimes preceded by skin lesion (usually non-ulcerated plaques) and followed by CNS disease. *Balamuthia* GAE was reported in one multivisceral transplanted patient after alemtuzumab therapy [256] and transmission via organ donation has been described in three clusters, including one asymptomatic donor [257–259]. *Acanthamoeba* GAE has been reported in a few SOT [260] and HSCT [261–263] recipients.

In SOT recipients, *Acanthamoeba* GAE presentation occurred at median time of 13 months (range: 3–48) after transplantation [260]. It may cause focal disease (such as keratitis, skin, pulmonary or brain lesions, sinusitis, or GAE) or disseminated disease that most often involves the skin and lungs. After onset of neurologic symptoms, there is a rapid disease progression leading to death. Early diagnosis is crucial for survival.

44.3.1.1 Diagnosis

Diagnosis is made by histopathological examination of infected tissues. Definite diagnosis requires identification of trophozoites in biopsies which usually show granulomatous inflammation and necrosis. Direct immunofluorescence or immunoperoxidase staining and PCR techniques [264] are highly sensitive and species-specific. Occasionally, trophozoites may be observed in CSF, or CSF–PCR positivity may allow diagnosis.

Serological tests, while not useful in *Acanthamoeba* infections, may aid in *Balamuthia* diagnosis, and in monitoring transmission and therapy in SOT recipients [259].

Acanthamoeba can be cultured on agar plates coated with Gram-negative bacteria.

44.3.1.2 Treatment

Optimal treatment for *Balamuthia* infections is unknown. Combinations of macrolides, pentamidine, anti-fungal agents (amphotericin B, azoles, and 5-flucytosine), albendazole, sulfadiazine, and miltefosine, either for pre-emptive or established disease, are usually administered for a long period of time [255]. Serologic monitoring may be useful to decide treatment duration. Pre-emptive treatment to asymptomatic recipients of infected donors has proven to be successful [259], but in patients with established GAE, mortality is high in spite of aggressive therapy.

Ideal treatment for *Acanthamoeba* species is also unknown. Cure has been achieved with rifampin and trimethoprim–sulfamethoxazole (TMP-SMX) [265]. Successful therapeutic alternatives include TMP-SMX, rifampin, fluconazole, ketoconazole, miltefosine, and pentamidine. Single brain lesions resection is recommended regardless of GAE etiological agent [260, 266].

44.3.2 *Naegleria fowleri*

N. fowleri is found in contaminated warm freshwaters. It causes a fulminant primary amebic meningoencephalitis (PAM) that mimics acute bacterial meningitis. *N. fowleri* reach the brain through the olfactory tract, when contaminated water moves up to the nose, such as during swimming or nasal irrigation. Transmission of *N. fowleri* through organ transplantation was not observed in 21 recipients from five donors with PAM. However, the risk of transmission may still exist [267].

44.4 Intestinal Protozoa

44.4.1 Cryptosporidiosis

Cryptosporidium species have gained increasing recognition as some of the most common enteric parasitic pathogens in humans and as a worldwide cause of diarrheal diseases in normal hosts [268, 269]. *Cryptosporidium* infection in immunocompromised patients can be asymptomatic, can cause transient gastrointestinal symptoms, produce chronic diarrhea, or cause life-threatening gastrointestinal and biliary tract disease [270]. In endemic regions, prevalence of up to ~30 % has been reported in kidney transplant recipients [271–273]. *Cryptosporidium* organisms are intracellular protozoan parasites that develop in the gastrointestinal tract of vertebrates, producing gastrointestinal disease; they do not require extraintestinal development [274]. Transmission of the *Cryptosporidium* infection occurs by four major modes: (1) person to person, which is especially relevant among household members, sexual partners, children in day care centers and their caretakers, and health care workers [275, 276]; (2) animal to human, which, although infrequent, is a higher risk for persons in contact with farm animals than for those who have contact with pets [274, 277]; (3) contaminated food; and (4) fecally contaminated water, untreated surface water, filtered swimming pool water, and even chlorinated or filtered drinking water [278].

44.4.1.1 Cryptosporidiosis in Solid Organ Transplantation

Reports of cryptosporidiosis have been published in kidney [270–273, 279–282], liver [282–286], small bowel [287, 288], and HSCT [289–295] recipients.

Infection spread out of the gastrointestinal lumen is very rare: One case of lethal *Cryptosporidium baileyi* infection with disseminated infection has been reported [280] and a case of sclerosing cholangitis secondary to intestinal cryptosporidiosis has been accounted for [296] in a kidney transplanted patient. *Cryptosporidium*-associated sclerosing cholangitis is a rare but severe complication that has been reported in adults and in children with liver transplantation [283, 286].

In small bowel transplant recipients, *Cryptosporidium* has been described to cause severe diarrhea [284, 287, 288] that needs to be differentiated from rejection and from other infectious agents [287]. Cryptosporidiosis in solid organ recipients has been associated with elevated tacrolimus levels and a transient worsening of kidney function [282].

44.4.1.2 Cryptosporidiosis in Hematopoietic Stem Cell Transplantation

Cryptosporidium infection in HSCT recipients causes diarrhea (which may be severe) [289], vomiting, anorexia, and weight loss [295]. Extraintestinal cryptosporidiosis with pulmonary involvement [291] has been reported. Intestinal cryptosporidiosis can mimic intestinal graft-versus-host disease (GVHD) and needs to be differentiated from it, since clinical management requires different approaches [294].

44.4.1.3 Diagnosis

Cryptosporidiosis should be considered in all transplant recipients with acute or chronic diarrhea or signs of biliary tract disease without biliary calculi.

The diagnosis of *Cryptosporidium* infection is made primarily by oocysts detection in a modified stool acid-fast staining. Oocyst excretion is intermittent, so multiple sam-

ples may be necessary to reach diagnosis. IFA and ELISA assays can significantly increase diagnostic sensitivity to as high as 100 % [297]; these techniques have been used in fecal or tissue specimens [268]. When available, polymerase chain reaction (PCR) testing is the diagnostic method of choice [298]. Serologic testing has a limited value for clinical diagnosis because antibodies can be elevated for more than 1 year after acute infection. Duodenal aspirates and biopsy specimens from affected gastrointestinal tissue [274, 284] may be required to reveal the parasite. A definite diagnosis of biliary tract cryptosporidiosis is made by the demonstration of oocysts in the bile or by histology. Stool specimens may or may not be positive.

44.4.1.4 Treatment

No reliable treatment for cryptosporidiosis exists. The resolution of *Cryptosporidium* infection depends mainly on the immune status of the host. Although the available treatments do not reliably eradicate the parasite, they do seem to suppress the infection [297]. Long-term therapy, including nitazoxanide, azithromycin, spiramycin, or paromomycin, may be effective [299, 300]. However, it is unclear whether therapeutic success can be achieved without reducing immunosuppression [288, 301], as impaired cell-mediated immunity and interferon-gamma play a key role in parasite clearance [301].

44.4.1.5 Prevention

Cryptosporidiosis is difficult to prevent because the oocyst is resistant to most of the standard water treatments and antiseptic solutions. Transplant recipients should limit their exposure to *Cryptosporidium* pathogens by avoiding contact with (including drinking) water from public swimming pools, lakes, and streams. Boiling water for 1 min or filtering it with submicron personal-use water filters may decrease the risk of infection, and these have been suggested as preventive measures, especially during outbreaks [302]. Ice made from tap water may be a source of infection, and patients should be advised accordingly. Bottled or canned carbonated soft drinks and pasteurized beverages are safe [302].

44.4.2 Microsporidiosis

Microsporidia are obligate, spore-forming, intracellular, highly diverged parasites [303]. Microsporidia are ubiquitous, highly resistant to degradation, and have the ability to survive in the environment for many months; in addition, they can infect the whole animal kingdom. *Enterocytozoon bieneusi* and *Encephalitozoon* spp. are the most common causes of human disease [303].

Fecal–oral and urinary–oral routes seem to account for most infections, although person-to-person transmission is possible due to the presence of spores in body fluids. Microsporidiosis is a zoonotic disease [303]. Birds, many animals, and insects are known reservoirs for microsporidial species that produce human illness. Also, there is evidence of waterborne and foodborne transmission [303]. Transmission to multiple recipients from an infected organ donor has been reported [304].

E. bieneusi and *Encephalitozoon* spp. infect the gastrointestinal and biliary tracts. In general, *Enterocytozoon* infections are limited to the intestine producing chronic diarrhea and weight loss [305]. *Encephalitozoon* spp. infects macrophages and disseminates widely, causing systemic infection with involvement of the intestinal and hepatobiliary tracts, the respiratory tract, sinuses, eye, brain, and kidney [305]. *Anncaliia algerae* an insect microsporidia, and causes myositis in immunocompromised patients [306, 307].

44.4.2.1 Microsporidiosis in Transplantation

E. bieneusi asymptomatic carriage [308] and symptomatic infection have been reported in transplant recipients [309]. *E. bieneusi* invades the intestinal epithelium and may spread to the hepatobiliary canals, producing cholangitis. Symptomatic infection in kidney, liver, and heart–lung [310–316] recipients is characterized by non-bloody, watery, protracted diarrhea; fatigue; abdominal discomfort; weight loss and fever [317]. In spite of chronic diarrhea, reports indicate that the macroscopic appearance of the intestinal mucosa at the time of endoscopic studies is normal [310, 312, 314, 315], whereas duodenal biopsy specimens show that mild, nonspecific duodenitis [314, 315], and colonic biopsy specimens are usually normal.

***Encephalitozoon* spp.** causes disseminated disease with multiorgan involvement, graft malfunction [318], and pulmonary disease. Disseminated infection has been reported in HSCT (with pulmonary involvement and with parasites identified in respiratory specimens) [319, 320]; in kidney recipients [321] (with involvement of kidney allograft in all cases, with cornea, lungs, and central nervous system among possible sites of dissemination) [322]; in a lung recipient (with pulmonary involvement and granulomatous interstitial nephritis) [323]; and in kidney–pancreas transplant (with parasites identified in the abdominal fluid) [324].

A. algerae was reported to cause fever, myositis, and axonal neuropathy that was lethal in two transplanted patients [306, 307].

Disseminated lethal infection due to ***Tubulinosema acridophagus*** has been reported in a HSCT patient [325].

44.4.2.2 Diagnosis

Microsporidial infection diagnosis requires not only a high level of awareness but also trained laboratory personnel and specialized technical approaches.

The diagnosis depends on identification of spores in clinical samples that are obtained on the basis of patient symptoms but may include stool, urine, sputum, bronchoalveolar lavage fluid, and cerebrospinal fluid [326]. Due to intermittent oocyst shedding, multiple specimens of urine and stool may be necessary to ensure diagnosis [326]. Routine examination for ova and parasites will not detect microsporidia spores.

Specialized methods that include Ritchie concentration, Weber trichrome stain, and fluorochrome stain are needed for detection. In tissue, microsporidia stain variably with hematoxylin and eosin; Gram stain and Warthin–Starry techniques considerably improve the visualization of these organisms. Electron microscopy, molecular assays, or indirect immunofluorescence or immunohistochemical stains are usually needed for species-specific identification, which has important therapeutic implications [326].

44.4.2.3 Treatment

The successful management of microsporidial infections may require immunosuppression decrease whenever feasible, as cell-mediated immunity is paramount in controlling microsporidial infection [326].

Therapy for microsporidiosis is species-dependent. *Encephalitozoon* species, including *Encephalitozoon cuniculi*, are treatable with albendazole (400 mg twice daily) [326]. Survival rates may be close to 80 % when treatment is timely initiated, but prolonged therapy may be necessary.

E. bieneusi can be treated with oral fumagillin (20 mg three times a day given for up to 14 days) with early resolution of diarrhea [327]. Reversible thrombocytopenia is the most important toxicity, and platelet monitoring is necessary throughout treatment. Tacrolimus blood levels usually decrease with fumagillin treatment, so through levels monitoring is needed [327].

44.4.2.4 Prevention

Sensible precautions include the avoidance of known reservoir hosts, especially pets; thorough cooking of meat [328] and water boiling; and refraining from swimming in lakes, rivers, and swimming pools [329] as this is a risk factor for microsporidial infections [330].

44.4.3 Other Intestinal Protozoa

Diarrhea may occur in up to 20 % of solid organ transplant recipients [331] and close to 50 % of HSCT patients in developing countries. In many of these cases, intestinal protozoa, sometimes as mixed infections, are the responsible etiological agents of significant and protracted diarrhea. Although worldwide distributed, transmission is more common in developing areas. They share the same transmission mechanisms, related to contaminated food and water, person-to-person spread, and zoonotic exposures. Asymptomatic carriage may occur, and progression to symptomatic disease may occur when the patients are immunosuppressed.

In the HSCT setting, awareness of potential infectious causes of diarrhea is specially important after engraftment, as diarrhea may be considered as caused by drug toxicities or graft-versus-host disease.

*44.4.3.1 **Entamoeba histolytica***

E. histolytica has been reported in both SOT [332] and HSCT recipients [333] as a cause of invasive diarrhea. Skin involvement with erythema nodosum-like lesions caused by *E. histolytica* has been reported in a kidney transplant recipient [334].

Treatment involves the use of amoebicidal drugs (metronidazole or tinidazole) active against trophozoites (the invasive form) followed by a luminal agent to eliminate cyst (paromomycin or iodoquinol). Asymptomatic carriage can be treated with a luminal agent to prevent transmission and development of invasive disease.

*44.4.3.2 **Giardia lamblia***

G. lamblia is the most common intestinal protozoan parasite in the Western world; however, reports of these infections in the transplantation setting are scarce [335–337].

Giardia has been found to account for ~20 % of symptomatic parasitic diseases in kidney transplant recipients from South Brazil [338] and 27 % of all infectious diarrhea episodes in SOT recipients in Turkey [339]. Duodenal villous atrophy with diarrhea, usually caused by mycophenolic acid, may be caused by *Giardia* infection in ~10 % of the cases, and diagnosis may need upper gastrointestinal endoscopy because of negative stool examinations [340].

Giardia can be treated with metronidazole, nitazoxanide, or paromomycin. Refractory cases can be treated with metronidazole plus quinacrine.

*44.4.3.3 **Blastocystis hominis***

In kidney transplant recipients, gastrointestinal symptoms with detection of *B. hominis* in the stool samples have been reported; the prevalence of infection was nearly 40 % [272]. Among infected patients with no other enteropathogenic microorganism, 61 % were symptomatic, and symptoms correlated with the presence of amoeboid forms and parasitic load [272].

B. hominis infection has also been reported in an allogeneic HSCT recipient with acute bowel GVHD. Symptoms resolved only after long-term treatment with metronidazole cleared *B. hominis* from stools [341].

B. hominis can be treated with metronidazole (200–750 mg three times daily for 5–10 days). Cotrimoxazole and nitazoxanide can also be effective, but therapeutic failure can occur with all agents.

44.4.3.4 *Cyclospora cayetanensis* and *Cystoisospora belli*

C. belli has been reported as cause of profuse diarrhea in liver [342, 343], kidney [344, 345], and intestinal transplant [346] recipients. *C. cayetanensis* was also reported as cause of diarrhea in a kidney transplant recipient [347]. All cases resolved with trimethoprim/sulfamethoxazole, which may be used at 160 mg/800 mg dose twice or eventually four times daily.

44.4.3.5 *Diagnosis of Intestinal Protozoa*

Standard stool examination is useful to detect all above-mentioned intestinal protozoa. Concentration methods and special stains or techniques enhance detection of certain pathogens.

E. histolytica and *G. lamblia* detection is improved using species-specific antigen testing or PCR (stool microscopy does not allow differentiation between *Entamoeba* species). Serology does not distinguish past from present infection, and may be positive in asymptomatic individual. It may be useful in extraintestinal forms of amebiasis.

Cystoisospora and *C. cayetanensis* oocysts can be detected by modified acid-fast staining of stool and safranin stain. Fluorescence microscopy is useful to detect *Cyclospora* oocysts, which are autofluorescent.

PCR techniques, when available, are the most sensitive methods for detection.

44.4.3.6 *Prevention*

Routine parasitological screening should always be considered in the pretransplant work up for patients at epidemiological risk. Asymptomatic carriage should prompt enhanced efforts on patient education on food and water safety, hand washing, and hygiene. Pre-emptive treatment before starting immunosuppression may avoid development of symptomatic disease.

44.5 Conclusion

Parasitic disease epidemiology is changing. Their human hosts move around the world, carrying them; also there is an increasing number of people traveling [348]. Because of immigration, in 2013, 232 million people—3.2 % of the world's population—lived outside their country of origin [349]. Global warming and climate change are also modifying the geographical distribution of infectious diseases vectors [350–352] with the emergence of exotic infections in unexpected places [353]. The practice of infectious diseases in transplantation is always challenging, as clinical manifestations in patients with blunted immune responses are frequently subtle and atypical. Parasitic infections add to this challenge the need to be aware of their occurrence in unexpected geographical areas. Efforts should be focused on performing a comprehensive history, maintaining a high index of suspicion, and adhering to preventive measures. In the pretransplantation period, a thorough history of possible geographic exposure, even in the remote past, is essential; this needs to include the patient's areas of residence and travel. Inquiries about past infection should not be limited to their clinical manifestations, but they should also include the specific treatments that might have been administered even in the absence of clinical disease. In an attempt to prevent overwhelming infections after transplantation, serotesting and a parasitologic examination should be performed whenever reasonable doubt is present. The investigation should be carried out when patients are placed on the waiting list to allow time for diagnosis and pretransplantation treatment. Living donors should be thoroughly evaluated early in the pretransplantation workup to allow risk appraisal, diagnosis, and treatment as needed. Deceased donors pose an altogether different problem. Because an extensive epidemiologic history might prove difficult to obtain, the risk potential may be best evaluated by using laboratory tests more liberally.

In the immediate post-transplantation period, a high level of suspicion is needed because the symptoms of parasitic diseases might mimic those of other infections or even of rejection, especially when they present with fever and allograft dysfunction.

In the late post-transplantation period, recent exposure to endemic diseases needs to be addressed at the time of differential diagnosis.

Parasitic diseases may jeopardize transplantation success, especially if the diagnosis, specific treatment, and adequate management of immunosuppression are not accomplished in time.

Part VIII
Infection Control

45 Infection Control Issues After Hematopoietic Stem Cell Transplantation

Sarah A. Longworth, Robin K. Avery, Melanie S. Curless, and David L. Longworth

45.1 Introduction

Preventing the acquisition and transmission of infections in hospitalized hematopoietic stem cell transplant (HSCT) recipients remains a challenge. Considerable clinical experience has been accumulated, but a paucity of randomized, controlled trials exists on the topic of infection control in this setting. The Center for International Blood and Marrow Transplant Research (CIBMTR), National Marrow Donor Program (NMDP), European Blood and Marrow Transplant (EBMT) Group, American Society for Blood and Marrow Transplant (ASBMT), Canadian Blood and Marrow Transplant Group (CBMTG), Infectious Diseases Society of America (IDSA), Society for Healthcare Epidemiology of America (SHEA), Association of Medical Microbiology and Infectious Diseases (AMMI), the Centers for Disease Control and Prevention (CDC), and the Health Resources and Services Administration published comprehensive evidence-based guidelines in 2009 (hereafter referred to as the "2009 Guidelines") for preventing opportunistic infections among HSCT recipients [1]. This report represents an update on earlier guidelines published in 2000 [2]. The 2009 Guidelines include 253 recommendations regarding hospital infection control practices in hematopoietic stem cell transplantation. The topics covered include room ventilation; construction, renovation, and building cleaning; isolation and barrier precautions; hand hygiene; equipment management; plants, play areas, and toys; issues involving health care workers (HCWs) and visitors to hematopoietic stem cell transplantation centers; patient skin and oral care; prevention of bacterial intravascular catheter-related infections; infection control surveillance; and prevention and control of specific nosocomial infections, including *Legionella* species, methicillin resistant *Staphylococcus aureus* (MRSA), Staphylococci with reduced susceptibility to vancomycin, vancomycin-resistant Enterococcus (VRE), multidrug-resistant gram-negative bacilli (MDR-GNB), *Clostridium difficile*, community respiratory viruses (CRVs), and viral gastroenteritis pathogens [1].

These 253 guidelines were stratified on the basis of the strength of the recommendations (A–E) and the quality of the supporting evidence (I–III). This document includes only 30 guidelines in category AI or II (strongly recommended) and two in category EII (never recommended) [1]. Table 45-1 summarizes the definitions of these categories and lists the 32 AI, AII, and EII guidelines.

In addition to the 2009 Guidelines, several general infection control policy guidelines are relevant to the care of the HSCT population. The most important of these for HSCT infection control are the "2007" Guideline for Isolation Precautions: Preventing Transmission of Infectious Agents in Health Care Settings" of the Healthcare Infection Control Practices Advisory Committee (HICPAC) [3], the 2003 "Guidelines for Environmental Infection Control in Healthcare Facilities" [4] from HICPAC, the 2002 "Guideline for Hand Hygiene in Healthcare Settings" [5], and the 2008 "Guideline for Disinfection and Sterilization in Healthcare Facilities" [6]. Additional guidelines specific to a particular pathogen (i.e., *C. difficile,* norovirus) were published after the 2009 Guidelines and will be mentioned in the relevant sections [7, 8].

45.2 Guideline Recommendations

45.2.1 Room Ventilation

Ventilation is an extremely important infection control measure, but one in which practices have varied from one center to another. All allogeneic recipients should be placed in rooms with at least 12 air exchanges per hour and central or point-of-use high-efficiency particulate air (HEPA) filters that are capable of removing particles larger than 0.3 mm in diameter (AIII) [1, 9, 10]. The efficacy of these protective isolation measures for autologous HSCT recipients has not been well established (BIII). Effective filtration is particularly

P. Ljungman et al. (eds.), *Transplant Infections*, DOI 10.1007/978-3-319-28797-3_45

TABLE 45-1. AI, AII, and EII recommendations stratified by strength and quality of supporting evidence in the 2009 Guidelines, infection control section

Categories

A. Strong evidence for efficacy and substantial clinical benefit;
B. Strong or moderate evidence for efficacy but only limited clinical benefit;
C. Insufficient evidence for efficacy or efficacy does not outweigh possible adverse consequences or cost of chemoprophylaxis or alternative approaches;
D. Moderate evidence against efficacy or for an adverse outcome;
E. Strong evidence against efficacy or for an adverse outcome.

Strength of supporting evidence

I. Evidence from at least one well-executed randomized, controlled trial;
II. Evidence from at least one well-designed clinical trial without randomization, cohort, or case-controlled analytic studies (preferably from more than one center), multiple time-series studies, or dramatic results from uncontrolled experiments;
III. Evidence from opinions of respected authorities based on clinical experience, descriptive studies, or reports of expert committees.

AI recommendations

1. When hands are visibly dirty or soiled with blood or body fluids, hands should be washed using soap and water.
2. When a definite or possible case of laboratory-confirmed nosocomial Legionnaires disease (LD) is identified in a person who was in the inpatient HSCT center during all or part of the 2–10 days before illness onset, or if two or more cases of laboratory-confirmed LD occur among patients who had visited an outpatient HSCT center, the hospital infection control team should be consulted and a thorough epidemiological and environmental investigation should be conducted to determine the likely environmental source(s) of *Legionella* species.
3. HSCT centers should follow published recommendations for preventing, controlling, and treating *C. difficile* infection.
4. All HCWs who have contact with a *C. difficile* infected patient or with the patient's environment should don gloves.
5. HCWs and close contacts of HSCT recipients should receive a yearly influenza vaccine at the start of the influenza season, preferably with inactivated influenza vaccine rather than with live attenuated influenza vaccine to avoid concerns about transmission of vaccine virus.

AII recommendations

1. HSCT centers should prevent birds from nesting near hospital air-intake ducts.
2. Construction and renovation areas should have negative air pressure relative to HSCT patient care areas to ensure that air flows from patient care areas toward construction areas.
3. A portable, industrial-grade HEPA filter should be used between a construction zone and the HSCT unit if a large area is under construction and negative pressure differential cannot be guaranteed.
4. Hand hygiene is the mainstay of infection prevention in a hospital and is an essential element of Standard Precautions for all patients.
5. In the absence of visible soiling of hands or contact with spore-forming organisms, the preferred method of maintaining hand hygiene is use of an alcohol-based hand rub because of its superior microbicidal activity, reduced drying of the skin, and convenience.
6. Every effort should be made to restrict all HCWs with infections that are potentially transmissible to HSCT recipients or candidates from direct patient care activities.
7. Work-exclusion policies should be designed to encourage HCWs to report their illnesses or exposures.
8. Staff should request that visitors with CRV leave the HSCT center until signs and symptoms of infection have resolved or, for recent exposures to communicable infections, until the incubation period for that infection has passed without the appearance of signs or symptoms suggestive of active infection.
9. If *Legionella* species are detected in the water being supplied to a HSCT center, the water supply should be decontaminated until *Legionella* species are no longer detected by culture.
10–13. To prevent MRSA, VRE, MDR-GNB, and CRV transmission, HCWs should maintain hand hygiene with either an alcohol-based hand rub or wash hands with soap and water if soiled before and after all patient contact or contact with the patients' potentially contaminated equipment or environment.
14–16. To prevent MRSA, VRE, and MDR-GNB transmission, HCWs should use Contact Precautions for patients colonized or infected with these pathogens, including the use of gloves and gowns.
17. All HSCT centers should have sufficient laboratory capability to identify all Staphylococcus isolates and their antimicrobial susceptibility patterns, including vancomycin susceptibility.
18. Medical and ancillary staff members who are responsible for monitoring antimicrobial use patterns in the facility should routinely review vancomycin use patterns.
19. HSCT center personnel should institute the prudent use of all antimicrobials, including vancomycin, to prevent the emergence of Staphylococcus with reduced susceptibility to vancomycin.
20. To reduce the risk of VRE infection, HSCT clinicians should minimize the use and duration of treatment with vancomycin and antimicrobial agents with anaerobic coverage.
21. HCWs and visitors with infectious conjunctivitis should be restricted from direct patient contact until the drainage resolves.
22. HSCT recipients with CRV infection should be placed on appropriate precautions for at least the duration of illness.
23. HSCT centers should ensure adherence to hand hygiene, appropriate isolation precautions, and environmental disinfection when patients develop viral gastroenteritis.
24. When a patient has viral gastroenteritis, appropriate precautions should be maintained for at least the duration of illness.
25. Contact Precautions and environmental disinfection should be used to control the spread of astrovirus infection among HSCT recipients during known outbreaks.

EII recommendations

1. Treatment of asymptomatic *C. difficile* carriers to prevent clinical infection.
2. Administration of Bacillus Calmette–Guérin vaccination to HSCT recipients.

From Tomblyn M, Chiller T, Einsele H, et al. Guidelines for Preventing Infectious Complications among Hematopoietic Cell Transplantation Recipients: A Global Perspective. Biol Blood Marrow Transplant. 2009; 15: 1143–1238.

Abbreviations: *HSCT* hematopoietic stem cell transplant, *CRV* community respiratory virus, *HCW* health care worker, *MDR-GNB* multidrug-resistant gram-negative bacilli, *MRSA* methicillin-resistant *Staphylococcus aureus*, *VRE* vancomycin-resistant Enterococcus.

[a]See text for updates from more recent guidelines regarding these points.

important and should be monitored frequently in HSCT centers undergoing construction and renovation (AIII) [11, 12]. When there is a shortage of such rooms to accommodate all HSCT recipients, room allocation should prioritize those at highest risk for invasive mold infection (BIII). In such instances, portable, industrial-grade HEPA filters may be used in non-protective environment rooms to minimize risk to vulnerable patients (BIII). Though portable HEPA filters have been demonstrated to remove airborne fungal spores and mycobacteria, their efficacy relative to the standard central or point-of-use HEPA filters in preventing infection has not been established [13, 14].

Opinion has evolved regarding the utility of laminar air flow (LAF) rooms, in which HEPA-filtered air moves in parallel in one direction and exits from the wall opposite where the air enters. Early studies suggested decreased mortality with use of LAF rooms for BMT patients [15, 16]. However, more recent work has not shown an overall survival benefit from routine LAF use in all HSCT recipients [17, 18]. Due to their inconvenience, added expense, and lack of clear benefit, LAF rooms are not currently recommended for newly constructed rooms in HSCT centers (DII).

Current recommendations do suggest that rooms have directed airflow with air intake and air exhaust at opposite sides of the room (BIII) and that each room has well-sealed windows, electrical outlets, floor and ceiling (BIII). Hematopoietic stem cell transplantation centers should prevent the access of birds to hospital air intake ducts (AII) because studies have linked such exposures to the subsequent development of invasive pulmonary infections in HSCT recipients [9, 19]. In addition, a positive-pressure differential of ≥2.5 Pa should exist between the room and adjacent hallways or anterooms (BIII) [1, 10] and continuous pressure monitoring should be employed to allow staff to monitor for engineering failures (BIII) [4, 20]. This pressure differential decreases the likelihood of introduction of airborne pathogens from adjoining areas. Self-closing doors are useful in maintaining this pressure differential (BIII). Anterooms are optional, except in cases of HSCT recipients requiring Airborne Precautions (BIII). For the management of a patient requiring a protective environment who concurrently has an airborne infection when an airborne isolation room with an anteroom is not available, a portable, industrial-grade HEPA filter should be placed in the room to augment the removal of spores (BIII) [4].

Walsh and Dixon summarized the investigations and point sources found in 25 outbreaks of nosocomial aspergillosis [19]. Most commonly, aspergillosis outbreaks in neutropenic patients have been related to hospital construction or contaminated ventilation systems [19]. The authors recommended environmental microbiologic surveillance and floor-to-ceiling barriers during hospital construction and renovation as important measures for aspergillosis control [19]. In another study, an air pressure differential between an oncology unit and the adjoining hospital areas was thought to be the source of an *Aspergillus* outbreak during hospital construction [21]. Although the room pressure was higher than the corridor pressure in the oncology unit, the unit as a whole had negative pressure with respect to other hospital areas [21]. This case illustrates the complexity of the investigations required for aspergillosis control.

Even when the systems conform to the above specifications, at times these systems may be nonfunctioning or shut down for maintenance. The 2009 Guidelines recommend the establishment of backup systems for power and air-handling in the event of a shutdown of the central ventilation system (BIII). In addition, provisions should be made for the prevention of exposure to fungal spores after air-handling systems are restarted following routine maintenance (BIII).

The 2007 Guideline for Isolation Precautions develops further the idea of a "protective environment" for HSCT recipients [3]. The elements of such an environment include "(i) HEPA filtration of incoming air, (ii) directed room air flow, (iii) positive air pressure relative to the corridor, (iv) well sealed rooms (including sealed walls, floors, ceilings, windows, electrical outlets) to prevent flow of air from the outside, (v) ventilation to provide more than 12 air changes per hour, (vi) strategies to minimize dust (i.e., scrubbable surfaces rather than upholstery and carpet, and routinely cleaning crevices and sprinkler heads), and (vii) prohibiting dried and fresh flowers and potted plants in the rooms of HSCT patients" [3]. More detailed recommendations are listed in Table 5 of the 2007 Guideline for Isolation Precautions [3]. It is important to note that this concept of a "protective environment" does not include barrier precautions beyond routine application of Standard Precautions for all patients and Transmission-Based Precautions when indicated. In addition, evidence is lacking to recommend this protective environment to immunocompromised patients other than HSCT recipients [3]. Moreover, the use of HEPA-filtered rooms alone is not enough to prevent infections and should not replace other standard infection control measures, nor create a false sense of security. In a study of 23 outbreaks of viral, fungal, and bacterial infection in HSCT units, the majority occurred despite the use of HEPA-filtered rooms [22].

45.2.2 Construction, Renovation, and Building Cleaning

The major concern with hospital construction or renovation is the increased risk of aspergillosis and other fungal infections due to the aerosolization of fungal spores during construction activity. Close collaboration and advance planning by a multidisciplinary team involving infection control personnel and individuals responsible for construction, are important [4, 23]. Published guidelines for environmental controls during construction should be consulted during the planning and implementation of construction (AIII) [4, 23].

Education of construction personnel and HCWs can help minimize infection control risks and mandatory infection control adherence agreements should be incorporated into construction contracts [4]. Construction of new facilities or renovation of existing facilities offers an opportunity to maximize patient safety by adherence to guidelines [4]. For example, regarding air intake and exhaust outlets, building design should ensure that exhaust outlets are located atleast 25 feet from intake systems; that outdoor air intakes are located atleast 6 feet above ground or atleast 3 feet above roof level; and that exhaust outlets from contaminated areas are located above roof level to minimize recirculation of exhausted air [4].

In addition, in anticipation of construction or renovation, aspergillosis-control measures (AIII) should be intensified. Recommended measures include the placement of airtight barriers between patient care areas and construction areas (BIII) [4]; limiting the opening and closing of doors or other barriers (BIII) [4, 24]; the use of dedicated entrances, stairways, and/or elevators for construction traffic; and limiting contact between construction personnel and patient care areas by controlling the flow of patients during the construction [4]. It is preferable for air exhaust from construction areas to be vented outside the hospital rather than recirculated (BIII); if that is not possible, the exhaust should be HEPA-filtered. In addition, construction and renovation areas should have negative pressures relative to HSCT patient care areas to ensure air does not flow from the construction areas to the patient care areas (AII) [21, 25]. If this pressure differential cannot be guaranteed and a large area is under construction, a portable, industrial-grade HEPA filter should be used between these two areas (AII) [21, 26]. Measures should be in place to avoid tracking of dust and construction debris out of the construction zone, such as the use of mats with tacky surfaces, damp-wiping tools, and removal of workers' protective outer clothing when leaving the construction zone. Regular monitoring of compliance is essential [4]. Any visible dust and debris tracked out of the construction zone should be removed using a HEPA-filtered vacuum [27]. The 2009 Guidelines [1] and the 2003 Guidelines for Environmental Infection Control [4] present more detailed discussions of specific measures and should be consulted prior to such projects.

HSCT recipients, HCWs, and visitors should avoid construction and renovation areas to the extent possible, and HSCT equipment and supplies should not be exposed to construction areas (AIII) [21, 28]. The use of N95 respirators during transport has been advocated for HSCT recipients passing near construction or renovation areas (CIII) [21, 28]. Training in proper use is necessary for maximal benefit. The routine use of N95 respirators by patients, however, has not been evaluated for preventing exposure to fungal spores during periods of non-construction [4]. Standard surgical masks provide little protection against the inhalation of fungal spores and should not be used.

There should be enhanced monitoring for clinical cases of aspergillosis and other invasive mold infections in order to identify trends that may suggest an environmental mold source (BIII). That said, the utility of routine microbiological air sampling for fungal spores in HSCT units has not been established and is not recommended (DIII) [29–31]. There may, however, be a role for such testing during suspected outbreaks to determine the environmental source (CIII).

Newly constructed areas should be cleaned before patients are permitted to enter them (AIII), as several guidelines outline [4, 23]. With regard to hospital cleaning, HSCT patient care areas should be cleaned at least daily using an Environmental Protection Agency (EPA)-registered disinfectant (BIII). Particular attention should be given to dust removal (BIII). Wet dusting methods should be employed to avoid dust aerosolization (BIII) [4]. Floor surfaces and furnishings should be smooth, non-porous, and easily disinfected to minimize dust levels and contamination with nosocomial pathogens (BIII) [4]. Carpeting should not be installed in HSCT patient care areas, as contaminated carpeting has been associated with outbreaks of aspergillosis in HSCT centers [32, 33]. HSCT recipients should not be exposed to activities such as vacuuming that may result in the aerosolization of *Aspergillus* spores (EIII) [23]. Vacuum cleaners should be fitted with HEPA filters [4, 25]. To avoid mold contamination, water leaks should be repaired as quickly as possible and ideally within 72 h (BIII) [4, 34].

45.2.3 Isolation and Barrier Precautions

Hematopoietic stem cell transplantation centers should follow the 2007 Guidelines for Isolation Precautions [3]. The concept of a protective environment has been discussed above, with regards to airflow and ventilation considerations [3]. Since the early years of transplantation, the trend has been away from strict longterm protective isolation for all transplant recipients, with the recognition that many infections are due to host flora rather than acquired via person-to-person spread [35, 36]. In addition, the psychological effects of protracted strict isolation should be taken into account [35, 36]. Hand hygiene is the most effective preventive measure studied (see "Hand Hygiene"). One study indicated that gown and glove precautions appeared to have a protective effect in addition to that of strict hand washing when they were used in a pediatric intensive care unit dedicated to solid organ transplant recipients [37]; however, no recommendations to implement these precautions for all HSCT recipients exist. Additional precautions recommended for the control of specific organisms, such as multidrug resistant bacteria, are discussed in "Control of Specific Nosocomial and Community-Acquired Pathogens."

HSCT recipients should be housed in single-patient rooms (BIII). If the availability of such rooms is limited, priority should be given to the most immunosuppressed patients,

including HSCT recipients during their initial transplant admission—especially allogeneic transplants—and patients receiving therapy for graft-versus-host-disease (GVHD) during subsequent admissions (BIII).

The 2007 Guidelines for Isolation Precautions update previous guidelines in a number of important ways [3]. Precautions are now defined by a two-tiered system composed of Standard Precautions and Transmission-Based Precautions. Standard Precautions are used for the care of all patients in health care settings, and include the following [3]:

- Hand hygiene
- Safe injection practices
- Use of gowns, gloves, masks, eye protection, and face shields depending on the type of anticipated exposure
- Respiratory hygiene/cough etiquette

Respiratory hygiene/cough etiquette includes a variety of measures, such as education of health care providers, patients, and visitors; posted signs; source control measures such as covering the mouth and nose with a tissue when coughing; hand hygiene after contact with respiratory secretions; spatial separation, ideally more than 3 feet in waiting areas, and placing masks on coughing patients if tolerated [3]. Health care personnel with respiratory infection symptoms should avoid direct patient contact; if such contact is unavoidable, then a mask should be worn while providing patient care [3]. If specific respiratory viruses are diagnosed or suspected in hospitalized patients, however, Transmission-Based Precautions should be instituted (see below).

Transmission-Based Precautions are tailored to specific infections that a patient is known or suspected to have [3], and are designed to prevent the spread of pathogens to other patients by preventing health care personnel-associated spread. Compliance is particularly important in the HSCT population, as HSCT recipients with respiratory and gastrointestinal viruses can experience prolonged shedding of organisms. The three categories of Transmission-Based Precautions are Contact, Droplet, and Airborne Precautions; utilization of these precautions depending on the mode of spread of the known or suspected pathogen [3]. In some cases, more than one type of Transmission-Based Precautions may be applied, as when awaiting the results of a respiratory viral panel that includes agents spread by either droplet or contact or both. Contact Precautions involve donning gowns and gloves upon entry into the patient's room and removing these just prior to leaving, followed by hand hygiene. Examples of infections handled with Contact Precautions include *C. difficile*-associated diarrhea (CDAD), norovirus, and VRE [3]. Droplet Precautions are used for pathogens spread by close respiratory or mucous membrane contact, and involve health care personnel donning a mask prior to room entry, and patients wearing a mask when traveling outside the room, for example, for radiography and tests [3]. Examples of pathogens handled with Droplet Precautions include influenza virus, adenovirus, and *Neisseria meningitidis* [3]. Finally, Airborne Precautions are used for agents that remain infectious over long distances when suspended in the air, including measles virus, varicella virus, and *Mycobacterium tuberculosis* [3]. These precautions involve the use of airborne infection isolation rooms whenever possible. Such rooms have negative air pressure relative to the surrounding area, and have 6 exchanges of air per hour for existing facilities and 12 exchanges of air per hour for new construction, with air exhausted directly to the outside or HEPA-filtered prior to return [3]. Health care personnel don a respirator prior to room entry [3]. In settings where Airborne Precautions cannot be implemented due to limited engineering resources (i.e., physician offices), masking the patient, placing the patient in a private room (i.e., office examination room) with the door closed, and providing N95 or higher level respirators (or masks if respirators are not available) for health care personnel will reduce the likelihood of airborne transmission until the patient is either transferred to a facility with an airborne infection isolation room or returned to the home environment. Appendix A of the 2007 Guideline for Isolation Precautions contains detailed information on the type and duration of precautions for each infectious agent. An infection control practitioner should be consulted regarding any questions about which precautions to apply or when it is safe to discontinue precautions.

Meticulous hand hygiene should be taught to patients. Some clinicians recommend that HSCT recipients wear a surgical mask or N95 respirator and gloves when they are outside their hospital room prior to engraftment, but the poor utility of disposable surgical masks for prevention and inhalation of fungal spores calls this recommendation into question (CIII). Time spent in crowded areas of the hospital, such as waiting rooms and radiology suites, should be minimized to avoid exposure to respiratory viruses (BIII).

The SHEA 2015 Guidelines for Isolation Precautions for Visitors specifically address the necessity of hospital visitor adherence to isolation precautions [38]. These guidelines, which are not specific for HSCT recipients, suggest that the use of isolation precautions among visitors be guided by the specific pathogen, the underlying infectious condition, and the endemicity of the pathogen in both the hospital and community. Compliance with hand hygiene is essential for visitors of all patients, especially those on isolation precautions. In general, the use of gown and gloves by visitors of patients on Contact Precautions for MRSA and VRE is *not* recommended in these new guidelines, since these organisms are prevalent in the community [38]. However, special consideration should be given for visitors who are immunosuppressed themselves, who are unable to practice good hand hygiene, or who interact with multiple patients. Frequent visitors of patients on Contact Precautions during prolonged hospitalizations may also benefit from the use of Contact Precautions because there are likely to be more interactions that could result in a

higher likelihood of transmission to the visitor. Furthermore, Contact Precautions are recommended for visitors of patients infected with enteric pathogens (i.e., *C. difficile* and norovirus) and strong consideration should be given to their implementation for visitors of patients with drug resistant GNB, since these pathogens are not widely prevalent in the community [38]. Surgical masks are recommended for visitors to patients on both Droplet and Airborne Precautions [38]. Visitors with extensive exposure to a symptomatic patient prior to hospitalization, such as household contacts, may be excluded from these precautions since they may already be immune to the pathogen or in the incubation period [38]. The application of these 2015 Guidelines to HSCT centers is yet to be seen, since this vulnerable patient population frequently experiences prolonged hospitalization, often complicated by acquisition of multidrug resistant organisms (MDRO), enteric pathogens, and other infections requiring Transmission-Based Precautions.

45.2.4 Hand Hygiene

Good hand hygiene practice in the care of HSCT recipients is of paramount importance (AII); the 2002 Guideline for Hand Hygiene in Health Care Settings updates previous recommendations [5]. Hand hygiene leads to a reduction in the carriage of potential pathogens on the hands. Multiple studies report that it reduces morbidity and mortality from health care-associated infections [5]. All persons, especially HCWs, should perform hand hygiene before entering and after leaving patient rooms. Hospital policies should encourage visitors to maintain hand hygiene before and after patient visits (BIII). In addition, HSCT recipients and their household contacts should be educated about the importance of maintaining good hand hygiene both in the hospital and following discharge (BIII).

Hand hygiene should be performed in the following situations: before direct contact with patients; after contact with blood, body fluid, mucous membranes, non-intact skin, or wound dressing; before and after touching an invasive medical device; after contact with a patient's skin; when hands will be moving from a contaminated to a clean body site during patient care; after contact with medical equipment or elements of the environment close to the patient, and before donning and after doffing of gloves. Gloving is not a substitute for hand hygiene and should be performed in addition to hand hygiene where indicated.

Hand hygiene should be performed either with plain or antimicrobial soap and water or with alcohol-based hand rubs. Use of the latter is preferred due to their superior microbicidal activity, reduced drying of the skin, and convenience (AII). However, washing with soap and water is preferred when there is visible soiling of the skin with blood or body fluids or contact with norovirus or spore forming organisms, such as *C. difficile* (AI). Care should be taken to ensure that hand washing is performed with the intended cleansing substance, as one outbreak of *Stenotrophomonas* infection in a transplantation unit was traced to a HCW who used moisturizer rather than hand washing soap due to faulty replacement of hand soap [39].

HCWs engaging in direct patient contact should not wear artificial nails or extenders because they have been associated with outbreaks of gram-negative bacilli and candidal infections (EIII). One study reported that 86% of HCWs with artificial nails carried gram-negative bacteria, *S. aureus*, or yeast, compared with 35% of those without artificial nails before hand washing with soap [40]. In this study, only 11% and 38% of those with artificial nails cleared pathogens with soap washing or with an alcohol-based gel, respectively, compared with 14% and 80%, respectively, of those without artificial nails [40]. Another study reported an association between artificial nails and long natural nails and a prolonged outbreak of *Pseudomonas* infection in a neonatal intensive care unit [41]. Educational campaigns encouraging short natural nails and meticulous nail hygiene should be conducted among HCWs who have contact with HSCT recipients. The 2002 Guideline for Hand Hygiene in Health Care Settings recommends keeping natural nail tips less than ¼ inch long [5].

45.2.5 Equipments, Plants, Play Areas, and Toys

HSCT centers should adhere to established guidelines for the cleaning, sterilization, disinfection, and maintenance of devices and equipment, and they should use only FDA- and EPA-registered agents (AIII) [6]. Although not required by current guidelines, some clinicians recommend wiping the stethoscope head with a sterile alcohol wipe between patients to reduce the potential for bacterial contamination [42, 43]. Sterile bandages and wound dressings should be discarded if they are beyond the expiration date, if the packaging is damaged, or if visible contamination by moisture or other substances has occurred (BIII). Arm boards, if they are used, should have only sterile dressing materials, which should be changed frequently (BIII). Non-sterile tongue depressors should not be used as splints for catheter sites because they have been associated with outbreaks of fatal invasive *Rhizopus* infection (DII) [44].

Although exposure to plants and flowers has not conclusively been shown to cause infection, guidelines discourage having plants, dried, or fresh flowers in HSCT units or areas caring for HSCT patients. The rationale for this prohibition is the isolation of *Aspergillus* species from the soil of potted plants, the surface of dried flower arrangements, and fresh flowers [19, 45, 46]. In addition, high colony counts of gram-negative bacteria, especially *Pseudomonas*, have been identified in vase water of cut flowers [4]. HSCT candidates and recipients should be instructed to avoid contact with soil-based materials such as clay and potting soil in order to minimize their risk of mold infection (DIII).

For pediatric centers, the 2009 Guidelines contain a detailed section on the maintenance of hygiene for toys, games, videos, and play areas [1]. Toys should only be used if they are disposable or if they can be subjected to frequent cleaning, including laundering in the hot cycle of a washing machine, dry cleaning, or washing with an approved disinfectant. In one instance, a rotavirus outbreak was traced to playroom toys that were not disinfected according to protocol [47].

The 2008 Guideline for Disinfection and Sterilization in Healthcare Facilities has many specific recommendations regarding disinfection and sterilization of hospital items [6]. This document uses the common Spaulding classification method of dividing items used in patient care into critical (objects that enter sterile tissue or the vascular system, such as surgical instruments and cardiac catheters), semicritical (objects that contact mucous membranes or non-intact skin, such as endoscopes and respiratory therapy equipment), and noncritical (objects that may contact intact skin but not mucous membranes, such as blood pressure cuffs, crutches, and computers) [6]. In addition, this guideline contains detailed descriptions of different chemical disinfection agents and sterilization methods, including those for multidrug resistant bacteria [6].

45.2.6 Animals

HSCT recipients may come into contact with animals in health care facilities. These may be service animals, therapy animals, or personal pets that visit. The 2009 Guidelines address infection risks posed by animal contact in the home, but no recommendations are given regarding animal contact in health care facilities. In 2015 SHEA published expert guidelines regarding animals in health care facilities [48]. A review of hospital policies in this guideline revealed that 30% of hospitals surveyed excluded immunocompromised patients from animal-assisted activities and 46% from personal pet visitation. This guideline makes the recommendation that, in general, service animals, animal-assisted activities, and personal pet visitation should not be permitted for patients who are significantly immunocompromised, including HSCT recipients, or for those with isolation precautions [48]. These guidelines are not evidence-based, but rather, are a set of practical, expert opinion-based recommendations made in the absence of robust evidence to support practice.

45.2.7 Health Care Workers

HCWs represent an important reservoir of infections that may be transmitted to immunocompromised patients. An ailment that may seem minor to the HCW may pose a significant threat to the HSCT recipient. Any HCW with a transmissible infection should not have direct contact with HSCT recipients (AII). The type of work restriction imposed—work leave vs. temporary reassignment to nonpatient care duties—depends on the specific infection. HCWs with draining skin and soft tissue infections or other lesions involving the skin or mucous membranes (i.e., herpes simplex virus lesions) that cannot be completely covered should be restricted from patient care activities (BIII). HSCT center HCWs with blood-borne pathogens—including HIV, Hepatitis B or C viruses—should not be restricted from patient contact (DIII) [49, 50]. HSCT centers should follow published guidelines regarding the duration of work restriction (BIII) [51, 52] and should formulate work-exclusion policies to ensure that HCWs report illnesses or potential exposures to communicable pathogens (AII) and to make certain that these workers are not penalized for work absences. In the current climate of personnel shortages, applying no pressure, whether direct or indirect, to HCWs to continue working during these illnesses is particularly important. This is an important aspect of an institutional culture of safety [3].

Immunizations of HCWs are of tremendous importance in protecting vulnerable patients. HSCT centers should have written policies regarding HCW immunizations that meet guidelines recommended by the CDC, the Advisory Committee on Immunization Practices, and the Healthcare Infection Control Practices Advisory Committee (BIII) [53]. If possible, HCWs in HSCT units should preferentially receive inactivated vaccines rather than live vaccines to minimize the potential risk of transmission of vaccine virus to HSCT recipients (i.e., inactivated influenza) (AIII).

Influenza vaccination is a particularly important focus of prevention. HSCT recipients may not mount an effective antibody response to the influenza vaccine until at least 1 year after transplantation or longer in those with GVHD. To protect patients, HCWs should receive yearly influenza immunization [54]. Some acute care centers have implemented mandatory vaccination policies for HCWs as a means to ensure high vaccination rates and promote patient safety. Unfortunately, considerable mythology surrounds the influenza vaccine in general public opinion. HSCT centers should mount educational campaigns emphasizing the value of influenza vaccination for HCWs and family members of patients. These campaigns should stress the low risk of adverse effects from the vaccine and the fact that relatively minor influenza symptoms in the HCW or family member could translate into respiratory failure for HSCT recipients. The availability of antiviral agents for postexposure prophylaxis should not be cited as a reason for HCWs to avoid influenza vaccination [55].

Varicella immunization for VZV-seronegative HCWs is also important. Although approximately 90% of adults are VZV-seropositive, seronegative HCWs are at risk of infection, and can transmit VZV before the onset of the typical rash. Similarly, VZV-seronegative household contacts of HSCT recipients should be vaccinated to protect the patient from exposure to acute varicella. Ideally, this should occur at least 4 weeks before the start of the conditioning regimen, since the vaccine is a live-attenuated virus strain [2, 56].

In general, educational programs for health care personnel about the importance of vaccines have been found to increase compliance with best practices [3] and contribute to patient safety overall. It is desirable to implement formal educational programs for all personnel with direct patient contact.

45.2.8 Visitors to Transplant Centers

Visitors with signs or symptoms suggestive of communicable infections or recent known exposure to communicable infections should be prohibited from direct contact with HSCT recipients or candidates (BII). Visitors should be asked to return only after signs and symptoms of infection have resolved or, for recent exposures to communicable infections, until the incubation period for that infection has passed (AII). The 2009 Guidelines recommend that all visitors to HSCT centers adhere to recommended hand hygiene guidelines and isolation precautions regardless of age (AIII). However, though the more recently published SHEA 2015 Guidelines for Isolation Precautions for Visitors differ in their recommendations, and stratify the need for visitor compliance with isolation precautions by pathogen, infectious condition, and prevalence of the pathogen in the community (see Sect. 45.2.3 for more details) [38]. The number of visitors permitted at one time should be limited to a number that permits the nursing staff to perform infection screening and adequate instruction and supervision of hand hygiene and isolation precautions, when appropriate (BIII). HSCT centers should have written policies concerning screening of visitors for potentially communicable diseases (BIII). At some institutions, trained personnel perform active screening of all visitors to HSCT centers. If this is not feasible, signs should be posted to inform visitors about visitation restrictions. In addition to educational programs for health care personnel, education of family members and visitors can make them partners in patient safety by helping to ensure that all who enter the room are utilizing best practices for hand hygiene and other procedures relevant to infection control.

45.3 Patient Skin and Oral Care

The oropharynx is an important source of potential pathogens during high-dose chemotherapy and transplantation, particularly when significant mucositis develops [57]. In particular, viridans streptococci may cause a devastating syndrome of sepsis and respiratory failure, which may be associated with antimicrobial prophylaxis, including fluoroquinolones [58–60]. Other streptococci, *Capnocytophaga* species, anaerobes, yeast, and gram-negative bacilli can originate in the oropharynx and produce infection. Education regarding the importance of good oral and dental hygiene for at least the first year following HSCT is recommended to minimize the risk of oral infections (AIII). If time allows, HSCT candidates should undergo evaluation for dental disease before transplantation (AIII) with the elimination of likely sources of infection (BIII), which may require restoration of teeth, repair of ill-fitting dental prostheses, and extraction of compromised teeth [61, 62]. Ideally, 10–14 days should elapse between the completion of dental therapy and the initiation of a preparative regimen to enable adequate healing (AIII) [62]. Use of keratinocyte growth factor-1, palifermin, can be considered in order to reduce the incidence, severity, and duration of mucositis, the incidence of febrile neutropenia, and possibly bacteremia after HSCT [63].

Oral hygiene should be maintained in HSCT recipients with the use of four to six oral rinses per day with normal saline, sterile water, or sodium bicarbonate solutions (AIIII) [64, 65]. Some centers also use chlorhexidine rinses to decrease oral soft tissue disease and microbial burden [66]; others add oral topical antifungal agents, such as nystatin, in an attempt to decrease candidal colonization. HSCT recipients and candidates should brush their teeth two to three times per day with either a soft toothbrush that is regularly replaced or a foam tooth swab if use of a toothbrush is intolerable, though the latter is less effective (CIII) [62]. Patients skilled at dental flossing may continue to floss daily as long this can be done without inducing mucosal trauma (BIII). HSCT patients should not wear fixed orthodontic appliances from the start of conditioning until mucositis resolves in order to decrease the risk of mechanical trauma and oral infection (EIII) [62]. Use of removable dentures should be minimized during conditioning and the early post-transplantation period; if used, they should be worn while eating, cleaned twice daily, and soaked in an antimicrobial solution that is changed daily (BIII) [62]. Patients with GVHD involving the oral cavity should undergo frequent dental evaluations, as dental caries can develop more quickly in this population (BIII) [67]. Regular brushing, flossing, rinsing, fluoride treatments, and management of xerostomia are essential elements of oral care for patients with GVHD (BIII) [67].

Maintenance of good skin care is equally important in patients undergoing HSCT. HSCT recipients should take showers or baths using a mild soap daily during and after transplantation (BIII). Patients with GVHD involving the skin should regularly moisturize dry, intact skin in order to decrease pruritus and maintain skin integrity [68]. However, HSCT clinicians should also be aware that an outbreak of *Paecilomyces lilacinus* infection was traced to a contaminated, commercially available skin lotion [69]. Daily inspection of the entire skin by a HCW should be encouraged, because prompt treatment of any breach in skin integrity may prevent the development of serious infection. Particular attention should be paid to sites that can serve as portals of infection, including intravascular access sites and the perineum (BII). During catheter care, any drainage, erythema, or tenderness should be immediately reported by the nursing staff; this plays a crucial role in the reduction of catheter-associated infections [70]. The use of razors,

haircutting scissors, or other sharp objects in the hospital room should be prohibited. When clipping of fingernails and toenails is needed, this should be performed carefully, preferably before transplantation, or by a HCW if after transplantation. The feet should be covered with soft booties to avoid injuries while barefoot and to prevent shoe-related chafing. When wound or other dressings are necessary, the dressings should be designed, to the extent possible, so that tape is applied only to the dressing surface and not to the patient's skin.

HSCT recipients and candidates undergoing conditioning therapy should maintain good perineal hygiene to minimize loss of skin integrity (BIII). Patients should perform gentle but thorough perineal cleaning after each bowel movement and thorough perineal drying after each episode of micturition. Following urination or defecation, female HSCT recipients should wipe the perineum from front to back to prevent urethral contamination (AIII). To prevent vaginal irritation that can lead to mucosal breakdown, menstruating HSCT recipients should not use tampons (DIII). The use of rectal thermometers, suppositories, enemas, internal rectal exams, and penetrating anal intercourse should all be avoided in HSCT recipients to prevent mucosal trauma (DIII). In addition, diarrhea is common in patients receiving conditioning chemotherapy regimens, and perianal irritation leading to skin erosions, perianal abscesses, and bacteremia is a constant risk. Centers should develop protocols for the care of perianal skin and the prevention of skin breakdown with the use of a topical protective paste or ointment; supervision of cleansing after defecation may help to avoid complications.

45.4 Prevention of Intravascular Catheter-Related Infections

Prolonged multilumen intravenous access is a necessity during the transplantation admission for infusion of stem cells and the administration of chemotherapy, intravenous fluids, blood products, antibiotics, and sometimes parenteral nutrition. Before transplantation, a large-bore pheresis catheter may be used for stem cell harvesting in the case of autologous HSCT recipients, and certain types of catheters may sometimes be used both for pheresis and during the transplantation admission [71]. Protocols for catheter care differ considerably from one institution to another [72].

Catheter-associated blood stream infections (CLABSI) are a leading cause of bloodstream infections in HSCT recipients, particularly during the preengraftment phase and in patients with GVHD [1]. HSCT centers should follow published guidelines for preventing intravascular device-related infections (AIII) [73, 74]. In 2014 SHEA/IDSA published an update to the 2008 Strategies to Prevent Central Line-Associated Bloodstream Infections in Acute Care Hospitals [75, 76]. The recommendations are divided into basic practices that should be adopted in all acute care areas prior to insertion, at insertion, and after insertion of intravascular catheters. Prevention practices before insertion include: providing clinicians with easy access to an evidence-based list of indications for Central Venous Catheter (CVC) use; requiring education about CLABSI prevention for all health care personnel involved in insertion, care, and maintenance of CVCs; and daily bathing with a chlorhexidine preparation for ICU patients over 2 months of age. The role of chlorhexidine bathing in non-ICU patients remains to be determined. At the time of insertion the following prevention practices are recommended: require an insertion checklist (or other process to ensure adherence to infection prevention practices); perform hand hygiene prior to catheter insertion or manipulation; avoid using the femoral vein in obese adult patients for non-emergent insertion; use an all-inclusive catheter cart or kit; use ultrasound guidance for internal jugular catheter insertion; use maximum sterile barrier precautions during insertion; and use an alcoholic chlorhexidine antiseptic for skin preparation. Recommended practices for preventing infections after insertion include: disinfecting catheter access sites before accessing the catheter; removing nonessential catheters; changing transparent and gauze dressings and performing site care with a chlorhexidine-based antiseptic at specific intervals for non-tunneled CVCs; replacing administration sets (except those used for blood, blood products, or lipids) at intervals not longer than 96 hours; and performing surveillance for CLABSI [75].

Although the efficacy of the CLABSI prevention bundle has not been studied in HSCT recipients, all five elements of the bundle are recommended for this patient population. In addition, despite growing literature on antibacterial-impregnated catheters, the 2009 Guidelines do not require the use of such catheters [1]. However, antibacterial-impregnated catheters and other measures such as chlorhexidine-impregnated dressings, antiseptic-containing connector caps, and antimicrobial locks are special approaches that may be considered, after a risk assessment, for use in locations and/or populations within hospitals when CLABSIs are not controlled by use of basic practices [75].

Patients and caretakers should be trained in the care of intravascular devices (AIII) [77]. Catheter and access site contact with tap water should be avoided and patients should cover the catheter ends during bathing or showering with an impermeable product (BIII). To reduce the risk of inadvertent catheter contamination, intravenous infusions given outside the hospital should be started by a caregiver rather than the patient (BIII) [78].

Despite meticulous catheter care, infections may occur; these are often related to skin flora, particularly staphylococci. For catheter-related infections occurring before transplantation, catheter removal, along with the administration of an appropriate course of intravenous antibiotics, is preferred to attempts to sterilize and use the same catheter. For post-transplant infections, catheter removal is preferred in many instances, but may be impractical in the setting of severe

thrombocytopenia. CLABSIs with coagulase-negative staphylococci are often possible to clear with the catheter in place, so an attempt to treat through the same catheter may be made as long as no tunnel infection is present and the bacteremia clears promptly. If one is attempting to clear a catheter infection with the catheter in place, the catheter lumens should be used sequentially for antibiotic administration. Regardless of whether the catheter is removed, repeat blood cultures should be performed after the completion of the course of intravenous antibiotics to document eradication of the infection. If fever or bacteremia fails to clear promptly, septic thrombophlebitis or, less commonly, endocarditis may be present, and these should be sought with appropriate ultrasound testing and echocardiography. The presence of endovascular infectious complications lengthens the duration of antibiotic therapy and may alter the timing of transplantation.

45.5 Food and Nutrition

In the early days of bone marrow transplantation, sterile or very low-microbial diets were recommended as part of a total protective environment, often in conjunction with the use of selective gut decontamination with oral nonabsorbable antibiotics. In recent years, sterile diets have been much less commonly used. The 2009 Guidelines do not comment on dietary restrictions post-transplantation, but the earlier guidelines published in 2000 recommended a low-microbial diet (BIII) for 3 months after autologous HSCT transplantation and until discontinuation of immunosuppression in those undergoing allogeneic HSCT transplantation [2]. Several studies have found no difference in infection rates in HSCT recipients that consume diets that exclude raw fresh fruits and vegetables [79–81], calling into the question the necessity of adhering to a low-microbial diet post-transplantation.

HSCT recipients should not consume any raw or undercooked meat, eggs, or seafood, and they and their caregivers should follow standard recommendations for food preparation and cleaning of utensils and surfaces [2]. Avoiding foods associated with listeriosis, including soft cheeses, hot dogs, turkey franks, and deli meats, is prudent for HSCT recipients. If these individuals eat leftovers, they should be reheated to steaming hot. Fast-food restaurants should also be avoided, especially in the early months after transplantation. HSCT recipients should also be reminded that naturopathic medications may contain molds [2], especially if they are derived from plant substances.

Total parenteral nutrition (TPN) may be necessary on a temporary basis for patients with severe mucositis or gastrointestinal GVHD. The issues concerning TPN in HSCT recipients have been reviewed [82]. Several studies have suggested that the addition of glutamine may have a beneficial effect in decreasing hospital stay and the incidence of positive blood cultures [82, 83]. Whether administration of intravenous lipids affects patients' risk of infection remains unclear; several studies have identified TPN as a risk factor for CLABSI [75], whereas one study showed no difference in bacteremia and fungemia rates with a moderate dose of intravenous lipids versus a low dose [84].

With the recent legalization of marijuana for medical use in several states in the USA, use of marijuana for control of nausea, pain, and appetite stimulation will likely increase in the coming years. There have been several case reports in the literature of patients with hematopoietic malignancies developing invasive *Aspergillus* infections following regular marijuana use, as *Aspergillus* and other molds can contaminate natural preparations of the drug [85, 86]. Though there are as yet no formal guidelines addressing this issue, HSCT recipients and candidates should avoid marijuana, particularly in its inhaled form, to minimize risk of invasive mold infections.

45.6 Control of Specific Health Care-Associated and Community-Acquired Pathogens

45.6.1 Legionella Species

Legionellosis (or Legionnaire's disease, LD) should be considered in the differential diagnosis of HSCT recipients who develop pneumonia (AIII) [4, 46, 87]. The incubation period is 2–10 days. Thus, patients with laboratory-confirmed LD who are hospitalized for more than 10 days before symptom onset have definite health care-associated legionellosis, and those who are hospitalized between 2 and 9 days before symptoms may have health care-associated infection. If LD is confirmed in a patient hospitalized on the HSCT unit for all or part of the 2–10 days before illness onset or if two or more cases of proven LD occur in patients visiting an outpatient HSCT clinic, the case(s) should be reported to the local or state health department if the disease is reportable in that region (AIII) (the reporting requirements of health departments can vary by region) and a thorough environmental and epidemiologic investigation should be performed by the infection control team (AI) [4, 46, 87]. This should include an assessment of cooling towers, hot water tanks, showers, and tap water faucets. In the United Kingdom, one survey of the water supplies of 85% of transplant units revealed *Legionella* species in 55% [88].

HSCT centers should follow published recommendations regarding the prevention of nosocomial LD (BIII) [4, 46]. Only sterile water should be used to fill nebulization devices and to rinse respiratory-care equipment following cleaning or disinfection (BII) [46]. Use of large volume air humidifiers that create aerosols should be avoided (DI), unless these devices are sterilized or subjected to daily high-level disinfection with sterile water (CIII) [46]. When a new hospital with an HSCT center is built, the cooling tower should be placed such that it is directed away from the hospital's air intake system and aerosol production should be minimized (BII) [46].

Decorative fountains should not be installed in HSCT units or in areas frequented by HSCT recipients (BIII). A clonal outbreak of LD linked to a decorative fountain has been reported [89]. Since HSCT recipients are at higher risk for disease and death from *Legionella*, periodic routine culturing for these organisms in water samples from HSCT center's potable water supply should be considered (CIII) [4, 46, 90, 91]. However, the optimal methodology and cost-effectiveness of environmental surveillance measures for *Legionella* have not yet been determined. The goal should be to maintain the water system free of bacteria (AIII) [4, 46], and if *Legionella* species are detected, the water supply should be decontaminated (AII) [92]. In this situation, patients should not take showers; instead, they should receive sponge baths with *Legionella*-free water (BIII). In addition, water from faucets contaminated with *Legionella* species should not be used in the HSCT unit, in order to prevent the creation of infectious aerosols (DIII). Finally, HSCT recipients should use sterile water for drinking, brushing teeth, or flushing nasogastric tubes (BIII) to prevent acquisition of *Legionella* and other water-borne pathogens.

45.6.1.1 Methicillin-Resistant Staphylococci

HSCT centers should follow published infection control guidelines to prevent health care-associated transmission of methicillin-resistant *S. aureus* (MRSA) [3, 93–96], including hand hygiene with either alcohol-based hand rub or soap and water before and after all contact with patients or potentially contaminated equipment or environment (AII); applying Standard Precautions to all patients at every encounter; use of Contact Precautions for patients colonized or infected with MRSA (AII); and compliance with standard environmental cleaning with an effective disinfectant (BIII) [3, 5].

Currently there is insufficient evidence to support routine screening of all HSCT recipients for MRSA or use of topical or systemic antimicrobial therapy for eradication of asymptomatic MRSA colonization; these are active areas of research. If basic infection control practices fail to prevent high rates of MRSA infection, consideration should be given to implementation of the following adjunctive strategies: collection of MRSA surveillance cultures on admission and serially throughout the hospitalization (BII) [97], with or without decolonization therapy (BII) [98]; routine bathing with chlorhexidine (BIII) [99]; cohorting of MRSA patients or placement of all such patients in single rooms; and designation of dedicated staff to the care of MRSA patients (CIII) [96].

The optimal duration of Contact Precautions for patients is unknown, though studies have demonstrated that patients can remain colonized for extended periods of time. HSCT centers may use different discontinuation criteria for the removal of Contact Precautions, including continuation of such precautions until antimicrobial therapy for MRSA is complete and three consecutive screening cultures collected on separate days are negative (CIII) [95]. For patients with recurrent MRSA infections, eradication of organism carriage can be attempted using any and/or all of the following techniques: application of 2% mupirocin calcium ointment to the nares, chlorhexidine bathing, or administration of systemic antibiotics, though none of these strategies have been shown to be consistently effective (CII) [100, 101]. High-level mupirocin resistant MRSA isolates have emerged in Europe, South America, and the Middle East [102–104], though they remain uncommon in the USA. Therefore, mupirocin use should be coordinated with the hospital infection control team to prevent incorrect use or overuse of this product, which may lead to antimicrobial resistance.

45.6.1.2 Staphylococci with Reduced Susceptibility to Vancomycin

Fortunately, staphylococci with reduced susceptibility to vancomycin are rare [105]. All HSCT centers should have laboratory facilities capable of performing antimicrobial susceptibility testing on all staphylococci (AII) [106–108]. In addition, routine surveillance for staphylococci with reduced susceptibility to vancomycin, which is defined as a vancomycin minimal inhibitory concentration (MIC) of greater than or equal to 2 mcg/mL for *S. aureus* and of at least 4 mcg/mL for coagulase-negative staphylococci, should be conducted (AIII). If such isolates are identified and confirmed, infection control personnel should be notified immediately and institute published guidelines for control of such isolates (BII) [107, 109, 110]. Current recommendations suggest that prudent use of antibiotics by HSCT centers, especially vancomycin, is essential in preventing the emergence of resistant staphylococci (AII). Antimicrobial use patterns in the facility should be monitored to prevent overuse of antimicrobials, including vancomycin (AII) [107, 109, 110].

45.6.1.3 Vancomycin-Resistant Enterococcus (VRE)

VRE infection is associated with poor outcomes in HSCT recipients [111, 112]. To reduce the risk of VRE infection, care providers should limit the use and duration of treatment with vancomycin and anti-anaerobic agents (AII) [107, 113–115]. Although oral vancomycin promotes overgrowth of VRE in the bowel, the risk of VRE acquisition should not be a major consideration when selecting oral vancomycin for the treatment of severe or recurrent *C. difficile* infection (BIII) [115].

Patients colonized with VRE usually remain colonized for prolonged periods of time, which can extend beyond the index hospitalization [116, 117]. Furthermore, VRE can re-emerge after previous negative cultures when the patient is exposed to antimicrobials [95]. For these reasons, Contact Precautions for HSCT recipients with prior VRE colonization

or infection should be continued during subsequent hospital admissions (AIII), though some centers do have protocols for removing VRE designations after a specified number of negative surveillance cultures. The 1995 HICPAC Guidelines for preventing the transmission of VRE suggest three negative stool/perianal cultures obtained at weekly intervals as a criterion for discontinuation of Contact Precautions [118, 119]. Adherence to the same infection control practices described in the MRSA section above is recommended to prevent VRE transmission in HSCT units (AII), including: hand hygiene; applying Standard Precautions to all patients at every encounter; use of Contact Precautions for patients colonized or infected with VRE; and compliance with standard environmental cleaning with an effective disinfectant [3, 5]. Eradication of VRE carriage has not been adequately studied and should not be attempted (DIII). The efficacy of surveillance cultures for VRE to prevent health care transmission of this pathogen is unclear. If there is evidence of nosocomial transmission of VRE in a HSCT center, use of VRE rectal or stool surveillance cultures to identify colonized patients may be considered (CIII) [93].

45.6.1.4 Multidrug-Resistant Gram-Negative Bacilli (MDR-GNB)

MDR-GNB are defined as GNB that are resistant to one or more classes of antimicrobial agents, including those that produce extended-spectrum β-lactamases (ESBL) and carbapenemases. In 2006, HICPAC published a detailed discussion of MDR-GNB and recommendations for their prevention [95]. Thoughtful use of antimicrobial agents is essential to limit the development of MDR-GNB (BII). In addition, adherence to the same infection control practices described in the MRSA section above is recommended to prevent MDR-GNB transmission in HSCT units (AII), including: hand hygiene; applying Standard Precautions to all patients at every encounter; use of Contact Precautions for patients colonized or infected with MDR-GNB; and compliance with standard environmental cleaning with an effective disinfectant [3, 5]. Successful control of MDROs has been documented in the USA and abroad using a variety of combined interventions. These include improvements in hand hygiene, use of Contact Precautions until patients are culture-negative for a target MDRO, active surveillance cultures, education, enhanced environmental cleaning, and improvements in communication about patients with MDROs within and between healthcare facilities.

The use of multiple concurrent control measures in these reports underscores the need for a comprehensive approach for controlling MDROs [120]. Evidence is mixed regarding whether active surveillance programs for MDR-GNB are useful in addition to basic infection control practices. Several studies reported a decrease in ESBL-producing *Enterobacteriaceae* over a 6-year period using a multipronged approached that included surveillance cultures [121, 122]. Other reports suggest that routine surveillance cultures are not required to control nosocomial MDR-GNB transmission [123]. That said, the CDC now recommends that a single round of surveillance cultures be sent in high-risk settings (i.e., hospital settings in which patients are exposed to broad spectrum antibiotics) if previously unidentified carbapenemase-producing GNB are isolated [120]. HSCT units suffering from high rates of MDR-GNB infection should implement and/or ensure basic infection control measures are in place. The use of active surveillance cultures as an adjunct to their standard infection control practices may also be considered (CIII).

45.6.1.5 Clostridium Difficile-Associated Diarrhea (CDAD)

In the mid-2000s, an epidemic strain of *C. difficile* spread rapidly in hospitals. HSCT centers should follow published recommendations for prevention, control and treatment of CDAD (AI) [7, 124, 125]. The 2014 Updated Guidelines by SHEA, IDSA, the American Hospital Association (AHA), and the Association for Professionals in Infection Control and Epidemiology (APIC) emphasize the importance of limiting inappropriate antimicrobial use in order to prevent CDAD in the hospital [7]. Patients with CDAD should be placed on Contact Precautions for the duration of their illness (BIII) [3, 7, 125], and placed in a private room, if possible [7]. HCWs entering the patient's room should wear gowns (BIII) and gloves (AI) regardless of whether they anticipate touching the patient or anything in the environment [3, 7, 124, 125]. The 2014 SHEA/IDSA/AHA/APIC Guidelines recommend placing patients with diarrhea on Contact Precautions while *C. difficile* testing is pending to limit transmission at a time when bacterial shedding is greatest [7]. Contact Precautions should remain in place at least until the patient is asymptomatic (BIII) [124], or at least 48 hours thereafter [7]. A "test of cure" to determine whether Contact Precautions can be discontinued is discouraged (DII) [7, 124]. If there is evidence of ongoing transmission of *C. difficile* despite compliance with basic prevention strategies, HSCT centers should consider maintaining Contact Precautions until hospital discharge, even if diarrhea resolves sooner (CIII) [7]. The following practices are **not** recommended for prevention of nosocomial *C. difficile* transmission: routine stool surveillance cultures or toxin assays for *C. difficile* among asymptomatic patients or HCWs (DIII); culture of *C. difficile* from hand swabs of HCWs (EIII); and treatment of asymptomatic *C. difficile* carriers (EII) [7]. Furthermore, the prophylactic use of lyophilized *Saccharomyces boulardii* to prevent diarrhea among HSCT recipients receiving antibiotics is contraindicated, as it has been associated with development of *S. boulardii* fungemia [126].

CDAD is one of the situations where hand washing with antimicrobial soap and water is preferred over alcohol-based hand rubs, as the latter are not sporicidal for *C. difficile.*

Proper hand washing technique, including washing for a minimum of 15–30 seconds, should be enforced (BI) [5]. *C. difficile* is more resistant than many organisms to standard disinfectants. An intervention study suggested that the use of 1 to 10 hypochlorite solution was more effective as an environmental disinfectant than was quaternary ammonium in the control of *C. difficile* in HSCT recipients [127]. The incidence of *C. difficile* diarrhea decreased from 8.6 to 3.3 cases per 1000 patient-days when the disinfectant was changed to hypochlorite and then increased again to 8.1 cases per 1000 patient-days when quaternary ammonium was again used [127]. The use of bleach-containing cleaning products for environmental disinfection should be considered if there is ongoing evidence of *C. difficile* transmission with standard procedures (BII). A variety of products with EPA-registered claim to activity against *C. difficile* are becoming available, including those that do not contain bleach. The optimal frequency and extent of cleaning with such agents remain uncertain, though at a minimum cleaning should be performed daily and when surfaces are visibly soiled; the agents should be applied for contact times recommended by the manufacturer. The 2008 Guideline for Disinfection and Sterilization in Healthcare Facilities gives further recommendations regarding environmental cleaning, and disinfection of equipment such as colonoscopes, to prevent transmission of *C. difficile* [6].

45.6.1.6 Community-Acquired Respiratory Virus Infections

CRVs can cause significant morbidity and mortality in HSCT recipients, especially those in the preengraftment phase [128, 129], and may produce health care-associated outbreaks if they are introduced into an HSCT center. Influenza, parainfluenza, adenovirus, respiratory syncytial virus (RSV), and human metapneumovirus (hMP) can produce severe disease, although reported mortality rates have varied. Pulmonary copathogens are common, possibly accounting for some of the observed mortality in CRV-infected patients [130].

Measures to prevent the introduction and spread of CRVs on the HSCT unit should be implemented (AIII) [46, 131]. To prevent health care-associated transmission, identifying HSCT recipients with respiratory virus symptoms and placing them under appropriate precautions is crucial. Patients should empirically be placed on Contact plus Droplet Precautions until a specific pathogen has been identified, after which these precautions can be modified based on the results (BIII). Droplet Precautions alone are appropriate for influenza, but RSV, parainfluenza, and adenovirus require both Contact and Droplet Precautions. Primary or disseminated varicella infection requires Airborne plus Contact Precautions, though single dermatomal zoster only requires Standard Precautions [3]. When a patient at the HSCT center has a viral upper or lower respiratory tract infection, HCWs and visitors should follow all Standard and Transmission-Based Precautions, with attention to hand hygiene before and after contact with a patient, after handling respiratory secretions or objects contaminated with respiratory secretions, and before donning and after doffing gloves (AII) [5, 46]. This practice is important because transmission of most CRVs occurs by contact, especially from hand to nose and eye. In keeping with Standard Precautions, HCWs should wear a face mask that fully covers the front and side of the face while performing aerosol-generating procedures—such as bronchoscopy, endotracheal intubation, and open suctioning of the respiratory tract—to avoid contamination with respiratory secretions (AIII). For patients with suspected or known influenza, such procedures should be performed using Airborne Precautions [132]. In outpatient waiting rooms, patients with CRV infections should be separated from other patients and should be encouraged to use respiratory hygiene/cough etiquette (BIII). Patients and their companions should be screened upon arrival for symptoms of CRV infections; those screening positive should be educated about proper use of facemasks, tissues, and hand hygiene, and should be provided with the supplies to implement these practices [132].

To minimize the risk of CRV spread on the HSCT unit, HCWs and visitors should be screened for upper respiratory infection symptoms (BII), and if present, should be restricted from contact with HSCT recipients and from individuals undergoing conditioning therapy (BIII) [51, 52]. HCWs should be re-assigned to non-patient care duties (BIII) and visitors should refrain from visiting (AII) until symptoms resolve. For influenza in particular, HCWs should be excluded from work for 7 days following symptom onset (BIII) [132]. HCWs and visitors with infectious conjunctivitis should be restricted from direct patient contact until drainage resolves (AII) [51].

All HSCT recipients or candidates with signs and symptoms of possible CRV infection should be promptly tested for the presence of such viruses (BIII). Nasopharyngeal throat swabs, washes, or aspirates and bronchoalveolar lavage fluid should be tested by viral culture, rapid antigen testing, or PCR (BIII). This strategy facilitates timely initiation of Transmission-Based Precautions and, in some instances, preemptive treatment of certain CRVs to prevent disease complications [46]. Retesting of patients may be performed to help determine whether patients have stopped shedding viruses following resolution of their symptoms (BIII). Prolonged CRV shedding may occur in HSCT recipients; viral shedding has been reported to last more than 22 days for RSV, 4 months for influenza, and 2 years for adenovirus [133–136]. Appropriate isolation precautions should be maintained for at least the duration of illness (AII), and consideration should be given to continuing them for the duration of hospitalization or viral shedding to prevent nosocomial transmission (CIII).

Routine virologic screening of asymptomatic HSCT candidates is performed by some HSCT centers to detect outbreaks and implement infection control measures early, though there is insufficient data at present to recommend this

practice. During outbreaks of RSV in a HSCT unit, HCWs may be cohorted to minimize nosocomial transmission [54, 137], though the 2009 Guidelines do not recommend this strategy for control of other CRV outbreaks. Two winter community RSV outbreaks were controlled using the following strategies on an adult bone marrow transplantation unit: identification, isolation, and cohorting of RSV patients; use of masks and gloves; prompt therapy with aerosolized ribavirin; screening of visitors; restricting visitation by children younger than 12 years of age and anyone with RSV symptoms; and restricting symptomatic hospital staff from working in the bone marrow transplantation unit [137]. Nasopharyngeal antigen testing of symptomatic individuals, Contact Precautions, and infection control education for HCWs controlled a parainfluenza virus outbreak on a bone marrow transplantation unit [138]. Weinstock and colleagues reported an outbreak of influenza A on a 30-bed HSCT unit and described interventions implemented to terminate the outbreak and to prevent nosocomial influenza the following season [139]. These interventions included strict isolation of patients with influenza, reverse isolation of all other patients on the unit during the outbreak, more rapid laboratory turnaround of diagnostic tests for influenza, restriction of visitors, cohorting of HCWs assigned to the unit, universal antiviral prophylaxis of all patients and HCWs on the unit during the outbreak, and an enhanced influenza vaccine campaign for HCWs the following season [139].

HCWs and close contacts of HSCT recipients should be vaccinated yearly for influenza, using the inactivated vaccine rather than the live attenuated vaccine to eliminate the risk of vaccine virus transmission (AI) [56]. Under certain conditions involving CRV outbreaks, influenza vaccine along with prophylactic antiviral treatment of a subgroup of patients, an entire unit, and/or family members and HCWs may be undertaken, particularly in the case of an influenza outbreak that is not controlled with other measures or that involves an influenza strain that is not contained in the current vaccine (BIII) [1, 54, 139]. Some clinicians have recommended chemoprophylaxis for all HSCT recipients who are less than 24 months from transplantation, as well as for those beyond 24 months who are still receiving immunosuppressive therapy [2]. However, ongoing changes in antiviral resistance require that any prophylaxis decisions be based on updated CDC recommendations regarding the strains and outbreaks that are occurring during a particular season [140].

45.6.1.7 Adenovirus

Adenovirus can cause large outbreaks in acute and chronic care facilities, including outbreaks of highly symptomatic respiratory and gastrointestinal infection [141]. Transmission can occur in multiple ways, including inhalation of aerosolized droplets, contact with contaminated surfaces, fecal–oral spread, exposure to infected tissue or blood, and rarely via contaminated water [142]. Strict infection control measures are required to prevent spread of this easily transmissible virus. Sputum and oral secretions of infected adults contain 10^6–10^7 viral particles/ml and the virus can survive up to 35 days on surfaces. As few as five virions are required to cause infection in immunocompromised adults [143], who can then asymptomatically shed the virus for months following infection. Patients with adenovirus gastroenteritis should be placed on Contact Precautions, while patients with respiratory illnesses, conjunctivitis, or disseminated disease require both Droplet and Contact Precautions to prevent nosocomial transmission [3]. Hand hygiene with either an alcohol-based rub or soap and water and standard environmental disinfectants effectively kill the virus [144, 145].

45.6.1.8 Viral Gastroenteritis

Like CRV, viral gastroenteritis can cause more severe disease in HSCT recipients than in normal hosts, and health care-associated outbreaks can develop if these pathogens are introduced into a HSCT unit. Commonly encountered pathogens include adenovirus (see above), norovirus, rotavirus, and astroviruses; all are spread via the fecal–oral route, and contact with infected persons and contaminated fomites. Compliance with hand hygiene, appropriate isolation precautions, and environmental cleaning are required to prevent nosocomial transmission of these pathogens (AII) [4]. At a minimum, isolation precautions should be maintained for the duration of the illness (AII), with consideration given to continuing these measures for the duration of the hospitalization or the duration of viral shedding, since HSCT recipients may asymptomatically shed virus following symptom resolution (CIII).

Rotavirus is the most common cause of severe gastroenteritis in the pediatric population worldwide. Due to high concentrations of viral shedding in stool and the ability of the virus to persist in the environment for more than 10 days, environmental contamination is common [146, 147]. Health care-associated outbreaks of rotavirus have been traced to contaminated toys and hands [47, 148]. Contact Precautions are required to prevent transmission of rotavirus (AIII). Alcohol-based hand rubs effectively kill the virus and are sufficient for hand hygiene, unless hands are visibly soiled. Prompt removal of soiled diapers and thorough environmental cleaning are essential to limit environmental contamination with rotavirus (AIII) [3].

Norovirus is the most common cause of outbreaks of nonbacterial gastroenteritis, and now causes >50% of foodborne infections in the USA. This virus is easily transmissible and less than 100 particles are required to cause infection in normal hosts. Immunocompetent individuals continue to shed virus up to 72 hours following symptom recovery, whereas some immunocompromised hosts can shed virus for months to years following infection. Unlike rotavirus, alcohol-based hand rubs and standard disinfectant agents do not effectively kill norovirus [3, 149]. Multiple infection control measures

should be implemented to prevent transmission, including: hand washing with soap and water, Contact Precautions, wearing masks while cleaning areas contaminated by feces and vomitus, and minimal handling of soiled bedding and garments (BIII) [1, 8]. Per the 2011 HICPAC Guidelines for the Prevention and Control of Norovirus Gastroenteritis Outbreaks in Healthcare Settings, Contact Precautions should be maintained for at least 48 hours after symptom resolution, and consideration should be given to extension of these precautions and to cohorting infected individuals if they have medically complex conditions, such as HSCT recipients and candidates [8]. A hypochlorite-based cleaning agent should be used on non-porous environmental surfaces (BII) [150]. Environmental cleaning and disinfection should be performed at least daily, when items are visibly soiled, and following hospital discharge (BIII). Heat disinfection to 60 °C can be utilized for items that cannot be cleaned with bleach-based disinfectants [151]. HCWs with norovirus should be excluded from work at least 48 hours after symptom resolution [8]. In addition, staff cohorting protocols should be implemented in the event of a norovirus gastroenteritis outbreak [8].

Astroviruses have caused outbreaks of viral gastroenteritis in hospitals, nursing homes, and daycare centers. The virus can survive in the environment for several months [4]. Contact Precautions and environmental disinfection are effective and should be implemented at HSCT centers during outbreaks (AII).

45.6.1.9 Tuberculosis

Tuberculosis (TB) may reactivate in HSCT recipients in the face of immunosuppression. Though the 2009 Guidelines do not comment on TB prevention methods, the 2000 Guidelines recommended that HSCT candidates be screened by history and chart review for a history of exposure to tuberculosis (AIII). A tuberculin skin test (TST) using five tuberculin units of either the Tubersol (Connaught-Aventis, Swiftwater, PA) or Aplisol (Monarch, Bristol, TN) formulations may be administered by the Mantoux method. This test result may be unreliable, however, because of the patient's baseline immunosuppression. For immunocompromised hosts, a positive skin test is defined as 5 mm or more of induration [152]. HSCT candidates with a recently positive skin test or a previously positive skin test and no prior preventive therapy should have a chest radiograph and an evaluation for active tuberculosis (AI). Studies are mixed regarding the efficacy of the interferon-γ-release assays (IGRA) in HSCT recipients. One study suggested that IGRA is a more sensitive and specific test than the TST for predicting active tuberculosis after transplantation in HSCT recipients [153], while a second found no difference in rates of positive IGRAs and TSTs and poor agreement between these test outcomes regardless of previous BCG vaccination [154].

HSCT centers should adhere to published recommendations concerning the control of TB in health care facilities. These guidelines include the institution of Airborne Precautions and use of negative-pressure rooms for patients with suspected or confirmed laryngeal or pulmonary tuberculosis (AII) [3]. When HCWs are caring for such patients, they should wear N95 respirators or Powered Air Purifying Respirators (PAPRs) during exposure to these potentially infected patients, including in airborne infection isolation rooms and when HEPA filters are deployed (AIII). To obtain a maximal benefit in their use, HCWs should be fit-tested and trained in the use of N95 respirators and/or PAPRs annually (AIII).

Vaccination with the Bacille Calmette-Guérin (BCG) vaccine is contraindicated in HSCT candidates and recipients because of the potential for disseminated and fatal infection due to BCG in immunocompromised hosts (EII) [155].

45.7 Infection Control Surveillance

HSCT centers should follow standard guidelines for surveillance of epidemiologically significant nosocomial pathogens and their susceptibility patterns, including MRSA, VRE, MDR-GNB, *C. difficile*, CRVs, and invasive mold infections (BIII) [3]. In the absence of clusters of infections, surveillance cultures of the environment or of equipment or devices used for pulmonary function testing, the delivery of inhalation anesthesia, or respiratory care are not indicated (DIII) [46]. In the absence of an outbreak of nosocomial fungal infection, HSCT centers should not perform routine fungal surveillance cultures of devices or dust in patient rooms (DIII). Routine sampling of air, ceiling tiles, ventilation ducts, and filters for mold detection is classified as CIII, and thus it is optional [1]. However, infection control surveillance for clinical cases of aspergillosis in HSCT recipients is advisable (BIII). An increase in the number of cases should trigger an investigation for potential environmental sources of mold exposure in the HSCT center (BIII). The ventilation system should also be evaluated to ensure appropriate filtration, air flow, and air pressure differentials (BIII) [9].

45.8 Summary

In the decades since the performance of the first bone marrow transplants, considerable experience has been gained. Advances in many areas have altered the topography of infection risk for the HSCT recipient. These include reduced intensity conditioning, use of growth factors, prophylaxis and preemptive therapy for infections, identification of emerging pathogens and techniques to facilitate their early diagnosis, availability of new and effective antimicrobials, and strategies for prevention and treatment of GVHD. Nevertheless, although agreement exists on general principles, basic issues such as optimal infection control measures remain unresolved to some extent. The 2009 Guidelines provide a comprehensive review

of literature up to that date. However, the relative paucity of recommendations for levels AI, AII, BI, and E in the infection control guidelines is striking. Among the AI and AII recommendations, most are global and generic recommendations that are derived from, and applicable to, other clinical settings. Therefore, there is a need for more evidence-based studies to define optimal infection control practices in these high risk patients undergoing HSCT. For future developments, the reader is advised to consult the CDC website (www.cdc.gov) for updated recommendations on infection control, prophylaxis, outbreaks, and emerging pathogens which may go beyond the recommendations cited in this chapter.

Infection Prevention and Control Issues After Solid Organ Transplantation

David B. Banach, Maria Teresa A. Seville, and Shimon Kusne

Transplantation has been accepted as a treatment modality for terminal organ failure. Therapies used to prevent rejection suppress the immune system and as a result, the transplant recipient is often at high risk of infection. Prolonged and frequent exposure to healthcare settings and multiple antibiotics may predispose the transplant recipient to colonization or infection with multidrug-resistant organisms. The use of good infection prevention and control practices is extremely important throughout the continuum of care for solid organ transplant (SOT) recipients. In the hospital setting, antimicrobial-resistant pathogens often cause the infections identified during admission or after discharge, resulting in increased morbidity and mortality.

This chapter reviews selected infection prevention and control practices that address common infections in transplant recipients. The U.S. Centers for Disease Control and Prevention (CDC) has issued guidelines for the prevention of infection for hematopoietic stem cell transplantation (HSCT) recipients, but not specifically for SOT recipients. Pertinent guidelines on infection prevention and control issues have been developed by the CDC and the Healthcare Infection Control Practices Advisory Committee (HICPAC) to provide specific recommendations that are pertinent to all patient populations. Guidelines referenced in this chapter include the Guideline for Hand Hygiene in Health-Care Settings—2002 [1], Guidelines for Preventing HealthCare-associated Pneumonia, 2003 [2], Guidelines for Environmental Infection Control in Health-Care Facilities, 2003 [3], Management of Multidrug-Resistant Organisms in Healthcare Settings, 2006 [4], Guidelines for Isolation Precautions: Preventing Transmission of Infectious Agents in Healthcare Settings, 2007 [5], and the Guideline for Disinfection and Sterilization in Healthcare Facilities, 2008 [6]. The American Transplant Society has published guidelines for the management and prevention of infections in organ transplant candidates and recipients which address specific aspects of infection control practices pertinent to transplantation [7]. The Society for Healthcare Epidemiology of America (SHEA) and the Infectious Diseases Society of America (IDSA) have also published a compendium of strategies to prevent healthcare-associated infections (HAIs) in acute care hospitals [8]. These strategies, most recently revised in 2014, highlight basic prevention practices that are often referred to as "bundles," guidance to infection control programs regarding implementation of these practices, as well as special approaches for infections that are not controlled using basic infection control practices. Despite the publication of expert guidance documents and guidelines some issues are still unresolved. The authors of this chapter describe some of the practices in their institutions, while acknowledging that different approaches to the same problem might exist.

46.1 Healthcare-Associated Infections

46.1.1 Prevention and Isolation Practices

Caregivers must maintain good infection prevention practices to minimize the transmission of infection in the healthcare setting. Invasive devices such as central venous catheters (CVCs), indwelling urinary catheters, and ventilators expose the patient to additional risks for infection. Most facilities have implemented infection prevention "bundles" designed to prevent these device-associated HAIs. Due to the success seen in reducing HAIs, the Centers for Medicare and Medicaid Services (CMS) issued new guidelines. After October 1, 2008, hospitals no longer receive additional payment for cases in which selected conditions were not present on admission, which include CVC-associated bloodstream infections and catheter-associated urinary tract infections [9]. What this means to hospitals is that claims are paid as though the secondary diagnosis was not present. These "Hospital-Acquired Conditions" (HACs) are considered "never events," but may still be problematic in transplant recipients. Careful attention must be given to good hand hygiene practices and CVC care, as well as to practices that decrease the risk of catheter-associated urinary tract infection. As a protective

P. Ljungman et al. (eds.), *Transplant Infections*, DOI 10.1007/978-3-319-28797-3_46

measure, patients may also be placed into protective precautions to heighten the awareness of the caregivers to the potential for serious infection.

Whereas the 1991 Occupational Safety and Health Administration (OSHA) Bloodborne Pathogens Standard focused primarily on employee protection [10], the CDC and HICPAC have published numerous patient-focused guidelines and recommendations for the prevention of HAIs. Revised in 2007, the Guideline for Isolation Precautions: Preventing Transmission of Infectious Agents in Healthcare Settings 2007 [5] updated and expanded the *1996 Guideline for Isolation Precautions in Hospitals*. The transition of healthcare delivery from primarily acute care hospitals to other healthcare settings (e.g., home care, ambulatory care, freestanding specialty care sites, and long-term care) created a need for recommendations that could be applied in all healthcare settings using common principles of infection control practice, but could be modified to reflect setting-specific needs. In this revision, the term "nosocomial infections" was replaced by "healthcare-associated infections" to better reflect the changing patterns in healthcare delivery. It may be difficult to determine the exact site of exposure to an infectious agent and/or acquisition of infection as patients move through the healthcare delivery system. The SARS experience, and more recently, the experience with Ebola virus disease, highlighted the need to better prepare for new emerging pathogens and focused on the ways minor breaks in infection control technique resulted in infections being transmitted to healthcare professionals. Sections of this guideline were created as evidence mounted that environmental controls could decrease the risk of fungal infections in severely immunocompromised patients. While the Protective Environment (PE) has been found to be of greatest benefit for patients undergoing allogeneic hematopoietic stem cell transplants, there may be some lessons to be learned from successful implementation in this group of patients. Organizational characteristics (e.g., nurse staffing levels and composition, establishment of a safety culture) are also identified as key components to promote adherence to recommended infection control practices. Combining the universal precautions and body substance isolation precautions, contact with human blood, body fluids, secretions or excretions (except for sweat), nonintact skin, mucous membranes, and contaminated items requires the use of personal protective equipment, as part of standard precautions. Respiratory hygiene/cough etiquette, safe injection practices, and the use of masks during insertion of catheters or injection of material into spinal or epidural spaces via lumbar puncture procedures were added to standard precautions in 2007. Transmission-based precautions are used, in addition to standard precautions, to prevent infections spread by airborne, droplet, and direct contact routes. Certain infections that had required disease-specific isolation precautions are now included under standard precautions.

Airborne precautions are used if a patient has a known or suspected infection with an agent that can be transmitted by evaporated droplets [droplet nuclei of <5 mm (micron)] that remain suspended in the air and that may be carried away from the infected patient. Measles, varicella, and tuberculosis are the primary infections included in this category; a patient infected with any of these must be housed in a room with controlled ventilation. Specialized air filters and negative pressure in the room prevent the infectious droplet nuclei from entering the general air supply and infecting others.

Certain diseases, such as influenza and adenovirus, generate droplets larger than 5 mm. These larger-sized particles are too big to remain suspended in the air; therefore, no special ventilation is required. Close contact with respiratory tract secretions is required for disease transmission, so masks should be worn by healthcare workers when they are working within 3 ft (0.9 m) of an infected patient to prevent the inhalation of infectious droplets.

Contact precautions are used to prevent the transmission of certain microorganisms that may be found on the patient's skin or on inanimate objects in the patient's environment. Included in this category are epidemiologically significant organisms, such as methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin-resistant enterococci (VRE), *Clostridium difficile*, and respiratory syncytial virus (RSV). Private rooms are recommended, but patients colonized or infected with the same organism(s) may be cohorted together, if necessary. If neither of these options is achievable, the immunosuppressive state of potential roommates should be evaluated. For example, placing a VRE-colonized patient with an otherwise healthy 30-year-old who has a broken leg would be preferable to placing that patient with a postoperative transplant recipient who might become more easily colonized and infected. Contact precautions require gloves and gowns be worn for contact with the patient or potentially contaminated items and areas in the patient room. While the likelihood of transmission to other patients through contact with clothing is remote, caregivers are likely to touch their own clothing (e.g., lab coat pockets) and thus transmit the organism on their hands. The 2006 HICPAC/CDC guideline, The Management of Multidrug-Resistant Organisms in Healthcare Settings, recommends donning gowns and gloves upon room entry and discarding them before exiting the room of a patient with organisms that have been implicated in environmental transmission (e.g., VRE, *C. difficile*, noroviruses and other intestinal tract agents, and RSV) [4].

The 1975 CDC isolation techniques manual defined a protective isolation category to protect neutropenic or immunosuppressed patients. Whereas other isolation categories were designed to prevent the transmission of disease from an infected patient to others, the purpose of protective or "reverse" isolation is to protect the highly susceptible patient. Neutropenic precautions are practices designed to reduce microbial contamination in the patient's environment. Because many infections in immunosuppressed patients are attributable to the patient's endogenous flora, the use of special environmental precautions is not recommended, except for allogeneic stem cell transplant recipients, for whom a

TABLE 46-1. Centers for disease control and prevention isolation precautions for selected infections

Infection	Precautions	Comments
Abscess, draining (minor)	Standard	Contact for major draining abscess
Adenovirus	Droplet, contact	
Aspergillosis	Standard	
Candidiasis	Standard	
Cellulitis	Standard	
Clostridium difficile	Contact	Private room preferred
Cytomegalovirus	Standard	
Epstein–Barr virus	Standard	
Fungus, endemic	Standard	Blastomycosis, coccidioidomycosis, histoplasmosis
Hepatitis, viral (HBV and HCV)	Standard	
Herpes simplex virus	Standard Contact	Encephalitis, recurrent mucocutaneous—skin/oral/genital Disseminated or severe mucocutaneous
Influenza	Droplet	
Legionnaires' disease	Standard	
Listeriosis	Standard	
Multidrug-resistant organisms (MRSA, VRE, and MDR-GNB)	Contact	Gown and gloves recommended on entry into room Private room preferred
Mycobacteria, nontuberculous	Standard	
Nocardiosis	Standard	
Parainfluenza	Contact	Respiratory infection in infants and young children
Parvovirus B19	Droplet	
RSV	Contact	
Rotavirus	Contact	
Tuberculosis	Airborne Airborne, contact	Pulmonary and/or laryngeal Extrapulmonary, draining lesion
Varicella-Zoster virus	Airborne, contact	Varicella (chickenpox), disseminated herpes zoster (shingles)
Zygomycosis (Mucor and Rhizopus)	Standard	

Abbreviations: *HBV* hepatitis B virus, *HCV* hepatitis C virus, *MRSA* methicillin-resistant *Staphylococcus aureus*, *MDR-GNB* multidrug-resistant gram-negative bacteria, *RSV* respiratory syncytial virus, *VRE* vancomycin-resistant enterococcus.

protective environment is necessary to minimize fungal spore counts in the environment and decrease the risk of invasive fungal infections [5]. To reduce the risk of infection, nursing care often focuses on skin integrity, indwelling intravenous devices, and good oral hygiene.

Isolation precautions for select organisms or disease syndromes are presented in Table 46-1. A complete list can be found in Appendix A of the CDC guideline on isolation precautions [5].

46.1.2 Definition of Healthcare-Associated Infections

The National Nosocomial Infections Surveillance (NNIS) system, a cooperative effort of the CDC and participating hospitals, began in 1970 with the purpose of creating a database to track nosocomial infections in the USA. In 2005, the National Healthcare Safety Network (NHSN) was established to integrate and supersede three surveillance systems at the CDC: the NNIS, the Dialysis Safety Network (DSN), and the National Surveillance of Healthcare Workers (NaSH). Patient-specific event data are entered into this Web-based system by individual facilities but comparative results can be found on the NHSN Web site (http://www.cdc.gov/nhsn) and are published annually in the *American Journal of Infection Control*. Many states have mandated that HAIs be reported through NHSN to better evaluate the magnitude of HAIs. The public reporting of infection data is state specific, ranging from all infections being reported in Pennsylvania to more limited requirements, such as primary bloodstream infections only. CMS requires reporting of certain HAIs as part of pay for performance initiatives. Healthcare facilities use the standardized definitions created by the CDC, previously in the NNIS program and now in the NHSN [11], to classify HAIs, thereby enabling comparisons to national benchmarks. For device-associated infections, such as ventilator-associated pneumonia, central line-associated bloodstream infection (CLABSI), and catheter-associated urinary tract infections, rates should be calculated (the denominator is device-days and numerator is the number of infections recorded; result is multiplied by a factor of 1000). Rates are thus recorded as the number of infections per 1000 device-days. HAI data are stratified into types of patient care areas (e.g., medical ICU, medical/surgical ICU, and SOT specialty care area) to provide infection rates according to the risk factors of the patient population served [12]. Operative procedure codes available for identification of surgical site infection (SSI) rates include liver, kidney, and heart transplant surgeries. Healthcare facilities reporting

HAIs to NHSN can get a standardized infection ratio (SIR) which is calculated by dividing the number of observed infections by the number of predicted (i.e., expected) infections. The number of predicted infections is calculated using infection probabilities estimated from multivariate logistic regression models constructed from NHSN data during a baseline period, which represents a standard population's infection experience. NHSN provides a p value and 95% confidence intervals to determine the statistical significance of the SIR for the healthcare facility's HAIs.

46.1.3 Central Line-Associated Bloodstream Infections

A general increase has occurred in the incidence of bloodstream infections caused by gram-positive bacteria, particularly *Staphylococcus* species. Many infections with coagulase-negative staphylococci are related to the increased use of various indwelling central lines. CLABSI is one of the primary infections seen in the immunosuppressed patient, because normal skin flora may colonize long-term access devices. In 2011, the CDC published Guidelines for the Prevention of Intravascular Catheter-Related Infections to help address this issue [13]. The incidence of infection varies with the type and intended use of intravascular devices. The two main device types are short term or temporary devices and those that are used for long-term access. Every device has some advantages and some risks. Attention should be focused on preventing site infections and on providing education for the patients and their caregivers if the catheter is not removed before hospital discharge.

The basic approaches to preventing CLABSI include the following [13]:

Before insertion

1. Educate healthcare personnel involved in the insertion, care, and maintenance of CVCs on CLABSI prevention.
2. Bathe ICU patients over 2 months of age with a chlorhexidine preparation on a daily basis.

At insertion

3. Use a catheter checklist to ensure adherence to insertion practices.
4. Perform hand hygiene before insertion or manipulation of a CVC.
5. Avoid the femoral vein for CVC access in adults, if possible.
6. Use maximal sterile barrier precautions during CVC insertion.
7. Use a chlorhexidine-based antiseptic for skin preparation in patients older than 2 months.
8. Use ultrasound guidance for internal jugular catheter insertion.

After insertion

9. Daily assessment of the need for the CVC and prompt removal of unnecessary CVCs.
10. Disinfect CVC hubs, connectors, and injection ports before accessing the CVC.
11. Change transparent dressings and perform catheter care with a chlorhexidine-based antiseptic every 5–7 days or immediately if the dressing is soiled, loose, or damp.
12. Use antimicrobial ointments for hemodialysis catheter insertion sites.

Several varieties of catheters and cuffs coated or impregnated with antimicrobial or antiseptic agents that reduce the risk of catheter-related bacteremia are available and have been shown to decrease the risk of CLABSI. Although catheters with chlorhexidine/silver sulfadiazine coatings, catheters impregnated with minocycline/rifampin or platinum/silver, and silver-coated cuffs may provide additional protection from skin flora [14, 15], they are more costly than the standard catheters and are recommended only if CLABSI rates could not be controlled using the basic approaches. The use of antimicrobial ointments for catheter insertion sites is no longer recommended, except for hemodialysis catheter insertion sites. Chlorhexidine-impregnated dressings may be beneficial in preventing CLABSI [16]. Daily chlorhexidine bathing may also reduce the rate of CLABSI in intensive care and bone marrow transplantation units [17, 18]. Although the routine replacement of catheters is unnecessary, the CVC site should be diligently monitored for evidence of infection. Guidewires should not be used for catheter exchange if any local redness, tenderness, or purulent material is present at the insertion site.

46.1.4 Prevention of Exposure from Healthcare Workers and Visitors

Employees and visitors may also transmit infections to the transplant recipient. Healthcare workers should undergo an evaluation of their health history and immunization status at the beginning of their employment [19]. Vaccination of healthcare workers who have no history of varicella infection or who are seronegative is strongly encouraged, because varicella can be life threatening in the SOT recipient. All staff members should receive the influenza vaccine annually, and, if they have not already been immunized for hepatitis B, they should receive hepatitis B vaccine at employment. Healthcare facilities should have well-defined policies to establish when potentially infectious personnel should not have patient contact. Employees should be encouraged to report any potential exposures or illnesses; human resource policies should permit temporary reassignment or furlough from duty to minimize the potential exposure of transplant recipients to

communicable infections. During the pretransplantation screening process, family members should be educated about infection prevention strategies and receive an annual influenza vaccination and ensure that their other vaccinations are up to date in order to better protect the transplant recipient [20]. Clinical personnel should monitor visitors for illnesses, such as colds, to prevent transmission. Posters may be displayed during flu season as additional reminders.

46.1.5 Fungal Infections

Despite the establishment of definition criteria, determining whether pneumonia is acquired in the hospital setting is one of the most difficult infections for the infection preventionist to classify. The CDC has three specific definitions of nosocomial pneumonia [11]. No defined incubation period exists when fungal pneumonia is suspected, so the traditional "onset of infection 48 hours after admission" standard that separates community-acquired infections from hospital-acquired infections is not valid. The isolation of fungal species from expectorated sputum may not be diagnostic, but clinicians often start antifungal therapy when they are encountered. These isolates could also represent transient colonization or a laboratory contaminant, not necessarily invasive disease [21]. Therefore, comparing fungal pneumonia rates among hospitals is difficult. Because of the ubiquitous nature of circulating fungal spores and of generally higher spore counts outdoors, determining whether a discharged patient who is readmitted with invasive fungal pneumonia acquired the infection while he or she was in the hospital is challenging. Comparative data on the incidence of nosocomial fungal pneumonia are unavailable, and many institutions have attempted to develop their own definitions of hospital-associated fungal pneumonia. Table 46-2 details the case definitions at some of the authors' institutions; an arbitrary hospitalization of 7 days prior to onset of infection is used to distinguish between hospital- and community-acquired fungal infections. A recent review of construction and renovation-related healthcare-associated fungal infections showed a decrease in number of outbreaks between 2010 and 2014, which may be due to effectiveness of infection prevention measures, or because of the high number of previously reported outbreaks [22].

Table 46-2. Case definitions

Term	Definition
Hospital-associated (nosocomial) infection	The patient has one or more positive cultures with the same pathogenic fungal species and clinical signs of infection and histopathologic or radiographic evidence of invasive fungal disease. OR Histopathologic or radiographic evidence of invasive disease with no microbiologic culture confirmation may be considered an infection if the patient is treated with an antifungal agent. Date of onset should be more than 7 days after admission with no evidence of active or incubating infection at the time of admission.
Colonization	Significant isolate(s) that cannot be classified as disseminated or locally invasive or if no systemic antifungal therapy is given.
Not significant	One isolate of a fungal species from a nonsterile site, no systemic antifungal therapy, or no correlation of routine microbiologic and fungal cultures.
Community-acquired infection	Signs or symptoms of infection are present at the time of admission and the patient was not hospitalized within the prior 2 weeks.

46.1.6 Aspergillosis

46.1.6.1 Environmental Concerns

Healthcare-associated aspergillosis is associated with the following three main mechanisms: airborne acquisition, which is typically secondary to contaminated ventilation systems; direct contact, through contaminated objects such as wound dressings; and airborne and contact, in which both mechanisms may be implicated, as is seen in sternal fungal osteomyelitis after sternotomy [23]. The hospital water system may be a potential reservoir for *Aspergillus* and other molds, which are then aerosolized [24]. No "safe levels" for bioaerosols have been recognized, and standards for the frequency of air sampling are also lacking. Rural outdoor air concentrations of fungi may be as high as 10,000 colony-forming units per cubic meter of air (CFU/m^3) without causing pulmonary infections in the general population. The establishment of a safe threshold limit in the indoor environment is problematic. Some studies have established a positive correlation between increased airborne spore counts and the incidence of invasive aspergillosis [25–27].

Researchers have collected air samples to quantify the number of airborne spores. Open agar plates, which are commonly referred to as "settle plates," should not be used to estimate the airborne concentration of fungal spores. The number of spores that settle on the agar due to the effects of gravity are presumed to be proportional to the airborne concentration, but are not reliable enough for routine use in facilities that perform organ transplants. Settle plates, however, may detect fungi aerosolized during medical procedures (e.g., during wound dressing changes), as described in an outbreak of aspergillosis among liver transplant patients [28]. Air sampling methods using calibrated sieve impactors or centrifugal samplers are recommended to provide standardized counts, the results of which are expressed as CFU per cubic meter. Routine air sampling for fungi is not generally recommended. During construction or renovation or in

times when isolates of *Aspergillus* or other fungi are identified in patient cultures, air sampling may be performed to assess the relative level of spores in the environment. Outdoor samples may be collected as appropriate controls. Fungal colony types found in the indoor samples should be the same as those from outdoor samples, but with a tenfold (1 log) reduction in indoor counts due to air-handler filtration [29]. Indoor samples that have a predominance of a particular fungus that is not in proportion to the outdoor samples may reflect contamination of the indoor environment.

46.1.6.2 Environmental Controls

The CDC guidelines for prevention of healthcare-associated pneumonia recommend protective environment units only for allogeneic HSCT recipient units; there are no specific recommendations for SOT recipients [2]. However, in 2003, the CDC published Guidelines for Environmental Infection Control in Healthcare Facilities which address specific controls applicable to all patients, and include recommendations specific to organ transplant recipients [3]. It is beyond the scope of this review to detail all recommendations in that guideline but several specific infection types are discussed. Facilities performing SOT surgeries should at minimum have contingency plans in case of disruption of HVAC services.

Specially designed isolation rooms that use laminar air flow (LAF) and/or high-efficiency particulate air (HEPA) filtration may provide the cleanest air possible. HEPA filtration, which provides a minimum of 12 air changes per hour, often reduces fungal spore counts. HEPA filters remove 99.97% of particles larger than 0.3 mm (micron). HEPA filters may be installed within the room ventilation system to provide a highly filtered, positively pressurized room, or portable units may be placed in any patient room for additional air filtration. Patient rooms should be tightly sealed to prevent contamination from outdoor sources, and their doors should remain closed to ensure positive pressurization. Reportedly, areas that use HEPA filtration and positive pressurization of patient rooms (fungal spore control ventilation) have total spore counts of less than 15 CFU/m^3, with *Aspergillus* counts of less than 0.1 CFU/m^3 [29].

Room design should focus on the use of easy-to-clean surfaces. The walls and horizontal surfaces should be smooth and nonporous to facilitate cleaning and to prevent entrapment of bacteria and spores. Porous ceiling tiles, carpeting, and fabric window treatments, such as shades and curtains, should be avoided as they may attract dust particles. Some new designs available are house curtains or shades within two glass panels which minimize dust collection while still providing privacy and controlling light. Vinyl or plastic blinds are safe if they are frequently cleaned.

Hospitalized SOT recipients should not travel through areas under construction or renovation. Severely immunocompromised patients requiring transport out of the protective environment should wear a high-efficiency respiratory protection mask, like N95, to prevent the inhalation of particulates [2]. Transplant recipients should also avoid dusty construction or excavation and landscaping sites after discharge. Historically, studies reported an association between the use of other protective isolation strategies, such as the restriction of fresh fruit and flowers with a decrease in the incidence of infection. The length of hospital stay is declining dramatically, so the benefits of a protective environment are being reevaluated. The most important risk factor for invasive aspergillosis remains the patient's underlying immunosuppressive condition. High-risk patients may develop invasive aspergillosis even with low fungal spore counts [25].

46.1.6.3 Construction Guidelines

Construction and renovation in the hospital are often associated with an increase in the number of cases of aspergillosis. At the beginning of renovation, airborne particulates and fungal spore counts may be exceptionally high because spores are dispersed into the environment during the demolition process. The Facility Guidelines Institute publishes guidelines for the design and construction of hospital and healthcare facilities [30]. Infection control personnel should be involved from the planning stages through project commissioning. Building owners are required to provide an infection control risk assessment (ICRA) to determine the potential risks of transmission of various infectious agents during the project. The ICRA is conducted by a panel with expertise in infection control and epidemiology, risk management, facility design, construction ventilation, and safety. An ICRA should be conducted during the early planning phase of the project, before construction begins, and continue through project construction and commissioning. Specific construction-related requirements mandated by the ICRA should be included in the contract documents. Many state health departments now require the ICRA submission before they will issue permits for hospital construction and renovation projects. When construction or renovation activities are planned in or near facilities that handle high-risk transplant recipients, even more strict protective guidelines and monitoring requirements may be established during the planning process [31]. Such guidelines help to define the appropriate barriers and techniques for preventing the spread of dust and debris into other areas of the facility. Construction and housekeeping personnel should be trained in the dangers of aspergillosis, with an emphasis on control measures. Strategies for the prevention of nosocomial aspergillosis will control any other fungi that are transmissible by dust, such as the zygomycetes (e.g., *Mucor* and *Rhizopus* species). Infection control interventions to prevent nosocomial aspergillosis were well illustrated during one construction-associated outbreak, in which the incidence of invasive aspergillosis rose from 3.18 to 9.88 cases per 1000 patient-days during the construction period [32]. The control measures that were used included portable HEPA filtration units, the installation of sealed windows and easy-to-clean tiles and shades, and the increased maintenance of the ventilation sys-

tem. The introduction of portable HEPA filter units was the most important step in this undertaking. After the institution of control measures, the infection rate decreased to 2.91 cases per 1000 patient-days.

When the construction activities are outdoors, the air intakes for the ventilation system may become heavily loaded with construction dust, potentially leading to an increased contamination of the indoor environment. An increased focus on filter maintenance is important, and successful containment may be possible, as a bone marrow transplantation unit reported during construction in its vicinity [31]. Maintaining the construction area at negative pressure, establishing plastic sheeting or drywall barriers, and controlling access to construction zones prevented dust from contaminating patient areas.

46.1.6.4 Surveillance for Fungal Healthcare-Associated Infection

If a case of nosocomial aspergillosis is suspected, it is crucial to look at the facility history of aspergillosis cases to assess background rates. An investigation of any ventilation deficiency is very important [2]. If there is a good chance that the case is healthcare-associated, then an epidemiologic investigation should be initiated in an effort to find and eliminate the source. *Aspergillus flavus* has frequently been identified in reports of construction-related contamination of the indoor environment [33]. Arnow et al. [34] reported an increase in spore counts of *Aspergillus fumigatus* and *A. flavus*, with a mean of more than 1 CFU/m^3 associated with the opening of a new hospital. An environmental assessment identified fungal contamination of the carpet, fireproofing material, and ventilation filters. Fungi may contaminate damp areas, discolored ceiling tiles, and peeling wallpaper. Most studies documented decreased indoor spore counts after the institution of appropriate control measures [31, 33]. Sometimes, air sampling is recommended for the assessment of air contamination after construction or HEPA filter changes and as part of an outbreak investigation. Repeat air samples may be collected after an identified source is decontaminated or removed. An environmental audit may also include periodic sampling. The role of fungal typing in the investigation of outbreaks is unclear; multiple fungal strains can cause healthcare-associated infections in one outbreak given the ubiquitous presence of fungi in the environment and the identification of different serial Aspergillus strains by whole genome sequencing within a single patient [35] may limit the application of this epidemiological tool.

Aspergillus species are certainly not the only significant fungal pathogen found in the environment. *Fusarium* and *Trichosporon* species, the dematiaceous molds, zygomycetes, and normally innocuous soil and plant fungi may cause infections in the immunocompromised patient. Good housekeeping practices are vital in high-risk patient areas. These areas should be visually monitored to ensure that all dust is contained and removed from the patient environment. If nosocomial infections occur within an institution, the renovation of ventilation systems to provide highly filtered air for high-risk patient areas may be considered. Although antifungal prophylaxis of patients may be useful, cases may still occur, necessitating the temporary closure of contaminated patient units or a suspension of transplant activities during hospital construction projects.

46.1.7 Waterborne Infections

Researchers at the University of Arkansas for Medical Sciences reported the results of a MEDLINE search of medical literature published from 1966 through 2001 to determine the number of HAIs caused by waterborne pathogens. Forty-three outbreaks had been reported, including many nosocomial outbreaks caused by *Pseudomonas aeruginosa* [36]. HAIs attributed to the use of contaminated water include those caused by *Legionella pneumophila P. aeruginosa; Aeromonas, Acinetobacter, Burkholderia, Enterobacter, Flavobacterium*, and other *Pseudomonas species; T. gondii*; and *Serratia*, Mycobacteria, and *Aspergillus* species. In 2006, the Environmental Protection Agency (EPA) published the Long Term 2 Surface Water Treatment Rule (LT2 rule), which addresses strategies to reduce disease incidence associated with *Cryptosporidium* and other disease-causing microorganisms in drinking water [37]. Individual state regulations or codes may identify requirements for maintaining hot water temperatures to protect patients from being scalded. Temperatures at the return should ideally be ≥124 °F (≥51 °C), and cold water temperature at <68 °F (<20 °C) in healthcare facilities [3].

46.1.8 Legionellosis

Transplant recipients are considered to be at increased risk of developing *Legionella* pneumonia, commonly known as Legionnaires' disease. Even after processing at water treatment plants, small quantities of these aquatic bacteria may enter homes and buildings and may live in the biofilm that lines the pipes. Legionella species multiply in warm water, with an ideal temperature range of 35–46 °C [38, 39]. Regulations concerning maximum water temperature, which are designed to prevent scalding accidents, often fall into this range, increasing the possibility that a facility will become contaminated with *Legionella* species and several other species of nontuberculous mycobacteria, including *Mycobacterium xenopi* [40]. Traditionally, it was believed that infection was caused by the inhalation of contaminated aerosols generated by humidifiers, air-conditioning units, cooling towers, and showers into the respiratory tract. The aspiration of contaminated water is an additional mechanism of transmission [41, 42]. Laboratory-confirmed Legionellosis in a patient who has spent ≥10 days continuously in a healthcare facility prior to the onset of illness is considered a definite case of healthcare-associated *Legionella*

pneumonia; that which occurs in a patient who has spent 2–9 days in a healthcare facility prior to the onset of illness is considered possible healthcare-associated Legionellosis [2, 3]. The 2003 CDC guidelines for the prevention of nosocomial pneumonia discuss issues of environmental monitoring and control. The recommendations state that facilities provide routine maintenance of their potable water systems and should consider the use of sterile water in immunocompromised patients if *Legionella* is isolated from the water to reduce the incidence of legionellosis [2].

L. pneumophila strains may be more virulent than the non-pneumophila strains. Advances in molecular fingerprinting techniques have been instrumental in associating patient isolates with Legionella species cultured from a facility's potable water supply. Furthermore, lawsuits have successfully linked nosocomial infection to perceived facility negligence [38].

46.1.8.1 Environmental Monitoring

Culturing plumbing fixtures, such as sink spouts, showerheads, ice machines, and drinking fountains, for *Legionella* species can identify potential sources of the bacteria in high-risk patient areas. The degree of contamination (percent of positive fixtures and quantity of bacteria present) varies significantly from building to building. The type of hot water system, the water temperature, location, and building age all play a role in the colonization of pipes within a facility [43]. The monitoring and control of *Legionella* species in a healthcare facility require a team effort, in which the microbiology laboratory, infection prevention and control, and maintenance departments must work together to provide a safe environment for high-risk patients. The CDC does not recommend routine environmental culturing for *Legionella*, but guidelines state that (1) this could be a component of *Legionella* prevention in healthcare facilities that provide care to transplant recipients, (2) may be appropriate to identify the source of infection as part of an outbreak investigation, and (3) to assess the effectiveness of water treatment or decontamination protocols [2, 3]. No guidelines regarding culturing frequency or acceptable levels of positivity are available. Generally, each facility will establish a policy on environmental monitoring that is dependent on the patient population. Environmental investigation to identify the source of *Legionella* is recommended when there is an outbreak, defined as one case of definite or two cases of possible healthcare-associated Legionnaires' disease within a 6-month period [3].

46.1.8.2 Legionella Control Measures in the Hospital

As a rule, if significant quantities of *Legionella* species are isolated in a facility, control measures to reduce the level of colonization should be instituted. Systems that use holding tanks or heaters that allow water to stagnate in the bottom of the tank provide a reservoir for the multiplication of *Legionella* species. For immediate control of Legionella in the setting of an outbreak, thermal eradication (superheat and flush) or hyperchlorination of the water supply is recommended [3]. Ongoing control of *Legionella* could be done with the use of copper/silver ionization systems, which release low concentrations of metal ions into the water distribution system, ultraviolet light sterilization, or maintenance of an elevated water temperature or chlorine content [44, 45]. Point-of-use filters have been found to be effective in eliminating *Legionella* and could be used without modification or disinfection of the potable water system [46], though are not on the current guidelines. In transplant units, shower heads and tap aerators should be removed, cleaned, and disinfected monthly using a chlorine-based, EPA-registered product; a 1:100 dilution of bleach may be used if no EPA-registered chlorine disinfectant is available [3]. In addition, large-volume room air humidifiers that generate aerosols should not be used unless they are subjected to high-level disinfection and only sterile water is used.

Even when control mechanisms are in place, healthcare-associated legionellosis may occur. Disruptions in the water distribution system, such as water main breaks, the use of fire hydrants, floods, and internal maintenance and construction disruptions, may cause changes in water pressure that disrupt the biofilm within the potable water system [38]. When pieces of the biofilm break free and enter the water supply, the water may appear cloudy or dirty. Local water authorities may issue water restrictions in the event of major contamination of the drinking water supply. Establishing water service disruption policies can be helpful for protecting immunosuppressed patients. Substitution of the appropriate bottled water is encouraged for drinking and for mouth care. Ice machine filters may become contaminated, so filters should be changed after restoration of water service [47]. Suspending showering until the water is determined to be safe may be necessary. When service is restored, all fixtures should be flushed until the water appears clear. Tub bathing may be acceptable because little aerosolization of the water occurs during the bathing process. Bed baths or other systems that do not generate aerosols are recommended.

The American Society of Heating, Refrigerating, and Air-Conditioning Engineers (ASHRAE) Standard 188p [48] establishes minimum risk management requirements to control legionellosis in water building systems, including inpatient healthcare facilities. An interdisciplinary designated team with the authority and responsibility to establish and implement a legionellosis risk management program, including but not limited to facilities staff familiar with the building water system and infection prevention and control staff should be formed. Components of the program include (1) description of the potable and nonpotable water systems in the building in water flow diagrams, including all water sources, water treatment systems and control measures, water processing, and end use points such as sinks, showers, water features, and ice machines, (2) identification of areas with higher probabil-

ity of infection based on the intended water use and the vulnerability to infection of patients in these areas, (3) identification of the control points where Legionella control measures can and should be put into place, (4) establishment of critical limits at the control points (e.g., temperature or chlorine level), (5) establishment of a monitoring system that includes the means, methods, and frequency for monitoring physical and chemical characteristics of the control measures to ensure they are within critical limits, (8) verification that the program is being implemented and validation that the control measures are effective in controlling Legionella, including a determination of if, when, where and how environmental cultures for Legionella are to be performed, and (9) documentation and communication of the plan.

46.1.8.3 Recommendations for the Discharged Patient

In areas where *Legionella* species have been identified in the water supply, patients who rely on well or spring water should be encouraged to have their own water supply checked [43]. One mistaken assumption is that all bottled water is safer or healthier than tap water; however, many water products are not processed to reduce bacterial contamination. Products such as spring water that emphasize natural properties may actually contain more bacteria than do other water products.

46.1.9 Antibiotic-Resistant Organisms: Vancomycin-Resistant Enterococcus, Methicillin-Resistant Staphylococcus, and Multidrug-Resistant Gram-Negative Bacteria

Infections caused by resistant organisms have emerged as a serious problem in hospitals all over the world. This is due in part to an increase in the nonselective use of broad-spectrum antibiotic agents for prophylaxis and treatment. The indiscriminate use of antibiotics reduces the normal host flora, predisposing the patient to colonization with endemic multidrug-resistant organisms and *C. difficile*. The emergence of *Streptococcus viridans* that is highly resistant to penicillin has been associated with the use of β-lactam antibiotics in neutropenic cancer patients [49]. Centers that routinely use quinolone prophylaxis for neutropenic patients have reported coagulase-negative *Staphylococcus* and gram-negative blood isolates that are resistant to these agents [50, 51]. HAIs with resistant gram-negative organisms (*Klebsiella species, Stenotrophomonas maltophilia,* and *Burkholderia cepacia*) are on the rise, a trend that may be related to the use of broad-spectrum antibiotics [52–54]. Gram-negative bacteria that produce extended-spectrum β-lactamases are becoming increasingly prevalent. Pretransplant broad-spectrum antibiotic use has been associated with post-transplant infections caused by multidrug-resistant organisms [55]. Antimicrobial stewardship programs and the use of local data to select appropriate treatments reduce the reservoir of multidrug-resistant pathogens within a medical facility. Reducing inappropriate antibiotic use by only prescribing an antibiotic when it is likely to be beneficial to the patient, minimizing the treatment of colonization, using broad-spectrum antibiotics judiciously, and discontinuing unnecessary and lengthy treatment with antimicrobials are the essence of antimicrobial stewardship. The CDC launched the "Get Smart for Healthcare" initiative to guide and support antimicrobial stewardship programs in different settings in order to improve antibiotic prescribing practices [56].

Patients who have longer inpatient stays before transplantation surgery may become colonized with multidrug-resistant organisms. Changes in the United Network for Organ Sharing (UNOS) allocation algorithm have resulted in an increased duration of preoperative hospitalization in some institutions. Data has demonstrated an increased number of cases of mediastinitis after heart transplantation caused by multidrug-resistant pathogens associated with an increased length of pretransplantation inpatient hospitalization prior to transplant [57].

Active surveillance identifies more patients colonized with resistant bacteria than clinical cultures alone, and this strategy can be used to control rates of colonization and infection due to resistant bacteria. The use of active surveillance for MRSA and subsequent decolonization with mupirocin has shown some effectiveness in reducing infections post liver transplantation [58] though some data have not demonstrated effectiveness [59]. Whereas the CDC guideline on the control of multidrug-resistant organisms recommends active surveillance for MRSA and VRE if other approaches have failed to control transmission adequately [4], the SHEA guideline recommends the use of active surveillance to identify patients colonized with MRSA and VRE among all high-risk patients [60]. Some states have mandated screening patients for MRSA. Active surveillance for MDR gram-negative organisms, including carbapenem-resistant enterobacteriaceae (CRE), is recommended in certain high-risk situations in order to prevent spread of these highly resistant and potentially virulent organisms [61]. Although active surveillance is not done routinely in most centers, the role of active surveillance for CRE in solid organ transplant candidates and recipients is unclear, and is an area worthy of future study.

46.1.9.1 Vancomycin-Resistant Enterococcus

Enterococci have become a significant infection control problem for decades, which is evidenced by the 20-fold increase in nosocomial infections reported to the NNIS from 1989 through 1993 [62]. Comparative data from the 1998 reports showed an additional 55% increase in VRE infections compared with that from 1993 through 1997. Between January 2006 and October 2007, 33% of enterococcal

device-related healthcare-acquired infections reported to the NHSN were caused by VRE [63]. The enterococci differ from other streptococci in their relative resistance to penicillins and cephalosporins and in their intrinsic low-level resistance to aminoglycosides and lincosamide antibiotics [64]. They are also resistant to bile, they are considered normal enteric flora in adults, and they generally exhibit low virulence. They may be isolated from the mouth, vagina, groin, and anterior urethra. The target of vancomycin in the cell wall is D-alanyl- D-alanyl, but, in VRE, this target is altered so that it has low affinity to vancomycin [65]. Using molecular typing techniques, VRE strains have been identified as comprising mainly three resistance phenotypes—van A, van B, and van C [64]. The van A phenotype is plasmid mediated, and, by definition, it is resistant to high levels of vancomycin and teicoplanin. The van B strains exhibit high-level resistance to vancomycin, but they are susceptible to teicoplanin. Class C shows constitutive low-level resistance to vancomycin; this is encountered in *Enterococcus gallinarum* and *Enterococcus casseliflavus*.

Risk Factors

Epidemiologic analysis has shown that enterococcal infection often originates from the patient's colonizing flora. Intraabdominal and cardiothoracic surgery and manipulation of the urinary tract are the risk factors for enterococcal infection. Reportedly, the severity of illness is one of the main risk factors for the development of VRE bacteremia [66–70]. Critically ill patients in the intensive care unit or those with underlying medical conditions, including immunocompromised patients residing on oncology and transplant units, are also at increased risk of colonization and infection with VRE strains. An increased length of hospitalization and antibiotic use contribute to the patient's risk [70]. Although vancomycin use is a predisposing factor for the acquisition of the organism, any antimicrobial agent that alters the normal gram-positive and anaerobic gut flora may allow VRE to flourish [66, 67]. In Europe, a glycopeptide (avoparcin) that is used in animal feeds has been associated with VRE in animals and humans. Antibiotics with antianaerobic activity have been shown to promote VRE high-density colonization both in animal models and in humans [70]. Both vancomycin and third-generation cephalosporins reportedly are independently associated with VRE prevalence in 126 intensive care units in the USA [71]. Reports have demonstrated the contact spread of the bacteria from patient to patient, both directly and indirectly via the hands of healthcare workers [72, 73]. Contaminated equipment and environmental surfaces are also sources for disease transmission [74].

In the setting of solid organ transplantation, most VRE infections occur in the early post-transplant period, with a strong association with antimicrobial use and surgical, specifically biliary, complications. Liver transplant recipients who developed VRE bacteremia were compared retrospectively with transplant recipients who developed bacteremia with vancomycin-sensitive enterococci (VSE) [75]. VRE infection was associated with increased episodes of recurrent bacteremia and persistent isolation of the bacteria from the original site of infection. Whether VRE strains are more virulent than VSE is still a controversial issue, but, in that study, few cases of endovascular infection were encountered among the VRE patients and none among the VSE control patients.

The VRE colonization rate of patients awaiting liver transplantation was reported to be 13% [76]. Another 18% became colonized after transplantation. Infection with VRE occurred in 23% of these patients. A recent meta-analysis demonstrated that post-transplant MRSA and VRE colonization was significantly associated with post-transplant MRSA and VRE infection [77]. Patients who were colonized with VRE either before or after transplantation had longer hospital and ICU stays. Those that acquired VRE after transplantation also had higher 90-day mortality.

The fecal carriage of VRE has also been studied in an outbreak on a renal unit. The authors used restriction enzyme analysis and ribotyping to show that the outbreak isolate was clonally related [70]. VRE was isolated from the stool of 15% of renal patients (i.e., those with end-stage renal disease), 5% of other patients in the hospital, and 2% of sampled patients in the community with no history of hospitalization or antibiotic use. Many studies have used DNA analysis to show that nosocomial transmission is the primary route of VRE colonization among patients.

Infection Prevention and Control Measures

The CDC Hospital Infection Control Practices Advisory Committee developed guidelines for preventing the spread of VRE [78]. The following four main points are crucial for prevention: (1) prudent vancomycin use, (2) an education program, (3) an effective microbiology laboratory, and (4) a multidisciplinary effort to control the organism.

The microbiology laboratory initiates the process of VRE control by promptly and accurately identifying the organism. Vancomycin resistance can be identified through routine bacterial susceptibility testing or through polymerase chain reaction (PCR) testing using primers to detect the vanA and vanB genes. When a vancomycin-resistant strain is identified, the infection control department, the patient's physician, and unit personnel should be notified. Those patients who are colonized or infected should be placed in single rooms, or they may be cohorted with other VRE-positive patients. Because the bacteria may colonize the intestinal tract, patients with poor personal hygiene or fecal incontinence may contaminate the environment with the bacteria. Patients may also contaminate their immediate environment by touching surfaces, such as bed rails, nurse call buttons, and television controls. This type of equipment may not be adequately disinfected after the patient leaves, increasing the risk of transmission for the next patient. The recommendation is that gloves and gowns should

be worn when one is entering the room of colonized patients, especially in endemic settings. Some groups report significant decreases in VRE infection and VRE colonization after the institution of enhanced infection control measures in conjunction with judicious restriction of certain antibiotics, such as vancomycin and third-generation cephalosporins [79, 80].

Various reports have documented the isolation of VRE strains from environmental surfaces [72, 73, 81]. Noncritical items, such as stethoscopes or thermometers, should not be used with other patients unless they are thoroughly disinfected after use for a VRE patient. Dedicated equipment is preferred, but it may be shared among cohorted patients. Patients may be screened for VRE carriage by the collection of rectal swabs or stool for cultures or PCR testing to identify additional cases. This information is useful for determining transmission between roommates or to others on a unit where infected patients have been identified. Despite the institution of contact precautions for carriers, the incidence of carriage may remain about the same [69]. VRE colonization may persist for long periods [82]; therefore, colonized or infected patients may require continuous isolation until their discharge. If a patient is being transferred to another facility, notifying the receiving institution about the patient's VRE status so that the appropriate precautions are taken is imperative. VRE-positive patients who are readmitted should be placed in contact isolation until surveillance cultures have been completed.

Concerns that a plasmid that carries the vancomycin resistance gene could transmit this resistance to other gram-positive bacteria, particularly *S. aureus*, do exist. Because of the multiple virulence factors associated with this pathogen, these infections would potentially be life threatening because the organism is already resistant to multiple antimicrobial agents. Vancomycin-resistant *S. aureus* (VRSA) has been isolated. Seven cases of VRSA were identified in the USA from 2002 to 2006. All isolates were vanA positive. All patients had a prior history of MRSA and enterococcal infection or colonization. They all had severe underlying conditions and most had received vancomycin prior to VRSA infection. Proper isolation precautions were in place and prevented person-to-person transmission in all seven cases [83]. As of 2014, 13 cases of VRSA have been identified [84].

46.1.9.2 Methicillin-Resistant S. aureus

MRSA is a well-recognized nosocomial pathogen causing significant infections in all patient populations. Contact precautions are used to isolate patients with MRSA infection or colonization. Some controversy exists over the use of masks to enter MRSA patient rooms. Because patients with nasal colonization may spread the organism into the surrounding air, some advocate that caregivers don masks to prevent their acquisition of the organism, thus minimizing spread to other patients. Transmission on the hands of colonized staff members may be increased if they touch their noses during patient care activities.

Risk Factors

As the Temple University experience illustrates [85], MRSA colonized patients are more likely to infect their surgical wounds. Researchers in a French study collected surveillance cultures from liver transplant recipients. The analysis of the infection data found that MRSA infection occurred more frequently in the MRSA carriers (7 of 8 patients, 87.5%) than in the MRSA noncarriers (8 of 79 patients, 10.1%) ($P<0.001$) [86]. Among liver transplant recipients, patients who underwent surgery within the prior 2 weeks were at markedly higher risk for MRSA infection [87]. A review of infections occurring from 1990 to 1998 in another liver transplant center in the USA showed that 23% of organ recipients became infected with MRSA, with significant increases in the incidence and prevalence of patients infected with MRSA over time [88]. The primary sites of infection were the vascular catheter (39%), the wound (18%), the abdomen (18%), and the lung (13%). CMV seronegativity ($P=0.01$) and primary CMV infection were significantly associated with MRSA infections ($P=0.005$). Although relatively uncommon, donor-derived MRSA transmission has been described following liver transplantation [89].

Infection Prevention and Control Measures

Quality improvement programs should be aimed at reducing HA-MRSA acquisition and infection rates and a multifactorial approach towards decreasing MRSA transmission has been described [90]. The collection of surveillance cultures may be cost-effective in all patient populations, and the high-risk transplant recipient group may be an ideal starting point for the process. An MRSA control program involving liver transplant patients consisting of active surveillance, use of contact precautions and cohorting of colonized patients, treatment with intranasal mupirocin at the time of transplantation, and education of patients and visitors on the importance of hand hygiene resulted in a decrease in the incidence of new MRSA colonization, MRSA bacteremias, and MRSA infections at other sites [58].

46.1.9.3 Multidrug-Resistant Gram-Negative Bacteria

There is no standard definition for multidrug-resistant gram-negative bacteria (MDR-GNB). Included in this category are bacteria resistant to multiple classes of antibiotics, such as *P. aeruginosa* and *Acinetobacter baumanii*, as well as Enterobacteriaceae (e.g., *Escherichia coli* and *Klebsiella pneumoniae*) with extended-spectrum β-lactamases (ESBLs) that hydrolyze β-lactam antibiotics including extended-spectrum cephalosporins [4]. There has been a substantial increase in MDR-GNB, defined as being resistant to three or more antimicrobial classes [91, 92]. *A. baumanii*, which is frequently resistant to multiple antibiotics including β-lactams, fluoroquinolones, and aminoglycosides, is becoming increasingly resistant to carbapenems, and isolates resistant to all

tested antibiotics have been reported [93]. Patients with infections due to MDR-GNB are more likely to experience delay in institution of effective antimicrobial therapy, have a higher mortality, and increased cost of care [94, 95].

Extended-spectrum β-lactamases are usually found in *K. pneumoniae, K. oxytoca*, and *E. coli*, but have also been reported in *Citrobacter, Enterobacter, Proteus, Salmonella, Serratia*, and other gram-negative bacteria [96]. Gram-negative bacteria with ESBLs are typically sensitive to the carbapenems, which are recommended as treatment for infections due to these organisms. Recently, *K. pneumoniae* with a carbapenem hydrolyzing enzyme, which confers resistance to all carbapenems, have been reported, and this organism caused 8% of device and surgery-associated HAIs [63, 97]. Though named KPC (*K. pneumoniae* carbapenemase) as this was initially found in *K. pneumoniae*, KPC has been reported in other enterobacteriaceae, including *E. coli, Enterobacter* species, and *Serratia* [94, 98]. There is variation in the geographic distribution of ESBL-containing organisms. While it occurs sporadically in various states, *K. pneumoniae* with KPC has become endemic in the eastern United States and spread throughout the USA is increasing [99]. Infections caused by carbapenem-resistant enterobacteriaceae are associated with high mortality rates among liver transplant recipients [100].

Resistance genes in gram-negative bacteria could be chromosomal, or could be located in mobile genetic elements, such as plasmids and transposons, which can be transferred between different species [101]. Some of these gene elements may contain multiple genes encoding resistance to penicillins, cephalosporins, carbapenems, and aminoglycosides conferring multidrug resistance [102]. Quinolone resistance is usually due to chromosomal mutations and not usually transferable, but transferable quinolones resistance genes encoded on plasmids have been identified, and recently, MDR-*K. pneumoniae* with a plasmid containing resistance determinants for carbapenems, aminoglycosides, and fluoroquinolones was reported [103].

Risk Factors

Risk factors for colonization or infection with MDR-GNB are similar to those for MRSA and VRE and include advanced age, underlying diseases and severity of illness, transfer of patients from another institution particularly from a nursing home, prolonged hospitalization, gastrointestinal surgery or transplantation, presence of invasive devices such as CVCs, and exposure to antimicrobial drugs [104]. Prior solid organ or hematopoetic stem cell transplantation has been identified as a risk factor for infections caused by carbapenem-resistant *K. pneumoniae* [105]. Bacteremia due to a KPC-2–producing *Enterobacter cloacae* and *Pseudomonas putida* has been reported in a liver transplant recipient [106].

Automated susceptibility testing systems have limitations in detecting drug resistance in these organisms [97, 107]. Providers and clinical microbiology laboratories should be familiar with these organisms and ensure that organisms are tested using methods that will provide reliable susceptibility results.

Hospital outbreaks due to MDR-GNB have been reported [97, 108]. Similar to MRSA and VRE, many more patients may be colonized than infected, providing an unrecognized reservoir, and active surveillance screening may be necessary to prevent cross-transmission.

Infection Prevention and Control Measures

Measures to control the spread of MDR-gram-negative bacteria are similar to other drug-resistant organisms which include (1) administrative support such as instituting automatic alerts and provision for adequate hand hygiene facilities, (2) education of personnel regarding MDROs and prevention methods, (3) judicious antimicrobial use, (4) surveillance, (5) contact precautions, and (6) enhanced environmental cleaning. Published guidelines have specifically addressed infection control guidance for the prevention of infections caused by carbapenem-resistant organisms which addressees active surveillance of high-risk units and contacts with infected patients [61].

46.1.9.4 C. difficile Infection

Numerous factors may cause diarrhea in transplant recipients, including immunosuppressants, antibiotics, enteral nutrition, and other agents that affect bowel motility. The extended use of antimicrobials alters the bacterial flora of the gut, providing a niche for the multiplication of *C. difficile*, an anaerobic, spore-forming, gram-positive rod that is resistant to many antimicrobial agents. Although the organism occurs as normal enteric flora in approximately 4% of adults, it may also cause severe gastroenteritis that manifests as either diarrhea or colitis. *C. difficile* produces the following two toxins: toxin A, or enterotoxin, and toxin B, or cytotoxin. These toxins act synergistically, resulting in cellular damage, hemorrhage, and the accumulation of fluid in the colon. Most patients have a history of antibiotic usage before the onset of diarrhea. *C. difficile* is the most common cause of healthcare-associated diarrhea, with higher rates of carriage, ranging from 15% to 30%, reported in hospitalized patients [109]. *C. difficile*-associated diarrhea occurs in 1–31% of SOT recipients [110].

In 2011, there were an estimated 453,000 cases of *C. difficile* disease (CDD) in the USA resulting in over 29,000 deaths [111]. One specific strain (NAP1/BI/027) has emerged that is more virulent and more resistant to antibiotics, particularly fluoroquinolones. It produces more toxin A and toxin B, and produces a third toxin, binary toxin. The disease is more severe and has affected patients with no underlying risk factors for CDD [112]. Outbreaks have been associated with fluoroquinolone use, though other antimicrobials have also been implicated [113, 114].

Risk Factors

Although any antibiotic agent can affect the normal balance of the intestinal flora, clindamycin, penicillins, fluoroquinolones, and the third generation cephalosporins have been particularly associated with the development of infection [115, 116]. Other factors that alter the gut flora also increase the risks of carriage of the organism in the bowel and of disease. The use of stool softeners and antacids has been associated with increased carriage [117]. Diarrhea has also been associated with older age, underlying disease, and enemas. Symptomatic patients usually have more risk factors, and certain intrinsic patient factors influence the relative risk of developing symptomatic infection [118]. In solid organ transplantation, most cases of CDD occur in the first 3 months of transplant, likely attributable to the increased rates of hospitalization and use of antibiotics during this time period [119].

46.1.9.5 Healthcare-Associated Transmission

Documented clusters of cases due to healthcare-associated transmission have frequently been associated with environmental contamination with bacterial spores. In one study, 21% of patients who were initially culture-negative admitted to a general ward acquired *C. difficile* while in the hospital; of these, 37% developed diarrhea [120]. The authors were able to prove transmission between patients with the use of an immunoblot technique, and they documented clustering in patient rooms with two occupants. Other authors have suggested other patterns of acquisition in situations in which no evidence of transmission to roommates exists [121]. One cluster investigation identified two case strains of bacteria by restriction endonuclease testing, in which most of the strains were associated with abdominal surgeries performed by one surgical team [122].

Because of spore production, this organism can survive well in the environment. *C. difficile* has been cultured from inanimate objects, such as medical instruments, toilets, bathroom floors, and furniture [123]. Bacteria have been cultured from the hands of medical personnel, and strains isolated from medical staff caring for patients with *C. difficile* were confirmed to be the same as those of the patient isolates [120].

Patients may become colonized with *C. difficile* via transmission through contact with other patients, contaminated rooms or equipment, or medical personnel carrying these bacteria on their hands. More environmental contamination with spores occurs in the room of a patient who has CDD, than with those with asymptomatic carriage. Nosocomial attack rates vary from facility to facility. Clinicians caring for transplant recipients should therefore be aware that nosocomial transmission of *C. difficile* is a real possibility and that the early implementation of infection control measures may prevent the occurrence of other cases.

Detailed strategies for the prevention of *C. difficile* in hospital settings have been published [124]. Patients should be placed in private rooms or cohorted with other infected patients. Symptomatic patients should be placed on contact precautions. Healthcare personnel should wear gloves and gowns when they enter the patient's room. Patient transport outside the unit should be minimized if the patient has diarrhea to avoid contaminating other areas with the bacterial spores. Good hand hygiene is essential. Soap and water or alcohol hand sanitizer may be used in routine or endemic settings; soap and water is preferred for outbreak or hyperendemic settings. Staff members must observe proper procedures, and visitors should be encouraged to wash their hands thoroughly before leaving the patient's room. A dilute (1:10) hypochlorite solution or a product with an EPA-approved claim for *C. difficile* activity should be considered in units with high *C. difficile rates* [6]. During outbreaks, environmental decontamination, isolation or cohorting of infected patients, and the limitation of clindamycin have significantly reduced CDD [125]. The use of dedicated patient equipment or of disposables, such as rectal thermometers, may significantly reduce the incidence of CDD in both acute and chronic care facilities and should be used whenever possible [126].

46.1.9.6 Antimicrobial Therapy Issues

Although the initial step in the treatment of *C. difficile* is the discontinuation of the antibiotic agent(s) to allow the recolonization of the gut with normal flora, oral metronidazole or oral vancomycin is often used to treat the infection [127]. A randomized double-blinded placebo-controlled study shows that patients with mild to moderate disease respond comparatively with either metronidazole or oral vancomycin. Patients with severe disease, however, had better clinical cures with vancomycin [128], and so vancomycin should be considered as the first-line agent for patients with severe disease. Fecal microbiota transplantation has emerged as a promising treatment for patients with frequent relapses of CDAD [129], however, its safety and efficacy in the setting of organ transplantation is unknown. Guidelines recommend against antimicrobial prophylaxis for patients at risk for CDD, treatment of asymptomatic carriage, and test of cure [124].

46.1.9.7 Outcomes

CDD has been reported to follow a more fulminant course in transplant recipients. A retrospective study of severe CDD showed that 13% of lung transplant patients had fulminant symptoms compared to 1.6% of all patients with CDD. Of those who required colectomy, 27% were transplant recipients, mostly lung transplants, though they actually had a better survival than nontransplant recipients [130]. The authors stated that improved awareness, lower threshold for surgery,

and closer follow-up may have paradoxically improved the outcome in transplant recipients. A review of cystic fibrosis patients showed that those who had lung transplants tended to have a more complicated disease course [131]. Other studies did not show more complicated disease, relapse rates, or mortality from CDD in SOT recipients [132, 133].

46.2 Community-Acquired Infections

46.2.1 Tuberculosis

Overall TB incidence rate in the USA has been declining, but TB in foreign-born and racial/ethnic minorities has been much higher compared to US-born Caucasians [134]. The proportion of cases in foreign-born persons has been increasing and accounted for 66% of cases reported in 2014, with Mexico, the Philippines, India, Vietnam, and China as the top 5 countries of origin [135]. Most cases of TB in foreign-born patients represented the reactivation of TB that had been acquired in the country of origin [136]. Between 1983 and 1994, the authors treated 14 liver transplant recipients (0.5%) for active TB; the most important risk factor was birth in a foreign country with endemic TB [137].

Multidrug-resistant (MDR) TB, defined as resistant to at least isoniazid and rifampin, appeared in the USA and worldwide in the 1990s, and required treatment with second-line anti-TB medications [138]. In the USA, the proportion of patients with MDR TB in those without previous TB has remained stable at 1% from 2009 to 2013. The percentage of MDR TB has remained below 1% in US-born cases, but of the total number of reported primary MDR TB, the proportion occurring in foreign-born cases increased from 30.8% in 1993 to 89.5% in 2013, accounting for 92% of primary MDR TB US cases in 2013 [135]. The CDC and World Health Organization (WHO) surveyed laboratories across the world and found that between 2000 and 2004, 20% of TB isolates were MDR and 2% were extensively drug-resistant (XDR) TB. The provisional definition of XDR-TB was an isolate resistant to isoniazid and rifampin and at least three or more of the six main classes of second-line drugs [138]. The definition was revised in October 2006 and XDR-TB is that which is resistant to isoniazid and rifampin, and resistant to any fluoroquinolone and at least one of three injectable second-line drugs (amikacin, kanamycin, and capreomycin) [139]. From 1993 to 2011, 63 such cases were reported in the USA, 17 of which occurred in 2000–2006 [140].

TB prevalence in the community and the presence of MDR- and XDR-TB [141] heighten the possibility that an immunosuppressed individual will be exposed to a case of active TB. Transplant recipients are susceptible to infection with *M. tuberculosis* species, and the progression to active disease can be quite rapid, similar to the experiences of patients infected with HIV [142]. In April 2007, three patients received organs from a 46-year-old US-born man with history of seizure disorder, alcoholism, homelessness, and incarceration, who was initially hospitalized for presumed aspiration pneumonia [143]. The two kidney recipients developed fever 6–7 weeks after transplant and cultures grew *M. tuberculosis* which matched the donor's *M. tuberculosis* isolate which grew from CSF postmortem.

46.2.1.1 Isolation

In the transplant unit, instituting appropriate isolation as quickly as possible when active TB is a possibility is essential. Patients who have an increased potential for TB should be placed in isolation rooms if active disease is even a remote possibility. In a 1990 nosocomial outbreak of TB that occurred among renal transplant recipients, the disease was transmitted from the source patient to five other patients on the same unit. The institution of airborne precautions was delayed because the TB infection had an atypical presentation in this patient [144]. Restriction fragment length polymorphism analysis confirmed the strain. Mortality in this patient group was 50%, with the shortest incubation time between exposure and active infection being approximately 5 weeks.

It is important to have a high index of suspicion for TB disease, in order to prevent transmission by prompt placement of suspect patients in an airborne infection isolation (AII) room until active TB is ruled out [145]. Airborne precautions can be discontinued when infectious TB is considered unlikely and either (1) another diagnosis is made that explains the patient's illness, or (2) 3 sputum specimens collected at 8-hour intervals, at least one of which is collected in the early morning, are AFB smear-negative. The Xpert MTB/RIF assay is an FDA-approved nucleic acid assay (NAA) that detects the presence of TB and rifampin resistance in sputum specimens; the negative predictive value for the presence of AFB smear positive TB is 99.7% after 1 negative assay and 100% after 2 negative assays [146]. CDC recommendations of 3 negative sputum specimens prior to discontinuation of airborne precautions in patients with suspected TB allow for the use of AFB smear, or NAA, or a combination of the two [147]. For patients with TB, decisions regarding discontinuation of AII require 3 negative sputum smears and clinical criteria.

The CDC guidelines describe ventilation system requirements for TB isolation rooms [145]. These include engineering controls to contain any droplet nuclei to prevent dissemination outside the patient's room. The AII room must be at negative pressure to the corridor, and exhaust air must be vented to the outside of the building or filtered through HEPA filters before it is recirculated. The AII room should have a permanently installed visual mechanism to monitor the pressure differential between the room and the corridor when occupied by patients with suspected or confirmed TB [30]. An ultraviolet germicidal irradiation device can be installed to irradiate the air in the conduit so bacteria are inactivated. There should be more than or equal to six air

changes per hour. New or renovated healthcare facilities should construct the AII room with more than or equal to 12 air changes per hour. Facilities may have to replace or retrofit their ventilation system to fulfill the safety criteria. This ventilation design is also required for varicella isolation. All employees must use a National Institute for Occupational Safety and Health (NIOSH)-approved fit-tested N95 respirator or powered air-purifying respirator when they enter the room of a patient with active or suspected TB.

46.2.1.2 Diagnosis

Active infection in the transplant recipient may not present with the traditional symptoms found in the general population [85]. Pulmonary infiltrates or pleural effusion may constitute TB infection without the other typical symptoms. Many transplant candidates with terminal organ failure are anergic, and after transplantation, most recipients remain or become anergic secondary to immunosuppressive agents that are administered to prevent organ rejection. Therefore, the use of the tuberculin skin test (TST) to monitor transplant recipients rarely provides useful information. Important information is provided when conversion from negative to positive tuberculin skin testing occurs, but negative results do not rule out infection. Furthermore, the value of the anergy testing is in question and is no longer recommended to be done routinely [145, 148]. Even when the patient reacts to one of the other antigens and his or her TST test is negative, the patient may still have latent infection or even active TB. Disseminated TB occurs more frequently in transplant recipients because the major host defense against TB is cell-mediated immunity [85].

TST testing of close family members may provide additional information on the patient's potential to spread this infection. In recent years, in vitro interferon gamma release assays (IGRAs) became available for diagnosis of latent TB (QuantiFERON TB test (Qiagen, Germany) and T-SPOT.TB test (Oxford Immunotec, UK)). These tests measure γ-interferon production when lymphocytes are incubated with synthetic peptides that simulate some proteins present in MTB [149, 150]. These tests are more specific than TST for detection of MTB infection, with much less false positive results related to previous BCG administration and previous exposure to atypical mycobacteria. Both tests are approved by the U.S. Food and Drug Administration. The CDC recommends using these tests for the same indications as the TST [145].

Fluorescent microscopy for the evaluation of acid-fast bacillus (AFB) smears and radiometric culture methods provide important diagnostic information, which may lead to the earlier initiation or discontinuation of patient isolation. Many microbiology laboratories now use rapid testing methods to detect and confirm TB, including nucleic acid amplification tests for detection of MTB in smear-positive and smear-negative respiratory specimens and DNA probes for species identification [151].

46.2.1.3 Post-exposure Follow-Up

If transplant recipients are exposed to a person with active TB, a contact investigation should be initiated. Recent TST or IGRA results and chest radiographs taken before the exposure may be used for baseline data. Additional TST testing should be performed 8–10 weeks after the exposure to evaluate for skin test conversion. Prophylactic isoniazid (INH) therapy should be considered for the prevention of the disease if the exposure is considered significant. If the source patient has a strain of TB that is either documented or suspected to be drug resistant, the use of alternative prophylactic regimens should be considered [152]. Prophylactic regimens for multidrug-resistant TB are not well established. In the past, the authors have used pyrazinamide with levofloxacin after such an exposure occurred among organ transplant recipients [153]. This regimen was associated with a high rate of discontinuation of the medication due to the adverse drug effects.

An international debate regarding the use of BCG vaccine for the prevention of TB spread has been ongoing. In the USA, indication for its use rarely exists [154]. Disseminated BCG disease is a risk in immunocompromised patients, including transplant recipients.

In June 2000, the CDC and the American Thoracic Society (ATS) formulated some new recommendations regarding TB prophylaxis and introduced two terms [155]. The first term is "targeted tuberculin testing" (i.e., TB testing by TST placement of patients at high risk for the development of TB). The second term is "latent TB infection" (i.e., patients who have been infected with TB but who have not developed TB disease). Chemoprophylaxis or preventive therapy is termed the "treatment of latent TB infection."

A skin induration of 5 mm or more after TST testing is considered positive for the following patient categories: patients infected with HIV, patients receiving immunosuppressive agents including transplant recipients, patients with recent contact with active TB, and patients who have an abnormal chest radiograph that is consistent with old TB. These patients are at high risk and are candidates for treatment of latent TB [145].

Three regimens for the treatment of latent TB infection exist. These are as follows:

1. INH for 9 months
2. Rifampin for 4 months
3. INH and rifapentine for 12 weeks

INH and rifapentine are convenient as the long half-life of rifapentine allows for once weekly dosing; the CDC recommends directly observed treatment with this regimen [156]. The clinician should note, however, that these regimens could have risks when used in SOT recipients. Cases of severe INH hepatitis have been reported [157]. Severe liver injuries, resulting in the death of five patients, occurred as a result of the rifampin–pyrazinamide combination [158] and it is no

longer recommended. Rifampin has also been associated with the severe rejection of solid organs, due to its interactions with cyclosporine and tacrolimus [159].

46.2.2 Varicella-Zoster Virus

Varicella is a highly infectious virus and up to 90% of seronegative household contacts may become infected after infection in the family.

46.2.2.1 Isolation

The infection control management of VZV in the immunosuppressed population involves some difficult issues. Varicella is transmitted via the airborne route during the primary infection (chickenpox) as virus particles are released from the airways of the patient into the environment. Transmission may also occur after direct contact with moist vesicles. Transmission of the virus usually starts 1–2 days prior to rash onset and lasts until the skin lesions are crusted. CDC guidelines require both airborne and contact precautions for patients with varicella and disseminated zoster [5]. One of the most difficult tasks for infection control is to define "disseminated" zoster for instituting room isolation. In localized dermatomal zoster, transmission occurs primarily through direct contact with the skin lesions, and only standard precautions are necessary.

In the immunosuppressed host, even small number of moist lesions and possibly respiratory secretions may contain enough viral particles to transmit the infection to other susceptible individuals through airborne routes or the shedding of the viral particles from skin lesions into the surrounding air. An adult cadaveric renal transplant recipient who occupied a private room adjacent to a patient with zoster developed fatal hepatitis after the nosocomial transmission of primary varicella infection [160]. Using PCR, Sawyer et al. confirmed VZV DNA in 82% of air samples collected in varicella patient rooms and in 70% of air samples collected in zoster patient rooms [161]. In a few samples, the virus was detected outside the door of negatively pressurized isolation rooms. Although this may represent a failure of the ventilation system to maintain negative pressurization of the room or of staff members leaving the door to the room open, obviously aerosolization of the viral particles does occur. The virus was also detectable up to 6 days after the onset of rash with the use of the same technique.

46.2.2.2 Patient Screening

Varicella infection in susceptible immunosuppressed patients may result in visceral disease, and it is associated with high mortality. In a series of three adult liver transplant recipients who developed varicella hepatitis, one patient died after developing adult respiratory distress syndrome and disseminated intravascular coagulation [162]. The introduction of a vaccine has significantly reduced varicella-zoster morbidity and mortality. Its use has been expanded since 1999 to include HIV-infected children with CD4 percentage of 15–24% and adults with CD4 count of at least 200 cells/μL [163]. There are two vaccines currently available: Varivax, a single-antigen varicella vaccine, and ProQuad, a combination of varicella and MMR vaccines. The latter contains more virus than the former vaccine [164]. Varicella vaccine is contraindicated in the transplant recipients, because it is made from a live, attenuated virus. However, the experience with leukemic children has shown that the vaccine is safe and effective [163]. Some reports have also demonstrated that the live, attenuated vaccine is safe and efficacious in susceptible pediatric kidney transplant recipients [165]. Researchers in that study administered the vaccine at candidacy; the results showed a reduced incidence of varicella after transplantation. There are also some reports of vaccination after transplantation. In one of these, seroconversion occurred in 20 of 31 (64.5%) children; 7 required multiple doses and only minor local skin reactions were observed [166]. The risk that healthy individuals will develop a rash after vaccination and transmit it to an immunosuppressed patient is low, and, therefore, vaccinating susceptible individuals, including healthcare workers, living in the same household with transplant recipients is not contraindicated [164]. The vaccine manufacturer does recommend that healthcare workers who develop vesicles should not care for susceptible individuals. Although some have hypothesized that the vaccine strain of virus may not be capable of causing secondary infections, a few such cases have been documented [167, 168]. The general consensus is that the benefits of vaccination of household contacts of immunocompromised individuals outweigh the very low risk of transmission of the vaccine virus to the transplant recipient. Varicella vaccine is also used in healthy persons as a post-exposure preventive measure, mostly in unvaccinated children, ideally within 3–5 days after exposure [169].

46.2.2.3 Post-exposure Management

Transplant coordinators must frequently evaluate the exposure of a transplant recipient to an individual with "possible" chickenpox. Most commonly, the exposure occurs after contact with a family member, usually a child. Defining the nature of the exposure by duration, proximity, and disease progression is an important step in the assessment process. Direct exposure is one that occurred face-to-face indoors. The duration of significant exposure is not clear; some experts say exposure for more than 5 min is significant, though others state that more than an hour is needed [163].

Documentation concerning each patient's varicella-zoster immune status must be easily accessible. Most adult patients are seropositive for VZV even if they do not recall having had chickenpox. After exposure to a patient with VZV infection the CDC's Advisory Committee on Immunization Practices

(ACIP) currently recommends VariZIG administration be considered for seronegative immunocompromised patients and certain other groups such as pregnant women and their newborns, for whom complications of disease could be life threatening [170].

VariZIG is expected to provide maximum benefit when administered as soon as possible after exposure, although it can be effective if administered within 10 days after exposure [170]. Although breakthrough infection after varicella-zoster immunoglobulin (VZIG) administration was common, its use ameliorated the severity of the disease. In one study in a SOT pediatric population receiving VZIG (median age of 8 years), 55% developed varicella, but only 4% developed severe disease [171]. The usual dosage is 125 units for each 10 kg of weight, up to a maximum of 625 units. If another exposure occurs more than 3 weeks after the administration of the VZIG dose, an additional dose of VZIG should be administered to provide continued passive immunity [169]. Patients who get monthly high-dose IVIG (>400 mg/kg) are protected if the last dose was given less than 3 weeks before exposure [161]. Because varicella immune globulin could prolong the incubation period by ≥1 week, patients given VariZIG should be monitored for signs or symptoms of varicella for 28 days after exposure. Antiviral therapy should be started as soon as signs or symptoms of varicella occur. Acyclovir may also prevent or attenuate infection after VZV exposure and may constitute a valid alternative, especially in those cases that come to medical attention more than 10 days after exposure. Some authors have advocated using it with VZIG in cases where life-threatening VZV infection is possible, such as in children with renal disease who are receiving steroids [172]. Acyclovir is FDA approved for the treatment of varicella in healthy children. The American Academy of Pediatrics (AAP) recommends consideration of acyclovir treatment of individuals at risk of moderate or severe varicella [173]. The value of acyclovir as a prophylactic agent in the immunocompromised host is unclear; VariZIG is recommended after exposure of these individuals to VZV. There is limited data to support the use of acyclovir for post-exposure prophylaxis in healthy children [174] though some experts support this approach in immunocompromised patients, particularly if VariZIG is unavailable.

46.2.2.4 Staff Considerations

Not all susceptible healthcare workers who report exposure to VZV develop chickenpox. In one report, the incidence of varicella after exposure approached 10% [175]. Susceptible healthcare workers who report such exposures should be furloughed from work from the 8th to the 21st day after exposure. This is based on the average incubation period of 14 days and the knowledge that transmission may occur up to 5 days before and 6 days after the onset of the rash [176]. Susceptible healthcare workers who are exposed to VZV put their transplant recipients at risk, but their furloughed absences also have cost implications and cause disruptions of patient care [177]. Therefore, CDC recommends the vaccination of susceptible healthcare workers if no contraindications are identified [178]. Healthcare workers who receive acyclovir prophylaxis may exhibit a longer incubation period before the development of a rash. Maintaining accurate records of employee data concerning vaccination or a previous history of chickenpox is important. Susceptible employees should be actively encouraged to receive varicella vaccine.

46.2.3 Respiratory Viruses

Most respiratory tract viral infections are seasonal, are more prevalent in children than in adults, and are transmitted by droplets rather than aerosols. Coughing, sneezing, or talking may generate droplets that are not usually projected farther than 3 ft (0.9 m) from the source patient. Special ventilation is not required for inpatient isolation. In the hospital setting, suctioning respiratory secretions and performing bronchoscopy may also generate droplets. The most common respiratory viral infections include RSV, influenza, parainfluenza, and adenovirus. The infection control aspects of respiratory viral infections are similar, and RSV is described here as an example. In recent years, the importance of these viruses in SOT recipients has received more recognition, as has the realization that these viruses cause significant morbidity [179]. These viral infections could be followed by superinfection with bacterial pathogens, leading to bacterial pneumonia, and they have also been associated with acute and chronic rejection, particularly in lung transplantation [180, 181]. In recent years the introduction of sensitive molecular techniques for clinical diagnosis of respiratory viruses has allowed not only early detection of these viruses [182], but also puts emphasis on other viruses like rhinovirus and metapneumovirus [183].

46.2.3.1 Respiratory Syncytial Virus

Overview

Respiratory syncytial virus (RSV) is an RNA virus that causes upper and lower respiratory tract infections, usually before 3 years of age. Reinfection is common, but, in the healthy host, it is self-limited and generally mild. Outbreaks in the community usually occur seasonally, with peaks in the late spring and autumn that last until winter [184]. There is variability of onset of infection from year to year as well as between various regions in the USA [185]. For example, in Florida, the RSV season comes earlier and lasts longer [186]. The virus may be spread in nurseries, causing severe respiratory infection in infants who have underlying medical conditions, such as bronchopulmonary dysplasia, congenital heart disease, or prematurity [187]. Viral shedding usually lasts for a week, but this period may be longer in infants who are younger than 1 month of age or in those with pneumonia [188]. Nosocomial infections often parallel outbreaks in the community.

RSV can survive drying, and it can stay viable for 6 hours on surfaces and fomites, including gloves [189]. Transmission occurs by direct contact with a person who sheds the virus in the form of droplets or from contact with contaminated hands, handkerchiefs, eating utensils, or other articles. Viral particles may be inoculated into the eyes and nasal mucosa by touching these areas with contaminated hands [189]. Therefore, nosocomial outbreaks may occur not only from patient to patient but also from caregivers or visitors having a "cold" [190, 191].

Immunocompromised patients may develop lower tract lung infection with pneumonia. RSV may infect SOT recipients [192, 193]. In recent years, cases have been reported not only in pediatric SOT populations [194] but also in adults presenting with respiratory symptoms [195]. Two liver transplant recipients younger than 15 months of age were intubated when symptoms began soon after transplantation, but they later died from RSV pneumonia [193]. This may suggest the direct inoculation of the virus in the lower respiratory tract, bypassing the upper airways. Ribavirin, administered orally or intravenously, may reduce the morbidity and mortality due to RSV, influenza B, and parainfluenza [196]. Nevertheless, its routine use has not been recommended because of possible toxicity to exposed healthcare providers (the inhalation form) and because of ongoing debate regarding its definitive beneficial effects.

There is no vaccine available for RSV prevention. Palivizumab, a humanized murine anti-RSV monoclonal antibody, can be given as a monthly IM injection beginning prior to and continuing through the RSV season (typically November to April in the northern hemisphere) for prophylaxis in infants and children at risk for severe RSV infection [197]. In a survey of pediatric solid organ transplant centers in the USA, almost 50% of responding centers use palivizumab prophylaxis [198].

Infection Prevention and Control Measures

Infection control measures should be promptly instituted to prevent nosocomial transmission. Contact precautions should be used for infants, young children, and immunosuppressed individuals. Gloves and gowns should be used when entering the room of patients with RSV, parainfluenza, or adenovirus to prevent contact with respiratory secretions. Mask and eye protection is necessary if procedures that generate vaporization of respiratory secretions are expected [2]. In outbreaks, cohorting of symptomatic patients while emphasizing hand hygiene may reduce transmission to others. Successful cohorting requires the early diagnosis of RSV when the epidemic is starting in the community. Shell vial cultures and rapid antigen detection by immunofluorescent assay (IFA) or enzyme-linked immunosorbent assay (ELISA) have greatly accelerated the diagnosis, compared with viral isolation techniques [199, 200]. More recently, more institutions have used PCR for the diagnosis of respiratory viruses, a molecular technique which is more sensitive [182, 201].

46.2.3.2 Other Respiratory Viruses: Influenza, Parainfluenza, and Adenovirus

Other respiratory viral infections that usually manifest as self-limited upper respiratory tract illness may result in potentially life-threatening lower respiratory infections in immunocompromised patients. At the University of Pittsburgh Medical Center, influenza was more prevalent among lung transplant recipients than it was among other organ recipients [202]. Secondary bacterial pneumonia occurred in 17% of the patients with influenza. Other complications occurred in three patients, including myocarditis, myositis, and bronchiolitis obliterans. Reports of transplant recipients who received the influenza vaccine but who developed influenza despite vaccination have been published [203]. This is due to the suboptimal response of transplant recipients to protein vaccines, and it raises the question of the use of antiviral chemoprophylaxis in the future. During the H1N1 April 2009 influenza A pandemic, of the reported 237 solid organ transplant recipients with H1N1, 32% developed pneumonia, 16% were admitted to ICU, and 4% died [204]. Organ recipients, their families, and the healthcare providers must realize the importance of receiving the annual inactivated influenza vaccine to reduce the risk of disease transmission. CDC, the Advisory Committee on Immunization Practices (ACIP), and the HICPAC recommended that all US healthcare workers get annual influenza vaccine [205]. The live, attenuated influenza vaccine (LAIV) administered as a nasal spray is not recommended for immunocompromised patients but may be given to close contacts of immunosuppressed individuals, though persons caring for patients in a protective environment should avoid contact with such patients for at least 7 days after receipt of LAIV [206].

Parainfluenza and adenoviruses may also cause life-threatening infection, and they may also be spread nosocomially [207, 208]. Rapid identification of these respiratory viruses, especially in pediatric wards, will help in cohorting staff and patients when an epidemic is recognized in the community [209]

46.2.4 Rotavirus and Viral Gastroenteritis

46.2.4.1 Overview

Viral gastroenteritis is usually a self-limited syndrome in the healthy host. Several viruses are associated with gastroenteritis, including rotavirus, norovirus, enteric adenovirus, caliciviruses, enteric coronavirus, and astrovirus [210]. Rotaviruses and noroviruses are the most epidemiologically significant agents of the gastroenteritis viruses, causing endemic and epidemic disease throughout the world. In particular, the rotaviruses have been associated with outbreaks in children and in developing countries where they have been associated with high mortality rates [211]. The symptoms often include vomiting, diarrhea, and dehydration. Fever may be present. Dehydration may be severe enough to

require hospitalization for intravenous fluid replacement. The incubation period ranges from 1 to 3 days, with symptoms usually lasting less than 1 week. The transmission of rotavirus occurs through the fecal–oral route, with maximum viral shedding in the stool occurring 2–5 days after the onset of diarrhea. Nosocomial infections have been associated with the insufficient use of appropriate infection control measures. Rotavirus infections represent between 20% and 40% of the cases of nosocomial diarrhea in children [212, 213]. There has been an association between rotavirus gastroenteritis and rejection of small bowel allograft but this may have been related to decrease in immunosuppressive agents due to diarrhea [214, 215]. In the USA, most infections occur in children between the ages of 6 and 24 months after maternal antibody protection wanes [216]. Infections occur more frequently between October and April. Usually, the virus produces a self-limited diarrhea; however, premature infants and transplant recipients may develop severe disease [210]. Although rotaviruses do not generally cause bloody stool, fecal occult blood loss has been reported in pediatric liver transplant recipients [217].

46.2.4.2 Healthcare-Associated Transmission

Rotaviruses can remain viable in water and on dry inanimate objects and hands for many days. An investigation in day care centers with rotavirus outbreaks demonstrated the virus by PCR on toys (39%) and environmental surfaces (21%) [217]. Rotavirus may be transmitted to the patients by aerosols. Contamination of inanimate objects occurs not only by feces but also by aerosols generated by bedpan cleaning [211]. Patient-to-patient transmission may result in mini-epidemics within the hospital [210]. Adult contacts of patients with rotavirus may exhibit subclinical illness [213]. Infection control measures should be instituted promptly whenever patients are incontinent or develop diarrhea. Standard precautions are adequate unless the patient is incontinent or diapered; contact precautions should be added in such cases. Good hand hygiene is essential, with glove and gown usage for patient contact if fecal contamination is likely. Cleaning of room surfaces with an EPA-registered hospital disinfectant is adequate for cleaning of surfaces in the patient's room [5]. The institution of infection control measures interrupted an outbreak in a pediatric oncology ward that was presumed to have occurred through contaminated toys [218]. These included contact precautions, and the daily cleaning of playroom with a dilute bleach solution.

46.2.4.3 Vaccination

The first rotavirus vaccine approved in 1998 in the USA was the Rotashield (Wyeth–Lederle Vaccines and Pediatrics), which was taken off the market 1 year later because of its association with intussusception [219]. In February 2006, a new vaccine, RotaTeq (Merck and Co.), was licensed in the USA. This is an oral live vaccine which was developed from human and bovine virus and has not been associated with intussusception [220]. It is given in three doses at 2, 4, and 6 months with completed administration by 32 weeks of age. A second vaccine Rotarix (GlaxcoSmithKline) was licensed in April 2008. It is live attenuated oral vaccine and is given to infants in two doses at 2 and 4 months infants. The two vaccines are equivalent. Although the original studies have not shown an association, post-licensure studies did demonstrate low risk of intussusception in certain populations [221], and support for use of the vaccine is universal. Between November 2007 and May 2008, delayed onset and reduced rate of rotavirus infection was observed [222], attributed to the introduction of the rotavirus vaccine. There are no data available regarding the safety and efficacy of this vaccine in immunosuppressed infants. It is believed that infants who live in the same household with immunosuppressed patients can still be vaccinated despite the small risk of transmission of the vaccine rotavirus [219].

46.3 Summary

Good infection prevention and control practices are essential for protecting highly susceptible transplant recipients. Quality management and patient safety initiatives have become driving forces in providing better patient outcomes. Insurers are interested in infection data to identify programs that have superior patient results. All of these process improvement initiatives are balanced by the evaluations of cost-effectiveness. Although some preventive measures, such as LAF, are highly effective, they may be too costly for routine use if they provide no additional benefit to the patient. While scientists are validating the use of new strategies, a renewed focus on best practices, including such basic concepts as hand hygiene, cleaning, disinfection, and preventing infections, is essential.

Part IX
Immune Reconstitution Strategies for Prevention and Treatment of Infections

47
Vaccination of Transplant Recipients

Per Ljungman

47.1 Introduction

Over the last 40 years the numbers of solid organ (SOT) and hematopoietic stem cell transplant (HSCT) patients have increased rapidly. The most attention, until recently, has been focused on preventing infections occurring during the early phase after transplantation usually through antimicrobial chemoprophylaxis. As the results of transplantation have improved, the numbers of long-term survivors increased. Many patients remain immunosuppressed for a long time either due to the interaction between the graft and the host, i.e., GVHD in HSCT recipients or by the immunosuppressive therapy given to prevent graft rejection in SOT recipients.

Immunizations are important for two main reasons. Obviously, the most important is the need to protect the recipient against serious infections that may occur during the early or late post-transplant period. However, another reason is the public health point of view namely to avoid having individuals vulnerable to important infectious agents, for example, measles and who can serve as sources of infection in the community. Both reasons require analysis of risks and benefits for the transplant recipient.

47.2 Hematopoietic Stem Cell Transplantation

47.2.1 Allogeneic HSCT

47.2.1.1 Transfer and Persistence of Immunity in Allogeneic HSCT Recipients

After an allogeneic HSCT, the immune system of the recipient is replaced by the immune system of the donor. The immune deficiency is caused by a combination of the preparative regimen given before HSCT, GVHD, and immunosuppressive therapy given after the transplantation. Many studies have shown that immunity to some infectious agents can be transferred by the graft and be detectable in the patient early after the HSCT [1–8]. Thus, it would make sense to immunize the donor pre-donation to improve the transfer of immunity. Studies have shown that pretransplant vaccination of the donor with tetanus toxoid, diphtheria toxoid, hepatitis B virus, *Haemophilus influenzae* type B (HIB), and pneumococcal conjugate vaccine increase the probability of transfer of B-cell immunity by the stem cell graft [5, 9–11]. The clinical effects resulting from the transfer of donor immunity have been best studied for hepatitis B virus [9, 12]. Case reports suggest that transfer of immunity from an HBV immune donor can clear detectable virus from an HBV-antigen and DNA positive recipient [13, 14]. Whether this transferred immunity can prevent a primary infection is unknown. It has also been shown that transfer of donor immunity is only of a finite duration unless also the recipient is vaccinated early after transplantation [6, 9].

There are no effective and safe vaccines available for most infections that are common and serious early after allogeneic HSCT. The infections for which pre-transplant vaccinations could be considered are influenza, HIB, pneumococci, and varicella-zoster virus (VZV). Molrine et al. showed that donor immunity to pneumococci can be transferred and early post-transplant vaccination with the conjugated pneumococcal vaccine (PCV) improved the immune response [10]. In contrast, donor immunization with the 23-valent polysaccharide vaccine did not improve the recipient immunity [11]. Ambati et al. studied influenza vaccine pre-transplant with either the donor or the recipient vaccinated followed by recipient vaccination at 6 months after transplantation [15] and showed some positive effect of vaccinating the recipient but no effect of vaccinating the donor. However, it is possible that an earlier post-transplant vaccination could have been beneficial.

Another infection for which transfer of donor immunity could be of importance is CMV. There are vaccines in development that might be used in future studies.

P. Ljungman et al. (eds.), *Transplant Infections*, DOI 10.1007/978-3-319-28797-3_47

There are several practical problems such as the timing of donor vaccination to give optimal conditions for immunity transfer. Furthermore, the ethical aspects of donor vaccination have to be considered, for example, to vaccinate children or unrelated donors with the aim to improve transfer of a specific immunity to the recipient when no efficacy data from donor vaccination exist.

Despite that transfer of specific immunity after allogeneic HSCT does occur, the long-term presence of specific antibodies after HSCT is not only dependent on the donor's immune status but also on the recipient's immune status before HSCT [6, 16, 17]. In most patients specific B-cell immunity is usually progressively weakened over time and an increasing number of patients becomes susceptible to infections such as tetanus [3, 17], poliovirus [18–20], and measles [16, 21] during extended follow-up. The loss of protective immunity is more rapid in patients who were immunized against measles compared to those who became immune after natural measles disease (Figure 47-1) [16]. Thus, the intensity of the original antigen challenge is of importance for the duration of specific immunity after HSCT.

The T and B cell immunity post-transplant must have been at least partially reconstituted for a vaccine to induce a clinically relevant immune response. B cell counts, which are very low in the first 1–3 months after HSCT, return to normal by 3–12 months post-transplant. In patients treated with rituximab post-transplant, B cell recovery is generally delayed for at least 6 months [22]. T cell counts are low in the first 1–3 months post HSCT. Thereafter, the recovery of T cells is influenced by patient age at HSCT, T-cell depletion of the graft, and eventual chronic GVHD. The technology of allogeneic HSCT is developing rapidly with the introduction of new stem cell sources (cord blood stem cells) and new donor categories (haplo-identical donors). Data are still limited regarding vaccination responses in these subgroups of allogeneic HSCT patients and current recommendations do not differentiate between these different subgroups [23, 24].

47.2.2 Studies of Immunizations in Allogeneic HSCT Recipients

Severe infections frequently occur early after HSCT when immunizations are ineffective. It would therefore be logical to immunize candidates before HSCT. Although most studies show that adult patients with hematological malignancies respond poorly to vaccination, vaccination prior to transplant may improve immunity [25], and guidelines suggest administering inactivated vaccines prior to HSCT if there is an interval of ≥2 weeks before initiation of immunosuppressive therapy [23, 24].

A T-cell response after vaccination can be induced 2–6 months after HSCT while antibody responses usually do not develop until 6–12 months after HSCT. Vaccines based on protein antigens such as tetanus toxoid or conjugated-polysaccharide-vaccines are able to elicit immune responses earlier after HSCT than polysaccharide-based vaccines. GVHD and/or its treatment might decrease T-cell and antibody responses to vaccines although studies show limited differences in responses in patients with or without chronic GVHD [20].

Current recommendations for vaccination of HSCT recipients are shown in Table 47-1. These are based on a recent consensus document [23, 24]. It should be recognized that risk/benefit and cost/benefit ratios might be different in different countries. The local epidemiological situation for certain infections such as measles or yellow fever as shown by recent outbreaks might make vaccination with a live vaccine the preferred option despite the risk for side effects.

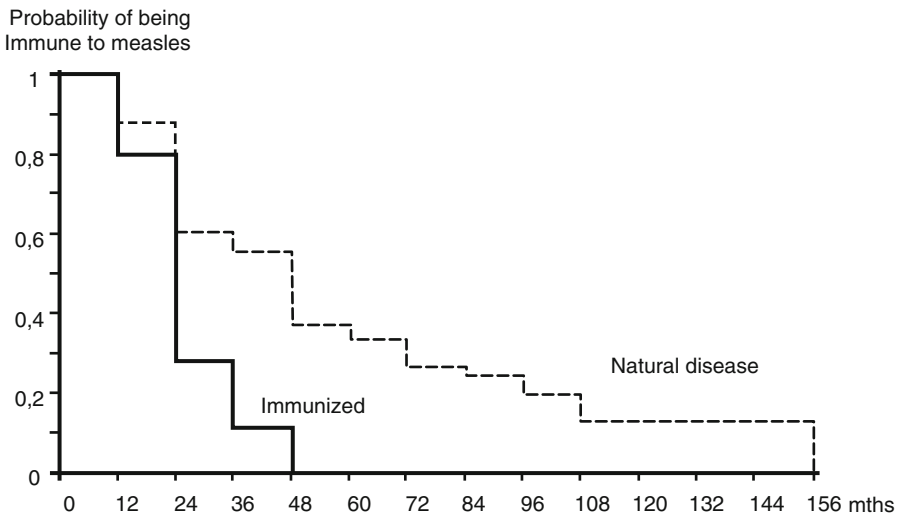

Figure 47-1. Kaplan-Meier probability for immunity in patients who had previous measles disease or who were immunized against measles. This research was originally published in Blood. Ljungman P, Lewensohn-Fuchs I, Hammarstrom V, Aschan J, Brandt L, Bolme P, et al. Long-term immunity to measles, mumps, and rubella after allogeneic bone marrow transplantation. TABLE 47-1. Vaccinations in stem cell transplant patients

Vaccine	Schedule	Comments
Pneumococcal conjugate vaccine (PCV13)	Three doses starting at 3–4 months after HSCT	A booster with either PCV13 or polysaccharide vaccine (PPV23) might be given
Haemophilus group B conjugate	3 doses starting at 3–6 months	
Meningococcal conjugate	Two doses given at 6–12 months	Follow national recommendations
Tetanus toxoid	3 doses starting at 6 months	Full dose
Diphtheria toxoid	3 doses starting at 6 months	Full dose (D)
Pertussis	3 doses to children <7 years	Full dose (P)
BCG	Not recommended	Risk/benefit ratio does not favor vaccination
Other live bacterial vaccines	Not recommended	Risk/benefit ratio does not favor vaccination
Inactivated influenza vaccine	Yearly staring at 4–6 months depending on season	Children <9 years should receive two doses. Family members and staff
Inactivated poliovirus vaccine	Three doses started at 6 months	
Hepatitis B virus	Three doses started at 6 months	The indication for HBV vaccination depends on the epidemiological situation for HBV in the country
Hepatitis A virus	Can be started at 6 months	Safe, can be considered in patients that might become exposed
MMR	1–2 doses started at 24 months	Only to patients without GVHD or ongoing immunosuppression
Varicella	Usually not indicated. Not before 24 months after HSCT	To seronegative patients without GVHD or ongoing immunosuppression
Zoster vaccine	Usually not indicated	To seronegative patients without GVHD or ongoing immunosuppression.
Other live viral vaccines	Not before 24 months after HSCT Usually not indicated	Risk/benefit ratio has to favor vaccination.

47.2.2.1 Inactivated Vaccines

Influenza Vaccine

Influenza A and B infections can be severe and life threatening in HSCT recipients and can occur several years after HSCT [26–29]. Only limited data exist in patients having received reduced intensity conditioning regimens [30] and there is almost no data in patients receiving cord blood or haplo-identical grafts. Existing data in children are also limited. In addition, with one exception, studies report the effect of the vaccine in inducing antibody responses and not protection against infection or indeed severe disease.

When vaccination should be initiated after HSCT depends in part on when an influenza outbreak is likely to occur in the patient's community. It has been shown that the time after HSCT is important for vaccine efficacy; patients vaccinated later after HSCT have better responses [31–33]. Engelhard et al. studied the antibody response to two doses of influenza virus vaccine in 35 allogeneic bone marrow transplant recipients (adults and children), who received a T-depleted transplant and vaccinated between 2 and 82 months after transplantation [34]. No patient vaccinated before 6 months from transplantation responded while more than 60% of the patients responded when vaccinated more than 2 years after HSCT. The second vaccine dose had only a marginal effect. In a study by Pauksen et al., the response rates were similar in patients vaccinated between 4 and 12 or >12 months after HSCT. Several studies were performed in HSCT recipients with the pandemic H1N1 vaccine. Issa et al. studied 82 patients vaccinated a median of 19 months after transplantation (2.5–94 months) with one dose of unadjuvanted vaccine [35]. Protective titers were found in 51% of the patients with better responses seen in patients vaccinated later after HSCT (OR 1.79/year) and poorer responses if the patient had received rituximab during the last year [35]. Engelhard et al. studied 55 patients vaccinated a median of 27 months (1–290 months) with two doses of an AS03-adjuvanted vaccine (Pandemrix, GSK). The protection rate after two doses was 48.7% and the seroconversion rate 41.9% [31]. Factors influencing seroconversion was the lymphocyte count and donor type but there was no effect of time after HSCT [31]. De Lavaillade et al. studied 26 allogeneic HSCT recipients receiving two doses of the same adjuvanted vaccine at a median time from HSCT of 39 months (6–127 months) [33]. The seroprotection rates were 45% and 73% after one and two doses, respectively, and significantly lower than in healthy controls. There was a positive effect of longer time after HSCT. Dhédin et al. reported similar immune responses after two doses of adjuvanted pH1N1 vaccine compared to natural infection [36]. No increased risk for side effects was found in any of the studies. Dhédin et al. reported, however, that four patients developed worsened chronic GVHD [36].

For inactivated influenza vaccine data regarding the effectiveness of a second dose in older children and adults have given conflicting results [31, 33, 37]. Children younger than 9 years of age who are receiving influenza vaccine for the first time require two doses administered 4 or more weeks apart. However, despite suboptimal immune responses, there might still be clinical effectiveness of vaccination. Machado et al. found that influenza vaccination performed at least 6 months after SCT had an efficacy in preventing influenza of 80% [30].

Even in cases where there is no serological response, T-cell responses may be elicited that possibly may prevent serious disease [33, 38, 39]. It is also possible that adjuvanted vaccines might improve immune responses although no controlled trial has been performed [39].

Yearly influenza vaccination is recommended to all allogeneic HSCT patients from 4 months after HSCT if there is a community outbreak and yearly thereafter [23, 24, 40]. Live attenuated influenza vaccine should not be used because the safety and efficacy of this vaccine in HSCT patients has not been established and an inactivated vaccine alternative exists. It is also recommended to immunize family members and hospital staff thereby reducing the risk for transmission of the infection to the patient [40].

Hepatitis B Virus (HBV) Vaccine

HBV infection is a major cause of morbidity in many parts of the world. One specific problem occurs when a seronegative HSCT patient is scheduled to receive a HBsAg positive marrow graft since these patients might develop severe HBV primary HBV infections after the HSCT [41]. Immunization against HBV in normal individuals usually requires three injections spread over a couple of months to ensure protective immunity. This might cause a problem when scheduling a HSCT. Furthermore, a subset of 5–15% of normal individuals will not respond to HBV immunization. No data exists regarding eventual protective efficacy of pretransplant immunization of the marrow recipient.

Immunization with HBV vaccine early after HSCT is likely to be ineffective unless the donor is immunized. The immunization of the marrow donor allows a transfer of immunity to the recipient [9, 12]. A transferred donor immunity can be long-lasting in at least 50% of the patients but revaccination of the recipient after HSCT is needed to obtain long-term immunity [42]. Vaccinated patients are significantly less likely to experience HBV reactivation compared to unvaccinated controls [43, 44]. Vaccination with HBV is recommended to allogeneic HSCT recipients from 6 to 12 months after HSCT but should be combined with antiviral prophylaxis [45].

Pneumococcal Vaccines

Fatal infections with pneumococci can occur both early and late after transplantation [46]. The risk for severe infections is increased in patients with chronic GVHD [47–49]. Protective immunity against pneumococci is mediated through antibodies directed against polysaccharides from the bacterial capsule. Two types of pneumococcal vaccines are licensed in most countries: conjugate vaccines (PCV) either containing 10 or 13 serotypes and a polysaccharide vaccine containing 23 serotypes (PPV23). PCV is more immunogenic than PPV23. However, the spectrum of protection is narrower since the vaccine contains fewer serotypes. Immunization with PPV23 can elicit antibody responses 6–12 months after HSCT in patients without GVHD but has been ineffective in eliciting adequate immune responses in patients with chronic GVHD [50–54]. In particular the specific IgG2 responses have been poor [54, 55]. The immune response was not significantly improved by two doses of pneumococcal vaccine as compared to one dose [50]. Children given pneumococcal polysaccharide vaccines had short-lived responses and low avidity [56] in contrast to adults in whom the avidity was good [57]. The functional capacity of the vaccine induced antibodies has also been studied. Parkkali et al. studied the opsonophagocytic activity against pneumococcal subtype 19 F and found that it was poor [58].

Three prospective trials demonstrate good antibody responses with the use of PCV7. Cordonnier et al. performed a randomized, controlled non-inferiority trial comparing vaccination with three doses of PCV7 given at 3 or 9 months after HSCT and there was no difference in the response rates between the two groups although patients in the early group lost immunity more rapidly especially those with chronic GVHD [59]. Molrine et al. performed a randomized study with PCV7 comparing pretransplant vaccination of the patients and their donors or no vaccination pretransplant. All patients thereafter received three doses of the vaccine at 3, 6, and 12 months after transplantation. The majority of patients (72–100% for different serotypes) developed protective antibody protection at 12 months after HSCT [10]. There was also an improved response (67% vs. 36%) to the first dose. Kumar et al. [60] conducted a randomized study comparing PPV23 versus PCV7 given to the donors before transplant and to the recipients 6 months post-transplantation. Rates of response at 12 months were low in both groups but better with PCV7. Meisel et al. immunized 53 children with 3 monthly PCV7 doses starting 6–9 months after transplantation [61]. A response (antibody titres ≥0.5 μg/ml) was noted in 74% of patients. A prospective uncontrolled trial studied the effect of four doses of the PCV13 and showed strong immune responses to the fourth dose. However, this dose resulted in an increased rate of side effects [62]. There was no beneficial effect of a subsequent dose of PPV23 but this dose was probably given too early after the fourth PCV dose to be ideal. It is also most likely necessary to give additional pneumococcal vaccine doses during follow-up of HSCT recipients to maintain immunity to pneumococci but the exact schedule needs to be defined by further studies [63].

The current recommendations are to use PCV and start vaccinating 3–6 months after HSCT. In patients with chronic GVHD a fourth dose is recommended while in patients without chronic GVHD, a dose of PPV23 is recommended to broaden the immune response [23, 24].

47.2.2.2 H. influenzae Type B Vaccine

H. influenzae can also cause severe infections in allogeneic HSCT recipients although fatal infections seem to be rare. Vaccination with conjugated HIB vaccine can elicit protective immune responses [50, 51, 53]. However, the time after HSCT is important since it was reported that early vaccination gave

poorer responses in transplanted children [64]. Immunization with the HIB vaccine is indicated to all allogeneic HSCT recipients [45, 65, 66].

Tetanus Toxoid, Diphtheria Toxoid, and Poliovirus Vaccine

Most HSCT patients will lose immunity to tetanus toxoid, diphtheria toxoid, and poliovirus during extended follow-up. Tetanus is a rare but life-threatening disease preventable by immunization. Sporadic cases of diphtheria do occur in many countries. Although the efforts to eradicate polio have been successful in many parts of the world, small outbreaks still occur in non-immune populations. Thus, there are good reasons for having an immunization strategy against these infections in HSCT recipients.

Several studies of immunization with these vaccines have been published [17–20, 67]. A new primary schedule with repeated doses of these vaccines is needed to obtain stable protective immunity [17–19]. Good and lasting immune responses can be obtained when immunizations are given at 6 months after HSCT [20, 67]. Gerritzen et al. immunized children before HSCT followed by revaccination already at 6 weeks after HSCT. Thirty percent of the patients responded to early immunization [68].

The inactivated poliovirus vaccine should be used to prevent a vaccine induced paralytic disease. It is also important that the inactivated vaccine is used in family members to HSCT patients and in hospital staff caring for these patients since transfer of the live vaccine virus from an immune competent to an immunosuppressed individual has been reported.

The vaccination of allogeneic HSCT recipients with three doses of tetanus toxoid, diphtheria toxoid, and inactivated poliovirus vaccine starting at 6–12 months after HSCT is recommended to all allogeneic HSCT recipients [45, 65, 66].

Pertussis Vaccine

HSCT recipients might be vulnerable to complications from pertussis due to pulmonary damage from chemotherapy and/or TBI, although the documentation for severe infections is limited [69, 70] even in the absence of chronic GVHD. In young children, it is logical to vaccinate against pertussis together with diphtheria, and tetanus since many available vaccines include the pertussis component (DTaP) some with added HIB and IPV components.

The immune response to vaccines containing low amounts of pertussis antigen (Tdap) has been shown to be poor [71]. In view of this, vaccines containing higher pertussis content are recommended. Whether combination vaccines have the same effect in adults as in young children have not been studied.

Other Killed Vaccines

Vaccination with a tetravalent meningococcal polysaccharide vaccine can elicit good responses in HSCT recipients both against serogroup A and C [72]. Mahler et al. studied the tetravalent conjugated meningococcal vaccine in 46 patients, mainly children, at a median of >2 years after HSCT [73]. The response rate to the different serotypes varied between 30% and 52%. Seven of 46 patients (15% responded to all serotypes and 35% did not respond to any serotype). Sixteen patients got a second dose and 50% responded against all serotypes.

Current recommendation state that HSCT patients should receive meningococcal vaccine if recommended to the general population in the country where the patient resides [23, 24, 40].

There is no data with the human papillomavirus (HPV) vaccine but studies are needed since papillomavirus-induced tumors are more common after HSCT than in a normal population.

Hepatitis A is a severe infection in many parts of the world and the vaccine is inactivated. Thus, vaccination could be indicated. However, limited data is available in HSCT recipients.

47.2.2.3 Live Vaccines

Measles, Mumps, and Rubella (MMR) Vaccine

Measles is still an important infection in many parts of the world. Until recently, the good vaccination coverage in the general population in Europe and USA reduced the risk for outbreaks and thereby the risk for transfer to HSCT recipients. However, during the last decade the vaccination rates of children in many countries decreased and many outbreaks have been reported [74, 75]. Many patients will become seronegative to measles during an extended follow-up especially if previously vaccinated [16, 21]. This is important since occasional severe and also fatal measles infections have been reported in HSCT recipients [76, 77]. During a large outbreak in Brazil, one of eight patients with measles developed interstitial pneumonia but all survived [21].

The available measles vaccines are live, attenuated and usually combined with rubella, and mumps vaccines (MMR). These vaccines are not recommended for use in immunocompromised patients since serious side effects are possible. Immunization can only be considered in allogeneic HSCT patients without chronic GVHD or ongoing immunosuppression. Data indicates that measles vaccine can be given safely to such patients at 2 years after HSCT [78]. During an epidemic in Brazil, patients were immunized at 1 year after HSCT and no severe side effect was observed [79]. The reported effect of vaccinations varies between different studies with a higher response rate in adults than in children [78, 80–82]. A second dose might therefore be needed in children. Earlier vaccination can be contemplated if the epidemiological situation in the community indicates that there is a significant risk for measles. In such situations, it is likely that the risk/benefit ratio will favor early vaccination.

The risk for severe rubella infection after allogeneic HSCT is likely to be low. However, with more patients undergoing transplantation after reduced intensity conditioning regimens, the pregnancy potential for patients is likely to increase.

The risk for severe mumps disease seems to be very low after HSCT. The indication for mumps vaccination is therefore weak. However, most vaccines are combination vaccines including measles, mumps, and rubella (MMR) and single measles vaccine is difficult to find in most countries. Current recommendations are therefore that MMR vaccine is used but it should not be given earlier than 2 years after HSCT and only to patients not having chronic GVHD or ongoing immunosuppression [45, 65].

Varicella-Zoster Virus (VZV) Vaccine

Primary VZV infections can be very severe early after allogeneic transplantation. The existing vaccine is live and attenuated and shall therefore not be used early post-transplantation. A seronegative patient should, if possible, be immunized before transplantation if enough time can elapse from the vaccination to the transplant procedure. There is no data allowing assessment of the minimum interval that is needed between immunization and transplantation but recent recommendations state an interval of at least 4 weeks [23, 24]. This strategy has not been formally studied although it is likely that children with acute leukemia, who have been immunized with the varicella vaccine, have subsequently undergone allogeneic HSCT. Vaccination of seronegative family members to allogeneic SCT recipients is also recommended [83]. A few uncontrolled studies have been performed and reported that varicella vaccination is safe and can result in seroconversion if performed >2 years after HSCT in patients without chronic GVHD, or ongoing immunosuppression [84–86].

A high proportion of HSCT patients develop herpes zoster that occasionally becomes severe. Redman et al. used heat-inactivated varicella vaccine and showed no reduction in the risk of developing herpes zoster but a reduced severity of the herpes zoster in the immunized group [87]. Issa et al. gave one dose of zoster vaccine to 58 allogeneic HSCT recipients and did not note any significant side effects [88]. Inactivated vaccines are currently in late clinical development. The immune response in allogeneic HSCT recipients was poor in a phase II study with a heat-treated vaccine [89]. A recent study of a subunit vaccine showed promising results in healthy elderly and should be evaluated in HSCT recipients as well [90]. Due to the proven efficacy and safety of acyclovir prophylaxis [91], vaccination with the live zoster vaccine is not recommended during at least the first years after HSCT.

Other Live Vaccines

Other live vaccines are typhoid, BCG, and yellow fever. Yellow fever is a life threatening infection primarily occurring in Central- and South America and southern and central Africa. The vaccine is live and attenuated. Rio et al. have presented three patients who were immunized at 5 years after BMT without severe side effects [92] and this experience has since then been expanded to 25 patients without any serious side effects (B Rio, personal communication). Immunization could be considered in patients who must visit areas where yellow fever is endemic. It seems likely that the same limitations are indicated as for other live virus vaccines.

Both live and inactivated vaccines against *S. typhi* exist. Therefore, use of the live vaccine should be avoided. BCG vaccine can cause severe infections in patients with depressed T-cell function and is not recommended in HSCT recipients.

47.2.2.4 Long-Term Follow-Up After Vaccinations

Limited data is available regarding long-term persistence of immunity after vaccination of HSCT recipients. Figure 47-2 shows own unpublished data for immunity at 4–12 years after vaccination against poliovirus type 1 with three doses of inactivated vaccine at 12, 13, and 18 months after allogeneic HSCT.

Cordonnier et al. studied antibody levels at 10 years after vaccination in patients previously participating in a randomized study of PCV7 followed by PPV23 and showed no significant decrease in antibody levels compared to 24 months after HSCT although with significant variability between different subtypes [63].

47.2.3 Autologous Bone Marrow Transplantation

47.2.3.1 Persistence of Immunity in Autologous HSCT Recipients

In autologous HSCT recipients the immune system is depressed by high doses of chemo- and radiotherapy but there is no immunological disparity between the graft and

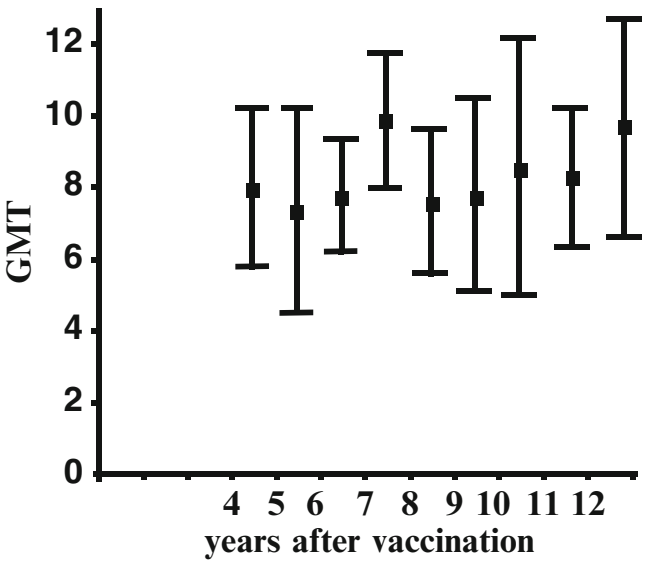

FIGURE 47-2. Geometric mean neutralization titers (± SE) against poliovirus type 1 in allogeneic HSCT patients during long-term follow-up.

the patients. The immune regeneration is, in most patients, quicker than after allogeneic HSCT and even more so after peripheral blood stem cell transplantation. Early severe infections caused by pneumococci and influenza have been reported [28, 46]. Less is known about late immune deficiency after autologous compared to allogeneic HSCT. Nordöy et al. reported that patients who had undergone autologous HSCT for lymphoma had persistent abnormalities in lymphocyte subsets for several years after the transplantation [93]. Previous treatment especially with anti-B-cell antibodies will negatively influence the immune reconstitution and responses to vaccination after autologous HSCT.

Several studies have shown that also autologous HSCT recipients will lose protective immunity to tetanus, poliovirus, and measles during extended follow-up [19, 94–97]. Similar to allogeneic HSCT recipients, poor responses to immunization are elicited if immunizations are given early after transplantation [32, 34]. One option in autologous HSCT recipients could be to immunize the patient either before stem cell harvest or just before the transplantation. Immunization against HBV elicited protective immune response when one dose was given before and one dose early after autologous HSCT [98]. However, the seroconversion was only transient in one-third of the responding patients. Immunization with conjugated *H. influenzae* type B vaccine and tetanus toxoid before marrow harvest followed by immunization at 3, 6, 12, and 24 months after autologous HSCT improved the antibody titers to both antigens already at 3 months after the transplantation [99].

47.2.4 Immunization of Autologous HSCT Recipients

Fewer studies of immunization have been performed in autologous than in allogeneic HSCT recipients. Most published recommendations do not differentiate between allogeneic and autologous HSCT recipients. Therefore, if no specific knowledge exists regarding autologous HSCT recipients, the recommendations are based on those given for allogeneic HSCT recipients.

Influenza The response to vaccination is likely to be suboptimal early after transplantation [32, 34]. In one study, no patient responded if the immunization was performed earlier than 6 months after autologous HSCT [34] and in a study that added GM-CSF to influenza vaccination, an antibody response was elicited in less than half of the patients vaccinated during the first year after HSCT [32]. It has been shown that rituximab blocks the immune response to influenza vaccine for at least 6 months after HSCT and probably longer in many patients [100–102]. Despite these limitations influenza virus immunization is recommended from 6 months after autologous stem transplantation and yearly thereafter [45].

Pneumococcal Vaccines Hammarström et al. showed that the majority of a group of autologous HSCT patients transplanted for various diagnose retained normal antibody levels to pneumococci [54]. In contrast Nordöy et al. showed in a group of lymphoma patients that the patients had lower antibody levels compared to controls already before HSCT [97]. However, there was no significant further loss of immunity after the transplant. Autologous HSCT patients are less prone than allogeneic patients to develop severe pneumococcal infections. Most infections occur early after the transplantation when the response to immunization is poor [46]. Vaccination before stem cell harvest with PCV7 resulted in significantly higher antibody levels at all studied time points up to 12 months after HSCT. However, there is no advantage vaccinating the patients before the stem cell harvest with PPV23 [11]. The response to a single dose of pneumococcal vaccination is poor regardless of the stem cell source [50, 103] and remains decreased compared to controls for several years after transplantation for lymphoma [97]. It is likely that treatment with rituximab will negatively influence the response to pneumococcal vaccination but it has not been systematically studied. Vaccination with the PCV7 has been shown to be effective and induced protective antibody levels in >60% of autologous HSCT patients [104]. Vaccination with PCV13 is recommended starting at 3–6 months after autologous HSCT [23, 24].

HIB Vaccine Immunizations with two doses of the conjugated HIB vaccine induced a protective immune response in 80% of HSCT recipients [50]. The immune response might be improved by immunizing the patient before the stem cell harvest. Immunization with a conjugated HIB vaccine before the harvest followed by immunization at 3, 6, 12, and 24 months after autologous HSCT improved the antibody titers already after the dose given at 3 months after the transplantation [99].

Tetanus Toxoid, Diphtheria Toxoid and Poliovirus Vaccine Autologous HSCT recipients have an increased risk compared to the normal population to lose protective immunity to poliovirus [95, 97], diphtheria [97], and tetanus [96]. Reimmunization with repeated doses of inactivated poliovirus vaccine, diphtheria toxoid, and tetanus toxoid effectively restores protective immunity in autologous HSCT recipients [19, 95, 97, 103, 105]. There was no difference in response in autologous HSCT or peripheral blood stem cell graft recipients [103]. Vaccination with reduced dose pertussis vaccine (Tdap) failed to induce immune responses in most autologous HSCT recipients [106]. Immunization with tetanus toxoid, diphtheria toxoid, and inactivated poliovirus is recommended after autologous HSCT [23, 24].

47.2.4.1 Live Attenuated Vaccines

Measles, Mumps, and Rubella Vaccine

Children previously immunized to measles before autologous HSCT frequently become seronegative during follow-up, but adults who before autologous HSCT experienced natural measles disease usually remain immune to measles during follow-up after transplant [94]. The risk for side effects after immunization seems to be low [94]. Earlier vaccination could be considered in high-risk epidemiological situations. Due to the lower risk to lose specific immunity in adults, determination of the antibody level and vaccination only of seronegative patients could be considered [65]. No data exists regarding efficacy and safety of mumps and rubella vaccines after autologous HSCT but are likely to be similar to the situation for measles vaccine. MMR vaccination is recommended for children and seronegative autologous patients not earlier than 24 months after HSCT [23, 24]. Two doses are recommended in children <9 years old.

Varicella-Zoster Virus Vaccine

No studies have been done with the varicella vaccine specifically in seronegative autologous HSCT patients. A small study showed seroconversion and no severe side effects in seronegative allogeneic and autologous HSCT recipients [84]. Sasadeusz et al. gave one or two doses of the live varicella vaccine 4.5–6 months after HSCT. The immune responses were rather poor but no severe side effects occurred [107]. Based on lack of information, varicella vaccination is not recommended during the first 2 years after autologous HSCT [23, 24, 45].

The only commercially available zoster vaccine is live and attenuated. Issa et al. vaccinated 52 autologous HSCT recipients around 2 years after transplantation and did not note any significant side effects [88]. There is, however, one death reported with the vaccine strain 4 years after autologous HSCT in patient with untreated NHL relapse [108]. The safety of live varicella or varicella-zoster vaccines after autologous HSCT must be balanced against other options such as acyclovir/valacyclovir prophylaxis.

Another possibility could be the use of inactivated vaccines after autologous HSCT. Redman et al. gave three doses of a heat-inactivated vaccine to a mixed group of stem cell transplant patients and was able to show a reduced severity but no reduction of the frequency of herpes zoster [87]. Hata et al. have published results of a randomized study in lymphoma patients, who had undergone an autologous transplant [109]. Four doses of vaccine were given, one before and three after HSCT. The risk for zoster was significantly reduced in the vaccinated group (13%) compared to the non-vaccinated group (33%; $p=0.01$). Furthermore, it was shown that vaccination improved the specific CD4+ response to VZV. There are now two different vaccines in development; one inactivated and one subunit vaccine. Stadtmauer et al. reported on a phase I/II placebo-controlled study in which 121 adult patients were vaccinated with three doses of the adjuvanted subunit varicella vaccine [110]. Patients receiving the vaccine had improved CD4+ and antibody responses compared to those given placebo. Mullane et al. studied four doses of the heat-inactivated vaccine. The vaccine was able to induce both antibody and cell-mediated immune responses [89]. Phase III studies are ongoing.

47.3 Solid Organ Transplant Recipients

The need for immunization SOT recipients arises from three components each causing a suppression of the immune system: the immunosuppressive activity of the underlying disease, for example, chronic renal failure, rejection of the organ graft, and the immunosuppressive therapy given after the transplantation. If possible, vaccinations should be given to candidates according to age appropriate schedules when the likelihood of an immune response is higher than after the SOT [23, 24]. The optimal time to begin vaccine administration after transplant is not defined. The immunosuppressive therapy is often most intense during first couple of months and might influence the effect of vaccination. However, this has not been well studied. A summary of the current recommendations is shown in Table 47-2.

47.3.1 Immunizations Given Before Transplantation

47.3.1.1 Hepatitis B Virus

HBV can be transmitted either by a hepatitis B antigen positive organ graft or through blood transfusions. HBV vaccination is recommended in HBV negative patients before SOT. However, the efficacy of HBV vaccine is lower in patients on hemodialysis [111, 112] and in patients with end-stage liver disease compared to healthy controls [113, 114]. In contrast, HBV vaccine elicited an immune response in 73% of children with biliary atresia awaiting liver transplantation [115]. Different schedules have been used attempting to improve the response to vaccinations including accelerated dose schedules and double strength dosages [116–119]. The seroconversion rates in the different studies varied from 31% to 62%. Factors associated with better responses were young age [116], a milder grade of liver disease [116], and specific HLA-types [116]. Besides poor responses to vaccination, the antibody levels decreased rapidly after liver transplantation so that up to 35% of the patients who had seroconverted became seronegative [116, 117]. Despite the less than optimal responses, pretransplant immunization is recommended [120].

TABLE 47-2. Recommendations for immunizations in solid organ transplant recipients

Vaccine	Recommendation before transplantation	Recommendation after transplantation	Comments
Killed vaccines			
Haemophilus group B conjugate	Yes	Yes	Age appropriate
Hepatitis A virus	Yes	Depending on serostatus	Liver transplant recipients
Influenza (inactivated)	Yes	Yes	
Hepatitis B virus	Yes	Depending on serostatus	Seronegative recipients
Pneumococcal conjugate	Yes	Yes	Age appropriate
Pneumococcal polysaccaride	Yes	Yes	Age appropriate
Meningococcal conjugate	Yes	Yes	Age appropriate
Poliovirus (inactivated)	Yes	Yes	Age appropriate
Papilloma virus	Yes	Yes	Age appropriate
Tetanus, diphtheria, and pertussis	Yes	Yes	Age appropriate
Live vaccines			
MMR	Yes	Not recommended	Age appropriate
Varicella vaccine	Yes	Not recommended	Before transplantation in seronegative patients
Zoster vaccine	Possibly; age appropriate	Not recommended	
Other live vaccines (rotavirus, yellow fever)	Possibly	Not recommended	

Pre-transplant vaccination combined with lamivudine therapy has been shown to be effective to prevent primary HBV infection in patients receiving liver grafts from either anti-HBC- or anti-HBc+ donors. Two of 60 patients (one from each donor cohort) developed a primary HBV infection during a median follow-up of almost 5 years [121]. Another possible indication for HBV vaccination would be to prevent reinfection of a liver allograft in HBV positive patients. However, this strategy has been ineffective [122].

47.3.1.2 Hepatitis A Virus

Hepatitis A virus (HAV) can cause decompensation and death in patients with chronic liver disease. Therefore, vaccination can be an important protective strategy. Patients with chronic liver or renal disease awaiting transplantation are able to respond to An HAV vaccination although the results are not as good as in normal individuals [123].

47.3.1.3 Varicella-Zoster Virus

Varicella-zoster virus can cause severe and potentially fatal disease in patients after organ transplantation. It is important to consider the vaccination of seronegative patients awaiting organ transplantation. Varicella vaccine given to uremic children awaiting renal transplantation was shown to be safe and reduced the post-transplant risk for varicella in pre-vaccination seronegative patients [124]. A follow-up study showed that the protection was long-lasting with 42% of the patients still having antibodies at more than 10 years after immunization. Furthermore, the risk for varicella was lower and the disease was significantly less severe in immunized than in non-immunized patients [125]. Similar results were seen in a study of children with chronic liver disease awaiting transplantation with a vaccination efficacy of 100% and no severe vaccine associated side effects [126].

47.3.1.4 Tetanus and Diphtheria Toxoid

Impaired vaccination responses have been reported to tetanus and diphtheria toxoid in dialysis patients. One year and five years after vaccination 35% and 32%, respectively, of patients were protected against diphtheria [127]. 65% of patients were protected against tetanus at 12 months after transplantation [127]. Children should if possible complete their primary vaccination schedule before transplantation. Boosters (Tetanus-reduced diphtheria; Td) can be considered to adults and older children.

47.3.1.5 Pertussis Vaccine

The incidence of pertussis is increasing in many countries and acellular pertussis vaccine is included in the primary vaccination schedule together with diphtheria and tetanus in many countries (DTaP). Although no data exists in solid organ transplant candidates, it is recommended that the primary DTaP schedule should be completed before transplantation if necessary by an accelerated schedule. A dose of tetanus-reduced diphtheria-acellular pertussis vaccine (Tdap) could be considered in adults and older children instead of only Td although no efficacy data exist for the pertussis component.

47.3.1.6 Pneumococcal and HIB Vaccines

Immunizations against *S. pneumoniae* and *H. influenzae* is recommended for children candidates for a SOT [128, 129]. For children below the age of 2 years, the conjugated (PCV7)

vaccine is recommended and if necessary in an accelerated fashion [130]. In older children, an additional dose of PPV23 to broaden the immune response can be considered although there is currently no data with such a strategy [130].

47.3.1.7 Measles-Mumps-Rubella Vaccines

MMR vaccinations have been given to infants awaiting renal transplantation with good responses to vaccination [131]. 88% of the patients developed immunity to all three components of the vaccine. Analyzing the components separately, 89% developed immunity to measles, 88% to mumps, and 100% to rubella.

47.3.2 Immunization Given After Transplantation

47.3.2.1 Killed Vaccines

Hepatitis B Virus Vaccine

The efficacy of HBV vaccination was reported to be low after solid organ transplantation with response rates between 5 and 15% [132, 133]. It was, however, reported that pediatric liver transplant patients can achieve good vaccination responses (70% seroconversion; [134]). The type of immunosuppression influences the vaccination response in that patient receiving triple immunosuppression (cyclosporine, corticosteroids, and azathioprine) responded less well than patients receiving cyclosporine only [134]. HBV vaccinations as protection against reactivation in patient transplanted for HBV cirrhosis have been used in two studies giving different results. Sanches-Fueyo et al. reported good results with this strategy using double dose of HBV vaccine [135] while Angelico et al. reported poor results with a similar strategy [136]. Two studies with vaccines including experimental adjuvants have given promising results with response rates of 50–80% in liver transplant recipients transplanted for HBV-related disorders [137, 138]. A booster with conventional vaccine might improve long-term retainment of immunity [139].

Hepatitis A Virus

Vaccination results after liver or renal transplantation are poorer compared to healthy individuals [140, 141] and antibody levels decrease more rapidly [141]. In a study including kidney transplant recipients in South Korea, 52 patients received two doses of HAV vaccine and the seroconversion rate was only 27% with lower serum creatinine and higher hemoglobin being positive predictors for response [142].

Influenza

Influenza can cause severe infections in SOT patients [26, 27] as shown by the experience during the 2009 H1N1 pandemic [143]. Results of immunization vary with the age of the patients. Adults have poorer antibody responses to influenza vaccinations than immune competent controls after renal transplantation [144, 145], liver transplantation [146, 147], and heart transplantation [148, 149]. In contrast, studies have shown normal responses to influenza immunization in children after renal [150, 151] [151, 152] and liver transplantation [153]. The type of immunosuppression given post-transplant influences the response. In lung transplant recipients, mycophenolate mofetil was associated with a poorer and sirolimus with a better vaccination response [154]. It has been suggested that intradermal vaccination can improve the immune response in renal transplant patients [155] but a randomized study did not find an improved effect except in subgroups [156]. Despite that systematic reviews have shown that SOT patients respond more poorly to influenza vaccine than healthy controls [157, 158], vaccinated transplant patients had a lower risk for influenza like illness and laboratory-verified influenza compared non-vaccinated controls [157]. Furthermore, Magnani et al. reported that vaccination of heart transplant recipients can reduce the proportion of patients developing influenza-like symptoms [159].

Several studies have shown no increased risk for graft rejection after influenza vaccination [135, 146, 148, 149, 159–163]. A large cohort study of >50,000 renal transplant recipients instead showed a reduced risk for allograft loss and death during the first year after transplantation in patients receiving influenza vaccine [164]. Although a possible immunizing effect cannot be entirely excluded, the benefits with influenza vaccination are far greater than the possible risks [165].

Annual inactivated influenza vaccine is therefore recommended to SOT recipients. Influenza vaccination is also recommended also to transplant candidates. No data exist with the live attenuated vaccine and it should therefore not be used [23, 24, 165].

Pneumococci and HIB

The HIB vaccine was reported being similarly effective in renal transplant recipients as in controls [166]. There have been conflicting reports regarding the efficacy of the PPV23 after transplantation. In some studies it was reported to be similar to healthy controls after liver transplantation [167], heart transplantation [148, 167], and renal transplantation [168] while in other studies, the antibody responses were reported being suppressed after heart transplantation [169] and liver transplantation [170]. Furthermore, it was reported that antibody levels declined faster than in controls [170]. Kumar et al. compared PCV7 and PPV23 in a double-blind, randomized study in renal transplant recipients. There was a trend to short term better responses after vaccination with PCV7 but at 3 years after vaccination, there was no difference and the titers had decreased significantly and similarly between the two vaccine groups [171, 172]. The same group reported no improvement by giving PCV7 followed by PPV23 (prime-boost strategy compared to PPV23 alone) [173].

Tetanus and Diphtheria Toxoid

In children, who had undergone renal transplantation, immunity to diphtheria was found in 38% and to tetanus in 90% [174]. Thus, immunity to tetanus seemed to be more d than immunity to diphtheria. A booster vaccination gave protective antibody levels to diphtheria in 95% if the patients but at 12 months only 76% remained protected [174]. All patients became protected against tetanus with antibody levels comparable to those reached in normal children. Boosters with tetanus and diphtheria (Td) are recommended following SOT.

Papillomavirus Vaccine

SOT patients are at higher risk for human papillomavirus-related genital warts, cervical cancer, and other anogenital malignancies. A small study in adolescent kidney and liver transplant recipients showed a 100% response rate to vaccination with the quadrivalent HPV vaccine [175]. Indications for vaccination against papillomavirus should be the same as for the general population but due to an increased rate of warts, the quadrivalent vaccine might be preferable in SOT candidates and recipients [23, 24].

Other Vaccines

No studies have been performed in solid organ transplant patients with meningococcal conjugate vaccine. However, the risks with these vaccines are negligible and vaccination could be considered as appropriate for age and the epidemiological situation.

In a phase II study, a gB based CMV vaccine given to seronegative patients receiving grafts from CMV seropositive donors given before and twice after liver and renal transplant patients was able to induce specific antibodies and was furthermore associated with fewer days of CMV viremia and fewer days of ganciclovir therapy [176]. A study performed in heart transplant patients reported lower vaccine response to tick-borne encephalitis vaccine compared to healthy controls [177].

47.3.2.2 Live Vaccines

Immunization with live vaccines is not recommended following SOT due to the risk for vaccine associated complications. Varicella vaccine has, however, been given to small groups of seronegative transplant recipients after transplantation and existing data suggest safety and reasonable effectiveness. A small study of varicella vaccination in renal transplanted children has been published showing good serologic responses and no severe side effects [178]. Weinberg et al. vaccinated 16 seronegative liver and intestine transplanted children 8.5 months to 5.5 years after transplantation [179]. Five patients developed mild side effects 3 of whom were given acyclovir. 87% developed both humoral and cell-mediated immune responses and no patient has during follow-up developed varicella despite five reported exposures. Similarly, Khan et al. reported seroconversion in 20/31 of varicella vaccinated pediatric liver transplant recipients 7 of whom required repeated doses [180]. In a study of 16 pediatric liver and small bowel transplant recipients, 87% of the patients developed both humoral and cell-mediated immunity [179]. Three of the 16 patients were given acyclovir for vaccine induced rash. However, there are also reports of significant varicella virus disease after varicella vaccination to SOT recipients [181, 182] and further studies are needed to assess both efficacy and safety of this approach.

A small series of liver transplant patients immunized with measles vaccine showed a rather poor response (7 of 18 immunized seroconverted) but no vaccine associated side effects were found [183]. Khan et al. retrospectively analyzed 26 liver transplanted children receiving MMR vaccine and 19 seroconverted although 18 needed repeated doses [180]. Only minor side effects were seen. Additional studies are needed to assess safety especially of MMR vaccination. Two case reports have been published of measles-associated encephalopathy in children with renal grafts [184].

There is no data regarding vaccination with other live vaccines such as rotavirus, yellow fever, or BCG either to candidates or after transplantation. However, infants awaiting transplantation can be vaccinated with live rotavirus vaccine according to national guidelines. This vaccine should not be administered after SOT.

Adoptive Immunotherapy for Infection Control Using Antigen-Specific Donor-Derived T Cells After Transplantation

Hermann Einsele, Götz-Ulrich Grigoleit, and Stephan Mielke

48.1 Potential of Adoptive Immunotherapy for Prevention or Treatment of Infections After Allografting

From an evolutionary perspective it was the immune systems major role to distinguish between "friend and foe" leaving the role of the foe largely to viral, bacterial, parasitic, or other microbiological invaders. In contrast, today's understanding of cellular immunotherapy puts a clear focus on the treatment of malignancies. This may be partly due to the fact that its most successful offspring, the transplantation of an allogeneic immune system has been providing cure to patients with otherwise fatal hematological and lymphatic diseases for several decades by now. However, from a broader perspective immunotherapy should be regarded as the transfer of cellular compartments of an autologous, allogeneic or xenogeneic immune system offering the opportunity to provide long-lasting beneficial effects to the recipient. These desired effects may include anti-malignant or anti-infectious properties or both and may also restore the host's immunological integrity in cases of imbalance such as immunodeficiency, GvHD, or autoimmune disorder. However, a primary function of the cellular immune system is to afford protection against pathogens such as viruses compromising the host's integrity. Therefore, allogeneic hematopoietic stem cell transplant (HSCT) and solid organ transplant (SOT) recipients who receive immunosuppressive therapy, which interferes with cellular immune functions, are prone to severe and potentially fatal infections, so efforts to restore protective immune responses by cellular immunotherapy are beneficial. Due to the conceptual attraction of immunotherapeutic approaches to infections in transplant recipients and the success of immunotherapy in experimental animal models and based on novel cell selection technologies, efforts to translate the basic principles that have been established in animal model studies to the clinical treatment of infections has made major progress. The objective of this chapter is to review the principles underlying cellular immunotherapy and the increasing number of strategies to apply adoptive immunotherapy for infections that are prevalent in immunocompromised transplant recipients.

Transplant recipients are vulnerable to progressive infection following the acquisition of a primary viral infection and from the reactivation of viruses that have previously established a latent or persistent infection in the host. Acute infection with seasonal respiratory viruses, such as influenza virus, respiratory syncytial virus (RSV), and parainfluenza virus, is a cause of serious infection in immunocompromised hosts during periods when infections with these viruses are prevalent in the community [1–5]. Infection of transplant recipients with such respiratory viruses can be self-limiting, as observed in immunocompetent hosts, but it often progresses to severe pneumonitis and death [1–3, 5]. Studies in murine models suggest that both B-cell and T-cell immunity are important for preventing and resolving these infections, but the unpredictable occurrence of these outbreaks and the antigenic diversity of the causative viruses make them less attractive as candidates for studies of cellular immunotherapy to restore potentially protective immune responses [6, 7].

Historically, a more prevalent problem for transplant recipients has been the acquisition of primary infections with cytomegalovirus (CMV) and Epstein–Barr virus (EBV), both of which could be transmitted to previously unexposed recipients by blood products and/or the hematopoietic stem cells or a solid organ transplant. If the transplant donor and recipient are both seronegative for CMV, the use of blood products from CMV-seronegative donor for transfusion can prevent primary infection of the recipient [8]. However, CMV-seronegative or EBV-seronegative HSCT or SOT recipient receiving hematopoietic stem cells or an organ from a CMV-seropositive or EBV-seropositive donor is at risk for the development of progressive disease caused by these viruses.

P. Ljungman et al. (eds.), *Transplant Infections*, DOI 10.1007/978-3-319-28797-3_48

The reactivation of endogenous latent viruses of the herpes group, including herpes simplex virus (HSV), varicella-zoster virus (VZV), CMV, EBV, human herpesvirus 6 (HHV-6), and potentially HHV-8, also results in significant morbidity and mortality in immunocompromised transplant recipients [8–11]. The administration of ganciclovir for CMV infection either prophylactically to prevent reactivation or after reactivation when it is detected by culture, antigenemia, or polymerase chain reaction (PCR) methodology is highly effective for preventing diseases in both allogeneic HSCT and SOT recipients, but it frequently causes neutropenia, especially after HSCT [12–17]. Studies in HSCT recipients have also demonstrated that the use of ganciclovir early after transplantation to prevent CMV disease may be associated with a delay in the reconstitution of CMV-specific T-cell immunity and with an increased incidence of late-onset CMV disease (disease occurring more than 100 days after transplantation) [18–22]. New antiviral agents (brincidofovir (CMX001) and letermovir) to be used for prophylaxis might have an impact on the incidence of CMV infection and early and late disease posttransplant [23–30]. Anti-CD20 antibody therapy has been successful in some patients with EBV-induced lymphoproliferative disorder (EBV-LPD) [31], but the emergence of CD20 negative B cells and PTLD in a subset of patients treated with anti-CD20 suggests that additional options to treat EBV-LPD are needed. Thus, although antiviral drugs constitute an important advance for the prevention or resolution of herpes viral infections, especially those occurring in the early posttransplantation period, the long-term control of persistent herpesviruses may require the host to mount and maintain an adequate immune response to the respective pathogen.

48.2 Effector Cell Populations and Control of Viral Infection

The development of cellular immunotherapy for individual viral infections should be predicated on an understanding of the nature of the host response that provides protective immunity in immunocompetent hosts. After acute infection with a pathogen, the healthy host mounts a multifaceted and coordinated immune response. The cellular components of this response can be broadly divided into the following two categories: (1) effector cells that are not antigen specific, such as natural killer (NK) cells and macrophages, which may be important in the initial containment of infection and (2) effector cells that express surface receptors that convey a high degree of specificity for antigens expressed by the virus, such as αβ+ T cells, γδ+ T cells, and antibody-producing B cells.

NK cells recognize and lyse target cells expressing low levels of class I major histocompatibility complex (MHC) molecules, and they might be expected to participate in the host response against viruses, such as CMV, HSV, and adenovirus, which downregulate the expression of class I MHC molecules in the infected cell [32–35]. NK cells exhibit antiviral activity in vivo, as studies in mice and in humans with selective NK deficiency have demonstrated, and they may be important during the early phase of infection prior to the development of virus-specific T cells [36, 37]. However, viruses such as CMV express genes that inhibit NK cell activation and lysis of the infected cells, potentially limiting the efficacy of NK cells in established infection [38]. In some reports, the administration of activated NK cells in patients with malignant disease has been associated with significant toxicity [39]; in others, NK cell transfer was extremely well tolerated even in the setting of haploidentical stem cell transplant (SCT) [4–42].

γδ+ T cells that recognize virus-infected cells have been identified, and these could be of benefit in adoptive immunotherapy [43, 44]. There is an increasing evidence that γδ T cells have potent innate antitumor and anti-infective activity [45]. Long-lasting expansion of Vdelta2(−)γδ T cells is a hallmark of CMV infection in kidney transplant recipients. γδ Tcell clones have been derived from several transplanted patients, and Vdelta1(−), Vdelta3(+), and Vdelta5(+) T-cell clones expressing diverse Vgamma chains, but not control Vgamma9Vdelta2(+) T clones, displayed strong reactivity against CMV-infected cells, as shown by their production of tumor necrosis factor (TNF)-α. Vdelta2(−) βδ T lymphocytes could also kill CMV-infected targets and limit CMV propagation in vitro. Their antiviral reactivity was specific for CMV among herpesviridae and required T-cell receptor engagement, but did not involve class I MHC molecules or NKG2D. Vdelta2(−) γδ T lymphocytes expressed receptors essential for intestinal homing and were strongly activated by intestinal tumor, but not normal, epithelial cell lines. High frequencies of CMV- and tumor-specific Vdelta2(−) γδ T lymphocytes were found among patients' γδ T cells. In conclusion, Vdelta2(−) γδ T cells may play a role in protecting against CMV and tumors, probably through mucosal surveillance of cellular stress, and represent a population that is largely functionally distinct from Vgamma9Vdelta2(+) T cells [46, 47].

The consensus from studies in animal models of experimental infection is that the induction and maintenance of virus-specific CD4+ and CD8+α β + T-cell responses are sufficient and often essential for the resolution of infection [48, 49]. Furthermore, α β+T cells provide immunologic memory that may be of major significance in settings where the patient will experience repeated exposure to the virus or where the virus has established a latent infection in the host [50, 51]. The methodology for isolating polyclonal and clonal populations of α β+T cells with defined specificity for viral antigens is well established for several viruses that cause disease in transplant recipients [52]. Therefore, strategies for developing adoptive cellular immunotherapy for transplant recipients have primarily focused on the use of virus-specific α β+T cells [53, 54].

Experiments performed in animal models to examine the cellular requirements for an effective host response to viral infection have included a detailed analysis of the contributions of class II MHC-restricted CD4+ T helper (TH) cells and class I MHC-restricted CD8+ cytotoxic T lymphocytes (CTLs). Initially, the adoptive transfer of purified T-cell subsets or

T-cell clones to augment individual responses or the administration of monoclonal antibodies to deplete the activity of a single T-cell subset was used as a strategy for the examination of the antiviral activity of CD4+ and CD8+ T cells [53–56]. Later studies used gene knockout mice rendered deficient in expression of class I or class II MHC molecules and that thus were unable to generate CD8+ or CD4+ T cells, respectively [57–59]. The results of these experiments demonstrated that, depending on the dose, route, timing, pathogenesis, virulence, and type of challenge virus, either CD8+ or CD4+ virus-specific T cells could provide protective immunity to the virus challenge and could resolve acute infection [55–59]. This analysis in animal models demonstrated the crucial role of CD8+ and CD4+ antiviral T cells and provided important insights into the cooperation between these subsets. These studies also suggested that the development of adoptive immunotherapy in humans should be guided by an understanding of the antiviral activity of CD4+ and CD8+ T-cell subsets for individual viruses.

48.3 Effector Mechanisms of αβ+ T Cells

Basic studies of T-cell biology have provided insight into the effector mechanisms used by CD4+ and CD8+ T cells to resolve viral infections.

48.3.1 CD4+ αβ+ T Helper Effector Functions

Antigen recognition by virus-specific CD4+ T cells involves an interaction between the αβ+ T-cell receptor and the class II MHC heterodimer containing a peptide fragment derived from a viral protein in its binding groove [60, 61]. The expression of class II MHC is primarily restricted to professional antigen-presenting cells (APCs), such as dendritic cells (DCs), macrophages, and B cells, but it can be induced on other cell types, including endothelial cells. The antigens presented to CD4+ T cells are usually endocytosed by the APCs and then degraded by proteolysis in endosomal compartments where the resulting peptides encounter and bind to class II MHC molecules that traffic to the cell surface. Because the viral antigens can be obtained by endocytosis at the site of infection or in the draining lymph nodes, the APC does not actually need to be infected with the virus to activate the CD4+ TH cells. Several viruses, including human immunodeficiency virus (HIV), CMV, EBV, and measles, do productively infect cells bearing class II MHC molecules, and, in this circumstance, endogenously synthesized viral proteins may also enter the class II processing pathway and then directly activate CD4+TH cells [61, 62].

A primary function of activated CD4+ TH cells is the production of cytokines that orchestrate a local and systemic host response to the pathogen by autocrine and paracrine effects. In addition, CD4+ T cells also condition professional APCs through the interaction of CD40 and the CD40 ligand, which results in APC maturation and superior stimulation of T cells [63, 64]. Mature differentiated CD4+ TH cells can be categorized into TH1, TH2, and a newly discovered TH17 subset with distinct profiles of cytokine production and differing functional roles in the immune response [65, 66]. Interferon-γ (IFN-γ) and interleukin-12 (IL-12) in the milieu favor the development of the TH1 phenotype; IL-4 and IL-10 promote the development of the TH2 phenotype; and IL-6, transforming growth factor (TGF)-β, IL-21, and IL-23 promote the development of the TH17 phenotype [66–69]. The participation of TGF-β in the differentiation of TH17 cells places the TH17 lineage in close relationship with CD4(+) CD25(+)Foxp3(+) regulatory T cells (Tregs), as TGF-α also induces differentiation of naive T cells into Foxp3(+) Tregs in the peripheral immune compartment.

The CD4+ TH1 subset produces IL-2, IFN-γ, and TNF, and it preferentially promotes cell-mediated immune responses [63]. IL-2 activates and induces the proliferation of NK cells, and it is the major growth factor for CD8+CTLs [70–72]. Indeed, in an animal model of persistent viral infection, the ability to mount a virus-specific CD4+ TH cell response was essential for sustaining virus-specific CD8+ CTL responses [73]. IFN-γ and TNF activate nonspecific effector cells, such as macrophages and NK cells, exert direct inhibitory effects on virus replication, and promote the resistance of uninfected cells to viral infection [74, 75]. The TH1 subset of CD4+TH cells produces IL-4, IL-5, and IL-10, and promotes the development of humoral immunity and the activation and differentiation of eosinophils and mast cells [76, 77]. The investigation of the differentiation, effector function, and regulation of TH17 cells has opened up a new framework for understanding T-cell differentiation, and the role of this TH subset in antiviral immunity remains to be elucidated.

Although little information exists concerning the role of distinct CD4+ TH cell subsets in the immune response to individual viral infections in humans, insights derived from murine models suggest that the subtype of CD4+ T cells used in adoptive therapy may affect its efficacy and safety. For example, in a murine model of influenza infection, the transfer of an influenza-specific CD4+ TH1 clone was protective, whereas the transfer of an influenza-specific TH2 clone failed to confer protective immunity [78]. In the RSV model, RSV-specific TH1 and TH2 cells exhibited antiviral activity and promoted clearance of virus, but the TH2 cells induced an eosinophil-rich infiltrate in the lungs and worsened the morbidity [79]. Studies of the antiviral properties of TH17 cells that appear to have a role in autoimmunity and are important for fungal and bacterial infections [80–83] are only now beginning. Recent studies in mice suggest that in some circumstances, a TH17 response may promote viral persistence [84]. These results indicate that, depending on the viral infection being treated, the selection of CD4+ T cells for use in therapy may be a decisive factor in its success or failure.

Tregs defined by the expression of the Foxp3 transcription factor represent yet another T-cell subset that plays a crucial role in balancing inflammation and antigen-specific immune responses. In chronic infectious diseases, Tregs dampen inflammation to limit tissue damage, but they can also inhibit ensuing effector immunity, thereby impairing pathogen clearance. Chronic persistent infections by human pathogens such as parasites, viruses, and (myco) bacteria can all result in the induction of both CD4(+) and CD8(+) Tregs. However, among the many different subsets of Tregs that are induced, mostly CD4(+) Tregs have been studied. A remarkably increased frequency has been observed at the site of infection, supporting a role in pathogen containment. Various populations of DCs are central to the orchestration of this control. Antigen specificity has been demonstrated for several pathogen-derived antigens and the related Tregs. A better understanding of the induction and activity of Tregs is relevant for the design of better vaccines that optimally induce effector immunity without coinduction of excessive Treg activity [85–88].

48.3.2 CD8+ αβ+ Cytotoxic T-Lymphocyte Effector Functions

CD8+ cytotoxic T cells recognize peptides bound to class I MHC molecules on the surface of cells [89]. The antigenic peptides displayed with class I MHC are primarily derived by the proteolytic cleavage of intracellular proteins by the proteosome complex [90] and are then transported from the cytosol into the endoplasmic reticulum (ER) by a heterodimeric protein complex termed the "transporter associated with antigen presentation" (TAP) [91]. In the ER, the peptides bind to the class I MHC heavy chain, leading to the formation of a stable trimolecular peptide–class I H chain–β2 microglobulin complex that is transported via the Golgi apparatus to the cell surface. Because class I MHC molecules are constitutively expressed or they are inducible in most cell types, CD8+ CTLs serve as the surveillance mechanism for detecting and eliminating virus-infected cells; these appear to be required for the clearance and resolution of most viral infections [48].

The interaction between the T-cell receptor and the relevant class I–peptide complex usually results in the direct lysis of the target cell and the production of TH1-type cytokines, including IFN-γ and TNF. However, in contrast to CD4+ TH1 cells, differentiated effector CD8+ CTLs, many of which have lost CD28 expression, produce reduced amounts of IL-2 following antigen stimulation, and they are dependent on IL-2-producing CD4+ TH for proliferation [92, 93]. The lytic signal delivered by CD8+CTLs involves the directed exocytosis of cytolytic granules containing perforin and serine esterases (granzymes) or Fas–Fas ligand (FasL) interactions [94]. Perforin disrupts the cytoplasmic and nuclear membranes of the target cell, facilitating the entry of the granzymes that induce DNA fragmentation and ensuring the destruction of the target cell and the cessation of virus replication. Activated CD8+CTLs also express FasL, and they may induce programmed cell death in virus-infected target cells expressing Fas.

The contribution of cytolytic granules to the antiviral activities of CD8+CTLs has most clearly been demonstrated in the murine lymphocytic choriomeningitis virus (LCMV) model. Mice with a disruption in the perforin gene cannot induce the membrane injury to lyse the target cell [95]. CD8+ T cells from perforin-deficient mice inoculated with LCMV proliferate in response to the virus challenge but exhibit only weak LCMV-specific cytolytic activity in vitro, an effect possibly mediated by Fas–FasL interactions [95]. Perforin-deficient mice fail to clear LCMV infection in vivo, illustrating the necessity for perforin-mediated lytic events for the resolution of this infection [95].

48.3.3 Cytomegalovirus-Specific T-Cell Immunity and Cytomegalovirus Disease in Immunosuppressed Transplant Recipients

CMV is a ubiquitous herpesvirus that infects 50–90 % of the population. Primary infection in immunocompetent hosts is largely unrecognized except as an occasional cause of mononucleosis, and viral persistence is not associated with any clinical sequelae. However, in patients with iatrogenic or acquired immunodeficiency, the reactivation of CMV in CMV-seropositive hosts or the acquisition of primary CMV infection from blood products or the donated organ often leads to progressive infection and visceral disease and represents a major obstacle to a successful outcome for transplant recipients.

The clinical manifestations of CMV infection may differ, depending on the type of transplant and associated clinical factors. SOT recipients who are CMV-seronegative and who receive an organ from a CMV-seropositive donor often develop a CMV syndrome consisting of fever, leukopenia, hepatosplenomegaly, myalgia, and occasionally pneumonitis [96, 97]. Reactivation of CMV in seropositive SOT recipients may also progress to visceral infection, especially in those patients who require intense therapy with immunosuppressive drugs to treat episodes of rejection. Allogeneic HSCT recipients who develop primary infection or reactivation with CMV may also develop fever and leukopenia, but interstitial pneumonitis or enteritis are the most common manifestations of CMV disease in these patients [9].

A critical role for αβ+ T cells in human CMV (HCMV) infection was first suggested by studies in the murine cytomegalovirus (MCMV) model. MCMV is genetically distinct from HCMV, but the pathogenesis of infection in immunosuppressed mice is similar to that for HCMV. In the MCMV model, the transfer of CD8+MCMV-specific CTLs alone was sufficient to protect mice from fatal CMV infection, although the administration of CD4+ TH cells was essential for eliminating salivary gland infection [98–100]. The

administration of CD8+ CTLs specific for the MCMV major immediate–early protein alone were sufficient to provide protective immunity from lethal virus challenge, suggesting that restoring even a limited repertoire of the host CTL response can be therapeutically beneficial [98].

The hypothesis that progressive HCMV infection in HSCT and SOT recipients is related to a quantitative deficiency of virus-specific αβ+ T-cell responses has been examined in several studies. Quinnan et al. [101] showed that the recovery of cytolytic activity for CMV-infected fibroblasts in samples of peripheral blood lymphocytes obtained from allogeneic HSCT and renal transplant recipients was associated with the resolution of CMV infection. Subsequent studies have cultured the peripheral blood lymphocytes from allogeneic HSCT recipients in vitro to distinguish more clearly the recovery of CD4+ and CD8+CMV-specific T-cell responses and to improve the sensitivity for detecting these responses [102, 103]. In all of the published reports, a correlation was observed between the presence of MHC-restricted αβ+ T-cell responses to CMV and protection from the subsequent occurrence of CMV disease, supporting the concept that αβ+ T-cell responses are an essential component of protective immunity to CMV [53, 54].

Analyses using newer technologies developed for the direct quantitation of antigen-specific T cells, such as intracellular cytokine staining or staining with tetrameric human leukocyte antigen (HLA) class I–peptide complexes, have further confirmed the role of CMV-specific T cells in controlling CMV infection. In healthy CMV-seropositive individuals, up to 40 % of all T cells in the peripheral blood can be specific for CMV [104], underlining the importance of a strong CMV-specific cellular immunity for containing persistent CMV infection.

These methods have also been applied to analyses of T-cell responses after allogeneic stem cell transplantation. Fluorochrome-conjugated tetrameric complexes of HLA-A2 molecules loaded with the epitope NLVPMVATV (NLV) derived from the CMV protein pp65 were utilized to quantify CMV-specific CD8αβ+ T cells in HLA-A*0201–positive recipients after allogeneic stem cell transplantation (Figure 48-1). In patients given allografts from a sibling in which both the patient and the donor were seropositive for

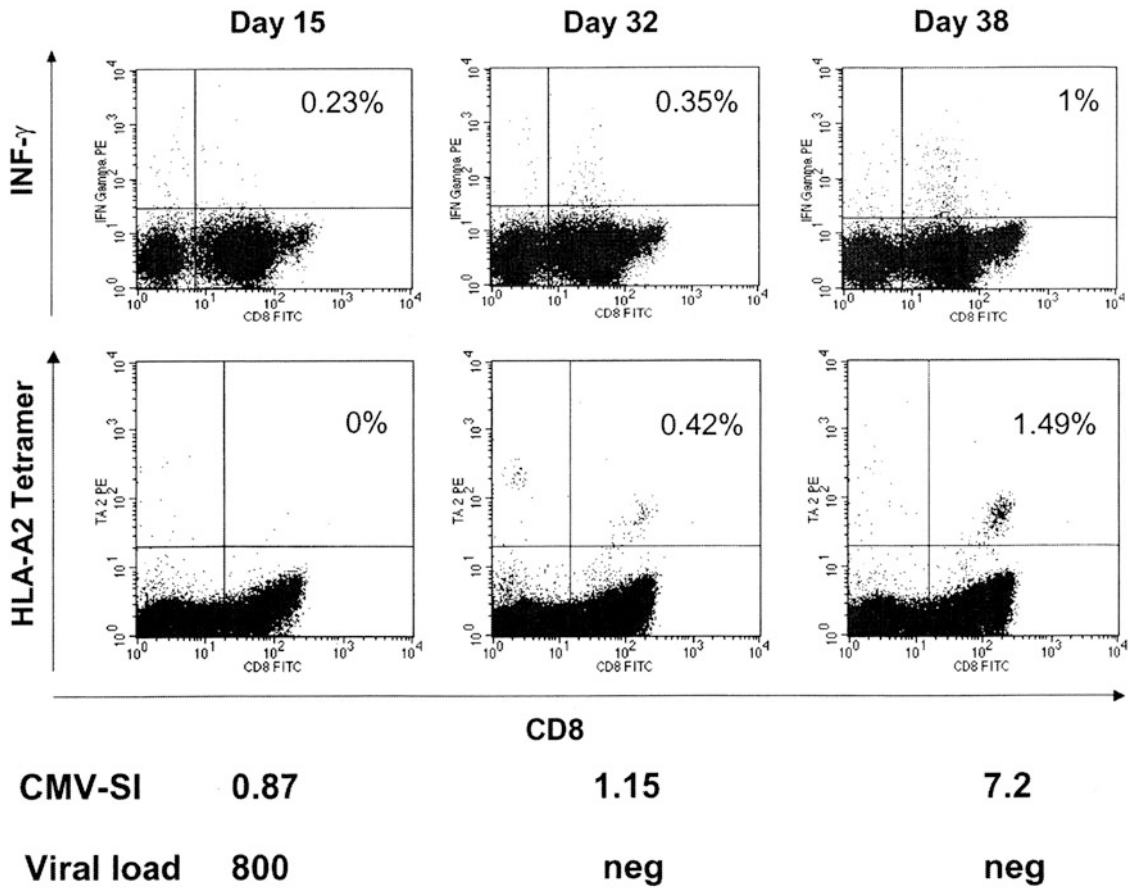

FIGURE 48-1. Reconstitution of cytomegalovirus (CMV)-specific T-cell responses and viral load after T-cell transfer. Patient number 4 had a high viral load at the time of T-cell transfer, but on day 15 after transfer, viral load had decreased to 800 viral copies per milliliter of blood. At day 38 when the virus had been cleared entirely, the reconstitution of CMV-specific lymphoproliferation and CMV peptide-specific A*0201-restricted CD8+ T cells was also shown by intracellular IFN-γ and tetramer staining.

CMV before stem cell transplantation, the recovery of CMV-specific CTLs was rapid, reaching up to 21 % of all CD8αβ+ T cells [105]. Early reconstitution was not observed if either the donor or recipient was seronegative for CMV. In the recipients of transplants from unrelated volunteer donors, the recovery of CMV-specific CTLs was delayed in comparison to that observed in the recipients of transplants from siblings, and no CTLs were observed within the first 100 days after transplantation [105]. Recovery of CMV-specific CTLs to levels greater than 10 cells/μL blood was associated with protection from CMV disease [105, 106]. Furthermore, the absolute number of A2-NLV-specific CD8+ T cells in the grafts correlated inversely with the number of preemptive ganciclovir courses that were administered. In contrast, CMV-seropositive patients receiving a transplant from a CMV-seronegative donor displayed a delayed reconstitution of CMV-specific CD8+ T cells [96]. Thus, the CMV serostatus of the donor, as well as the enumeration of CMV-specific CD8+ T cells in the graft, may identify SCT recipients at risk for developing CMV disease [107].

48.3.4 Specificity of CD8+ αβ+ Cytomegalovirus-Specific T Cells

The CMV genome may encode more than 200 proteins in permissively infected cells, providing a large number of potential antigens that could be presented to CD8+ cytotoxic T cells. Definition of the specificity of CTL responses in individuals with protective immunity to CMV is a critical prelude to the development of effective adoptive immunotherapy to ensure that the T cells selected for use in therapy represent the protective responses in immunocompetent hosts. CMV expresses its genes in a temporal sequence, with discrete phases of gene expression that are called the immediate early (IE), early (E), and late (L) phases [108]. Infected cells expressing a limited array of viral proteins can be prepared by the timed addition of inhibitors that block viral protein or RNA synthesis; this methodology was used to determine whether CTLs preferentially recognized proteins produced at IE, E, or L stages of the replicative cycle. Surprisingly, the introduction of an RNA synthesis inhibitor to target cells just prior to virus exposure to prevent the production of newly synthesized viral proteins after viral entry did not prevent the recognition of these infected cells by CD8+ CMV-specific CTL lines and most CTL clones isolated from healthy CMV-seropositive individuals [109]. This demonstrated that expression of the viral gene in the target cell was not required to sensitize the cell for lysis and that the virion proteins introduced into the target cell cytosol following viral entry, rather than newly synthesized IE, E, or L proteins, were important target antigens of the host CTL response. The specificity of the CD8+ CMV-specific CTLs that recovered after allogeneic bone marrow transplantation and their association with protection from subsequent CMV disease were similarly analyzed, and these CTLs were also specific for epitopes derived from structural virion proteins [108].

The contribution of individual virion proteins as antigens for CTL was assessed by pulsing peptide fragments of purified proteins onto target cells or by infecting target cells with recombinant vaccinia viruses encoding a single CMV gene. Reportedly, the matrix protein pp65 is the most frequent target of the major host response, although strong responses to a second matrix protein pp150 do occur in some individuals [110–112]. Insight into the biologic importance of CTLs for structural virion proteins was suggested by studies evaluating the ability of these CTLs to kill CMV-infected cells at different stages of the replication cycle. CMV-infected target cells are rapidly sensitized (<1 h after virus inoculation) for lysis by CD8+ CTLs specific for pp65 or pp150, and the infected cell remains a target throughout the entire replicative cycle. Thus, these CTLs should be effective in limiting virus dissemination after reactivation by promptly eliminating the newly infected cells. However, the rapid recognition of structural proteins such as pp65 and pp150 is not observed with CTLs specific for virus envelope gB protein. CTLs specific for gB lyse CMV-infected cells poorly at all stages of the replicative cycle, and, in CMV-seropositive individuals, these are present at a substantially lower frequency than are the CTLs for pp65 or pp150 [112, 113]. The fact that CTLs specific for pp65 and/or pp150 are maintained at an extremely high frequency for life in healthy CMV-seropositive individuals suggests that, even in immunocompetent hosts, virus reactivation occurs intermittently but remains subclinical because of rapid control by the host immune response.

An HCMV deletion mutant that is deleted of the four viral genes that are responsible for interfering with class I MHC presentation has also been used for analysis of CMV-specific CTLs in normal CMV seropositive individuals. With this approach, a large fraction of the CD8;+ CTL response was found to be specific for viral antigens expressed during the IE and E phases of virus replication and presented by fibroblasts infected with RV798 but not wild-type CMV [114, 115]. Similar results were obtained with the use of overlapping peptide panels spanning the entire CMV genome [116]. Thus, reconstitution of T-cell immunity in immunodeficient patients by cell therapy or by vaccination may need to target multiple viral antigens to completely restore immunologic control of CMV.

48.3.5 Specificity of CD4+ αβ+ Cytomegalovirus-Specific T-Cell Responses

CD4;+ TH responses to antigen preparations extracted from CMV-infected cells are readily demonstrable in healthy CMV-seropositive individuals. Recombinant gB, pp65, IE2, p52, and IE1 CMV proteins have been generated and used to determine the specificity of CD4;+ TH responses. Detectable

responses occurred to all the antigens studied, with approximately 70% of the individuals tested responding to gB, pp65, and IE2, and a smaller proportion responding to IE1 and the DNA-binding protein p52 [117–120]. This data, and studies with peptide panels [105], suggest that considerable diversity exists in the CD4;+ TH response to CMV.

Animal model studies have illustrated the potential importance of characterizing the cytokine profile of the CD4;+ TH cells that are going to be used in adoptive immunotherapy to improve the safety and efficacy of therapy. The cytokine profile of CD4;+ CMV-specific TH clones isolated from CMV-seropositive individuals has been analyzed; all of the clones tested produced IL-2 and IFN-γ characteristic of TH1 cells, but many also produced IL-4 consistent with an overlapping phenotype. Whether the phenotype of these cells can be fixed to a TH1 or TH2 pattern in vitro, and if this will be necessary for the safety and/or efficacy of immunotherapy with CD4;+ CMV-specific T cells remain to be determined.

48.3.6 Immune Evasion Strategies Used by Herpesviruses

Several viruses have evolved strategies for evading recognition by the host immune response, and the identification of the mechanisms utilized by these viruses should assist in selecting the appropriate effector cells to use for restoration of protective immunity in adoptive immunotherapy. Herpesviruses can enter a latent state that allows the virus to persist even during the height of the immune response, although the cellular sites of latency and the status of viral gene expression in such cells are not completely defined [108, 121].

Once the virus reactivates from latency and initiates replication, the infection is likely to progress in the absence of a host response to limit dissemination. One strategy that CMV uses to elude the destruction of permissively infected cells by CD8+CTLs is to inhibit the cellular processes involved in delivering class I MHC molecules bearing antigenic peptides to the cell surface. Studies of cells replicating CMV have demonstrated a reduced surface expression of class I MHC at the E and L stages of the replicative cycle [101]. The mechanisms involved in the downregulation of class I MHC were elucidated with the identification of four viral genes—US2, US3, US6, and US11—that interfere in a coordinated fashion at discrete steps in the antigen-presentation pathway [122–126]. These virus-encoded proteins collectively impede the efficient presentation of viral proteins expressed after the IE stage of replication and provide a biologic basis for the relative immunodominance of CD8+ CTLs directed against structural virion and IE proteins that are presented before this global blockade in class I antigen presentation.

The IE protein is produced in abundance immediately after infection before the decline in cell surface class I MHC expression. Conceptually, this would be a good antigen to target in adoptive immunotherapy, and IE-specific T cells can be isolated from many CMV-seropositive donors [113]. Surprisingly, IE-specific CTLs fail to lyse permissively infected target cells even if virus replication is arrested at the IE stage of replication [113]. One study demonstrated that the pp65 protein that is introduced into the cytosol after virion entry and before IE synthesis selectively interferes with the presentation of IE peptides [127]. It remains to be determined whether these immune evasion strategies that interfere profoundly with CTL recognition in vitro are as effective in vivo. It would seem prudent to utilize T cells for adoptive therapy that are specific for structural virion proteins and IE proteins since these are typically the dominant responses in healthy donors.

The early and sustained decrease in surface class I MHC expression in CMV-infected cells should enhance their susceptibility to recognition by NK cells and suggests a potential role for this effector population in eliminating permissively infected target cells. Although no homology exists between the genes encoding HCMV and mouse CMV (MCMV) that modulate the expression of class I MHC, both viruses effectively use analogous and redundant gene functions to inhibit antigen presentation [128]; the studies of interactions with NK cells have used murine models. NK lymphocytes monitor the expression of class I MHC molecules by different cell surface receptors, which transduce signals leading to the inhibition or activation of the NK cells. The following three groups of inhibitory NK receptors screen cells for downregulated expression of class I MHC molecules: (1) the killer cell immunoglobulin (Ig)–like receptors in primates, (2) the lectin-like receptors Ly49 in rodents, and (3) the heterodimer of CD94 and NKG2A molecules shared by rodents and primates [129]. However, these three families of class I MHC-specific receptors contain stimulatory receptors as well (e.g., KIR2DS and KIR3DS, Ly49D and Ly49H, and NKG2C and NKG2E). In addition, NK cells express a variety of other receptors that recognize nonclassic MHC molecules and non-MHC-related proteins [130, 131].

Binding of the C-type lectin receptor NKG2 to its ligand can overcome inhibitory signals [132]. The NKG2D homodimer is a potent activating receptor in both humans and mice; it is expressed not only on NK cells but also on activated macrophages (in mice) and γδ+ T cells, where it functions as a coactivating receptor [133]. Murine NKG2D interacts with the following two cell surface ligands that are related to class I MHC molecules: (1) Rae-1 and (2) H-60 [134, 135]. MCMV glycoprotein 40 (gp40) was recently shown to downregulate H60, a high-affinity ligand for NKG2D receptors, thereby inhibiting NK cell activation. The deletion of m152 abolishes this function, rendering otherwise resistant virus-infected cells susceptible to NK cells.

The arsenal of stealth tactics used by HCMV also extends to the evasion of NK recognition. CMV encodes UL18, a molecule that is homologous to class I MHC; when UL18 is expressed on the cell surface, it delivers an inhibitory signal

to the NK cell and prevents NK-mediated lysis [38]. The ligands for NKG2D in humans, such as class I MHC chain-related chain A (MICA) and class I MHC chain-related chain B (MICB), can be induced by cellular stress [136]; malignant transformation; or infection with herpesviruses, including CMV [137]. However, CMV infection downregulates MICB through the expression of UL16 [131, 138], but MICA expression is retained and costimulates NKG2D expressing CMV-specific CD8+ T cells even in situation where class I MHC molecules are downregulated [132].

48.4 Clinical Studies of Adoptive Immunotherapy with Cytomegalovirus-Specific T Cells

The investigation of adoptive immunotherapy with CMV-specific T cells is difficult for some subgroups of transplant recipients. For CMV-seropositive recipients of a stem cell graft from a CMV-seronegative donor generation of CMV-specific T cells is difficult. Isolating and expanding autologous virus-specific T cells before transplantation for use in immunotherapy after SCT is technically difficult because of the extremely low precursor frequency of such cells in the peripheral blood in the absence of prior natural infection. One potential strategy would be to induce virus-specific T-cell responses in the CMV-seronegative recipient or CMV-seronegative donor by vaccination before transplantation and then to isolate these cells for use in therapy as augmentation of the endogenous response during the period of posttransplant immunosuppression. The increasing availability of safe and effective vaccines for eliciting CMV-specific T-cell responses will help to further develop this strategy [138].

There are two alternative approaches: a selection of virus-specific T cells from a partially matched seropositive third-party donor which was successfully demonstrated before but could be hampered but a limited time of persistence following adoptive transfer. CTL lines with partial HLA matches from CTL banks were successfully administered to patients with a PTLD after solid organ transplantation, with a trend of better responses with higher number of CD4+ T cells infused and closer HLA matching between donor and recipient [139]. In addition, successful transfer of CMV-specific T-cell lines from a third-party donor only matched for 1 HLA-allele was reported after haploidentical HCT [140].

Another strategy is to boost endogenous HCMV-specific T-cell reconstitution by donor monocyte-derived DCs pulsed with HCMV peptides as shown successfully in ten patients after allogeneic SCT [141]. No side effects or induction/aggravation of acute GVHD were observed. In the setting of HLA-identical allogeneic HSCT, the CMV-specific T cells that will be used for posttransplantation immunotherapy should be derived from the donor because the immune system that develops in the host after transplantation is derived from donor hematopoietic cells.

Recipients of HSCTs from a CMV-seropositive donor provide the most favorable setting for the investigation of CMV-specific T-cell therapy because T cells with reactivity for CMV antigens can be readily isolated from the donor by in vitro stimulation with autologous APCs expressing CMV antigens. The generation of polyclonal populations of CMV-reactive T cells from the donor is technically feasible, but these polyclonal populations may also contain T cells that are not reactive with CMV, including T cells that could recognize recipient minor histocompatibility antigens. Thus, one concern with the use of polyclonal donor T cells for adoptive transfer is the potential for inducing graft-versus-host disease (GVHD). Indeed, researchers have frequently observed GVHD when polyclonal T cells are administered to HSCT recipients to treat EBV-induced lymphomas [142]. This potential problem could be avoided if individual CMV-specific T-cell clones or highly enriched populations of CMV-specific T cells are isolated and selected.

The first evaluation of adoptive immunotherapy with virus-specific T cells in humans was performed in allogeneic HSCT recipients. The study examined the safety and immunomodulatory properties of administering CD8+ class I MHC-restricted CMV-specific cytotoxic T-cell clones [143]. CD8+ CTLs were selected for initial investigation because the data from animal models of CMV infection and reconstitution studies in humans suggested that CD8+ CTLs were necessary and sufficient for protective immunity [18, 102]. CD8+ CMV-specific T-cell clones were isolated by limiting dilution cloning from polyclonal T-cell lines established from the bone marrow donor. Clones that were αβ+ T-cell receptor, CD3+, CD8+, and CD4+ and that recognized epitopes derived from structural virion proteins in the context of class I MHC were selected for intravenous administration to the recipient. Fourteen patients were treated with four escalating doses of CMV-specific T cells beginning 28–42 days after HSCT. No serious acute toxicities occurred, even at the highest cell dose in any of the 14 patients treated, and the patients did not require hospitalization for the infusions. Two patients experienced minor side effects that included transient fever and chills [144]. CTL responses were evident within 2 days after the first infusion, and they increased with each subsequent infusion such that the responses measured 2 days after the fourth infusion were equivalent to those present in peripheral blood lymphocytes obtained from the healthy donor [144].

Patients who recovered CD4+ CMV-specific TH cell responses maintained strong CD8+ CTL responses. New techniques such as the peptide-MHC multimer technology as well as the cytokine capture assay have been developed that allow the easier selection of CMV-specific T cells for use in therapy. To avoid generation of virus-specific cell lines by repetitive stimulation and long-term in vitro culture which interfers with in vivo persistence and proliferation novel

strategies for direct cell selection without the necessity of long-term culture were developed.

The first technology, which was transferred to the clinic, was the isolation of Ag-specific T cells from the blood of CMV-seropositive donors based on the interferon γ (IFNγ) secretion of T cells after ex vivo stimulation with viral antigens [145]. Using these technologies 18 patients after allo SCT from HLA-mismatched/haploidentical or HLA-matched unrelated donors were treated for chemorefractory CMV-infection with polyclonal CMV-specific T cells generated by ex vivo stimulation with CMVpp65 antigens followed by isolation of IFNγ-producing cells. After the transfer of a mean of 21×10^3/kg CMVpp65-specific T cells 83 % of patients cleared the viral infection or showed a significantly reduced viral load. The viral control was associated with in vivo expansion of CMV-specific T cells in 12 of 16 evaluable patients [146].

Following the introduction of novel multimer techniques such as tetramers and pentamers for the identification and quantitation of antigen-specific T cells, a modification of this technology—the streptamers were established for antigen-specific T-cell selection and transfer under GMP conditions [147, 148]. The high purity of this selection technology allows successful transfer of virus-specific T cells with a very low risk of alloreactivity [148]. In spite of the fact that often only low doses of streptamer-selected donor-derived T cells can be isolated with this technology the strong pathogen-specific T-cell expansion mediated effective anti-HCMV activity [149]. The transfer of CMV-specific CD4+ T cells was shown to be effective in inducing CMV-specific CD8+ T-cell responses and reducing CMV DNA load (Figure 48-2) [145]. This study extended the results of previous studies that suggested that T-cell infusions comprising predominantly the CD4 subset may be efficient for the control of CMV viremia in immunosuppressed patients. A single infusion of T cells resulted in the clearing of CMV viremia in 5 of 7 patients, and a second infusion was associated with resolution of viremia in an additional patient, with 6 of 7 patients achieving resolution of CMV. This study along with others illustrates the critical requirement for the presence of CD4+ T cells in the control of many chronic viral infections.

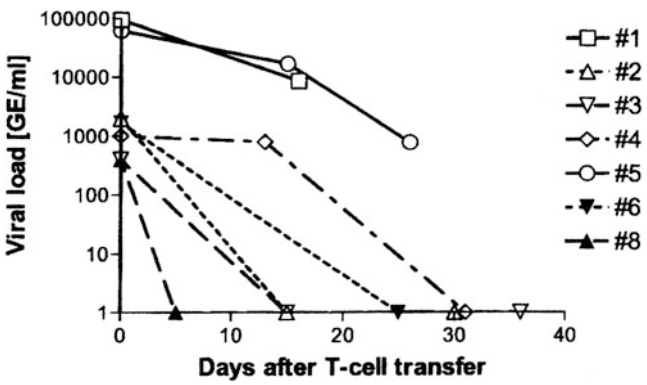

FIGURE 48-2. Decrease in cytomegalovirus (CMV) load following T-cell therapy. The viral load of all seven patients with detectable CMV DNA at the time of T-cell transfer is presented (virus copies per milliliter of blood). In three patients (numbers 1, 5, and 8), virus load increased again; patient number 5 responded to a second T-cell infusion.

48.5 T-Cell Immunotherapy for Posttransplantation Epstein–Barr Virus Infections

EBV infects approximately 90 % of the adult population, and it establishes persistent latent infection in the oropharyngeal and gastric epithelium and in B lymphocytes [150]. The establishment of latency appears to be an important mechanism for immune evasion by EBV. The viral genome persists in latently infected cells as an episome, and three distinct forms of EBV latency have been distinguished on the basis of the expression of different viral proteins [131]. The EBNA-1 protein is expressed in all EBV-associated malignancies, and, therefore, it would be an attractive target antigen for a host T-cell response. However, the expression of EBNA-1 protein is also essential for all three forms of EBV latency, suggesting a mechanism for preventing the presentation of this protein to CD8+ CTLs must exist. The presence of a region containing repetitive sequences of glycine and alanine in the EBNA-1 protein prevents the processing and presentation of EBNA-1, rendering this protein invisible to host CD8+ CTLs [152].

In immunocompetent hosts, EBV infection can be associated with the later development of malignancies, including Burkitt lymphoma, a proportion of cases of Hodgkin disease, and nasopharyngeal carcinoma [137]. These EBV-associated malignancies in immunocompetent hosts typically express very few EBV proteins and exhibit decreased expression of class I MHC molecules and an absence of adhesion molecules to evade immune recognition [153].

In immunodeficient hosts, such as allogeneic SOT and HSCT recipients and patients with acquired immunodeficiency syndrome, EBV infection of B lymphocytes induces their proliferation, and this can progress to a monoclonal immunoblastic lymphoma [154–158]. These EBV-associated lymphoproliferations in immunodeficient hosts typically occur in recipient's B cells in solid organ transplantation and in the B cells from the donor in hematopoietic stem cell transplantation. Several EBV proteins that are targets of the CD8+ CTL response in healthy immunocompetent hosts are expressed in the EBV-infected proliferating B cells, and these cells are not deficient in expression of class I MHC or adhesion molecules. Indeed, the phenotype is strikingly similar to that of EBV-transformed B cells (EBV lymphoblastoid cell lines [EBV-LCL]) that spontaneously grow from blood cultures of EBV-seropositive individuals if T cells are

depleted from the culture or if cyclosporin A is added [159]. Thus, the pathogenesis of EBV lymphomas in immunodeficient hosts appears to reflect the absence of sufficient T-cell immunity to control reactivation of EBV [160], and adoptive immunotherapy with EBV-specific T cells has the potential to restore the requisite effector cells in the host to promote tumor regression [161].

48.5.1 Epstein–Barr Virus-Specific T-Cell Immunity and the Pathogenesis of Epstein–Barr Virus-Induced Lymphoproliferation

The major recognized clinical syndrome of EBV reactivation in immunodeficient hosts is EBV-LPD, which usually occurs in those individuals who are the most severely immunosuppressed. Thus, patients receiving T-cell-depleted bone marrow to prevent GVHD or T-cell-specific antibodies to treat organ rejection or GVHD are at high risk for EBV-LPD [162–168]. Among the recipients of allogeneic T-cell-depleted bone marrow, the risk of EBV-LPD varies from 11 % to 26 %, depending on the method of T-cell depletion and the type of posttransplantation immunosuppression [161, 168]. Recipients of unmodified bone marrow rarely (1 %) develop EBV-LPD unless they require intense posttransplantation immunosuppression with anti-T-cell monoclonal antibodies or antithymocyte globulin (ATG) to treat GVHD.

The type of SOT and the intensity of immunosuppression influence the risk of EBV-LPD in SOT recipients. Those who are EBV-seronegative and who then acquire EBV as a primary infection from the donor organ or blood products are at particularly high risk of developing EBV-LPD after transplantation, presumably because these individuals have no pre-existing T-cell immunity to EBV [158, 169]. The incidence of EBV-LPD increases for all SOT recipients if T-lymphocyte antigen (OKT3) is used as prophylaxis or therapy for rejection episodes [166]. Assessing EBV load by PCR has been found to be useful in predicting the subsequent occurrence of EBV-LPD [170], and interventions using the anti-CD20 antibody or T-cell therapy as immunotherapy are increasingly being used preemptively in patients with a rising EBV DNA load in the peripheral blood [171].

A strong EBV-specific CD8+ cytotoxic T-cell response is elicited in immunocompetent hosts following primary infection with EBV, and it correlates with the resolution of the clinical manifestation of EBV. Reconstitution of EBV-directed T-cell responses is essential for controlling the proliferation of EBV transformed B cells. However, even after autologous peripheral blood stem cell transplantation, EBV-directed cellular immune reconstitution can take up to 6–12 months [172]. Lucas et al. [173] analyzed the temporal recovery of EBV-specific cytotoxic T-cell responses after unmodified or T-cell-depleted hematopoietic stem cell transplantation using EBV-transformed B lymphocytes as stimulator cells [173]. Profound deficiencies of EBV-specific cytotoxic T cells were observed 3 months after transplantation in most individuals, but they were recovered in most patients by 6 months after transplantation [173]. The relative frequencies of T cells specific for different EBV peptides in HSCT recipients closely reflect those of their respective donors.

Most cases of posttransplantation EBV-LPD develop in the first 4 months after transplantation, coincident with the most severe deficiency of EBV-specific CTLs. Moreover, those patients who develop EBV-LPD have weak or undetectable EBV-specific cytolytic activity [167, 168, 173]. These observations combined with the occasional spontaneous regression of established EBV-LPD after a reduction in the intensity of immunosuppressive drug therapy suggest a critical role for T cells in preventing the outgrowth of EBV-infected B cells.

Insights into the roles of different effector populations in controlling EBV-LPD have also been derived from studies in severe combined immunodeficient (SCID) mice inoculated intravenously or subcutaneously with EBV-transformed LCL. Depending on the route of inoculation, these mice develop disseminated or localized EBV lymphomas, and they have been used as models for assessing the roles of αβ+ T-cell subsets and NK cells in promoting tumor regression. In this model, the infusion of CD8+ EBV-specific T-cell lines or clones delayed or completely prevented the outgrowth of EBV lymphoma. CD4+ EBV-specific TH cells also mediated protection in some instances; however, NK or lymphokine-activated killer (LAK) cells were ineffective [174–176]. Studies in mice with established subcutaneous EBV lymphomas have demonstrated that the infusion of EBV-specific CTL lines results in the preferential migration of the infused T cells to the sites of tumors and to tumor regression [177].

48.5.2 Specificity of αβ+ CD8+ and CD4+ Epstein–Barr Virus-Specific Cytotoxic T Lymphocytes

EBV-specific CD8+ CTL responses can be readily elicited from EBV-seropositive donors in vitro using autologous EBV-LCL as stimulator cells. Only a minority of these EBV transformed B cells undergoes full EBV replication and lytic infection. Most cells express only six EBV nuclear antigens (EBNA-1, EBNA-2, EBNA-3A, EBNA-3B, EBNA-3C, and EBNA-LP) and two membrane antigens (LMP-1 and LMP-2) [153, 154]. These eight EBV antigens are also expressed in the infected B cells in EBV-LPD in immunosuppressed hosts. Vaccinia recombinant viruses encoding these individual EBV proteins have been constructed and used to assess the specificity of EBV-reactive CTLs elicited after the stimulation of peripheral blood lymphocytes with EBV-LCL. In most of the individuals studied, one or more of the EBNA-3A, EBNA-3B,

and EBNA-3C antigens were immunodominant, with lesser responses against EBNA-2, EBNA-LP, LMP-1, and LMP-2 [178, 179]. Notably, EBNA-1 was not recognized as a target antigen by any of the EBV-specific CD8+ CTLs.

Detailed studies of the role of individual EBV proteins expressed in EBV-LCL as target antigens for CD4+ EBV specific TH cells have been performed [151]. In contrast to CD8+ T cells, CD4+ T cells can recognize EBNA-1-positive targets. In healthy EBV-seropositive individuals, 0.5 % of all peripheral blood CD4+ TH1 cells can be specific for EBNA-1, which may represent an interesting target for adoptive immunotherapy with antigen-specific CD4+ T cells [180].

48.5.3 Clinical Studies of Adoptive Immunotherapy with Epstein–Barr Virus-Specific T Cells in Posttransplantation Epstein–Barr Virus Lymphoproliferative Disorder

EBV-LPD occurs more frequently in SOT recipients than in HSCT recipients [167]. However, in allogeneic HSCT recipients, the marrow donor can be used as a source of T cells for immune reconstitution. This strategy was first evaluated in a study by Papadopoulos et al. [142] in which five recipients of T-cell-depleted bone marrow transplants who had developed EBV-LPD received infusions of peripheral blood mononuclear cells (PBMCs) from their EBV-seropositive donors. The dose of T cells administered was 1×10^6 CD3+ cells/kg, and this therapy resulted in the complete regression of EBV-LPD in all five patients within 30 days; three of the five patients became long-term survivors [142]. The authors reported that both acute and chronic GVHD were observed consistent with the presence of alloreactive T cells, as well as EBV-reactive T cells, in the infused cell population. The patients receiving this therapy experienced dramatic increases in circulating EBV-specific CTLs that were consistent with the rapid expansion of this subset after antigen stimulation in vivo. Fourteen additional patients have been treated with cell doses as low as 1×10^5 cells/kg, and 17 of 19 (89 %) of these patients have had complete eradication of the EBV-LPD [176]. The incidence of acute and chronic GVHD was 16 % and 42 %, respectively [176].

The administration of EBV-specific CD4+ and CD8+ T-cell lines that exhibit cytolytic activity for EBV-LCL has been used for the treatment and prevention of EBV-LPD after T-cell-depleted hematopoietic stem cell transplantation [181]. The enrichment of polyclonal CD4+ and CD8+ T cells for EBV reactivity by in vitro culture has been effective in eliminating GVHD as a toxicity of the therapy [182, 183]. In these studies, researchers transduced the T-cell lines with a retroviral vector encoding neomycin phosphotransferase to permit an analysis of the persistence and migration of T cells after adoptive transfer. These studies have demonstrated that the infusion of gene-marked T cells in a dose of 1×10^8 cells/m^2 induces the regression of established EBV-LPD and that it prevents the development of EBV-LPD in susceptible individuals. Moreover, the marked T cells persisted for more than 18 months after infusion, suggesting that the coinfusion of CD4+ and CD8+ T cells may result in the establishment of immunologic memory [182]. In addition, therapeutic efficacy has been demonstrated by the adoptive transfer of EBV specific CTLs to allogeneic unrelated SCT recipients during periods of increasing EBV viral load [31, 184], as well as to patients suffering from chronic EBV infection [185].

For all immunotherapy, a hypothetic concern has been that mutations in virus-specific antigens may lead to viral escape. Researchers reported a patient who developed lymphoma after marrow transplantation in spite of having received donor-derived EBV-specific CTLs. Sequence analysis of the gene coding for the two CTL epitopes in the tumor virus revealed a 245 base pair deletion that had removed these CTL epitopes. Escape mutants may be a serious problem when CTL therapy is directed against unstable tumor cell-derived targets [186].

An updated analysis Doubrovina et al. [187] update the experience of EBV-specific donor-derived adoptive T-cell therapy after allo SCT. Forty-nine patients received EBV-specific T-cell lines from the SC third-party donor on day 4 posttransplant. > 70 % of patients responded associated with a strong proliferation of EBS-specific T cells. The group at Baylor College summarized the experience with the transfer of EBV-specific T cell lines after allo SCT [188]. None of 101 patients who received the transfer prophylactically developed EBV-LPD, whereas 11 of 13 patients treated with EBV-specific T-cell lines for proven LPD achieved a complete remission. Gene marked EBV-specific T cells were detectable up to 9 years after the transfer.

48.5.4 Current Technologies of Enriching Virus-Specific T Cells

48.5.4.1 Selection Strategies for Multipathogen-Specific T Cells

The de novo cell surface expression of the TNF-receptor family member CD137 (4-1BB) or CD154 identifies recently activated, but not resting, human CD4+ and CD8+ memory T cells. Maximum CD137 as well as CD154 expression level is uniformly observed in both T-cell subsets at 24 h after stimulation with antigen [189, 190]. In experiments with CMV- and EBV-reactive T cells the specificity of CD137 and/or CD154 expression by costaining with peptide/HLA tetramers could be confirmed. Substantial proportions of CD137+ as well as 154+ T cells did not produce IFN-γ, suggesting that CD137 and CD154 detects a broader repertoire of antigen-specific T cells. Activated CD137+ and/or CD154T cells could be easily purified by immunomagnetic

selection and expanded in vitro thereafter. This CD137- and/or CD154-based enrichment method was capable of isolating twofold higher numbers of antiviral CD4+ and CD8+ T cells compared to the IFN-γ secretion assay. The CD137 and/or CD154 assay is most attractive for the simultaneous targeting of antiviral TH and effector cells in monitoring studies and adoptive immunotherapy trials.

Using peptide pools covering relevant CMV, EBV, adenovirus as well as Candida- and aspergillus-specific immunodominant antigens we [191] were able to select multipathogen-specific donor T cells using the CD154 selection strategy and depleting efficiently alloreactive T cells.

48.5.5 Obstacles to Effective T-Cell Therapy for Herpesviruses

Despite considerable success in the development and application of T-cell therapy after transplantation, several challenges remain. The efficacy of adoptive immunotherapy in humans can be limited by the failure of Ag-specific T cells, particularly CD8+ T cells, to persist in vivo. Poor persistence may be due in part to the immunosuppressive drugs that many patients receive, but may also reflect intrinsic qualities of the infused T cells, a rather tolerogenic immune environment of the host as well as a lack of support from CD4+ lymphocytes. The pool of lymphocytes from which CD8+ T cells for adoptive immunotherapy can be derived includes naive T cells and antigen-experienced memory T cells, which can be divided into central memory and effector memory subsets that differ in phenotype, homing, and function. Central memory cells express CD62L and CCR7, which promote migration into LNs and proliferate rapidly if reexposed to antigen. Effector memory cells lack CD62L, enabling migration to peripheral tissues, and exhibit immediate effector function. In response to antigen stimulation, both memory subsets proliferate and differentiate into CD62L-cytolytic effector T cells that express high levels of granzymes and perforin but are short lived. Thus acquisition of an effector phenotype during culture has been suggested as a reason for the poor survival of transferred T cells.

Recent work in nonhuman primates has demonstrated that the derivation of effector T-cell clones affects their persistence after adoptive transfer, and the ability to establish durable immune memory. CMV-specific CD8+ T-cell clones derived from central memory T cells, but not effector memory T cells, persisted long-term in vivo, reacquired the phenotype and function of memory T cells, and occupied memory T-cell niches. These results demonstrate that clonally derived CD8+ T cells isolated from central memory T cells are distinct from those derived from effector memory T cells and retain an intrinsic capacity that enables them to survive after adoptive transfer. These results could have significant implications for the selection of T cells to expand or to engineer for adoptive immunotherapy of human infections or malignancy [192]. New strategies using sequential positive and negative selection based on the streptamer technology allow to successfully enrich for antigen-specific central memory T cells which will allow long-term engraftment after adoptive transfer to the patient.

An additional issue is that isolating donor-derived T cells for immunotherapy remains difficult when the allogeneic donor lacks specific immunity, such as in the case of seronegative recipients of EBV-seropositive organ grafts or of CMV-seropositive patients receiving a stem cell graft from a CMV-seronegative donor.

48.5.6 Potential Future Application of Adoptive T-Cell Therapy for Other Infectious Complications After Transplantation

48.5.6.1 Adenovirus Infection

Adenoviruses can establish acute and persistent infections that are generally mild and subclinical in the healthy population but that can be severe or even fatal in immunocompromised hosts. The importance of adenovirus as a cause of disseminated disease has remained underappreciated. Recently, however, the overall importance of this virus has been emphasized, primarily in pediatric patients after stem cell transplantation, and studies of host immunity to adenovirus have been initiated.

An intracellular cytokine secretion assay revealed adenovirus-specific T cells in 171 healthy control persons and 59 immunosuppressed long-term renal transplant recipients [194]. The responding T cells were CD4+ TH cells that showed a considerably homogenous expression of markers characteristic of antigen-experienced memory and/or effector cells of the TH1 phenotype. Using the cytokine-capture assay, adenovirus-specific CD4+ and CD8+ T cells were successfully isolated from stem cell donors [193] and transferred to patients with refractory adenovirus infections posttransplant [194]. Increasing knowledge about the T-cell epitope for adenovirus-specific T cells will further help to improve monitoring and manipulation of adenovirus-specific immune responses posttransplant [195–198].

In a recent publication [199] for 30 patients with Adv disease and/or viremia Adv Hexon-specific T cell lines were selected by stimulation with Hexon-derived peptides and the cytokine catch assay. Complete viral clearance was observed in 86 % of patients with Adv-specific T cell responses. Again after cell selection based on the cytokine-catch assay no acute toxicity or induction of GvHD was observed.

48.5.6.2 Fungal Infections

T cells play a potential role in the host defense against fungal infections. Recently, CD34-derived DCs were shown to

demonstrate an increase in the fluorescent intensity of HLADR, CD80, CD86, and CD54, as well as an increased production of IL-12 upon exposure to *Aspergillus fumigatus* [200]. The activated DCs stimulated proliferation of the autologous lymphocytes, producing high levels of IFN-γ but not IL-10. Moreover, DCs generated from CD34+ progenitors collected prior to stem cell transplantation also partially restored the in vitro antifungal proliferative response of lymphocytes obtained from patients at 1 month after transplantation, indicating that ex vivo-generated DCs may be useful in restoring or enhancing the antifungal immunity after stem cell transplantation.

In the mouse model, the group from Luigina Romani has demonstrated that pulmonary DCs are able to internalize the conidia and hyphae of *A. fumigatus* through distinct phagocytic mechanisms and recognition receptors, discriminate between the different forms of *A. fumigatus* in terms of cytokine production, undergo functional maturation upon migration to the draining lymph nodes and spleen, and instruct local and peripheral TH cell reactivity to the fungus [201]. The phagocytosis of the conidia induced IL-12 production, whereas that of hyphae induced IL-4 and IL-10 production. The same group reported that DCs transfected with yeast or hyphal RNA induced protective immunity to *Candida albicans* in a hematopoietic transplantation model. DCs transfected with yeast but not hyphal RNA expressed fungal mannoproteins on the surface, underwent functional maturation, and produced IL-12 but not IL-4. These cells were also capable of inducing TH1-dependent antifungal resistance when they were delivered subcutaneously in nontransplanted mice in vivo, and they helped to accelerate the functional recovery of *Candida specific* IFN-γ-producing CD4+ donor lymphocytes in mice that underwent allogeneic bone marrow transplantation. These results indicate the potential efficacy of DCs pulsed with fungal RNA as a fungal vaccine [202].

Researchers have investigated the importance of cytokine dysregulation as a risk factor for the development of invasive fungal infections in a murine haploidentical bone marrow transplantation model [203]. At 2 weeks after transplantation, high levels of TH2 cytokines and impaired production of TH1 cytokines were associated with a high susceptibility to disseminated and mucosal *C. albicans* infections, whereas at 5 weeks after transplantation a predominant production of TH1 cytokines was associated with resistance to infection. In addition, the therapeutic ablation of IL-4 and IL-10 increased resistance to invasive candidiasis. The potential additive antifungal effect of adjuvant treatment with immunostimulatory cytokines or the antagonism of TH2 cytokines is further supported by clinical observations, such as the successful management of rhinocerebral zygomycosis in non neutropenic patients by a combination of granulocyte-macrophage colony-stimulating factor, antifungal therapy, and surgical treatment [204].

With the growing body of evidence that T cells are important in the host defense against *Aspergillus* T cells, techniques to select and adoptively transfer anti-*Aspergillus* TH1 cells are being evaluated to reduce infectious mortality in HSCT recipients. Rapid methods for the clinical-scale generation of functionally active anti-*Aspergillus* T cells according to GMP conditions using *Aspergillus* antigens are being developed [205]. *Aspergillus*-specific T cells can also be selected using the IFN-γ secretion assay [205] as well as multipathogen-specific T cells including Candida- and Aspergillus-specific T cells [191, 206]. Recent experiments [207, 208] indicate that also NK cell infusions might mediate antifungal activity and would be applied clinically.

The Perugia group successfully transferred *Aspergillus-specific* T cells to patients after haploidentical HSCT with documented invasive aspergillosis and demonstrated improved control of this devastating infection when compared to historical control patients receiving antifungal pharmacological treatment [209].

48.6 Summary

Considerable progress has been made in understanding the immunobiology of viral infections in immunocompromised hosts. Insights derived from animal models and human studies have provided the rationale for investigating immunotherapy with αβ+ T cells to restore responses considered essential for protective immunity to CMV and EBV. Ongoing studies will address the role of adoptive immunotherapy in the prevention and treatment of adenovirus and invasive fungal infection. The use of genetically modified T cells has been evaluated clinically, and it offers the potential for improving the safety and efficacy of immunotherapy and for removing obstacles to its successful use. Although these studies are in the early stages and they present considerable technical challenges, the results suggest that cellular immunotherapy will be a fruitful area for investigation in the future.

49 Emerging and Rare Viral Infections in Transplantation

Staci A. Fischer

Viral infections are common following solid organ and hematopoietic stem cell transplantation, as detailed in other chapters. While cytomegalovirus (CMV) remains the most prominent virus in transplantation, and the clinical manifestations and complications of infection with other herpesviruses (e.g., herpes simplex virus, Epstein–Barr virus, and human herpesviruses 6 and 8) are well described, improvements in diagnostic techniques have led to the recognition of a number of additional viruses with potential pathogenicity in the immunocompromised host. Outbreaks of emerging viruses, the resurgence of vaccine-preventable viral infections, and the identification of viruses which cause self-limited infection in immunocompetent children but significant disease in transplant recipients have highlighted the breadth of pathogens in this patient population. Some of these emerging and unusual viral pathogens are discussed in alphabetical order below.

49.1 Astrovirus

Astrovirus is a common cause of viral gastroenteritis throughout the world and has been a cause of outbreaks of diarrheal disease in schools, hospitals, nursing homes, and military bases [1–3]. Several recent reports have highlighted the impact of this RNA virus on immunocompromised hosts. In addition to its role in gastroenteritis in these patients, one astrovirus subgroup (VA1/HMO-C) has been reported to cause encephalitis in allogeneic hematopoietic stem cell transplant (HSCT) recipients and children with X-linked agammaglobulinemia [4, 5]. Molecular techniques including reverse-transcription polymerase chain reaction (RT-PCR), RNA sequencing, and next-generation sequencing have demonstrated the presence of this subgroup in the cerebrospinal fluid (CSF) and brain tissue of infected patients. Immunohistochemical staining on biopsy tissue has confirmed the presence of invasive infection. There are no known antiviral treatments available, and central nervous system (CNS) infection has been fatal in the cases reported to date. Additional study is needed to determine the prevalence of astrovirus infection in transplanted patients.

49.2 Bocavirus

Bocavirus is a human parvovirus that causes upper and lower respiratory tract infection, gastroenteritis, and encephalitis in children [6, 7]. Infection is most common in the late fall and winter, and most commonly presents with rhinorrhea, fever, cough, wheezing, or diarrhea. Thirty percent of children develop hypoxia, and a variety of radiographic findings have been reported, including peribronchial cuffing, lobar infiltrates, and pleural effusions. Nosocomial infection has occurred [8]. Bocavirus infection has been reported in the first few weeks following hematopoietic stem cell transplantation, presenting with fever, rhinorrhea, cough, diarrhea, and hypoxia [9]. Virus has been detected in high quantities in plasma, nasopharyngeal aspirates, and stool. Fecal shedding occurs for several weeks to months after clinical resolution of infection [10]. Severe and prolonged diarrhea has been described in liver transplant and hematopoietic stem cell recipients [11]. It has been suggested that bocavirus, like respiratory syncytial virus (RSV) and parainfluenza, may play a role in the development of bronchiolitis obliterans, a manifestation of chronic rejection in lung transplantation [12–14]. To date, there are no data on antiviral efficacy against bocavirus.

49.3 Chikungunya Virus

Chikungunya virus, a mosquito-borne alphavirus transmitted by *Aedes aegypti* and *Aedes albopictus*, is a tropical infection which has caused epidemic disease in India, Thailand, Malaysia, Madagascar, and Reunion Island [15, 16]. It is endemic in eastern, central, and southern Africa. In 2013, chikungunya was reported in St. Martin, with epidemic

P. Ljungman et al. (eds.), *Transplant Infections*, DOI 10.1007/978-3-319-28797-3_49

spread throughout the Caribbean, Central America, South America, and Florida, where infection spread locally via *A. aegypti* [17].

After an incubation period of 2–4 days, infection presents with high fever, headache, myalgias, and arthralgias, and can resemble dengue. Arthralgias are typically symmetric and involve large joints, particularly in the legs and arms. Frank arthritis may also occur in the interphalangeal joints, wrists, and ankles. Half of patients also develop a rash, which can be maculopapular, petechial, or bullous and is most commonly located on the trunk, with occasional involvement of the face, extremities, palms, and soles. Ocular pain has also been reported. Rarely, meningoencephalitis, myocarditis, or hepatitis can occur. Symptoms resolve in 7–10 days, although arthralgias and joint stiffness may persist for weeks to months after fever resolves. Severe manifestations of infection with fatal outcomes have been reported in patients with underlying diabetes, lung disease, or chronic neurologic conditions.

Laboratory findings include lymphopenia, thrombocytopenia, elevated transaminases, and hypocalcemia. Diagnosis may be made serologically or by RT-PCR. IgM antibodies develop as fever resolves, typically 1 week after symptom onset. There is currently no known effective antiviral therapy for chikungunya.

During a widespread outbreak of infection on Reunion Island in the Indian Ocean, organ and tissue donors were screened for the presence of chikungunya infection [18]. Corneal donors were found to have serologic and PCR evidence of infection in serum and corneal tissue. Transmission of infection with corneal transplantation is presumed to occur. There have been no reports of transmission of chikungunya in solid organ or stem cell transplantation to date although with reports of infection in Asia, Europe, and North America in travelers from endemic areas, the risk of transmission and the clinical course of infection in these patients require further study.

49.4 Coronavirus

In February 2003 a worldwide outbreak of severe respiratory infection occurred, infecting more than 8000 patients over several months in 29 countries, most severely affecting southern China, Hong Kong, and Canada, with well-described healthcare-associated outbreaks [19–26]. Eighty percent of those affected were previously healthy, with no comorbid conditions. The outbreak began in Guangdong Province, China, in November 2002 and with global travel spread rapidly to multiple continents. The infection of numerous health care workers and the rapidly fatal course of infection, even in healthy hosts, were remarkable. Named Severe Acute Respiratory Syndrome (SARS), this infection was quickly determined to be due to a new strain of coronavirus, a group of viruses known to cause human disease since the 1960s [27].

Patients initially noted high fever, myalgias, headache, and cough, and subsequently became dyspneic [19, 20, 25, 28]. A productive cough was seen in nearly one third of patients, while rash and lymphadenopathy were absent. Lymphopenia, thrombocytopenia, mild elevation of transaminases, prolonged prothrombin time with elevated D-dimers, elevated lactate dehydrogenase (LDH) and creatine kinase (CK), and hyponatremia were common lab findings [25]. Chest radiographs revealed focal airspace consolidation or ground glass opacities, initially without the interstitial infiltrates most characteristic of viral pneumonitis, with lower lung field predominance [22, 25]. Pleural effusions and mediastinal lymphadenopathy were generally absent. Histopathologic findings in lung biopsies and at autopsy included diffuse alveolar damage consistent with adult respiratory distress syndrome (ARDS), with significant alveolar edema, minimal inflammation, and no viral inclusions.

Treatment included corticosteroids and intravenous or oral ribavirin. Although published data are not yet available in humans, animal models suggest that monoclonal antibody to SARS coronavirus (SARS-CoV) is effective in decreasing viral replication and improving outcomes [26]. The overall case fatality rate during the SARS epidemic was nearly 10% [19]. A novel coronavirus was rapidly isolated and identified as the cause of SARS and sequenced, allowing for RT-PCR and serologic testing to be developed [29, 30].

During the SARS outbreak in Toronto, a liver transplant recipient was fatally infected while visiting a medical center for an outpatient clinic visit nearly 10 years posttransplant [31]. Disseminated infection was described in a lung transplant recipient in whom virus was detected in lungs, bowel, lymph nodes, liver, kidney, skeletal muscle, and brain at autopsy [32, 33]. Tissue viral loads were significantly higher in transplant recipients than in their immunocompetent counterparts [34]. The last of the nearly 8000 reported cases of SARS-CoV was reported in May 2004, after which no additional cases have been reported, for unclear reasons.

In September 2012, initial reports of infection with another novel human coronavirus began in Saudi Arabia, with rapid spread to neighboring Egypt, Iran, Jordan, Kuwait, Lebanon, Qatar, Oman, Yemen, and the United Arab Emirates, then to other continents with airline travel [35]. Middle East Respiratory Syndrome Coronavirus (MERS CoV) has been reported to cause severe respiratory tract infection in adult patients, with a mortality rate as high as 60%, most commonly in those with diabetes mellitus and end stage renal disease [36]. After a median incubation period of 5 days (range, 2–14 days), patients often present with fever, cough, dyspnea, and diarrhea after close contact with an infected case and/or travel from an area where infection is active. Coryza, headache, nausea, vomiting, and abdominal pain have also been reported [37]. Laboratory findings include thrombocytopenia, leukopenia, lymphopenia, and elevated

transaminases and LDH. Coinfection with other respiratory viruses has been reported [38]. As with SARS-CoV, health care workers are at risk for infection [39, 40]. Dromedary camels have been reported to harbor infection in the Arabian Peninsula, although the mode of transmission of infection has not yet been elucidated [41].

Several cases of MERS CoV infection have been reported in hematopoietic stem cell and solid organ transplant recipients, who have developed bilateral pulmonary infiltrates with respiratory failure, acute renal failure, leukopenia, thrombocytopenia, and elevated transaminases, at times without fever [36, 42].

While difficult to grow in cell culture, MERS CoV may be diagnosed by RT-PCR on respiratory secretions. Virus has been detected with these techniques in urine and stool as well. To increase the yield of testing, it is recommended that multiple specimens from different sites (e.g., nasopharyngeal swab, sputum, BAL fluid, serum, and stool) be tested using RT-PCR, which is available from the CDC and local health departments in the USA [37]. Due to the risk of transmission of infection to health care workers, contact and airborne precautions are recommended in caring for the suspected MERS-CoV infected patient [39, 40].

While there have been no randomized, controlled clinical trials of antivirals against MERS-CoV, ribavirin and mycophenolate mofetil (an immunosuppressive agent used commonly in transplantation) have in vitro activity against the virus [43]. Ribavirin (in combination with interferon α-2b) has demonstrated promise in decreasing lung injury and viral replication in rhesus macaques infected with MERS-CoV [44]. A retrospective cohort study describing the use of ribavirin and interferon α-2a in twenty patients with severe infection demonstrated an early survival benefit [45].

Whereas coronaviruses made world headlines with the SARS epidemic in 2002–2004 and the MERS-CoV emergence in 2012, coronaviruses OC43 (group 1) and 229E (group 2) have been known for decades to cause upper respiratory tract infections during the fall and winter months. Coronavirus NL63 (group 1) has been reported to cause upper and lower respiratory tract infections in immunocompetent hosts in the Netherlands, and coronavirus HKU1 (group 2) has been reported to cause pneumonia in Hong Kong and France [21]. Non-SARS coronaviruses have recently been associated with severe lower respiratory tract infections in hospitalized patients, including lung and liver transplant recipients [46]. Coronavirus 229E has been isolated from hematopoietic stem cell transplantation recipients with fever and cough associated with interstitial and alveolar pulmonary infiltrates [46]. Pancytopenia may be present. Radiographic infiltrates are most commonly interstitial, although 28% are alveolar. Pleural effusions may be present, and pneumothorax has been noted in a minority of patients. Diagnosis may be made by culture in human hepatoma HUH7 cell line, or by RT-PCR [46, 47].

49.5 Hepatitis E

Hepatitis E is endemic in developing countries and has been reported to cause epidemic disease in Asia, Africa, and Latin America via fecal–oral transmission [48]. Travel-related infection has been reported in those returning from endemic areas with poor sanitation. Recent reports have highlighted the important role of this infection in transplant recipients.

Hepatitis E virus (HEV) is an RNA virus with four major genotypes with presumed reservoirs in pigs, wild boars, deer, and mollusks [49, 50]. Seroprevalence surveys indicate that infection in blood donors, even in France and the USA, is significant; in some areas, hepatitis E is more prevalent than hepatitis A [51, 52]. Epidemics of infection have been described from ingestion of contaminated water, mollusks, and undercooked deer, boar, or pig meat [53–55]. Blood transfusion-transmitted infection has also been described [56–59]. After an incubation period of two to nine weeks, patients develop jaundice, abdominal pain, anorexia, and nausea. Fever and chills may occur as well, although rash is unusual. Diagnosis can be made by RT-PCR detection of HEV RNA, which is present between 2 and 6 weeks after infection, as symptoms occur [60]. IgM antibodies develop as symptoms resolve, approximately 4 weeks after infection. Elevated transaminases occur, peaking approximately 6 weeks after infection. While viremia resolves within 6 weeks of infection, virus remains detectable in stool for several weeks after viremia resolves and IgG appears. Serum IgG antibodies persist for years after acute infection.

Approximately 10% of patients with acute HEV infection develop fulminant hepatitis with acute hepatic failure; the presence of pregnancy or underlying chronic liver disease (e.g., chronic hepatitis C infection or cirrhosis) increases the risk for severe infection [61, 62]. Histopathologic findings on liver biopsy include lymphocytic infiltration of portal triads. Chronic hepatitis appears to be rare in immunocompetent hosts.

Disease in organ transplant recipients has been characterized by a high incidence of chronic infection (in up to 60% of acutely infected patients) with progressive fibrosis and eventual cirrhosis [63–66]. Reactivation of infection has been described in liver and allogeneic HSCT recipients, in whom nearly half of infections became chronic [67–69]. Liver transplant recipients appear to be at increased risk for chronic infection resulting from reactivation of HEV after transplantation, as well as acute graft hepatitis from reactivation or primary infection [70]. Extrahepatic manifestations of infection in transplant recipients have included glomerulonephritis and neurologic involvement [69, 71].

There are no FDA-approved therapies for HEV infection, although decreasing immunosuppression appears to have helped control viremia in some chronically infected transplant recipients. In small studies, interferon alpha and ribavirin have been reported to decrease viremia in these patient populations [72, 73].

49.6 Lymphocytic Choriomeningitis Virus

Lymphocytic choriomeningitis virus (LCMV) gained notoriety as a pathogen in solid organ transplantation in 2005, when the first two outbreaks of donor-transmitted infection were described [74–76]. Additional donor-transmitted outbreaks have recently occurred in the USA and Australia [77–80]. Four clusters of donor-derived infection have occurred in the USA to date.

LCMV is a rodent-borne Old World arenavirus that causes asymptomatic or mild, self-limited illness in the immunocompetent host. Rodents, especially common house mice, laboratory mice, and hamsters, often acquire infection congenitally, resulting in lifelong, asymptomatic excretion of virus in urine, saliva, and feces [81–84]. Human infection occurs via direct contact with infected rodents or aerosolized infected excreta (e.g., with cleaning soiled cage bedding). Symptoms described in immunocompetent humans include fever, headache, and myalgias, with CSF findings consistent with aseptic meningitis (e.g., lymphocytic pleocytosis). In the normal host, infection is self-limited and carries a mortality rate of less than 1% [85].

In the transplant clusters, infection with LCMV has been fatal in more than 80% of cases [74, 78, 80]. Patients have presented within the first month posttransplant with fever, diarrhea, abdominal pain, and dyspnea. Rash, headache, lethargy, hypotension, and the presence of pulmonary infiltrates are variable. Thrombocytopenia and anemia have been present, with variable peripheral leukocyte and lymphocyte counts. Acute hepatitis with elevated transaminases has been noted, as well as coagulopathy with prolonged protimes. Patients have developed rapidly progressive multisystem failure with encephalopathy prior to death. In one cluster, while the donor had no evidence of infection in multiple tissues tested, a pet hamster present in the donor's home for several weeks prior to donation was found to have LCMV in multiple tissues [74]. Virus isolated from the hamster was identical to that isolated from the infected transplant recipients. The survivor in that cluster, a kidney recipient, was treated with discontinuation of all immune suppression except corticosteroids and with intravenous ribavirin. Similar approaches have been used in more recent cases [80].

With four donor-derived infection outbreaks in the USA alone, LCMV infection is likely more common than previously recognized in transplant recipients. Detailed workup of potential organ donors with aseptic meningitis or meningoencephalitis may prevent transmission in some cases. Whether LCMV infection occurs posttransplant in recipients with exposure to pet hamsters or house mice is unknown.

49.7 Metapneumovirus

Human metapneumovirus is a single-stranded RNA paramyxovirus of worldwide endemicity that causes respiratory tract infection in children, the elderly, and immunocompromised adults, with outbreaks reported in long-term care facilities [86–90]. Infection occurs in the late winter and early spring (January through April), similar to the seasonality of respiratory syncytial virus (RSV). Upper and lower respiratory tract symptoms, including rhinorrhea, sore throat, cough, dyspnea, and fever, have been described.

Infection has been described following lung and heart–lung transplantation, resulting in acute pneumonia with diffuse alveolar damage and hyaline membrane formation [91, 92]. Lung transplant recipients with metapneumovirus pneumonia have a 14% mortality rate and are at higher risk for acute and chronic rejection [92, 93]. In renal transplant recipients, pneumonitis due to metapneumovirus has been reported 3 years posttransplant [94]. In one study of HSCT recipients, human metapneumovirus was isolated via RT-PCR in 26% of symptomatic patients undergoing bronchoscopy and carried a mortality rate of 80% [95]. Infection occurred within the first few weeks following transplant, and was characterized by fever, nasal congestion, and cough, with rapid development of hypoxia, hypotension, and progressive pneumonia, with diffuse alveolar hemorrhage in three of five patients [94–96]. Pleural effusions and nodular infiltrates may be seen, which may help differentiate infection from RSV. Coinfection with RSV, rhinovirus, and CMV has been described following lung transplantation [97].

Ribavirin has been demonstrated to decrease human metapneumovirus replication in the lungs in a mouse model [98], and intravenous ribavirin has been effective in the treatment of several lung transplant recipients with metapneumovirus infection [99].

49.8 Measles

Measles outbreaks have occurred in multiple states in recent years, with an attack rate of greater than 90% among susceptible patients, including unvaccinated children and adults [100–108]. Affected patients develop fever, cough, and coryza, associated with a characteristic rash. Infection may be complicated by pneumonia, encephalitis, or dissemination, with significant mortality noted in solid organ and HSCT recipients [109]. Infection has been associated with waning immunity and is diagnosed serologically. There are no data on antivirals for treatment of measles.

49.9 Mumps

Mumps has been increasingly reported in the USA, with more than 10,000 cases reported in a large multistate outbreak in 2005–2006 [110–116]. Patients present with acute onset of unilateral or bilateral parotitis; infection may be complicated by orchitis, oophoritis, pancreatitis, mastitis, meningitis, and encephalitis [117]. Infection may be diagnosed serologically or via PCR [118, 119]. No antivirals have been investigated in the treatment of mumps. Enhanced efforts at immunization against measles and mumps pretransplant as well as active surveillance posttransplant are warranted.

As a result of the re-emergence of these vaccine-preventable viruses, recent guidelines suggest vaccination with the measles, mumps, and rubella (MMR) vaccine 2 years following hematopoietic stem cell transplantation in patients without evidence of graft-versus-host disease [120, 121]. If at all possible, patients undergoing solid organ transplantation who do not have evidence of protection against measles and mumps (e.g., positive IgG antibody to each) should be vaccinated prior to the initiation of immunosuppressive therapy.

49.10 Norovirus

Noroviruses are caliciviruses that cause over 20 million cases of gastroenteritis annually in the USA and over half of all epidemics of gastroenteritis worldwide [122–129]. Infection is acquired via consumption of contaminated foods (including raw oysters, fruit, and vegetables) or via ingestion of or swimming in contaminated water, with spread via fomites and from person to person [130–145]. Infection is extremely contagious and often spreads rapidly as a result of prolonged fecal shedding in affected patients after resolution of symptoms. Outbreaks of infection have been described in multiple settings including military barracks, restaurants, hospitals, long-term care facilities, schools, and cruise ships [122].

Infection may be asymptomatic or present with the sudden onset of nausea, vomiting, and diarrhea after an incubation period of less than 48 h. Some studies have suggested that vomiting is more common in children, with diarrheal symptoms predominating in infants and adults [138, 148]. Infection is most common in the winter months, with symptoms lasting 1–7 days [122, 142, 148]. Attack rates in some outbreaks have been 50–90%, with health care workers at substantial risk for infection [127, 130, 137–139, 144–147].

Noroviruses cannot be cultured in vitro, but RT-PCR and enzyme immunoassay (EIA) assays are available for diagnosis in stool specimens [148–150].

Norovirus infection in solid organ transplant recipients is common, and marked by risk for chronic and relapsing infection [150]. Infection presents with watery diarrhea, which can cause volume depletion and acute renal failure in renal transplant recipients [126, 142, 149, 151]. Patients may be symptomatic for months and may shed virus in stool for years. Hematopoietic stem cell transplant recipients have been reported to develop acute and chronic diarrheal disease from norovirus infection, which has been associated with the subsequent development of chronic GVHD [151, 152]. Receipt of cord blood, induction with fludarabine, and receipt of alemtuzumab have been reported to be risk factors for norovirus infection in this setting. Nosocomial outbreaks of infection in HSCT units have resulted in infection of staff and patients, with sepsis from bacterial translocation complicating several cases [152, 153].

Treatment of norovirus infection in transplant recipients has not been investigated in randomized, controlled trials to date. Reduction of immunosuppression resulted in clearance of infection in one intestinal transplant recipient with norovirus infection [154]. There are no available antiviral therapies to date. Noroviruses are highly resistant to disinfectants, propagating prolonged transmission in many environments.

49.11 Parvovirus B19

Parvovirus B19 infection is common, with 60–90% of adults having serologic evidence of prior infection [155]. In children, parvovirus infection causes erythema infectiosum, a febrile illness with a characteristic “slapped cheek” rash. Adults with acute parvovirus infection develop a flu-like illness, sometimes with resultant arthropathy. A pathogen of erythroid progenitor cells, parvovirus B19 causes severe anemia in patients with underlying hemolytic disorders and hydrops fetalis in pregnancy. In recent years, neurologic involvement including meningoencephalitis has been described, which may be more common in immunocompromised hosts [156, 157].

In transplant recipients, anemia is the most common presentation of infection. Fever occurs in 25% of patients and arthralgia or rash occurs in less than 10% of those affected [158]. Pancytopenia may be present. Other manifestations described in the transplant population include hepatitis, myocarditis, pneumonitis, encephalitis, meningitis, peripheral neuritis, and collapsing glomerulopathy [155, 157–160]. Those with CNS infection may develop sequelae including seizures, cognitive deficits, stroke, and muscle wasting [157]. Donor-transmitted infection has been described, presenting with allograft dysfunction, fever, arthralgia, and pancytopenia, often without a rash [161–164]. Chronic or recurrent anemia may be seen posttransplant, as well as pure red cell aplasia [165, 166]. Parvovirus B19 infection has also been associated with the subsequent development of thrombotic microangiopathy in kidney transplant recipients, including a cluster of cases in Iran; hemophagocytic lymphohistiocytosis has also been described in this population [167, 168]. The significance of the frequent finding of parvovirus DNA in renal allografts pre- and posttransplant is under investigation [169]. In other transplant populations, parvovirus may be associated with chronic cellular allograft rejection [170].

Diagnosis of parvovirus B19 infection may be made by serology, PCR, or bone marrow examination in immunocompetent hosts. The yield of serologic testing (especially IgM) is limited in transplant recipients who may not mount an adequate antibody response to infection, so that RT-PCR on blood, bone marrow, or other involved tissues is necessary to detect infection in many cases [155].

Infection may respond to intravenous immunoglobulin (IVIg), with relapses occurring in up to 25% of immunosuppressed hosts [155]. There are no published data on the use of antivirals in parvovirus infection.

49.12 Polyoma Viruses (KI, WU, and Merkel Cell Carcinoma Polyomaviruses)

Human polyoma viruses such as BK virus and JC virus are well known pathogens in transplantation and are discussed elsewhere. In recent years three additional polyoma viruses have been described as potential pathogens in immunocompromised hosts. Like BK and JC, these viruses frequently cause asymptomatic primary infection in healthy patients and are capable of establishing latent infection which can be reactivated in the setting of immune suppression. KI and WU viruses (named for the institutions in which they were discovered, Karolinska Institutet and Washington University) have been isolated in children with acute respiratory symptoms including wheezing as well as in the setting of pneumonia [171, 172]. Respiratory infection has also been described in HIV-infected patients, in whom higher viral loads have been demonstrated in those with lower CD4 counts [173].

KI and WU polyomaviruses have been isolated in nasopharyngeal, sputum, and bronchoalveolar lavage specimens in hematopoietic stem cell and solid organ transplant recipients [174, 175]. These viruses have also been detected in transbronchial biopsy specimens in lung transplant recipients, who in many cases were asymptomatic. Coinfection with other viral and bacterial pathogens has been reported. RT-PCR results should be interpreted with caution in transplant recipients, in whom severe infection has not been described to date. There are no available data on the role of decreasing immunosuppressive therapy or the use of antiviral agents in the development or treatment of infection with KI and WU polyomaviruses.

Merkel cell carcinoma is a neuroendocrine malignancy of the skin which is most common in immunocompromised hosts including transplant recipients [173, 176]. Over 80% of these tumors contain a polyoma virus named Merkel Cell polyomavirus (MCPyV); virus has also been found in respiratory secretions in asymptomatic transplant recipients. Further study of each of these polyomaviruses is ongoing in the transplant population.

49.13 Rotavirus

Rotavirus, the most common cause of enteritis worldwide and a common pathogen in healthy children under the age of 3, has become increasingly recognized as a pathogen in pediatric and adult recipients of solid organ transplants [177]. Epidemics have occurred through fecal–oral transmission, primarily in the winter and spring. Affected patients present with watery diarrhea, nausea, vomiting, abdominal pain, and, in some cases, gastrointestinal bleeding from colonic ulcers. Infection may be diagnosed by antigen detection in stool specimens using ELISA, latex agglutination, or quantitative PCR. Infection is generally self-limited with weaning immunosuppression during the acute phase of illness. There are no published data on antiviral activity against rotavirus; treatment remains symptomatic.

Rotavirus has been associated with a high risk of acute cell-mediated rejection in intestinal transplant recipients, which has been proposed to be related to poor absorption of immunosuppressive agents in the setting of vomiting and diarrhea, as well as immune reactivation of gastrointestinal tract-associated lymphocytes in the setting of infection [178]. In HSCT recipients, rotavirus infection may be difficult to differentiate clinically and histopathologically from GVHD.

In 1998, a live, oral, tetravalent rhesus–human reassortment rotavirus vaccine (RotaShield, Wyeth-Ayerst Laboratories, St. David, PA) was licensed and recommended for routine immunization of infants in the USA; it was voluntarily withdrawn from the market in 1999 due to its association with intestinal intussusception noted in postmarketing surveillance [179–181]. Two additional Rotavirus vaccines have been studied (RotaTeq, Merck & Company, Whitehouse Station, NJ; Rotarix, GlaxoSmithKline Biologicals, Rixensart, Belgium). Both vaccines are oral and contain live virus, and are thus contraindicated in highly immunocompromised patients. Fecal virus shedding has been noted with both vaccines, with transmission of vaccine-associated virus to household members noted with Rotarix [181].

Current vaccination guidelines in immunocompromised hosts recommend that HSCT and solid organ transplant recipients not receive this live virus vaccine. Household contacts of patients with immune deficiency may be vaccinated, but the transplant recipient should not change diapers for 4 weeks after vaccination, the usual duration of viral shedding in stool [182].

49.14 West Nile Virus

West Nile virus (WNV) was initially isolated from a febrile patient in the West Nile Province in Uganda in the 1930s and has been enzootic in Africa, Asia, the Middle East, and parts of the Mediterranean and Europe, causing asymptomatic disease

or a self-limited febrile flu-like illness [183]. This flavivirus was first detected in the northeastern USA in 1999 and has caused outbreaks of infection in the late summer and early fall throughout the USA since then [184, 185]. Birds are the primary reservoir of infection. Mosquitoes acquire lifelong infection after biting viremic birds, spreading infection from their salivary glands to other species, including humans, with a subsequent bite. In human infection, the incubation period is 2–14 days [186]. While approximately 80% of infections are asymptomatic, 20% of patients develop West Nile fever, characterized by fever, malaise, anorexia, nausea, myalgias, headache, and occasionally lymphadenopathy [187]. One in 150 symptomatic patients develops meningitis and/or encephalitis [188]. Meningitis presents with photophobia, phonophobia, meningismus, and hyperreflexia; CSF analysis reveals a lymphocytic pleocytosis (<500 leukocytes/mm^3, glucose usually normal). Patients with encephalitis develop altered mental status, cranial nerve palsies, seizures, and movement disorders. A minority of patients develop rapid asymmetric weakness that may progress to flaccid paralysis mimicking poliomyelitis, associated with hyporeflexia or areflexia [184, 189, 190]. Acute neuromuscular respiratory failure may develop, which carries a mortality rate of more than 50% [188]. Hemorrhagic fever characteristic of other flaviviruses has also been described [191]. The presence of severe weakness and hyporeflexia in a patient with meningoencephalitis should raise the suspicion of WNV infection. MRI may demonstrate meningeal or periventricular enhancement, sometimes mimicking ischemic changes [186].

Transmission of WNV via dialysis has been suggested [192], and transmission via blood transfusion and organ transplantation has been well documented [193–197]. In immunocompromised hosts, central nervous system involvement is common, although CSF pleocytosis may be minimal [198–200]. Community-acquired infection has been reported following solid organ transplantation, occurring 2 months to 10 years posttransplant [185, 199–202]. A study of WNV infection during an outbreak in Toronto noted that liver, kidney, and heart transplant recipients had 40 times the risk of symptomatic infection as normal hosts [203]. In all cases, the recipients had participated in outdoor activities without the use of insect repellant or other personal protective measures. Fever often preceded neurologic symptoms. A delayed serologic response was noted in the transplanted cohort in which infection carried a mortality rate of 25%, versus 9% in the general population. In a Colorado outbreak in 2003, 11 transplant recipients (4 kidney, 2 liver, 2 kidney/pancreas, 1 lung, and 2 HSCT) developed infection requiring hospitalization [204]. Ten (91%) developed meningoencephalitis, one developed acute flaccid paralysis without encephalitis, and three patients had meningoencephalitis and paralysis. Two patients died (18% mortality), and three suffered significant neurologic sequelae. It appears that transplant recipients are more likely to develop meningoencephalitis in the setting of acute West Nile virus infection than immunocompetent hosts, perhaps with a higher mortality rate. Prolonged infection can also occur [205].

Several cases of WNV infection have been reported in HSCT recipients [206, 207]. Infection occurred 3–5 months posttransplant in the most well-described cases, after engraftment but while on calcineurin inhibitor-based prophylaxis or treatment of chronic graft-versus-host disease. Fever, lethargy, progressive bilateral extremity weakness, and hyporeflexia or areflexia were present. CSF contained 0–6 white blood cells/μL; IgG and IgM were negative in CSF and blood in most cases. Diagnosis of WNV infection was made by PCR performed on serum and CSF. All of the described patients died.

Diagnosis of WNV infection in immunocompetent hosts may be made serologically or via RT-PCR. An IgM antibody capture assay is available and becomes positive in CSF 3–5 days after onset of symptoms in nonimmunosuppressed hosts [202, 207], before serum antibody develops; CSF IgG appears approximately 5 days later. Antibody presence may be confirmed with viral neutralization studies. IgM antibodies may persist in serum for up to 12 months after infection resolution, and IgG may persist for years. As in the hematopoietic stem cell recipients noted above, immunocompromised patients demonstrate delayed seroconversion, making diagnosis of acute infection difficult at times. Nucleic acid testing in plasma and/or CSF is the most useful diagnostic test in this setting [208].

There are no antiviral agents that have proven efficacy in the treatment of WNV infection. Ribavirin possesses in vitro activity but demonstrates poor clinical efficacy [186, 209]. IVIg with high titers of anti-WNV antibodies (e.g., from Israel, where infection is endemic) has demonstrated significant clinical benefits in animal models, although antibody titers are low in immune globulin derived from the US donors, which have proven ineffective in treating acute infection [184, 210, 211]. A report of successful treatment of donor-transmitted WNV infection in a liver transplant recipient by reducing immunosuppression and administering plasma from seropositive blood donors has been published [212]. Overall case fatality rates of infection with WNV are 4–20% [189, 192], with significantly higher rates in transplant recipients.

Unlike the case in other neuroinvasive viral infections, the severity of initial clinical presentation does not predict the prognosis of WNV infection [187, 190, 213]. Survivors frequently suffer from prolonged fatigue, myalgias, cognitive deficits, memory loss, and tremors. Parkinsonism, excessive somnolence, and postural instability are reported. Phase I trials of a vaccine have been promising [214]. Transplant recipients should be educated about the transmission of West Nile virus and urged to remove any stagnant water collections and to use insect repellant when outdoors at dusk during the later summer and fall in order to prevent infection.

49.15 Conclusion

Viruses remain the most significant and elusive pathogens infecting patients following solid organ and hematopoietic stem cell transplantation. The days of "it's just a virus" are clearly behind us, as immunosuppression has changed, post-transplant longevity is increasing, and molecular diagnostic methods have dramatically improved [215]. Serology may be of limited value in immunocompromised hosts in the diagnosis of acute infection as well as in detecting reactivation of latent infections. Multiplex, quantitative real-time PCR assays are now available to detect multiple viruses, including panels of PCRs for detection of respiratory viruses and CNS pathogens [216, 217]. These sensitive techniques are being evaluated carefully in transplant populations for their specificity and for their potential utility as markers of early infection with surveillance monitoring. The impact of community-acquired respiratory viral infections on the development of acute rejection and bronchiolitis obliterans in lung transplantation appears to be significant and warrants further study [218, 219]. Continued vigilance in detecting emerging viral infections and continued study of potential antiviral therapies in the transplant population will likely improve patient survival.

50 Travel Medicine, Vaccines, and Transplant Tourism

Camille Nelson Kotton

50.1 Introduction

As their overall health improves after transplant, transplant recipients may wish to experience foreign travel (including visiting friends and relatives). Such travel may entail exposures to endemic and sometimes unexpected pathogens. Transplant recipients are more likely to have complications from travel-related infections, are less likely to develop protection from vaccines, and are at higher risk for having drug interactions when they take new medications [1]. In addition, active infections and vaccines are immunomodulatory and could potentially impact immunologic tolerance. This review will summarize the medical literature regarding travel medicine and travel-related vaccines in the adult transplant recipient population. "Transplant tourism" (involving travel of either the organ donor or recipient strictly for purposes of organ transplantation) will also be covered here.

A travel medicine specialist familiar with their immunocompromised state and medications should see transplant recipients who wish to travel. Optimal care of this vulnerable population should include up-to-date, comprehensive advice and education on travel medicine, and various methods of protection. Travel health specialists for complex patients should confer with the traveler's other physicians (i.e., transplant physicians) as needed to develop an appropriate plan. Three surveys of transplant centers found insufficient rates of pre-travel counseling and intervention, and significant rates of illness in transplant recipients during foreign travel. In a survey of 267 solid organ transplant (SOT) recipients at the University of Toronto, 95 (36%) indicated that they had traveled outside Canada and the USA; 66% of travelers sought pre-travel advice, primarily from their transplant physician. In general, many of the recommended preventative measures were overlooked: 63% traveled to areas where hepatitis A is endemic, but only 5% had received hepatitis A immunization; 50% traveled to dengue- and malaria-endemic areas, but only 25% adhered to mosquito prevention measures; and 10% reported behaviors that exposed them to blood or body fluids [2]. A review at the Mayo Clinic, Rochester, Minnesota found that of 1130 solid organ transplant recipients, 303 (27%) reported travel outside of the USA or Canada after their transplant; 49 solid organ transplant recipients (16%) traveled to destinations at higher risk for infectious diseases. Travelers to these destinations were more likely to be male (73% vs. 54% of low-infection risk travelers, $P=0.018$) or born outside the USA or Canada (29% vs. 6% $P<0.0001$) [3]. Liver recipients were more likely to travel than other organ recipients. 96% of travelers reported that they did not seek specific pre-travel healthcare before their trip. 24 travelers (8%) required medical attention because of illness; illness was more likely among travelers to high-infection risk (18%) than low-risk (6%) destinations, $P=0.004$. Another cross-sectional, descriptive study of 290 Dutch kidney transplant recipients evaluated their travel health knowledge, attitudes, and practices while staying abroad. 34% had traveled outside Western Europe and Northern America; 22% of these travelers did not seek pre-travel health advice and 29% were ill during their most recent journey [4]. Transplant physicians were most frequently consulted for pre-travel advice (53%). Four of seventeen ill recipients (24%) were hospitalized, reflecting the high morbidity of travel-related disease in transplant recipients.

Optimizing the timing of travel may limit complications. Transplant recipients more than 2 years post-HSCT and who are not on immunosuppressive drugs and without graft-versus-host disease, or solid organ transplant recipients more than 1 year after transplant without heavy doses of immunosuppression or recent treatment for rejection are less immunocompromised and could be better able to face the risks associated with travel [5]. The spectrum and details of immunocompromise seen in transplant recipients are expansive [5, 6]. Those who also have AIDS with low CD4 counts, active leukemia or lymphoma, generalized malignancy, aplastic anemia, graft-versus-host disease, congenital immunodeficiency, or those who have received recent radiation therapy, treatment for rejection after SOT, or significantly immunosuppressive

P. Ljungman et al. (eds.), *Transplant Infections*, DOI 10.1007/978-3-319-28797-3_50

medications. Patients with chronic hepatic disease, chronic renal disease, diabetes, asplenia, and nutritional deficiencies are generally considered moderately immunocompromised, depending on the details of their disease.

In general, many of the recommendations for vaccination are the same in immunocompromised and non-immunocompromised hosts, with a few exceptions [1, 7]. When possible, vaccination for travel after transplant should be started several months before the trip, to allow time for further serologic evaluation and/or possible additional boosters. Emergency travel may present a potentially high-risk situation in which passive immunization could be used, such as administration of intramuscular immunoglobulin (i.e., gamma globulin) to protect against hepatitis A virus and other infections. To optimize the immunologic response, immunocompromised hosts should be vaccinated during periods of no or low exogenous immunosuppression when possible, i.e., before solid organ transplant, or well after HSCT. Vaccination may be avoided in the initial 3–6 months after SOT or hematopoietic stem cell transplant (HSCT), since this is usually their period of highest immunosuppression [8–10] when vaccines are less likely to trigger a robust immune response, and also to avoid confusion with early graft dysfunction or rejection. Whether vaccinations could contribute to acute rejection or graft-versus-host disease has been an area of debate, although this seems unlikely based on the available data.

Measurement of antibody titers following immunization may sometimes be useful. In general, a fourfold increase in titer is often considered evidence of seroconversion, and titers above a certain levels are considered evidence of seroprotection; both of these concepts were derived from data in normal hosts. Transplant recipients are less likely to have a significant immunologic response, although partial protection may be useful. Immune responses to vaccination also wane more rapidly. Booster doses of vaccine are occasionally administered to those with lower or undetectable antibody titers, but such practices have not been subjected to rigorous trials nor evaluated for protective efficacy.

50.2 Routine Vaccines

Adults often miss standard vaccines [11] and transplant recipients are no exception [12]. Some physicians, perhaps concerned about causing harm, may elect to skip vaccination of this vulnerable population. Annual recommendations for routine adult vaccinations, including immunizations for immunocompromised individuals, are available through the Advisory Committee on Immunization Practices and the Centers for Disease Control and Prevention website; other recent publications also have helpful travel-related guidelines for immunocompromised hosts [1, 6, 13–19]. Table 50-1 includes information on both routine and travel-related vaccinations in immunocompromised hosts.

HSCT recipients lose immunologic memory of previous exposure to infectious agents and vaccines, and therefore need to be revaccinated. There are numerous collaborative guidelines for revaccination after HSCT [20–22]. Standard recommendations for revaccination after HSCT include diphtheria and tetanus toxoids, pertussis vaccine, *Haemophilus influenza* type B conjugate, 23-valent polysaccharide and 13-valent conjugate pneumococcal vaccine, inactivated influenza and polio vaccines, and live attenuated measles–mumps–rubella vaccine, as well as others [23]. Re-immunization protocols may vary among transplant centers but should be considered in all recipients.

Tetanus is rare in the industrialized world, where vaccination rates are quite good; it has a much higher prevalence in resource-poor regions, although is still rare among travelers. Tetanus boosters are routinely recommended for SOT and HSCT recipients and should be up-to-date before traveling. Diphtheria is common in resource-poor regions with 5–10% mortality among normal hosts despite therapy. A diphtheria antibody level of >0.1 IU/mL suggests adequate protection. Patients with a lower titer and those vaccinated more than 10 years prior to travel should be revaccinated before entering an area in which diphtheria is endemic or resurgent. For immunocompromised travelers entering high-risk areas, diphtheria antibody levels may be measured a month or more after vaccination. Acellular pertussis vaccine is included in the combination vaccine with tetanus and diphtheria called Tdap. This has not been studied in immunocompromised hosts thus far, but could be considered for use in the appropriate setting [7].

Vaccination against influenza should occur annually in most immunocompromised hosts [7, 24]. Vaccination may be delayed in those who underwent transplantation, treatment of rejection, or other profound immunosuppression in the past few months, balancing the risks of infection with the likelihood of developing an immune response. Given the year-round influenza activity in the tropics, it may be prudent to vaccinate all immunocompromised travelers to those areas if they were not vaccinated within the past year. Influenza immunity wanes and it is not known whether such travelers should be given booster vaccines prior to travel. Pneumococcal vaccine should be given to immunocompromised hosts [24], and it may be sensible to vaccinate before travel. Data suggests that immunity to pneumococcal vaccine wanes more rapidly in renal transplant recipients, and conjugate vaccine does not improve the durability of response when compared with the polysaccharide vaccine [25]. Current guidelines recommend the use of conjugate pneumococcal vaccine followed by the polysaccharide vaccine [24, 26].

Measles is a global illness, with approximately 30 million cases annually, resulting in approximately 750,000 deaths. Measles vaccination in the USA is usually performed with a trivalent live viral vaccine (measles–mumps–rubella [MMR] vaccine). Live vaccines are generally contraindicated in immunocompromised individuals [5, 7, 15, 24, 27, 28].

Table 50-1. Vaccination in transplant recipients

Vaccine	Recommendation
Routine vaccines	
Influenza-parenteral	Yearly
Influenza-intranasal[a]	Contraindicated in patients/family members
Pneumococcal polysaccharide & conjugate	Recommended, with boosters
Tetanus/diphtheria/pertussis	Recommended
Human papilloma virus	Recommended
MMR[a]	Contraindicated
Varicella[a]	Contraindicated
Varicella zoster[a]	Contraindicated
Vaccines for selected transplant recipient travelers when indicated by destination and/or circumstances	
Bacille Calmette-Guerin[a]	Contraindicated
Hepatitis A	Recommended when indicated
Hepatitis B	Recommended when indicated
Japanese encephalitis	Recommended when indicated
Meningococcal polysaccharide	Recommended when indicated
Meningococcal conjugate	Recommended when indicated
Polio (OPV)[a] (oral)	Contraindicated in patients/family members
Polio (IPV) (injectable)	Recommended when indicated
Rabies	Recommended when indicated
Salmonella typhi Ty21a[a] (oral)	Contraindicated
Typhim Vi (injectable)	Recommended when indicated
Yellow fever[a]	Contraindicated

Adapted from "Advising Travelers with Specific Needs: The Immunocompromised Traveler" in Centers for Disease Control's "Health Information for International Travel" [5], the "Advisory committee on immunization practices recommended immunization schedule for adults aged 19 years or older--United States, 2015" [24], "Travel medicine and transplant tourism in solid organ transplantation" [1], and the "2013 IDSA Clinical Practice Guideline for Vaccination of the Immunocompromised Host" [7].
[a]*Live, attenuated.*

Although some pediatric data suggests vaccination may be immunogenic and without complications [29, 30]. Prior to travel to endemic areas, documentation of serologic evidence of immunity against measles, mumps, rubella, and varicella should be considered in transplant recipients. Immune globulin should be considered for measles-susceptible, immunosuppressed travelers who travel to measles-endemic countries and are at risk for exposure [31]. In general, MMR could be given to patients at least 24 months after HSCT and not on immunosuppressive medications [7, 21, 22].

Immunization against hepatitis B before travel may be indicated for certain immunocompromised hosts, including those living in endemic areas for extended periods, those with new sexual partners while traveling, or who are likely to need transfusions or medical procedures. Compared to the immune response following immunization pre-transplantation [15, 27], the efficacy of standard hepatitis B vaccination is reduced after transplantation (with response rates of 5–15%) [32]. In comparison, 20 liver transplant patients given extra doses of hepatitis B vaccine with one of two new adjuvants demonstrated a serologic response rate of 80% [33]. A group of 24 renal transplant patients who did not respond to intramuscular vaccine had an overall response rate of 63% to a series of eight intradermal vaccinations followed by an intramuscular vaccination [34]. For immunocompromised adults, some authorities recommend immunization with a vaccine containing 40 mcg of hepatitis B surface antigen (i.e., two 1 mL Engerix-B® vaccines, each containing 20 mcg, or a special formulation of Recombivax-HB®) given at one site, in a three- or four-dose schedule [35], although this regimen has been predominantly evaluated in dialysis patients. In a cohort of 292 recipients of unrelated or related allogeneic hematopoietic cell transplants given recombinant hepatitis B vaccine, 64% of patients seroconverted; in multivariate analyses, response was adversely affected by age older than 18 years and history of prior chronic graft-versus-host disease but not by donor type or by use of T-cell depletion, adoptive immunotherapy, or rituximab [36]. Interestingly, 89% of the non-responders mounted a threefold or greater rise in polio titers following 3 doses of inactivated poliovirus, thus the response to vaccination can be variable.

Varicella is less common in childhood in the tropics, especially in rural areas, and thus it is more common for an adult to have chickenpox than in the higher latitudes. Varicella (Varivax®) and varicella zoster (Zostavax®) vaccines are lower and higher doses, respectively, of the attenuated live Oka strain of varicella and in general their use should be deferred in transplant recipients until there is more data regarding their safety [24]. When possible, patients who are

seronegative for varicella should be vaccinated with two separate doses of varicella vaccine at least 1–3 months before undergoing exogenous immunosuppression, i.e., pre-solid organ transplant. There are several small studies in carefully selected pediatric SOT recipients given varicella vaccine, but similar data has not yet been shown in adult SOT recipients. One pilot study of 9 autologous HSCT recipients who were seropositive for varicella and who were vaccinated 3–4 months after HSCT with the Oka strain demonstrated a boost in varicella-specific cellular immunity as measured by lymphocyte proliferation, without significant systemic side effects [37]. One of the nine subjects developed varicella zoster at 3 months after vaccination. Heat-killed varicella vaccine was shown to be effective in HSCT recipients when given before and during the first 90 days after transplant but is not available outside of research settings [38].

50.3 Travel-Associated Infections and Recommended Immunizations

50.3.1 Hepatitis A

The risk of hepatitis A in non-immune travelers in resource-poor regions has been estimated to be 1 in 1000 per week for those on a usual tourist route, and 1 in 200 for those on more adventuresome travel [39]; a recent Swiss study showed much lower rates, with an actual incidence of hepatitis A in travelers to countries of high or intermediate risk of transmission of 3–11 per 100,000 person-months abroad for all travelers [40]. Hepatitis A could be a devastating illness in immunocompromised hosts. Pooled immunoglobulins, given as intramuscular gamma globulin, are 85–90% effective at protecting against hepatitis A infection, although this effect only lasts for 3–6 months (dependent on dose given). Some transplant recipients with hypogammaglobulinemia are given routine immunoglobulin repletion with intravenous immunoglobulin (IVIG); this dose is much higher (0.66 mL/kg, delivering at least ~100 mg/kg immunoglobulin) than the dose used for gamma globulin (0.02 mL/kg, the dose recommended for 3 months protection against Hep A, which delivers ~3 mg/kg immunoglobulin) and such patients would not need additional antibody protection. The preparations are similar, although IVIG has had immune aggregates removed such that it can be given safely intravascularly.

Hepatitis A vaccine is less effective in solid organ transplant recipients. In a study of 37 hepatitis A seronegative liver transplant recipients who were given hepatitis A vaccine 6 months apart, only 8% had seroconverted at 1 month following vaccination, and only 26% at 7 months (1 month after the second vaccination) [41]. In another study, zero of eight liver transplant recipients responded to the two doses of vaccine given 2 months apart [42]. In a third trial, liver and renal transplant recipients (39 in each group) received 2 doses of hepatitis A vaccine 6 months apart [43]; response after the primary dose occurred in 41% of the liver transplant patients and 24% of the renal transplant patients, while after the second dose, the respective conversion rates were 97 and 72%. A recent study of kidney transplant recipients showed a seroconversion rate of only 27% after two doses of vaccine [44]. Discrepancies between studies may be explained by differences in patient selection, severity of liver disease, immunosuppressive medications, and type of vaccine used. Importantly, organ transplant recipients have a more rapid antibody decline than controls: 2 years after vaccination, only 59% of liver transplant and 26% of renal transplant recipients who had seroconverted retained protective titers [45], in contrast to mathematical models of vaccination in normal hosts which predict antibodies to persist for at least 20–25 years [46]. Hepatitis A vaccine has not been well studied in the HSCT population, although a recent publication showed a seroconversion rate of 77% [47].

Overall, hepatitis A vaccine among transplant recipients results in attenuated rates of immunologic response and shortened durability. Use of higher or three or more doses of hepatitis A vaccine has not been studied in the immunocompromised population. If there is enough time before travel, it may be useful to vaccinate SOT recipient travelers with two doses of hepatitis A vaccine 6–12 months apart when the transplant recipients are at least a year after transplantation and are on a modest dose immunosuppressive regimen; titers could be checked to document seroconversion. SOT recipients who do not have adequate time before travel or do not respond to immunization should be given intramuscular immunoglobulin prior to travel [5].

50.3.2 Salmonella enterica serovar Typhi

An estimated 21 million cases and 222,000 typhoid-related deaths occur annually worldwide, according to the WHO (http://www.who.int/immunization/diseases/typhoid/en/). Approximately 400 cases of typhoid fever are reported in the USA each year, with 90% related to international travel, of which >75% involved India, Bangladesh, or Pakistan [48]. Severe complications can occur in immunocompromised individuals during infection with *Salmonella enterica* serovar Typhi and they should be immunized against typhoid prior to travel to endemic areas. There are currently two vaccines commonly available: the injectable polysaccharide vaccine (Typhim Vi®, Aventis Pasteur SA), and the oral live, attenuated vaccine Ty21a (Vivotif®, Berna). The live oral typhoid vaccine has not been shown to cause disseminated disease; however, for theoretical reasons, the inactive parenteral vaccine should preferentially be administered to immunocompromised individuals. While data are minimal in immunocompromised hosts, the immune response in immunocompromised hosts to either typhoid vaccine is usually

poor. A study of HIV positive patients vaccinated with the injectable polysaccharide vaccine found lower levels of antibody against *Salmonella enterica* serovar Typhi in vaccinated HIV-infected individuals compared with vaccinated healthy controls; the antibody responses in patients with CD4 cell counts of <200 cells/mm^3 were significantly lower compared with patients with ≥200 cells/mm^3, with geometric mean titers of antibodies to the *Salmonella* Vi antigen of 4 versus 35 arbitrary units (versus 106 in healthy volunteers), suggesting that HIV-infected individuals, even after vaccination, are more susceptible to an infection with *Salmonella typhi* when traveling to countries with a high incidence of typhoid fever [49]. Typhoid vaccination has not been well studied in HSCT and SOT recipients. As a relatively well-tolerated vaccine in general [50], and given the significant morbidity and mortality with typhoid fever, it may be prudent to vaccinate these populations with the injectable vaccine when they travel to endemic areas [48].

50.3.3 Polio

Poliomyelitis caused by wild-type poliovirus has been eradicated from the Western hemisphere; wild-type virus exists in sub-Saharan Africa and South Asia. Outbreaks of vaccine-associated poliomyelitis occasionally occur, due to neurovirulent reversion of live attenuated poliovirus from the oral polio vaccine. Vaccine-associated outbreaks of poliomyelitis have recently occurred in Hispaniola (Haiti and the Dominican Republic), the Philippines, Madagascar, and Cape Verde. Worldwide, two forms of the polio vaccine are available: the orally administered, live, attenuated virus (OPV or Sabin), and the injected inactivated poliovirus vaccine (IPV or Salk). Since attenuated vaccine strain polioviruses may spread through fecal–oral contact, transplant recipients and household contacts of immunocompromised individuals should not receive OPV. OPV is no longer distributed in the USA and Canada. Travelers should have received a primary series of polio vaccine during childhood and at least one booster as an adult. Some authorities recommend booster immunization if more than 10 years have elapsed since administration of the last polio vaccine, especially for individuals traveling to areas of the world with a polio outbreak or with circulating wild-type polio viruses.

The longevity of the response to revaccination with poliovirus after allogeneic stem cell transplant was studied in 134 patients who were given three doses of trivalent inactivated polio vaccine starting 12 months after HSCT and who survived at least 5 years after vaccination with a mean follow-up of 8 years (range, 1–19 years) [51]. 21 (15.6%) patients became seronegative to at least one of the poliovirus serotypes during follow-up; in multivariate analysis, the only risk factor for loss of immunity was younger patient age, and there was a strong trend for patients with chronic graft-versus-host disease to lose immunity more rapidly. All 14 patients given a booster dose of an inactivated poliovirus vaccine responded. Poliovirus immunity was thus shown to be retained long term after revaccination in most patients after allogeneic SCT. Response to vaccination after SOT has not been well studied, although should be considered in anyone traveling to an endemic regimen.

50.3.4 Meningococcus

Meningococcal disease has high case-fatality rates (5–15%). In the USA, a quadrivalent polysaccharide (*Neisseria meningitidis* A, C, Y, W-135) vaccine has traditionally been used; a similar protein conjugate vaccine was more recently approved for use. The meningococcal vaccine is indicated for individuals traveling to areas of the world with known outbreaks of invasive meningococcal disease, those traveling to the meningitis belt of sub-Saharan Africa (especially during the dry winter months of December through June), and for those traveling to Saudi Arabia for the Muslim pilgrimages of *hajj* or *umra*, where proof of vaccination is required. The response of solid organ transplant recipients to immunization with the quadrivalent protein meningococcal vaccine is poor, less than 50% were able to mount an immune response [52]. The majority of 44 patients who were given the vaccine 8 or 20 months after HSCT had significant immune responses to serogroups A and C; these responses were higher in individuals 20 months after transplantation than 8 months after transplantation and declined sharply over the first 6–12 months after vaccination suggesting revaccination should be considered for those at risks of exposure to meningococcal infection [53]. Data in pediatric patients after HSCT [54] suggests a good response to meningococcal serogroup C vaccination, while a less robust response was seen in pediatric oncology patients [55], especially those on chemotherapy or with lower B cell counts. Whether booster doses or combinations of polysaccharide and protein conjugate vaccinations are indicted is not clear for meningococcal vaccination; a study of pneumococcal polysaccharide and protein conjugate vaccinations in pediatric SOT did not show significant boosting [56]. A recently developed serogroup B vaccine may provide additional protection [57]. As transplant recipients are more likely to have significant morbidity and mortality from meningococcal disease, vaccination would seem prudent for those with potential exposure; safety and efficacy remain to be ascertained.

50.3.5 Yellow Fever

Yellow fever, a mosquito-borne viral hemorrhagic fever with a high case-fatality rate, occurs in tropical regions of South America and sub-Saharan Africa and kills an estimated 30,000 people every year. Case fatality may surpass 20% in normal hosts; no specific treatment exists. Yellow fever may

be a risk for travelers to endemic countries. The yellow fever vaccine contains a live attenuated viral strain and is distributed only through Department of Public Health-certified vaccination centers, including travel clinics and some county health departments.

As a general rule, the yellow fever vaccine should not be given to immunosuppressed individuals [5, 15, 58–60]. While a few mildly immunosuppressed travelers have tolerated the vaccine (including individuals with early HIV infection or a distant history of hematological malignancy not currently being treated with immunosuppressive agents) [61–64], complications including death have been reported in immunosuppressed individuals [5, 65]. Optimally, the immunocompromised traveler should avoid regions where yellow fever is endemic, or decrease risk by avoiding travel to those regions during peak season (i.e., January–March in Brazil, and July–October in rural West Africa) [5]. Transplant recipients should understand the risks of travel and minimize exposure to mosquitoes. When vaccination is deferred, a physician's letter stating contraindications to vaccination is acceptable to most governments. Such letters should bear the stamp of an official, approved yellow fever immunization center. Some countries may deny entry without immunization [5]. Family members of immunosuppressed persons may receive yellow fever vaccine.

When given prior to transplant, yellow fever vaccine has been shown to provide protection after SOT; in a series of 53 SOT recipients (including 29 kidney and 18 liver recipients) vaccinated prior to transplant, all but one (98%) had protective titers of neutralizing antibodies at a median duration of 3 years (range, 0.8–21 years) after transplant [66], suggesting adequate protection. However, the Advisory Committee on Immunization Practices 2015 guidelines, which state that a single primary dose of yellow fever vaccine provides long-lasting protection and is adequate lifetime protection for most travelers, recommend that HSCT recipients who had a dose of yellow fever vaccine pre-transplant and who are sufficiently immunocompetent to be safely vaccinated (generally, more than 2 years out from HSCT, without GVHD, and not on immunomodulatory therapy [5]) should be revaccinated before their next travel to yellow fever virus endemic regions, as prior immunity wanes significantly [67].

50.3.6 Rabies

Many travelers are at an increased risk of exposure to rabid animals while traveling. Long-term travelers, individuals expecting intense animal exposure, and individuals who plan to be far from medical care should be considered candidates for pre-travel immunization against rabies. Since transplant recipients may not mount adequate antibody responses to the rabies vaccine (titers >0.5 IU/mL are considered adequate), some authorities recommend administration of human rabies immunoglobulin (HRIG) after all at-risk exposures (normally, HRIG is only given to previously non-immunized individuals) [68]. Intradermal administration of rabies vaccines may result in variable immune responses even in immunocompetent individuals and is not recommended by most authorities. Data are minimal in SOT and HSCT recipients. One study of seven HIV+ patients with low CD4 T lymphocyte counts (<200 cells/uL) found poor neutralizing antibody responses to pre- and post-exposure rabies vaccination (even with doubling of the intradermal doses of cell-culture rabies vaccine); three HIV-infected patients with higher CD4 T lymphocyte counts (range 295–472 cell/uL) tended to have better antibody responses to post-exposure rabies vaccination [69]. Since transplant recipients may be less likely than others to participate in adventure travel or to spend long amounts of time away from civilization, vaccination should be considered in those with significant risks factors, and careful post-exposure prophylaxis is strongly advised.

50.3.7 Japanese Encephalitis

Japanese encephalitis (JE) may cause up to 10,000 deaths annually in Asia. Immunization against Japanese encephalitis should be considered for individuals with intense rural travel in areas of Asia endemic for JE, especially during periods of increased transmission [70]. The JE vaccine is an inactivated viral vaccine (although can be live attenuated, which should be avoided in transplant patients on active immunosuppression) and estimated to be 80–90% effective; hypersensitivity reactions in immunocompetent individuals occur in 0.6% of recipients and include generalized urticaria and/or angioedema, and less rarely neurologic adverse reactions including acute disseminated encephalomyelitis. The efficacy of the JE vaccine is largely unstudied in adult transplant recipients. In a trial in Thailand in pediatric HSCT recipients, 9/18 (50%) seroconverted at 3 months after a live attenuated single JE vaccination, although only 3/9 of these patients had sustained protective titers; 7/9 (78%) seroconverted at 3 months after a second JE vaccine injection, and all of these patients sustained protective titers at 12 months [71]. Another study showed that 7/8 pediatric living donor liver transplant recipients seroconverted when given inactivated JE vaccine >1 year after transplant [29].

Since this vaccine is more likely to elicit systemic reactive side effects, careful observation after administration with an eye to transplant graft function would be prudent.

50.3.8 Bacille Calmette-Guerin

Bacille Calmette-Guerin (BCG) is one of the most commonly administered vaccines in the world; a live, attenuated strain of *M. bovis*, it is used to prevent tuberculosis, especially in infants and children. BCG is rarely given in the travel medicine setting, and should be deferred in immunocompromised hosts, as they can develop a disseminated

infection. No specific prophylaxis other than infection control measures have been shown to be helpful in the immunocompromised population. IC hosts may wish to wear masks when in healthcare settings in areas endemic for tuberculosis. Pre- and post-travel tuberculosis skin tests with the purified protein derivative (PPD) or the newer gamma-interferon-based testing may be helpful, although they are more likely to be falsely negative in the immunocompromised population.

50.4 Vaccination of Close Contacts of Immunocompromised Hosts

Close contacts of transplant recipients could transmit some live, attenuated vaccine strains to the immunocompromised host. In general, certain live viral vaccines (including oral polio, nasal influenza, and smallpox vaccines) should be deferred from use in close contacts of immunocompromised hosts. Administration of other live vaccines such as measles, mumps, rubella, yellow fever, oral Salmonella, varicella (Varivax®) [72], and zoster (Zostavax®) vaccines are less likely to be transmitted and may be given to close contacts of immunocompromised hosts. If a rash develops with varicella vaccine, the immunocompromised host should avoid direct contact with the rash.

50.5 Non-Vaccine Preventable Illness and Immunocompromised Hosts

Diarrhea is the most common illness of travelers, affecting 10–60% of travelers to developing regions. Travelers' diarrhea may be life threatening to travelers with compromised immune systems. Dehydration may compromise renal function, and markedly increase toxicity of immunosuppressive agents such as tacrolimus. Complications of diarrhea may include bacteremia, metastatic seeding, and altered intestinal absorption (with concomitant alterations in the absorption of oral immunosuppressive medications). The oral cholera vaccine, available outside of the USA, has not been studied in immunocompromised hosts but has been safe in populations of healthy people and may provide protection. Prior to international travel, organ recipients should be instructed in appropriate food and water precautions. In general, SOT recipients should be cautioned to drink boiled or bottled water and other beverages, and to avoid food sold by street vendors and raw foods (except fruit and vegetables that can be peeled). If transplant recipients develop diarrhea for more than 1–2 days while traveling, especially with fever, vomiting, and/or bloody stools, they should consider seeking medical attention, and they should carry appropriate self-treatment such as ciprofloxacin or azithromycin. Due to microbial resistance, trimethoprim–sulfamethoxazole is generally ineffective against travelers' diarrhea. There are no data regarding the use of antimotility agent in transplant recipients with diarrhea, but such agents may serve to delay clearance of toxins from the gut. In the gastrointestinal tract, bismuth subsalicylate (i.e., Pepto-Bismol) is converted to salicylic acid and insoluble bismuth salts; transplant recipients with decreased renal function may be at higher risk for salicylate toxicity. Prophylaxis against bacterial traveler's diarrhea with daily antibiotics is rarely indicated and should only be considered for short-term use, after considering the risks of antibiotic resistance, *Clostridium difficile* colitis, potential for drug interactions and side effects.

Respiratory infections are the second most common infection affecting travelers [39]. Endemic fungal pulmonary infections, such as histoplasmosis and coccidioidomycosis in North America, and penicilliosis due to *Penicillium marneffei* infection in Southeast Asia, could be acquired during travel [73]. SOT recipients are at higher risk for invasive fungal infection, and should avoid activities such as spelunking and excavating, activities that have been associated with exposure to *Cryptococcus neoformans* or endemic fungi. The appropriate use of masks may be helpful. For those with significant exposure to tuberculosis, pre- and post-travel testing may be indicated. Interferon-gamma release assays, i.e., Quantiferon TB or T SPOT TB, have been shown to be more sensitive than tuberculosis skin testing in transplant recipients [74].

Travel to the tropics has been shown to result in higher rates of multidrug-resistant Enterobacteriaceae, with travel to these regions posing a risk factor for colonization with such organisms during the first 3 months after return, but not beyond [75]. A survey of travelers from the Netherlands found that 30% acquired extended-spectrum β-lactamase-producing Enterobacteriaceae during travel [76]. Such exposure could be a concern for transplant patients who are more vulnerable to infection.

Malaria and dengue fever are the most common arthropod-borne illnesses of travelers. Most cases of dengue fever are self-limited in the normal host; the risk for complications in transplant recipients is unknown. Malaria is a significant risk for all travelers to endemic areas. Prophylaxis against malaria should be based on the travel itinerary; the CDC Yellow Book provides country-specific guidelines. Transplant recipients should be instructed on ways to minimize insect bites, including use of repellents containing DEET (*N*,*N*-diethyl-3-methylbenzamide), bed nets, protective clothing, and permethrin-impregnated clothing.

Travelers to endemic regions may contract parasitic infections such as *Strongyloides stercoralis* infections, when larvae from contaminated soil penetrate skin or mucous membranes. Unlike other intestinal parasites, *Strongyloides* can replicate inside the human host, which allows the perpetuation of autoinfection; *Strongyloides* infection may persist for decades. *Strongyloides* infection can flourish in the setting of immunosuppression, resulting in hyperinfection.

Travelers should wear socks and shoes to avoid contact with this and other pathogens. Swimmer's itch (due to *Schistosoma* spp.), cryptosporidiosis, and other parasitic infections can be prevented by avoiding swims in non-chlorinated fresh water.

Transplant recipients have a markedly increased risk of skin cancer that correlates with the intensity of sun exposure, and it is important to recommend the use of hats, sunglasses, protective clothing (also useful for arthropod-borne infections), and sun protection lotions with ultraviolet A and B protection.

Travelers who rapidly ascend to altitude are at risk for altitude sickness. Acetazolamide accelerates acclimatization and decreases the risk of altitude sickness [77]; its use in organ transplant recipients is unstudied. Travelers to high attitude should be advised to avoid vigorous activities for the first few days at altitude. Acetazolamide should be offered to those travelers ascending rapidly to greater than 2500 m since there is at least a 15–25% risk of altitude sickness.

Drug interactions are of particular concern in transplant recipients, and they should be cautioned about using new medications that may be given by unknowledgeable practitioners or purchased "over the counter." Chloroquine can increase serum levels of cyclosporine and perhaps sirolimus and tacrolimus. Data are limited regarding other possible interactions between travel-associated drugs and immunosuppressive medications (Table 50-2). Short courses of ciprofloxacin or azithromycin for travelers' diarrhea seem unlikely to have a major impact on cyclosporine levels.

Acquisition of new virus should be avoided, either by safer sex practices, use of clean needles and syringes or avoidance of blood transfusions in foreign countries. Sterile needles and syringes may be given to a traveling transplant recipient with a physician's letter stating they are for medical use. Patients with end-stage renal disease, either prior to or after organ transplant, and who undergo hemodialysis in resource-limited countries, where suboptimal infection control policies pose a risk of exposure to blood-borne viruses, are at significant risk of acquiring new viral infections A number of cases of hepatitis C have been reported in Western travelers to the Indian subcontinent, Tenerife, Saudi Arabia, Singapore, and Slovakia [78, 79]. Such exposures may have an impact on policies in transplant centers regarding evaluation of those on the waiting list for solid organ transplant [80].

Educational topics for traveling transplant patients are covered in Table 50-3, and many of these points should be emphasized both during travel medicine visits and by the transplant clinicians discussing travel.

50.6 Transplant Tourism

Medical tourism has emerged as a global health care phenomenon, estimated at $60 billion worldwide in 2006 [81]. Transplant tourism, defined as travel with the intent of receiving or donating a transplanted organ, has grown tremendously in the past decade. While "emotionally related" transplants may be occurring in these regions, the majority is likely to be for payment to the donor, also known as "commercial transplants." A review of US national waiting list data identified 373 foreign transplants (173 directly noted; 200 from data validation); most (89.3%) were kidney transplants, and male sex, Asian race, resident and nonresident alien status, and college education were significantly and independently associated with foreign transplant in 35 countries, led by China, the Philippines, and India [82]. Numerous international transplant organizations, including The Transplantation Society and The International Society of Nephrology, have made major efforts to decrease such purchase and sale of organs on ethical grounds [83]. The practice of "transplant tourism" is relatively common and increasing, nonetheless, and transplant clinicians should be aware of the infectious disease risks [84, 85].

Table 50-2. Interactions between transplant and travel-related medications

	Calcineurin inhibitors (CNI)	Trimethoprim/sulfamethoxazole	Sirolimus, everolimus
Azithromycin	May ↑CNI levels		
Mefloquine	May ↑CNI levels	May increase risk of cardiac toxicity, QT prolongation, torsades de pointes or cardiac arrest	May ↑ sirolimus levels
Atovaquone-proguanil		May increase risk of proguanil of bone marrow toxicity	
Doxycycline	May ↑CNI levels		May ↑ sirolimus levels
Chloroquine	May ↑CNI levels	May increase risk of cardiac toxicity, QT prolongation, torsades de pointes or cardiac arrest	
Ciprofloxacin, levofloxacin	May increase risk of cardiac toxicity, QT prolongation, torsades de pointes or cardiac arrest		
Primaquine	May ↑CNI levels		
Sulfadoxine/pyrimethamine	May ↓CNI levels	May increase risk of bone marrow toxicity	
Acetazolamide	May ↑CNI levels		

Significant interactions of travel medicines and azathioprine, mycophenolate mofetil, and corticosteroids have not been reported; significant interactions of transplant medicines and diphenoxylate hydrochloride and atropine sulfate tablets or loperamide have not been reported; minimal data available. Adapted from MicroMedex® DrugReax® interactive drug interactions and Lexi-Comp OnlineTM interaction analysis.

TABLE 50-3. Educational topics for transplant recipients who wish to undergo travel

Timing of travel after transplant (>1 year for SOT, >2 years for allo-HSCT)
Destination and level of risk of infectious complications, availability of medical care for transplant patients
Clean food and water; administrations of antibiotics and hydration with significant diarrhea
Mosquito and insect precautions
Avoiding blood-borne infections from transfusions, injections, tattoos, and avoiding sexually transmitted diseases
Carry extra transplant medications, first aid kit
Sun protection
Drug interactions and risks of fake medications
Risk of *Vibrio* infections from ocean water (especially with liver disease)
Notify clinicians about recent travel if ill upon return

A meta-analysis comparing the risks of participating in transplant tourism by acquiring a kidney abroad to the risks associated with domestic kidney transplant demonstrated that transplant tourists are significantly more likely to contract cytomegalovirus, hepatitis B, HIV, post-transplantation diabetes mellitus, and wound infection than those receiving domestic kidney transplant, with lower patient- and graft-survival rates [86]. Many of these organ transplants are not recorded in databases, so the incidence of infection is unknown. The extent and quality of the pre-transplant evaluation of the donor and recipient is likely to be quite variable. When serologic evaluation is performed, the quality of the testing may be substandard. A significant number of foreign-born transplant recipients will return to their country of origin for organ transplants, and are at risk both for reactivation of latent infections as well as acquisition of new indigenous infections; knowledge of the specific infections existing in those regions, as outlined in a recent review [87], can direct further evaluation. Documentation and communication with the transplant center may be limited, and prophylaxis against infection may be imperfect [88].

Rates of hepatitis B, HIV, and other infections may be much higher in certain regions, including Asia. One review found new, transplant-related infections of HIV at rates of 4–6% and hepatitis B at rates of 2–12% in recipients who had undergone commercial transplants in foreign countries [88]. In a study comparing 540 patients who had received commercial renal transplants in India between 1978 and 1993 with 75 recipients of emotionally related renal transplants performed at two participating institutions in the Middle East, they found that graft-survival rates were similar, but that there was a higher incidence of human immune deficiency virus (HIV) infection (5% vs. 0%), and hepatitis B virus infection rate (8% vs. 1%) [89]. A case report from England documents de novo hepatitis B infection in a patient who received a renal transplant in India, with subsequent infection of 4 patients in England (due to breaks in infection control practices), including another renal transplant recipient and his wife [90].

Several institutions in more industrialized countries have described their experience with transplant tourism, and the subsequent risks of infection. A series from Turkey compared 115 patients who had been commercially transplanted in various countries (India (106 cases), Iraq (7 cases), and Iran (2 cases)) and subsequently seen at their center for post-transplant care between 1992 and 1999 with those with a living related transplant performed at their center [35]. The post-transplant course in the commercially transplanted recipients was more complicated, with infections caused by malaria (10 cases), invasive fungal infections and tuberculosis (5 cases each), and pneumonia due to various opportunistic pathogens. A survey of 16 patients in Australia who underwent commercial renal transplantation abroad found higher rates of infectious complications, including 2 who acquired hepatitis B at the time of the transplant and subsequently died from the infection [88]. A review of 10 patients who underwent evaluation for transplant in Minnesota and subsequently had transplants abroad (8 in Pakistan (all Somali origin), one in China (Chinese origin), and one in Iran (Iranian origin)) found that complications were primarily infectious, with six potentially life-threatening infections in four patients, including severe wound infection, *Acinetobacter* bacteremia/sepsis, central nervous system *Aspergillus* infection, severe urosepsis in 2, and CMV infection [91]. A survey of 18 patients who traveled from western Scotland to Pakistan from 2000 to 2007 for renal transplant found that overall, they did relatively well, with one case of malaria, and no cases of hepatitis B, hepatitis C, or HIV infection [92]. A review of 33 kidney transplant recipients who traveled abroad for transplant and returned to University of California, Los Angeles had post-transplantation outcomes compared with a matched cohort of patients who underwent transplantation at UCLA [93]. Most patients traveled to their region of ethnicity with the majority undergoing transplantation in China (44%), Iran (16%), and the Philippines (13%). Seventeen (52%) patients had infections, with nine requiring hospitalization. One patient lost her graft and subsequently died from complications related to donor-contracted hepatitis B. Almost all of these studies report reduced graft and patient survival, higher infectious complications, and higher rates of rejection.

When these transplant recipients return to transplant centers in industrialized countries, it is prudent to consider screening them for blood-borne pathogens, including HIV, HBV, and HCV, as well as bacteremias, urinary tract infections, and other endemic pathogens depending on their clinical course (malaria, tuberculosis, Chagas disease, etc.). Optimizing their post-transplant prophylaxis against infection and obtaining further information about their surgical procedure(s) and immunosuppression may also help optimize their care.

50.7 Conclusion

Every year there are more transplant recipients with an increasing variety of immunologic deficits. As their health improves, they may wish to travel more frequently. Research on vaccines and transplant recipients in recent years has been quite helpful in eliciting the potential immunogenicity and safety of various vaccines in this population. Hopefully within the next 5 years we will begin to understand more of the immunology in these hosts, which should allow for better vaccination. Improved vaccines, the ability to safely give adjuvants to boost immunogenicity, and more selective immunosuppression may allow for better protection of travelers in this vulnerable population.

In summary:

- Transplant recipients are increasing in number, as is the extent of global travel, thus this issue will continue to expand. Further studies are needed and will help guide clinical management. Prior to foreign travel, it is prudent to have transplant recipients seen by travel medicine specialists familiar with this complex and vulnerable population. Travel vaccines should be guided by the details of the travel in combination with details of the immunosuppressive regimen.
- Transplant recipients are more vulnerable to infection and are less likely to have a strong immunologic response to immunization. Vaccination either before undergoing immunosuppression, or optimizing the time of vaccination after immunosuppression, may help optimize the immunologic response.
- Routine immunization is important to consider and may have been overlooked or avoided in this population. Routine immunization should be considered before patients undergo solid organ or stem cell transplant. In addition, booster doses should be considered, especially after HSCT.
- Although not generally evidence based, additional or higher doses of certain vaccines may result in better protection, as has been demonstrated with hepatitis B vaccine in immunocompromised hosts.
- Immunoglobulin may provide protection against hepatitis A, measles, and other illnesses when the recipient is less likely to have an immunologic response, vaccination is contraindicated, or does not have enough time to develop protection.
- Evaluation of serologic response after vaccination may provide an index of seroprotection and may help guide the use of additional vaccinations. Serologic response is primarily a measure of humoral immunity and does not generally include information on cellular immunity. Even in situations where the antibody titers are low or undetectable, these subjects may be more protected than those that were never vaccinated (i.e., even minimal immunity may be better than none).

Microbiome in Transplantation

Ying Taur

51.1 Introduction

The human microbiota refers to the collective of microorganisms inhabiting the human body, and the human microbiome refers to the aggregate of microbial genomes from that consortium. These complex populations harbor a vast amount of microbe-to-microbe diversity, but also vary greatly from person-to-person and body site-to-body site [1]. Close ties exist between these microbes and the human they inhabit, performing essential tasks that are mutually beneficial. Given the dependence of human hosts on these microbes for continued health, it may not be surprising that many human diseases have been found to be related to disturbances of the microbiome. Disorders with observed links to the microbiota span many medical disciplines, including *Clostridium difficile* infection, inflammatory bowel disease, obesity, type 2 diabetes, asthma, eczema, and autism [2–6]. The full extent by which the microbiome is linked to human health may not yet be fully realized.

Study of the human microbiota has been made more feasible through significant advances in molecular approaches which allow researchers to profile microbial communities in great detail. Previous approaches that relied on microbiologic culture provide a biased and incomplete view, consisting of a very small subset of microorganisms comprising the microbiota. DNA sequencing data can now be obtained from entire microbial communities simultaneously in parallel fashion, at a fraction of the cost compared with conventional sequencing methods [7]. These approaches have allowed for large scale endeavors such as the Human Microbiome Project, which seeks to comprehensively characterize and catalogue the human microbiome [1], but also smaller studies at the individual investigator level.

The earliest and most commonly used approach is to target and sequence the 16S rRNA gene, a conserved region which can be used to identify bacteria and differentiate to species level. Similarly, ITS1 and ITS2 regions have been used as targets for fungal identification [8]. Metagenomic studies, in which the entirety of DNA of an entire community is sequenced, can be accomplished using shotgun sequencing, in which millions of random genomic fragments are sampled from a microbial community. These methods are more expensive and require more sequencing depth compared with targeted sequencing of 16S or ITS1, but can provide data on functional content of microbes.

The data resulting from amplicon sequencing and whole metagenome sequencing can be analyzed using a variety of methods. Sequences can be matched to reference sequences to infer taxonomic classification or functional content, and/or grouped into clusters of similar sequence identity referred to as operational taxonomic units (OTUs). The relative abundance of various OTUs can be used to calculate estimates of overall diversity in the sample. Shotgun reads can be assembled to determine functionality by matching to functional databases [9].

In addition to DNA sequencing, advances in mass spectrometry methods have given rise to metabolomics, in which the complete set of small molecule metabolites in a particular environment are quantitatively measured. This technology has also been applied to microbiome studies, often complementing sequencing data and providing further understanding of microbial dynamics and its relationship to host.

In the setting of hematopoietic stem cell transplantation (HCT) and solid organ transplantation (SOT), the microbiome has been studied for clinical relevance, using the approaches described above, and has shown itself to be an exceedingly important factor in the outcomes of transplant recipients. This chapter will provide an overview of the structure and function of the human microbiota, including characteristics of its most important and notable members. With this foundation, the relevance of the microbiota in the transplantation setting will be reviewed.

51.2 Overview of Human Microbiome

An adult human body is home to approximately 100 trillion bacteria, distributed over several body sites [10]. Each geographic body site represents a specific microbial niche, each with a distinctive composition and based on surrounding environmental factors [1]. The microbiome within the gastrointestinal tract is the most well-studied ecosystem, which has demonstrated numerous orchestrated interactions with the host, as well as the clearest links to human health. Moreover, the intestinal microbiota is the largest and houses the greatest variety of bacteria, many of which are not found in any other environment.

The host intestinal tract exerts influence and control over the composition of the microbiota by producing factors designed to resist pathogens and favor beneficial commensal bacteria, including antimicrobial peptides such as defensins [11]. Immune systems specific to the intestinal tract serve to resist translocation and systemic dissemination of bacteria into outside tissues; these include gut-associated lymphoid tissues, such as Peyer's patches, dendritic cells, and specific T- and B-cell subsets [11]. The mucus layer produced by Goblet cells also helps to provide further protection against dissemination. In turn, healthy commensal members of the intestinal microbiota help to modulate these host mechanisms, contributing to microbial stability within the gut lumen.

Under normal circumstances, the intestinal microbiota is largely comprised of anaerobic bacteria that are essentially non-pathogenic and serve a variety of functions that are beneficial to the human host, such as absorption and breakdown of nutrients, production of short chain fatty acids and vitamins, amino acid synthesis, detoxification of foreign substances, maintenance of mucosal wall integrity, and stimulation and development of host immunity [11, 12]. An important function of the healthy microbiota is to promote colonization resistance, which allows the microbial community to resist overgrowth or infection by pathobionts [13]. Many commensal organisms in the gut exhibit this behavior, suggesting a deep and long-lived relationship with their human hosts.

To gain an understanding of the structure and function of the human microbiome, an overview of the bacterial phylogeny of typical microbiome inhabitants is useful. Figure 51-1 shows a phylogenetic tree of common intestinal bacteria. At the phylum level, the four most abundant groups are Firmicutes, Bacteroidetes, Actinobacteria, and Proteobacteria. Of these, Firmicutes and Bacteroidetes have the highest abundance; normally, at least 90% of all intestinal bacteria belong to one of these phyla in human adults. Actinobacteria and Proteobacteria are less abundant but almost always present in a stable gut microbiome. These four phyla are described briefly here.

51.2.1 Firmicutes

Firmicutes are the most abundant phylum in the gastrointestinal tract, typically occupying over half of the microbiota in healthy adults. Included are potential pathogens such as *C. difficile*, *Staphylococcus aureus*, *Streptococcus* spp., and *Enterococcus faecium*. Most members are Gram-positive, but in some cases can be Gram-negative, and metabolically can range from aerobic to obligately anaerobic.

Clostridia represent the largest class within Firmicutes, which house a large number of Gram-positive spore-forming obligate anaerobes. Phylogenetic studies have shown great heterogeneity in these bacteria, and have shown that older classifications of these bacteria were flawed, bringing to light several misclassifications, and at times necessitating revisions of taxonomic classification within these bacteria. One phylogeny-based grouping approach divides Clostridia into approximately 20 clusters, numbered I through XIX, and can be used to differentiate and describe these microbes [14]. These groups demonstrate several lines of divergence within the evolutionary phylogeny of Clostridia, which form the basis of heterogeneity among these bacteria. For the most part, potentially pathogenic Clostridia seem to largely reside exclusively within two clusters: Cluster I, which includes toxin-producing bacteria such as *Clostridium perfringens*, and Cluster XI, which includes *C. difficile* and *Clostridium sordellii*. The remaining clusters, however, constitute a significant portion of the healthy commensal microbiota. In particular, Clostridium clusters IV and XIVa, whose members span the families Ruminococcaceae and Lachnospiraceae, are most abundant and appear to be critically important members. These groups perform beneficial functions such as degradation of complex sugars. *Faecalibacterium prausnitzii* of cluster IV, for example, has been well studied for its ability to degrade sugars in its various forms to short chain fatty acids such as butyrate [15]. Furthermore, these bacteria can modulate inflammation through several mechanisms, such as induction of regulatory T-cells [16, 17]. Lachnospiraceae, a family which includes *Clostridium scindens*, have been shown to have suppressive effects on *C. difficile* infection [18, 19].

Non-clostridial members of Firmicutes include the genera *Streptococcus*, *Enterococcus*, and *Staphylococcus*, which are known for their potential for pathogenicity and are responsible for a great many human infections. Antibiotic resistant forms such as MRSA and VRE are particularly difficult challenges in the clinical setting. Under normal circumstances, these exist in relatively low abundances, and may even participate in breakdown of nutrients [20]. However, expansion and domination can occur in the setting of microbiota perturbation, leading to several important infections, such as bloodstream infection during HCT [21].

51.2.2 Bacteroidetes

Bacteroidetes are Gram-negative anaerobic bacteria that typically inhabit the gut microbiota in high abundance, and include members such as *Bacteroides* spp. and *Prevotella* spp. These bacteria are highly suited for the gut; some members, such as *Bacteroides fragilis*, can only be found exclusively in the gastrointestinal tract of humans. This is evidenced by the fact

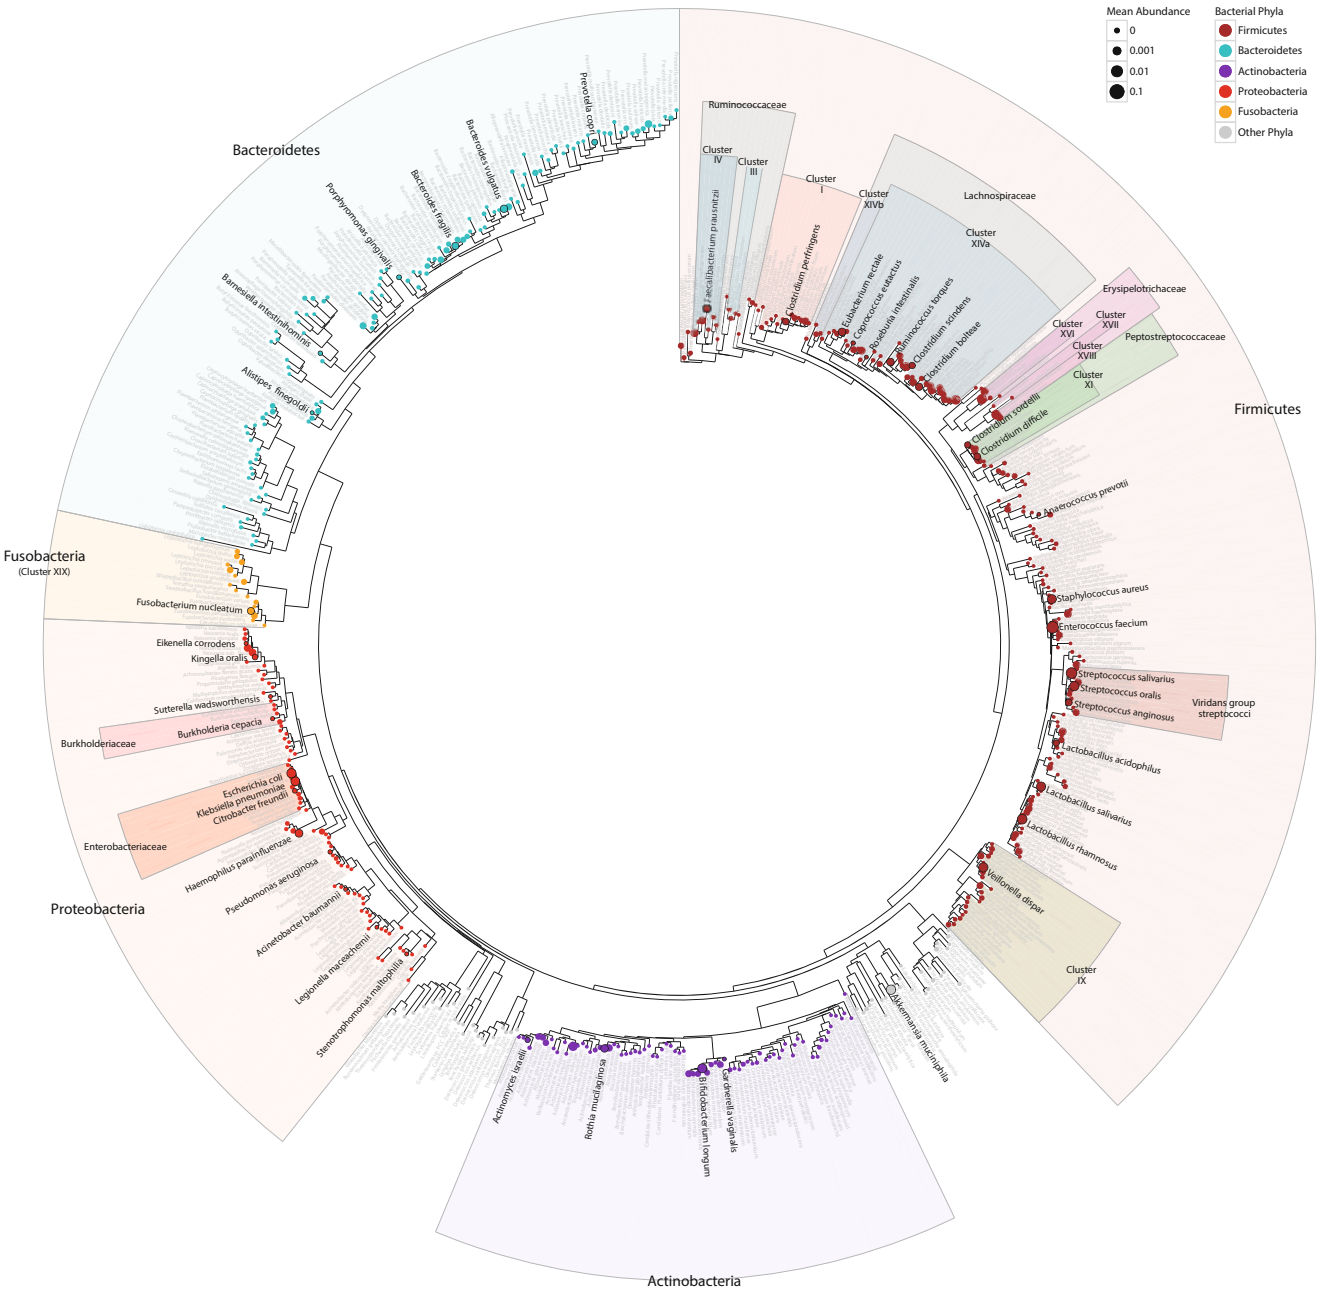

FIGURE 51-1. Phylogenetic tree of most common bacteria found in the human microbiome. *Colored circles* represent single bacterial species, size reflects the approximate mean intestinal abundance observed in HCT recipients. Species labels are listed in *black* for notable or particularly abundant members. *Outer labels* represent the bacterial classification at phylum level; *middle labels* show several bacterial groups at the family level. Clostridium clusters and viridans group streptococci are also labeled; note that these are not true taxonomic classifications.

that Bacteroidetes are specifically selected for colonization by host immunity; stable residence in the gastrointestinal tract is dependent on host–microbe interactions such as toll like receptors [11, 22]. Established Bacteroidetes, in turn, induce the homeostasis of regulatory T-cells [23], making them the most stable.

Bacteroidetes perform essential metabolic conversions important for the host, perhaps most notably the fermentation of complex carbohydrates, with the resulting production of short chain fatty acids, which are absorbed and utilized by the host and other bacteria for energy and maintenance of gut health [24, 25]. Bacteroidetes offer protection against *C. difficile* infection: individuals with recurrent CDI were deficient in Bacteroidetes, and replenishment of Bacteroidetes with fecal microbiota transplantation resulted in durable cure [26, 27].

51.2.3 Proteobacteria

The Proteobacteria phylum is perhaps best known for containing many well-known Gram-negative intestinal pathogens, such as Enterobacteriaceae, a family of bacteria that includes *Escherichia coli* and *Klebsiella pneumoniae*, and *Citrobacter freundii*. Other known pathogens within Proteobacteria include *Pseudomonas aeruginosa*, *Acinetobacter baumannii*, and *Stenotrophomonas maltophilia*. The predilection for various forms of antibiotic resistance in these bacteria has given rise to some of the most difficult-to-treat infections in humans.

Despite its pathogenic members and wide genetic variety observed in culture, Proteobacteria represent only approximately 1 % of a stable gut microbiota, under normal circumstances [28]. However, under aberrant conditions, potentially pathogenic members can bloom, increasing in abundance to become dominant in the microbial space, which can enable certain Proteobacteria to become pathogenic.

51.2.4 Actinobacteria

The Actinobacteria phylum is a group of Gram-positive bacteria that colonize several body sites including gastrointestinal tract and skin. Familiar members of this phylum include *Bifidobacterium* spp., *Propionibacterium acnes*, *Corynebacterium* spp., *Gardnerella vaginalis*, *Actinomyces israelii*, *Nocardia asteroides*, and *Mycobacterium tuberculosis*. Though some are implicated in infections, Actinobacteria in general are highly adapted to stable colonization within humans [29]. In the intestinal tract, members such as *Bifidobacterium* spp. appear early in gut colonization, occupying a significant portion of the intestinal microbiota during infancy. Given their observed beneficial impact on human health, some are formulated in probiotics. These bacteria perform a variety of metabolic functions that are beneficial to the host, including fermentation of simple and complex sugars, deconjugation of primary bile acids to secondary bile acids, and protein degradation [28].

Other functions of Actinobacteria may be relevant in HCT; these bacteria also are known to promote mucosal barrier integrity, enhance secretory IgA, induce regulatory T-cells, and promote colonization resistance against potential pathogens such as Enterobacteriaceae and *C. difficile* [17, 30–34]. These benefits may have been reflected in preliminary observations in HCT; recipients with greater abundances of Actinobacteria were observed to have improved outcome in one study [35].

51.3 The Microbiome in Hematopoietic Stem Cell Transplantation (HCT)

In the transplant setting, allogeneic HCT recipients have been the most extensively studied for clinical ties to the microbiome, particularly in the intestinal tract. This is in part related to the fact that the gut is seemingly at the center of many transplant-related complications. During HCT, recipients are subjected to combination of chemotherapy, total body irradiation, and broad-spectrum antibiotics, which significantly impact host immunity, damage intestinal epithelial linings, and disrupt previously stable microbe communities. These simultaneous insults help explain the frequency of complications such as bloodstream infections, *C. difficile* infection, and graft-versus-host disease.

The importance of the intestinal microbiota in HCT is supported by the observation that patients with low bacterial diversity at the time of stem cell engraftment are significantly more likely to die over the next 3 years compared to those with higher diversity microbial communities [35]. One prospective study showed an association between microbial diversity and transplant-related mortality that was independent of other established risk factors such as disease status, pre-transplant comorbidity, and myeloablative intensity. However, the specific details and potential mechanism of this observed link are still unknown.

Disruption of the intestinal microbiota primarily occurs during the early phase of HCT (Figure 51-2), shortly after administration of conditioning chemotherapy and radiation, along with antibiotics, given either prophylactically or as treatment [21]. The degree by which the microbiome is affected during this period varies greatly from person-to-person, even among recipients undergoing treatment of similar intensity. Some of this heterogeneity can be explained by antibiotic administration. Ultimately however, the factors influencing the degree to which a recipient's microbes can resist the disruption of microbial diversity during transplant are still relatively unresolved. The consequences arising from the perturbation of the intestinal microbiota can be seen in several infectious and non-infectious complications of allogeneic HCT; some are discussed below.

51.3.1 Vancomycin-Resistant Enterococcus (VRE) Bloodstream Infections

VRE bloodstream infections have increasingly become a major cause of bloodstream infection in patients with severe or prolonged absolute neutropenia, such as in the pre-engraftment phase of HCT [36–40]. VRE has become the most common pre-engraftment bloodstream infection at many transplant centers [39].

Numerous studies indicate that antibiotic administration, particularly treatments with activity against anaerobic bacteria, is the primary driver of VRE colonization [41–43]. In this setting, VRE has a remarkable ability to densely populate the small and large bowel, quickly occupying over 98 % of the intestinal microbiota niche [44].

Intestinal domination of the microbiota by VRE is frequently observed in HCT, and has the notable consequence of systemic infection during pre-engraftment neutropenia. Longitudinal study of the intestinal microbiota in alloge-

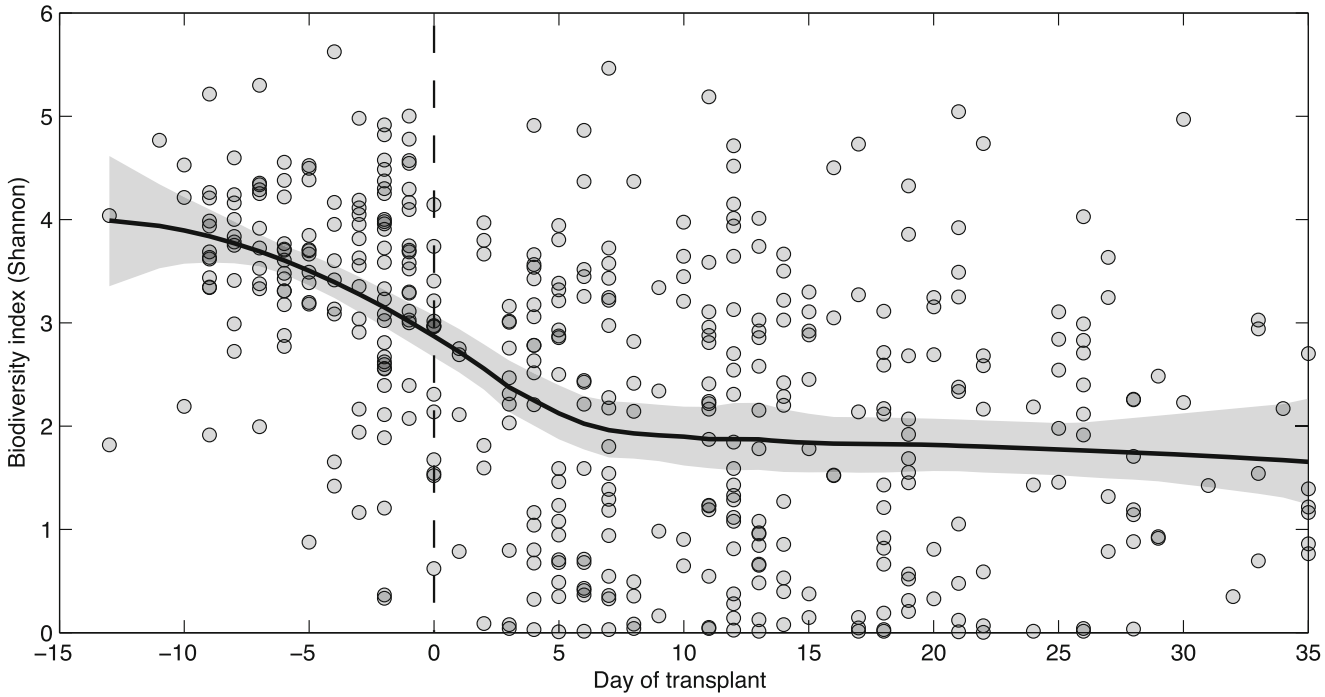

FIGURE 51-2. Changes in microbial diversity within the intestinal tract during allogeneic HCT. Diversity of intestinal bacteria, quantified by Shannon index, is shown for 439 fecal specimens (*circles*) collected serially from 94 patients over the course of transplantation. Intestinal diversity decreases during this time (moving average shown as *solid black line* with 95% confidence interval). Taur Y, Xavier JB, Lipuma L, et al., Intestinal domination and the risk of bacteremia in patients undergoing allogeneic hematopoietic stem cell transplantation, Clin Infect Dis, 2012, 55(7):905–14, by permission of Oxford University Press.

neic HCT has shown that VRE expansion precedes VRE bloodstream infection [21]. This expansion, in turn, is frequently preceded by prior administration with metronidazole, a drug with potent anti-anaerobic activity. This indicates that antibiotic disruption of healthy anaerobic microbiota (e.g., Bacteroidetes, Clostridium clusters IV and XIVa) is a fast and effective route by which VRE can achieve intestinal domination of the intestinal tract. The premise that anaerobic killing leads to VRE expansion is not a new one; a number of older studies using culture-based approaches demonstrate similar findings in other populations [41–43].

Interestingly, unlike metronidazole, administration of intravenous vancomycin is not clearly correlated with VRE colonization. In fact, intravenous vancomycin is less disruptive of the microbiota [21]; this may be related to the fact that gut penetration of intravenous vancomycin is often relatively low, especially if only given for several days [45, 46].

An ongoing subject for study is to determine if the microbiota can be protected against VRE domination, through colonization by specific robust commensal members. Some preclinical murine data indicate that colonization with *Barnesiella* spp., a group of Gram-negative anaerobes within phylum Bacteroidetes, is strongly resistant to VRE domination, and can be transplanted to a naïve gut to confer protection against domination [47].

51.3.2 Gram-Negative Bloodstream Infections

Systemic bloodstream infection with Gram-negative bacteria such as Enterobacteriaceae is of particular concern in patients with severe and/or prolonged neutropenia, which includes the pre-engraftment period in HCT. Prophylactic administration of fluoroquinolones can reduce the incidence of this infection, and is practiced at many transplant centers [48, 49]. Highly antibiotic resistant Gram-negative infections such as carbapenem-resistant Enterobacteriaceae (CRE) are of particular concern, and nosocomial transmission of these pathogens has been studied and documented, using detection of single-nucleotide polymorphisms using whole-genome sequencing [50]. However, transmission and/or colonization with Proteobacteria does not necessarily result in infection, and a robust microbial community can exert colonization resistance to resist expansion of these potential pathogens and maintain them at low abundances.

Study of the intestinal microbiota in HCT demonstrated that prophylactic fluoroquinolone administration markedly reduced the incidence of intestinal expansion by Gram-negative bacteria [21]. Furthermore, intestinal domination by aerobic Gram-negative bacteria is associated with subsequent development of Gram-negative bacteremia, providing confirmation of the gut origin of these infections.

The manner and circumstances in which Gram-negative bacteria achieve intestinal domination remains an active area of investigation. Intestinal inflammation and neutrophil recruitment into the gut may be contributing factors [51–53]. Commensal families such as Porphyromonadaceae, which resides within the Bacteroidetes phylum and contains *Barnesiella* spp. described in the prior section, offers some evidence that it may provide some degree of colonization resistance against pathogenic Gram-negative bacteria [54].

51.3.3 Viridans Group Streptococcal Bloodstream Infections

Viridans group streptococci are known to cause a particularly severe, life-threatening, toxic shock-like syndrome under certain settings of severe or prolonged neutropenia. Risk of this infection is very much determined by conditions and practices favoring oral mucositis, such as pre-engraftment phase of HCT and administration of high-dose cytosine arabinoside [55]. Since viridans group streptococci are known to be particularly abundant in the upper part of the gastrointestinal tract [28], systemic dissemination during neutropenia is most likely during administration of chemotherapy agents that favor upper gut mucosal damage [56]. Centers encountering this infection have adopted prophylaxis strategies to prevent these infections, such as administration of penicillin or vancomycin [57, 58]. Administration of intravenous vancomycin during the peri-transplant period in allo-HCT is currently a routine practice in some centers, and appears to be extremely effective [58], though current treatment guidelines for fever and neutropenia recommend against the routine use of Gram-positive agents such as vancomycin for prophylaxis [59].

It is notable that intravenous vancomycin provides effective prophylaxis against infection by viridans group streptococci, despite the fact that intestinal domination nonetheless occurs in approximately 40 % of HCT recipients, based on one study [21]. As discussed previously, intravenous vancomycin does not penetrate well into the gut lumen [45], so protection against viridans group streptococcal infections presumably takes place at the level of blood, in systemic circulation. This contrasts with fluoroquinolone prophylaxis against Gram-negative infections, where effects on the microbiota can be clearly seen.

51.3.4 *C. difficile* Infection

There is little doubt that *C. difficile* infection (CDI) results from disruption of the intestinal microbiota, due to antibiotic administration and other perturbations. In HCT recipients, rates of CDI are generally felt to be very high in comparison with other patient populations; reported CDI rates typically range from 12 % to 18 %, but can range greatly from as low as 5 % to as high as 30 % [60–66]. This may in part be a reflection of the degree of microbiota dysbiosis experienced by these patients.

Examination of the fecal samples of patients during HCT indicates that about 40 % of patients are asymptomatically colonized with toxigenic *C. difficile* at the start of HCT [66]. It is from this pool of pre-colonized recipients that CDI occurs, suggesting that the high rates of infection in this population cannot readily be explained by nosocomial transmission.

The exact factors and mechanisms that determine the risk of vegetative growth and toxin production by *C. difficile* in the transplant setting and other populations are still unclear. Patients in the non-transplant setting with recurrent CDI demonstrate relatively reduced microbial diversity in their feces [67]. Thus, as a means to restore this lost diversity, fecal microbiota transplantation (FMT) has gained notoriety as an effective way to cure patients with recurrent CDI, often succeeding in instances where other treatments have failed [26]. There are now several published forms of evidence for the effectiveness of FMT [27, 68, 69], including a randomized clinical trial demonstrating substantial benefits in the form of a durable cure [70].

Examination of the microbiota composition for evidence of protective elements against CDI has brought to light several commensal candidates that may have potential for treatment in the form of bacteriotherapy. *Bifidobacteria* spp. and *Lactobacillus* spp., both commonly formulated in commercial probiotic formulations, have shown some degree of evidence that they could offer protection from CDI [33, 71, 72]. However, these data are still considered limited, and CDI guidelines have not recommended the use of currently formulated probiotics [73].

Commensals from the Bacteroidetes phylum may have durable protective effects against CDI; in patients with recurrent CDI who were cured using FMT, examination of the microbiota before and after the procedure revealed that the most obvious microbial change was significant colonization with Bacteroidetes, where it had been previously completely lacking [26, 27]. Further evidence can be seen in fidaxomicin, which was shown to be non-inferior to oral vancomycin for the treatment of CDI, but with fewer observed recurrences [74]. This difference has been attributed to the fact that fidaxomicin specifically is capable of sparing *Bacteroides* spp. during treatment.

Members of family Lachnospiraceae (Clostridium cluster XIVa) have also demonstrated potential for protection against CDI. Colonization with one strain of Lachnospiraceae was able to confer colonization resistance against CDI in mice [18]. In a subsequent study, a mathematical model constructed from microbiota data from HCT recipients with and without CDI revealed highly distinctive protective effects from *C. scindens*, another member of Lachnospiraceae. Colonization of mice with *C. scindens* conferred protection against CDI [19]. The mechanism of protection was shown

to occur through production of secondary bile acids which were previously thought to inhibit vegetative growth of *C. difficile* [75, 76].

51.3.5 Graft-Versus-Host Disease (GVHD)

As early as the 1970s, the gut microbiota has been suspected to play a role in mediating outcomes in allogeneic HCT, particularly GVHD. Early studies in mice and humans suggested a link between the intestinal flora and propensity for graft-versus-host disease [77, 78]. This led to the practice of total or selective gut decontamination and environmental protection through laminar airflow isolation, which were done routinely at transplant centers in the hopes of preventing transplant-related complications. This was based on several initial studies which were promising [79, 80]. However, these practices failed to demonstrate consistent benefit over time in subsequent studies [81–83], and have largely fallen out of favor at most transplant centers.

More recently there has been renewed interest in findings means to prevent GVHD through modulation of the microbiota, given our better understanding of host immunity-microbiome dynamics. In studies of either mice or humans comparing the microbiome of individuals with GVHD with those without, a consistent pattern of microbial shift has been observed. Prospective studies have shown that individuals with GVHD have a preceding intestinal composition that is deficient in obligate anaerobes within Clostridia, regarded as healthy members that are beneficial for production of short chain fatty acids and prevent inflammation by upregulating regulatory T-cells through a variety of mechanisms [84, 85]. Instead, these individuals demonstrate domination by more oxygen tolerant microbes, including *Lactobacillus* spp., *Enterobacteriaceae*, and *Enterococcus* spp. [84, 86].

51.4 Solid Organ Transplantation (SOT)

Fewer studies of the microbiome have been performed in solid organ transplant compared with HCT. These patients are treated with fewer antibiotics and do not experience the initial fall in microbial diversity at the beginning of transplantation [87]. Nevertheless, several notable studies of solid organ transplant recipients have shown that the microbiome is clinically relevant and may have implications in medical management.

In renal transplant recipients, the intestinal microbiota was shown to influence the dosing of immunosuppressant medications. Specifically, patients colonized with *F. prausnitzii*, a commensal member of Clostridium cluster IV, required increased doses of tacrolimus in order to achieve therapeutic levels, compared with patients who were not colonized [87].

In another study of solid organ transplant recipients taking pharmacological immunosuppressants, evaluation of salivary microbiome revealed compositional differences among transplant recipients compared with control subjects not taking immunosuppressant medications. Specifically, patients taking corticosteroids and/or mycophenolate mofetil exhibited salivary samples with high microbial diversity [88]. This suggests that cell-mediated immune suppression may serve to create an oral environment that is more permissive of bacterial colonization with opportunistic pathogens, but without affecting other members through domination, in contrast to observations of HCT recipients.

In lung transplantation, a connection between the microbiota inhabiting airways and chronic lung allograft rejection has been hypothesized [89]. In this model, immune suppression must be carefully balanced; sufficient immune suppression is necessary to prevention allograft rejection, but allograft rejection is also strongly correlated with airway infection, which occurs if immune suppression is excessive. Furthermore, whether colonization of the airway with certain microbes confers higher or lower risk of lung allograft rejection has been a subject of interest. In one preliminary study, lung transplantation recipients showed higher bacterial diversity in lung fluid obtained by bronchoalveolar lavage, as compared with non-transplant controls [90]. Furthermore, compositional differences in lung microbiome were observed, including a strikingly higher abundance of Burkholderiaceae, a family within the Proteobacteria phylum, in lung transplantation recipients.

51.5 Summary and Future Directions

The initial observations thus far suggest that the microbiome is particularly important in the transplantation setting, having implications in immune status, risk of infection, and health of the allograft. Future microbiome studies will need to continue to examine and further define the full clinical implications of commensal microbes on transplant outcomes, and the underlying mechanisms behind these associations, in order to gain insights that can lead to potential interventions that can improve outcomes in transplantation.

Therapeutic interventions aimed at maintaining the microbiota in an ideal state during transplantation may be the logical result of these findings. Future consideration and exploration of these interventions are needed to bring the knowledge of the microbiome into practical importance.

For instance, an improved mechanistic understanding of the impact of antibiotics on commensal populations may help guide antibiotic stewardship more accurately. Based on observations thus far, emphasis on avoiding drugs with potent anti-anaerobic activity, and simultaneous de-emphasis of stewardship over drugs with minimal intestinal lumen penetration could be of benefit and should be further studied.

Replenishment of microbial populations following treatment-related perturbations with interventions such as fecal microbiota transplantation (FMT) may also be of benefit in certain transplant populations.

In addition to efficacy in the treatment of recurrent *C. difficile* infection, FMT could potentially serve to improve other transplant-related outcomes, such as transplant-related infections or GVHD. However, FMT has generally not been well studied in transplant recipients, and it is not yet clear whether additional safety concerns exist in treating these immune compromised patients in this manner. Given the uncertainty surrounding FMT, alternative therapeutic approaches to consider might include diet modification to induce conditions favorable for colonization with beneficial microbes (prebiotics), or bacteriotherapy either with single beneficial "keystone" members or with bacterial consortia. These approaches have been proposed as interventions that could be performed safely and effectively.

Additional areas of potential investigation includes study of the microbiota and risk for non-bacterial transplant infections (e.g., cytomegalovirus and adenovirus), relevance of commensal fungi and viruses (mycobiome and virome), and whether regional differences exist and are pertinent. Further study and understanding of these complex microbial populations and their interactions with human hosts can be used to inform transplantation practices and improve outcomes.

52 Special Considerations for Long-Term Survivors After Hematopoietic Stem Cell Transplantation

Merav Bar and Mary E.D. Flowers

52.1 Introduction

Advances in hematopoietic cell transplantation (HCT) practices and supportive care have led to improved transplant outcome and an increasing number of long-term survivors [1]. Long-term (LT) transplant survivors are at risk for developing late complications as summarized in Table 52-1. Among 2 and 5 years HCT survivors, the main reported causes of death include relapse of the original disease, chronic graft-versus-host disease (GVHD), and late infections (Figure 52-1) [2–4]. This chapter focuses on late infections and infection-related complications that occur beyond day 100 after HCT. Late infections after transplant are generally localized to the skin, the upper respiratory tract, and the lungs [5]. Viral infections are responsible for more than 40 % of late infections after transplant, bacteria are responsible for approximately 35 % of infections, and fungi cause approximately 20 % of the late infections after transplant [6].

52.2 Risks for Late Infections After HCT

Late infections with bacteria, viruses, fungi, and other organisms are most common (1) in patients with delayed immune reconstitution, (2) in patients with chronic GVHD, (3) in recipients of cord blood transplant, (4) in recipients of T cell depleted allogeneic HCT, and (v) in CD34-selected autologous HCT recipients. The adoption of maintenance therapy with novel chemotherapy and immunomodulatory agents after autologous HCT for multiple myeloma [7–9] has also resulted in increased risk for late infection complications in this patient population as well [10–12].

It is standard practice to administer prophylaxis for infections caused by varicella zoster virus (VZV), *Pneumocystis jiroveci* (formerly *Pneumocystis carinii*), *Toxoplasma gondii*, and encapsulated bacteria (*Neisseria meningitidis, Haemophilus influenzae,* and *Streptococcus pneumoniae*) after HCT and to continue long-term prophylaxis beyond 100 days post-transplant in patients with chronic GVHD. However, no evidence based data is available to guide specific recommendations for duration of infection prophylaxis beyond 100 days after HCT, and practice is variable based on type of transplant, GVHD status, immunosuppression therapy, herpes serology status pre-transplant of patients and donors, diagnosis at transplant, prior treatment with certain chemotherapeutic agents, and prior history of infections.

A comprehensive review and guidelines for preventing infectious complications among HCT recipients, including beyond 100 days post-transplant, have been published and last updated in 2009 [13]. General practice for late infection prophylaxis at the Fred Hutchinson Cancer Research Center (FHCRC) and the Seattle Caner Care Alliance (SCCA) is summarized in Table 52-2. Vaccination is recommended in HCT long-term survivors to prevent infections (as discussed in detail in Chap. 48).

52.2.1 Immune Reconstitution After HCT

Reconstitution of the immune system after HCT is critical for both prevention and control of infectious disease and for prevention of recurrence of the original malignant disease for which the transplant was indicated.

Immune reconstitution following allogeneic HCT is a stepwise process. First, the innate immune system including epithelial barriers, monocytes, granulocytes, and natural killer (NK) cells recovers within weeks after transplantation. The adaptive immunity recovers significantly slower, and although B and T cell counts may normalize during the first months after transplantation, the B and T cell function may remain impaired for years [14].

The T cell compartment after transplant is repopulated through a thymus-dependent pathway by development of new lymphocytes from progenitor cells, and through thymus-independent pathway by peripheral expansion of residual mature donor and recipient lymphocytes by

P. Ljungman et al. (eds.), *Transplant Infections*, DOI 10.1007/978-3-319-28797-3_52

Central and peripheral nervous system problems
Recurrent malignancy
New cancers
Psychosocial effects

antigenic stimulation and homeostatic cytokines [15–17]. The thymus-independent pathway may recover within a number of months after transplant, while the thymus-dependent pathway may not fully function for years [18]. Thymus-dependent pathway depends on lymphoid-commitment progenitor cells derived from the hematopoietic stem cell graft as well as adequate thymus microenvironment for the development of T lymphocytes. However, the function of the thymus in a transplant patient is damaged in HCT recipients by age-related thymic involution, exposure to cytotoxic drugs or radiation, and GVHD [19], therefore the delay in the thymus-dependent immune recovery after transplant.

B cell count is low during the first couple of months after bone marrow grafting, but it subsequently increases and becomes supranormal by 1–2 years after transplant, as demonstrated in some studies [20]. Most B cells are naive and initially produce immunoglobulin M (IgM) rather than IgG or IgA [21].

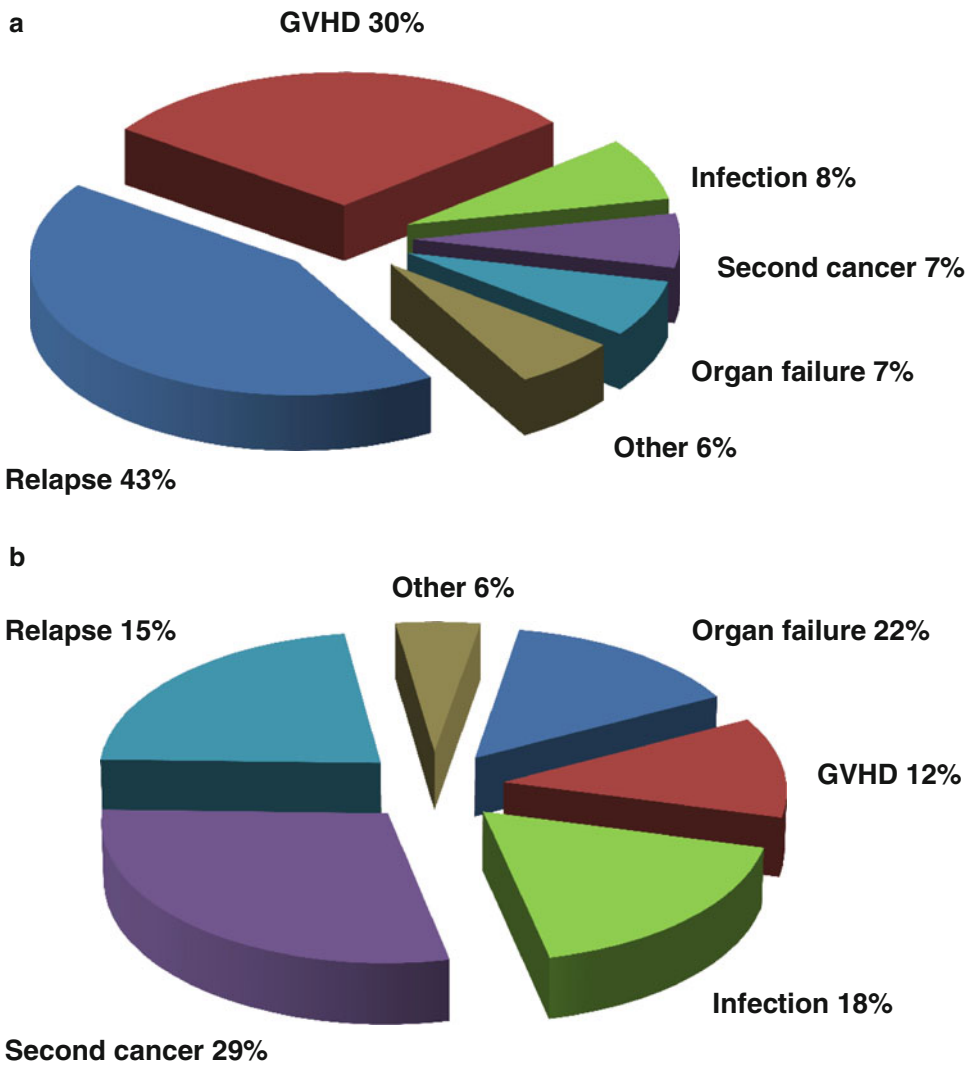

FIGURE 52-1. Causes of deaths after allogeneic HCT for hematological diseases. (**a**) COD among 2-year survivors. Represents abstracted data from two studies [2, 3]. (**b**) COD among 5-year survivors. Represents abstracted data from [4].

TABLE 52-2. Anti-microbial prophylaxis guidelines for adult patients after HCT at the Fred Hutchinson Cancer Research Center

Organism	Prophylactic agents	Prophylaxis after allogeneic HCT	Prophylaxis after autologous HCT
VZV	Acyclovir 800 mg twice daily OR Valacyclovir 500 mg twice daily	Continue for at least 1 year after transplant or 6 months after cessation of all immunosuppression, whichever occurs later.	One year after transplant. Longer prophylaxis if patient receives maintenance therapy post-transplant (e.g., bortezomib after transplant for multiple myeloma).
PJP	Trimethoprim/Sulfamethoxazole (TMP/SMX)—the most effective prophylaxis against PJP Double strength (DS) tablets of 160 mg trimethoprim and 800 mg sulfamethoxazole One DS tablet twice daily twice a week on 2 consecutive days It is recommended that patients with sulfa allergies will undergo desensitization. Alternative Prophylactic Therapy[a]: Dapsone 50 mg PO twice daily. Atovaquone 1500 mg oral suspension, once daily.	Continue for at least 6 months post-transplant in patients without chronic GVHD. Patients with chronic GVHD who are on immunosuppressive therapy may receive daily prophylaxis with TMP/SMX for both PJP and encapsulated bacteria prophylaxis for at least 6 months after completion of immunosuppressive therapy.	Continue for 6 months post-transplant.
Encapsulated bacteria	TMP/SMX—Double strength tablet once daily. Alternative prophylaxis[a]: Penicillin-based prophylaxis: Penicillin VK 500–750 mg twice daily. Other options: doxycycline, quinolones, and macrolides.	It is recommended that prophylaxis be started upon initiation of immunosuppression for chronic GVHD, and be continued until 6 months after discontinuation of all immunosuppression. Patients with active manifestations of chronic GVHD after discontinuation of all systemic immunosuppressive medications remain at increased risk for serious infections with encapsulated bacteria. Thus, continuation of prophylaxis against encapsulated bacteria as long as chronic GVHD manifestations remain active may be considered on a case-by-case basis.	
Toxoplasma	PJP prophylaxis with TMP–SMX has some activity against toxoplasmosis; For high-risk patient with TMP–SMX intolerant see text.	See for PJP section	See PJP section
Candida species	Fluconazole (400 mg/day)	Until day 75 post HCT or until discontinuation of steroids, whichever occurs later.	Until resolution of neutropenia and mucositis.
Mold (Aspergillus species, Zygomycetes)	Voriconazole Posaconazole may be considered for patients who receive high dose steroids for prolonged period of time since its greater activity against mold.	No data is available about the efficacy and toxicity of antifungal prophylaxis beyond day 100 post-transplant. Decision regarding late use of anti fungal prophylaxis should be made based on the patient's infection history, immunosuppression therapy, main organ function, etc. to assess potential benefit and risks for the individual patient.	

[a]As a general principle, alternative drugs should only be used if absolutely necessary, and should be prescribed for only short period of time. Potential reasons for alternative PCP prophylaxis include: severe neutropenia not explained by other causes, gastrointestinal intolerance, renal toxicity, and hepatotoxicity. Resumption of TMP–SMX prophylaxis should always be attempted as soon as possible. In the case of TMP–SMX allergy, desensitization should be attempted.

Many parameters have been shown to affect immune recovery after transplant as: (1) disease status at time of transplant; (2) patient/donor-specific factors (e.g., patient and donor ages, human leukocyte antigen (HLA) compatibility, and CMV serological status); (3) graft source and composition; (4) transplant-specific factors (e.g., use of granulocyte colony stimulating factor (G-CSF), immunosuppressive therapy, polyclonal antibodies as part of conditioning, presence and extent of GVHD, and CMV reactivation) [22–24].

52.2.2 Chronic GVHD

Chronic GVHD is a major cause of late morbidity and mortality after allogeneic HCT, mainly due to its inhibitory effect on immune recovery, and toxicities of glucocorticoids and other immunosuppressive agents used for GVHD treatment. Risk factors for the development of chronic GVHD are: use of a mobilized peripheral blood as the stem cell source, multiparous female donor into a male recipient, HLA mismatch, and old age [25]. Risks factors for chronic GVHD-related mortality are: direct progression from acute GVHD, platelet counts below 100,000/mcL at time of chronic GVHD diagnosis, hyperbilirubinemia, extensive skin disease, severe chronic GVHD by the National Institute of Cancer criteria, and low clinical performance score [26, 27]. If not treated adequately and in severe form of the disease, chronic GVHD can result in disability, major or recurrent infections due to delayed immune reconstitution, pulmonary insufficiency (due to bronchiolitis obliterans (BO) or restrictive lung disease related to scleroderma or fasciitis), skin ulcers, severe joint contractures, esophageal stenosis, vaginal stenosis, severe keratoconjunctivitis sicca, and others [28, 29].

Clinical and experimental data have shown that immune reconstitution is directly impaired by chronic GVHD due to destruction of bone marrow hematopoietic niches, inhibiting lymphopoiesis, and damage to the thymus microenvironment, which inhibits thymus-dependent T cell immunity [30–34]. Additional inhibition to immune recovery is mediated by the immunosuppressive therapy of chronic GVHD.

The mainstay of chronic GVHD treatment is glucocorticoids, but approximately 50% of patients require additional immunosuppressive agents for GVHD control [35, 36]. Most patients require immunosuppressive therapy for at least 2 years from the initial diagnosis of chronic GVHD, and approximately 10% of patients require continued immunosuppressive treatment beyond 5 years [37]. The prolonged use of glucocorticoids and other immunosuppressive therapy used after allogeneic transplant has significant effect on delayed immune reconstitution, including inhibitory effects on a broad range of specific immune responses mediated by T and B cells, as well as potent suppressive effects on the effector functions of phagocytes [38–40]. Because of their inhibitory effects on both acquired and innate immunologic function, the prolonged use of immunosuppressive agents significantly increases the risk of late infection after HCT [41–49].

52.2.3 Late Infection Risks After Cord Blood Transplant

Umbilical cord blood (UCB) transplantation is associated with delayed immune reconstitution, largely due to impaired thymopoiesis and late memory T cell function [50]. UCB contains mostly naive, antigen-inexperienced T lymphocytes, which do not transfer protective T cell memory function to the recipient. Additionally, UCB T cells display impaired capacity for effector cytokine production and reduced cytolytic activity [51, 52]. Consequently, UCB transplant is associated with delayed and incomplete immune reconstitution. As a result, infectious complications and viral reactivation represent the most prevalent causes of post-transplant morbidity and mortality in UCB transplant recipients [50, 53, 54].

52.2.4 Late Infection Risks After T Cell Depleted HCT

Depletion of T cells from the stem cell product (in vitro or in vivo) reduces the risk of GVHD by limiting the number of allo-reactive T cells but it also results in an increased risk of infections. In the first several months after HCT, the circulating T cell repertoire is essentially recruited from the progeny of the donor lymphocytes that are cotransplanted with the hematopoietic progenitor cells. Hence, in recipients of a T cell–depleted graft product, T cell–repertoire reconstitution is often delayed or incomplete compared with recipients of unmanipulated product. The limited size of the initial pool of T cells in combination with the length of time it takes the cells to repopulate in the recipient's blood is likely a major contributor for the lack of complexity in T cell repertoires in the first year after T cell–depleted HCT, and for the increased risk of late infections in this patient population [55]. Most common late infections after a T cell depleted HCT include those caused by herpesvirus, Epstein–Barr virus, and others [56–58].

52.2.5 Late Infection Risks After Haplo-Identical Transplant

Haplo-identical HCT offers the benefits of rapid and nearly universal donor availability, and has been accepted worldwide as an alternative for patients with hematologic diseases who do not have a completely HLA-matched sibling or who require urgent transplantation. Unfortunately, serious infections resulting from delayed immune reconstitution remain a major cause of mortality in haplo-identical HCT recipients, particularly in those receiving extensively T cell–depleted allografts [59, 60]. Haplo-identical HCT is characterized by prolonged B cell lymphopenia and low thymic function, which render patients susceptible to late viral and fungal infections [61]. The risk of late infections in recipients of un-manipulated graft from a haplo-identical donor with

post-transplant cyclophosphamide has not been compared to that of recipients of an un-manipulated graft from an HLA-matched unrelated donor using conventional immunosuppression post-transplant. However, a recent prospective cohort analysis of 70 recipients of un-manipulated haploidentical HCT with post-transplant cyclophosphamide demonstrates high incidence of viral infections/reactivations in the early and late post-transplant period, but with a quite low incidence of late bacterial and invasive fungal infections [62].

52.2.6 Late Infection Risks After Autologous HCT

Late infections are not common after an un-manipulated autologous HCT, but late herpesvirus infections are not uncommon in recipients of CD34+ selected grafts. Moreover, the increased use of novel drugs (i.e., proteasome inhibitor bortezomib and the immunomodulators thalidomide and lenalidomide) before and after autologous transplant has been associated with an increased risk for late viral infections in this setting, especially caused by herpesviruses [63–66].

52.3 Late Infections After HCT

52.3.1 Late Bacterial Infection

Encapsulated bacteria (*S. pneumoniae, H. influenza,* and *N. meningitidis*) are the most significant late bacterial infection after HCT. The most significant risk factor for late infections with encapsulated bacteria, particularly *S. pneumonia*, is chronic GVHD, due to persistent low levels of opsonizing antibodies, low CD4+ cell count, poor reticuloendothelial function, and long-term use of immunosuppressive therapy, especially corticosteroids, with their suppressive effects on phagocytosis [13, 67].

Optimal selection of prophylaxis should consider local patterns of pneumococcal resistance and individual allergies or toxicities associated with available antibiotic choices that include penicillin VK, trimethoprim–sulfamethoxazole (TMP–SMX; cotrimoxazole), second generation cephalosporins, quinolones, and azithromycin. None of these strategies has been tested in randomized trials but historical data indicate that fulminant septic events can occur without prophylaxis due to the profound immunosuppression [68]. Detailed recommendations for prevention of late bacterial infections (i.e., beyond 100 days after transplant) can be found in the 2009 international guidelines for prevention of infection after HCT [13].

Due to the emergence of penicillin resistance encapsulated organisms, and the concomitant need for *Pneumocystis jiroveci* pneumonia (PJP) prophylaxis in patients with chronic GVHD some experts favor TMP–SMX given as one double strength tablet once daily as the first-line drug for both chemoprophylaxis for infections with encapsulated bacteria and PJP for patients with chronic GVHD. If TMP–SMX is not tolerated, second generation cephalosporins, quinolones, and azithromycin prophylaxis may be substituted for coverage of encapsulated organisms, and dapsone, atovaquone, or aerosolized pentamidine added as alternative for PJP prophylaxis [13]. Encapsulated organism prophylaxis after transplant may also be considered in patients without GVHD but receiving glucocorticoid, patients with persistent or recurrent manifestations of chronic GVHD without ongoing use of immunosuppressive medications, patients who are receiving treatment for malignancy after transplant, and asplenic patients. At our center, chemoprophylaxis for encapsulated organisms is continued for at least 6 months after discontinuation of all immunosuppression medications for patients with a chronic GVHD history. For patients with prior splenectomy, the chemoprophylaxis is continued until age 6 OR 2 years after splenectomy, whichever occurs later. While continuation of chemoprophylaxis until 6 months after discontinuation of systemic immunosuppression represents the opinion of some experts and is not evidence based, such recommendation is based on the observation that most exacerbation of chronic GVHD occurs within 6 months after discontinuation of primary immunosuppressive treatment [35, 36], and the speculation that flare of GVHD may be triggered by infections via upregulation of alloreactivity associated with its proinflammatory milieu.

Late bacterial infections after transplantation may also be due to other organisms, such as Gram positive and Gram negative aerobic bacteria [69–71]. Therefore, empirical antibiotic treatment in HCT survivors with clinical suspicion for infection should include broad-spectrum coverage until the infecting organism is identified.

Severe hypogammaglobulinemia (i.e., IgG levels <400 mg/dL) can be associated with bacteremia or recurrent sinopulmonary infections. While routine monthly intravenous immunoglobulin (IVIG) administration to HCT recipients beyond 100 days after allogeneic or autologous HCT is not generally recommended as a means of preventing bacterial infections, administration of IVlG to maintain IgG levels higher than 400 mg/dL may be considered for patients at risk of late bacterial infections (e.g., patients with chronic GVHD and those with severe hypogammaglobulinemia) [13, 68]. At our center, IVlG is recommended during the first year after allogeneic HCT for patients with IgG levels of 400 mg/dL or less if other risk factors are present. IVlG is also recommended for patients with chronic GVHD with recurrent sinus/pulmonary infections with low serum IgG levels. Some experts recommend monitoring IgG levels and administering IVlG in patients with chronic GVHD and IgG levels lower than 400 mg/dL regardless of prior history of recurrent sinus/pulmonary infections or type of systemic immunosuppression treatment used, but there are no data demonstrating that this approach improves outcome [72].

52.3.2 Late *Pneumocystis jiroveci* Pneumonia (PJP)

P. jiroveci pneumonia (PJP), formerly known as *Pneumocystis carinii* pneumonia (PCP), used to be a common opportunistic infection in immunocompromised patients. However since effective PJP prophylaxis is routinely used after HCT, PJP infection after HCT is infrequent. The rare cases of late PJP after transplant are usually due to non-compliance or inadequate prophylaxis. The 2009 international guidelines for infection prevention after HCT recommend PCP prophylaxis from engraftment until at least 6 months after allogeneic HCT, with longer prophylaxis in patients who continue to receive immunosuppressive drugs [13]. At our center, PJP prophylaxis is given at least for 6 months after autologous transplant, and for 6 months after discontinuation of all immunosuppression after allogeneic transplant. TMP–SMX is the most effective PJP prophylaxis, thus generally accepted as the first choice for this purpose [73, 74]. Approximately 15–30 % of patients require therapy other than TMP–SMX because of drug allergy, gastrointestinal intolerance, renal or liver toxicity, and possibly marrow suppression. While breakthrough cases of PJP can occur with all alternative agents, use of daily dapsone is associated with acceptable prevention [75]; limited data exist on atovaquone in the allogeneic HCT setting [13] and breakthrough cases have been observed [75]. Pentamidine can be given as aerosol or intravenously, but it appears to be less effective [76, 77].

52.3.3 Late Toxoplasma Infection

Toxoplasmosis, caused by *Toxoplasma gondii*, is a potential fatal opportunistic infection following allogeneic HCT [78]. Toxoplasmosis after HCT is rare, and nearly exclusively develops as reactivation in seropositive transplant recipients who did not receive adequate prophylaxis [78, 79]. The incidence of *Toxoplasma gondii* disease varies according to the seroprevalence in the geographic area. Toxoplasmosis usually presents as encephalitis 2–6 months after transplantation in the setting of severe T-lymphocyte deficiency, but later occurrence has also been reported in patients receiving long-term immunosuppression [78, 80, 81]. Dissemination with encephalitis, myocarditis, pneumonitis, hepatitis, and other sites may occur and worsens the prognosis. The preferred regimen for Toxoplasma prophylaxis is TMP–SMX, which is routinely used for PJP prophylaxis after transplant. The efficacy of other PJP prophylactic drugs (e.g., dapsone and atovaquone) for *Toxoplasma* prevention is unknown [82–85]. The international guidelines for infection prevention after HCT recommend a strategy for prevention of *Toxoplasma gondii* in high-risk patients who are intolerant to TMP–SMX [13]. According to these guidelines, such patients can either receive prophylaxis with one or more drugs effective against *Toxoplasma gondii* (i.e., clindamycin, pyrimethamine plus leucovorin, pyrimethamine plus sulfadiazine, or pyrimethamine and sulfadoxine plus leucovorin) or be monitored with PCR testing and given preemptive treatment [86]. However, there are no published prospective studies on the benefit/risk ratio of such strategies.

52.3.4 Late Viral Infections

52.3.4.1 Varicella Zoster Virus Infection

Varicella zoster virus (VZV) disease is a common late viral infection after HCT [87]. VZV can present with skin or visceral disease. Although most VZV disease after HCT is caused by reactivation of endogenous VZV, HCT recipients who are VZV seronegative, or VZV seropositive and immunocompromised, should be advised to avoid exposure to persons with active VZV infections. In a randomized, double-blind trial, oral acyclovir at doses of 800 mg twice daily for 1 year after transplant prevented VZV infection after allogeneic HCT without rebound disease after discontinuation of prophylaxis [88]. The international guidelines for infection prevention after HCT recommend acyclovir to prevent VZV infection for the first year after HCT in VZV-seropositive allogeneic and autologous HCT recipients [13]. Acyclovir prophylaxis may be continued beyond 1 year in allogeneic HCT recipients who have chronic GVHD or require systemic immunosuppression. The optimal duration of prophylaxis is poorly defined in patients with chronic GVHD, as there appears to be a persistent risk of VZV reactivation disease even after discontinuation of all systemic immunosuppressive treatments and with CD4 cell count exceeding 200 cells/mL [13, 89]. At our center, acyclovir is given prophylactically to all allogeneic transplant recipients for 1 year after HCT or at least 6 months after discontinuation of all systemic immunosuppressive medications, whichever occurs later, and for 1 year after autologous transplant. According to the international guidelines for infection prevention after HCT the recommended dose of acyclovir prophylactic is 800 mg twice a day [13]; however, lower doses may be sufficient for VZV prophylaxis [90–92].

52.3.4.2 Cytomegalovirus Infection

Cytomegalovirus (CMV) disease usually occurs during the first year after HCT, but may occur later in patients with ongoing immunosuppression [93, 94]. Gastroenteritis and pneumonia are the most common late manifestations of CMV disease, but few cases of retinitis, encephalitis, and marrow failure have been reported [94–97]. CMV seropositive recipients of allogeneic transplants are at the highest risk of developing CMV infection and disease [98, 99]. Other groups at increased risk for the development of CMV disease are autologous HCT recipients of a CD34-selected graft.

Due to potential toxicities, no CMV prophylaxis is usually given to patients after HCT except for UCB transplant recipients, which represent the highest risk group for late CMV reactivation and disease [100]. Routine CMV blood monitoring and preemptive therapy, however, are recommended and useful for all patients at risk for late CMV disease. Polymerase chain reaction (PCR) testing is the standard assay in the USA for CMV surveillance in blood in high-risk patients. The assay is highly sensitive and provides reliable quantitative measurements of CMV load in plasma. While antigenemia testing also performs well for CMV monitoring, quantitation and sensitivity may be affected by delay in performing the test from specimen shipped from a distant location.

Studies have demonstrated that certain allogeneic transplant recipients are at increased risk for late CMV disease and CMV-related mortality after HCT; these patients include those treated for CMV infection in the first 100 days after transplantation, CMV seropositive recipients of cord blood transplants, and those treated with corticosteroids or other systemic immunosuppressive agents for chronic GVHD [101–103]. Continued monitoring for CMV reactivation after 100 days following HCT is recommended for these high-risk patients on a weekly basis. Weekly testing is recommended due to the rapid replication kinetics of virus in these immunocompromised hosts, and because CMV disease can develop in the interval between a negative assay and the next sample if the tests are spaced 2 weeks apart. Few studies examined when late surveillance can be safely discontinued. In our practice, non-cord umbilical blood HCT recipients who are not receiving high levels of immunosuppression (e.g., < 1 mg/kg/day corticosteroids or treatment with mycophenolate mofetil) and who have had three consecutive negative surveillance tests after day 100 post-transplant can be changed to every other week blood CMV monitoring; if taper of immunosuppression continues and patient remains negative, CMV blood testing may be stopped after two additional tests. If treatment with corticosteroids is increased or secondary therapy for chronic GVHD is added, particularly initiation of treatment with mycophenolate mofetil, we resume CMV monitoring on a weekly schedule.

CMV seropositive UCB transplant recipients may be at increased risk for developing CMV reactivation and disease. Despite using standard preemptive strategies in CMV seropositive UCB transplant recipients, an evaluation of this population at our center revealed that almost 100 % reactivated CMV and 25 % developed CMV disease [100]. While some centers have reported lower rates of CMV reactivation and disease, comparable with standard allogeneic transplants [104], others also have found high rates of CMV reactivation in the UCB population [105]. Therefore, we recommend prophylactic CMV therapy in addition to virologic surveillance and preemptive therapy in UCB transplant recipients at risk. The preferred CMV prophylaxis beyond day 100 after HCT for cord blood recipients with a prior history of CMV reactivation in the early post-transplant phase is valganciclovir 900 mg PO once daily [106]. This regimen, while effective, may not be tolerated due to the risk of neutropenia. In these cases, we have used a modified regimen of high dose valacyclovir (oral valacyclovir 2 g three times daily) [107]. This regimen is also our preferred CMV prophylaxis for cord blood recipients who did not experienced early CMV reactivation (i.e., before 100 days after transplant). For patients who are unable to take oral formulations and who are deemed at high risk for late CMV disease, intravenous regimens of acyclovir (500 mg/m2 IV every 8 h) [107] or ganciclovir 5 mg/kg/day are used [108].

Several studies indicate that preemptive treatment is effective to prevent CMV disease and improve outcome after HCT [109, 110]. In a randomized trial, preemptive CMV therapy in patients with plasma CMV DNA levels of 1000 IU/mL or rising DNA levels (i.e., greater than 5 times of baseline level within 1 month) was as effective as prophylaxis for prevention of late CMV disease [106].

Since the risk of CMV acquisition via blood products continues late after transplantation, all blood products given to seronegative HCT recipients should be CMV negative or leukocyte reduced [13].

52.3.4.3 Respiratory Virus Infections

Patients with and without chronic GVHD are at risk for acquisition of late respiratory tract infections such as those caused by influenza virus, parainfluenza virus, human metapneumovirus, and respiratory syncytial viruses; however, lower respiratory tract complications appear to be higher in patients with chronic GVHD. Respiratory virus infections represent a major contributor to development of severe pulmonary airflow decline and are associated with risk of developing lung GVHD (i.e., bronchiolitis obliterans) [111–117]. Inactivated Influenza vaccine is recommended after HCT as early as 6 months after HCT and for individuals with close contact with the transplant recipient (as discussed in detail in Chap. 48) [118].

52.3.4.4 Other Virus-Related Late Complications

Other potential viral-related late complications after HCT are chronic hepatitis and cirrhosis due to hepatitis B and C infection (as discussed in Chap. 37), BK virus associated late hemorrhagic cystitis, human papilloma virus infection, EBV lymphoproliferative disease (discussed in Chap. 26), and recurrent HSV disease, especially in patients receiving no or insufficiently doses of acyclovir prophylaxis (discussed in Chap. 29). No routine surveillance of such viral infections is recommended, but specific evaluation should be performed if clinical suspicion is raised, and patients should be treated accordingly.

52.3.5 Late Fungal Infections

Late fungal infections are most common in allogeneic HCT recipients receiving high doses of corticosteroids. Antifungal prophylaxis beyond 100 days following allogeneic HCT may be considered, especially in patients with chronic GVHD who are receiving high dose corticosteroids (i.e., greater than 1 mg/kg/day prednisone or equivalent) or other immunosuppressive agents. While little evidence-base recommendations are available for antifungal prophylaxis beyond 100 days after transplantation, routine use of antifungal prophylaxis in the early period after allogeneic HCT has been shown to decrease invasive fungal infections from 12 % to 4 % [119]. Invasive aspergillosis remains, however, a principal cause of infection-related mortality after HCT, with the majority of cases occurring beyond day 100 after transplant [120–122], and with main risk factors being chronic GVHD and prolonged treatment with high dose corticosteroids [120, 121]. While evidence-base is lacking for prolonged use of voriconazole or posaconzole prophylaxis beyond day 100 after transplant, the National Institute Cancer chronic GVHD Supportive Care consensus recommends antifungal prophylaxis in patients with chronic GVHD receiving high dose corticosteroids [68]. Until randomized studies to evaluate the safety of prolonged voriconazole or posaconzole prophylaxis are conducted, the decision whether to start or continue prophylaxis with either of these agents in patients who receive high dose immunosuppression beyond 100 days after transplant should be determined by the treating physician based on the patient's clinical status, expected duration of high dose corticosteroids therapy, and prior history of fungal infections.

52.4 Long-Term Follow-Up Recommendations After HCT

Long-term clinical monitoring is necessary to identify early signs of chronic GVHD, infections, and other potential late complications after transplant, in order to prevent severe morbidity and mortality. Table 52-3 summarizes the FHCRC guidelines for long-term follow-up post-transplant.

Routine monitoring and supportive care directed at organ-specific complications are crucial to the management of late complications after HCT. While most of long-term monitoring and supportive care guidelines for patients beyond 100 days after HCT are based on expert opinion rather than controlled studies, many of our practices at the FHCRC have been evaluated retrospectively [88]. The FHCRC long-term post-transplant general guidelines are systematically updated based on the published literature and can been found at the following link: http://www.fredhutch.org/en/treatment/long-term-follow-up/information-for-physicians.html.

TABLE 52-3 General long-term follow-up recommendations for adult patients after HCT at the Fred Hutchinson Cancer Research Center

1. Screening for secondary malignancies. Routine oncologic evaluation at yearly intervals is recommended due to increased risk of new malignancies after HCT. Annual oncologic screening as per recommendations to the general population and additional screening including yearly oral exam by a dentist and an yearly skin thorough exam due to the increased risk for head, neck, and skin cancer after HCT. Secondary malignancies rarely occur earlier than 2 years after transplantation, but the risk of developing cancer increases progressively after 5 years.
2. In patients transplanted for chronic myeloid leukemia or Philadelphia chromosome-positive acute lymphoblastic leukemia, routine monitoring for *BCR/ABL* transcripts by molecular testing of a blood sample is recommended every 6 months for the first 2 years after transplant, and yearly thereafter if the results remain negative. If *BCR/ABL* is positive in blood, examination of bone marrow by conventional morphology, cytogenetic analysis, molecular studies for the *BCR/ABL*, and chimerism is recommended.
3. Measures to prevent osteoporosis in women and all patients receiving long-term treatment with corticosteroids include:
   - Calcium 1500 mg/day in the diet or in supplements to meet daily requirements
   - Vitamin D 800 IU/day in the diet or in supplements to meet daily requirements
   - Daily weight-bearing exercise for 20–60 min
   - Dual photon densitometry at day 80–100 post-transplant evaluation and yearly thereafter
   - Sex hormone replacement therapy if levels are low and the benefits are thought to offset the risks.
4. Pulmonary function tests (PFTs) at day 100 post-transplant, at time of initial diagnosis of chronic GVHD, 1 month after resolution of respiratory virus infection, at 1 year after allogeneic HCT, and after 1 or 3 months if there has been abnormal testing in a previous time period or if there are new signs or symptoms concerning for pulmonary disease. PFTs should be monitored every 3–6 months during the first 2 years after the initial diagnosis of chronic GVHD or if clinically indicated.
5. Thyroid function testing annually, especially in patients who have received prior irradiation.
6. Ophthalmologic examination at annual intervals.
7. Immunizations (see Chap. 48).

53 Special Considerations for Long-Term Survivors After Solid Organ Transplantation

Hakim Azfar Ali, Scott M. Palmer, and Oriol Manuel

53.1 Introduction

The field of solid organ transplantation has made remarkable progress in the second half of twentieth century starting from experiments in skin transplants to successful transplantation of visceral organs in common practice. It has come out of the shadows, to change from an experimental treatment modality to a mainstream therapeutic option, for treatment of multiple end stage disease processes.

This change in scene for organ transplantation has been driven by multiple factors including better immunosuppressive medications, better surgical technique, a more in depth knowledge of immunology and advanced support modalities to get patients through surgery in addition to the development of better antibiotics and preventive strategies to reduce the burden of infectious complications. The introduction of 6-mercaptopurine in 1950s and azathioprine in 1960 provided a boost to immunosuppression and the introduction of calcineurin inhibitor cyclosporine in 1980s markedly improved graft survival. Meanwhile the surgical techniques were developed and improved upon to decrease the early post-operative complications.

Early post-operative morbidity and mortality in solid organ transplant (SOT) recipients still remains a daunting challenge. Besides the direct surgical complications this also stems from other factors including early graft dysfunction, acute and hyperacute rejection, ischemic injury, early infections, and drug toxicity. However as these immediate and early post-operative issues are improving, more organ transplant recipients are surviving beyond one year.

The median survival of SOT recipients has improved remarkably to 12.1 years for a kidney transplant, 10.1 years for a liver transplant, and 5.1 years for lung transplant. Liver transplant outcomes at 1 year have improved from a dismal 30% in the pre-cyclosporine era to more than double in the post-era [1] and are now at over 90%. Similar results were observed in kidney and cardiac transplant [2] fields after introduction of cyclosporine and tacrolimus. Long-term graft failure at 10 years post-transplant has declined to an all-time low (Figures 53-1 and 53-2) (http://m.srtr.org/2011/chapters/lung/adults/outcomes.aspx).

As SOT recipients survive longer the focus is shifting to include delayed causes of morbidity and we are recognizing a large number of long-term complications which in some cases can be organ and life threatening. The definition of long-term complications is arbitrary and can be taken to mean complications occurring after 3 months or after a year from surgery. In any event, these complications have serious implications for the quality of life of organ transplant recipient.

The common complications range from long-term side effects of the immunosuppressant medications to development of malignancies, effects of chronic rejection, and late-onset infections. Other complications that often get overlooked include metabolic and cardiovascular diseases similar to the non-transplant patient except that some of these have an altered course and progression in the organ transplant recipients (Table 53-1). Some of these complications are common across the board for all solid organs and others are more specific to the organ transplanted (Table 53-2).

53.2 Late-Onset Infections After Solid Organ Transplantation

Most of the infectious complications developing after transplantation occur during the first weeks post-transplant, and it is within this period when most preventive strategies are set up to decrease the burden of infection [3]. Because of the prolonged survival of SOT recipients observed over the last decades, some infections may now appear very late after transplant. While these infections are usually community acquired, some patients may still present opportunistic infections with atypical presentations. Unfortunately, there

The original version of this chapter was revised. An erratum to this chapter can be found at https://doi.org/10.1007/978-3-319-28797-3_54

is no extensive literature about the epidemiology and clinical characteristics of infection occurring in stable SOT recipients, months or years after transplantation. Follow-up of patients included in randomized controlled trials usually stops at 12 months post-transplant. In prospective cohorts, the capture of infectious episodes is usually more challenging than early after transplant, when the patient is followed by the original transplant center. In a large Spanish cohort, the incidence of late infection (>6 months) was eight times lower than during the first 6 months post-transplant (from 0.4 to 3.5 episodes of infection per 1000 transplantation days, respectively) [4]. In this study, risk factors for late infection were lung transplantation, previous bacterial infection, surgical complications, acute rejection, and chronic allograft dysfunction, highlighting a subgroup of patients at higher risk for health-care associated and opportunistic infections.

Bacterial infections are the most common infectious complications after transplantation, and represent approximately 70–80% of all infections. *E. coli*, *Enterococci*, and *Pseudomonas* are the most prevalent pathogens involved in these infections. Late-onset bacterial urinary tract infections (UTI) are particularly frequent in kidney transplant recipients [5]. The impact of these late infections in impairing allograft outcomes has not yet been elucidated; while in some studies, late recurrent UTI seemed to be associated with an increased risk for allograft dysfunction and loss [6, 7], this has not been found in other studies [8]. Also, bacterial pneumonia is a significant cause of community-acquired infection after lung transplantation [9]. Incidence of pneumococcal disease is estimated to be more than 10 times

higher in SOT recipients than in the general population, and it is a cause of late infections [10]. In a large Canadian cohort, median time to presentation of pneumococcal disease was 2.75 years post-transplant, with a range reaching up to 24 years post-transplant. The efficacy of novel vaccination strategies using the 13-valent conjugated pneumococcal vaccine should be evaluated in SOT recipients [11]. Tuberculosis may reactivate (or being acquired) late after transplant [12]. Transmission of tuberculosis may occur through the liver, lung, or kidney grafts as well besides reactivation of the recipient disease particularly in cases of bilateral lung transplantation [13]. Because tuberculosis may present with atypical manifestations and because treatment is challenging due to drug–drug interaction and toxicity, it is associated with significant morbidity in SOT recipients. Diagnosis and therapy of latent tuberculosis infection in transplant candidates and in contact transplant recipients are of paramount importance to decrease the burden of the disease after transplant [14]. Listeria in SOT recipients is rare (0.12% in a Spanish series), presenting late after transplant (>50% of cases presenting after 6 months post-transplant) and associated with significant mortality [15]. Risk factors associated with listeriosis include diabetes, use of high-dose steroids, and absence of cotrimoxazole prophylaxis.

Viral infections are a common complication after transplantation. Cytomegalovirus (CMV) remains associated with significant morbidity in SOT recipients and the incidence of CMV replication may reach up to 70–80% in high risk patients (seronegative recipients receiving an organ from a seropositive donor), and approximately 15–30% of those patients will develop CMV disease [16]. CMV disease currently develops in the weeks following the discontinuation of antiviral prophylaxis, usually during the first year post-transplant. However, a minority of patient may develop CMV disease even later on after transplant. In a randomized controlled trial comparing 3 vs. 6 months of antiviral prophylaxis, 12% of all episodes of CMV disease were diagnosed between 1 and 2 years post-transplant [17]. The causes of this late onset of CMV infection are not completely understood, but it can be related with enhanced immunosuppression due to chronic rejection, delayed cell-immune control in patients receiving long-term antiviral prophylaxis, immunosenescence in older recipients, or late primary infection acquired by natural transmission, such as in case of contact with virus shed from the upper respiratory tract from children or by sexual contact. Interestingly, patients with very late-onset CMV disease usually have atypical manifestations, such as chronic gastrointestinal involvement with low viral loads in blood [18].

Lung Transplant—Outcomes, Scientific Registry of Transplant Recipients, Figure 5-7 Post-transplant events among adult lung transplant recipients (http://m.srtr.org/2011/chapters/lung/adults/outcomes.aspx). Accessed 7/25/15.

Some cases of very late CMV replication due to drug-resistant viruses after exposure to antiviral agents have been described [18]. There are no proposed screening strategies for CMV after the second year post-transplant, so that a high index of suspicion is needed in case of unexplained clinical symptoms compatible with CMV disease.

Incidence of zoster is increased up to 3–5 years post-transplant and can be associated with significant morbidity, such as postherpetic neuralgia [19]. BK virus associated nephropathy is a common cause of chronic allograft dysfunction in kidney and kidney–pancreas transplant recipients. BK virus associated nephropathy generally appears during the first 12–24 months after transplantation, but series of late-onset BK virus nephropathy has been described, particularly in patients with enhanced immunosuppression [20, 21]. Infection by community-acquired respiratory viruses, such as influenza virus, RSV, PIV, or rhinovirus, may occur in any post-transplant period [22]. Although time from transplant appears to have a major impact on the outcome of influenza in SOT recipients (with high mortality in the early post-transplant period), cases of allograft dysfunction following influenza have also been observed late after transplant [23]. Thus annual vaccination with influenza vaccine remains highly recommended in all SOT recipients [24]. HPV infections are a significant problem after transplantation, due to an increasing incidence of oropharyngeal and genital cancer. Vaccination against HPV of young male and female transplant candidates and recipients is thus of importance to decrease the burden of HPV related cancers [25]. Other late viral infections reported in the literature include HHV-8 and EBV-related proliferative disorders. Chronic hepatitis E virus (HEV) infection has recently described as a problem in SOT recipients in endemic regions, probably related with consumption of undercooked game/pork meat, although the epidemiology of this infection in the transplant setting is not completely known [26].

Fungal infections can manifest late after transplant. Because of the direct contact of the lung allograft with the environment, lung transplant recipients are particularly at increased risk of developing invasive fungal infection. Risk factors for late aspergillosis have been described, and include chronic allograft dysfunction, previous respiratory infection, and need for renal replacement therapy [27]. Invasive candidiasis is particularly frequent during the post-operative period and much less frequent afterwards; no studies have assessed the prevalence of candidiasis late after transplantation. There are also scarce data on the epidemiology of other invasive fungal infections, such as mucormycosis, cryptococcosis, and black molds. Cases reported usually occur in oversuppressed patients due to chronic rejection.

Because of the lower incidence of infection in SOT recipients and the absence of well-defined risk factors, preventive strategies of infection in long-term survivors after transplantation are not well established. An important point is to identify patients with incomplete vaccination schedule and to administer missing vaccines after transplantation [11]. Specific teams dedicated to assess the vaccination status of transplant candidates and recipients can improve the administration of these vaccines. Because cotrimoxazole is usually well tolerated and cheap, long-term prophylaxis with this drug is widely used. In particular, patients with sustained low lymphocyte counts may benefit from extended duration of prophylaxis. Some authors suggest screening for hypogammaglobulinemia, hypocomplementemia, and low lymphocyte subpopulation counts to identify patients at higher risk for infections. Antibiotic prophylaxis (besides cotrimoxazole) for prevention of recurrent urinary tract infections (UTI) should be evaluated in an individual basis in kidney transplant recipients. The reduction on the number of episodes of UTI should be balanced with the acquisition of antibiotic resistance, particularly with the use of quinolones [28]. The experience with other drugs for UTI prophylaxis in kidney transplant recipients, such as fosfomycin or nitrofurantoin, is lacking [29]. Long-term antiviral or antifungal prophylaxis is not generally recommended, except in selected patients with recurrent infections (for example, acyclovir for HSV infection), or at high risk for a particular infection (for example, lung transplant recipients with environmental risk for aspergillus infection). In some settings, such as in lung transplantation, long-term inhaled antifungal or antibiotics may be preferred to avoid safety concerns associated with the administration of systemic antibiotics [30].

53.3 Renal Failure/Chronic Kidney Disease

Chronic kidney disease (CKD) is a common complication of renal and non-renal solid organ transplants and serves as a significant cause of morbidity and mortality, besides driving up the healthcare costs of solid organ transplantation. There is a lot of variability in the reported incidence of chronic renal failure in this population because of the lack of defining parameters and inconsistencies in reporting and definition. The incidence of renal dysfunction reported in non-renal organ transplant recipients varies from 10% to 80% [31]. As the longevity of the solid organ recipients increases a large majority of them will develop some degree of chronic renal disease.

An analysis of 70,000 non-renal transplant recipients from the US SRTR registry found an adjusted risk of 20–25% of Stage IV to V CKD at 5 years [32]. In this study cumulative incidence of severe renal failure (defined as creatinine clearance less than 29 ml/min/1.73 sq m BSA) at 5 years was found to be 18.1% in liver, 10.9% in heart, 15.8% in lung, 6.9% in heart–lung, and 21.3% in intestinal transplant recipients. The majority of renal transplant recipients have a higher creatinine and a lower GFR at 1 year.

CKD complicates the care of SOT recipients both directly by increasing hospitalizations and infectious complications and indirectly by limiting the use of certain drug classes including immunosuppressants and antibiotics. CKD has been shown to increase mortality two- to fourfold amongst affected recipients. In the above mentioned analysis relative risk for death associated with CKD was 4.55 compared to the transplant recipient without CKD.

The glomerular filtration rate will tend to drop in the first few months after transplant with subsequent stabilization although a significant number will progress to ESRD. In one study the cumulative risk of ESRD was 4.7% and an annual ESRD risk of 1.5–2% [33].

The development of CKD in the organ transplant population is attributed to a number of risk factors, predominant amongst them being medication induced nephrotoxicity, pre-existing renal disease, and metabolic risk factors like diabetes, dyslipidemia, hypertension, and hepatitis [34]. Advancing age, cardiovascular disease, pulmonary hypertension, and episodes of acute renal failure have all been found to be risk factors for development of CKD in heart, lung, and liver transplant recipients. The perioperative factors causing acute renal injury may also factor into development of chronic kidney disease in the long run. The underlying disease like chronic hepatitis C in liver transplant recipients and immune mediated injury in connective tissue disease patients are additional CKD risk factors to be considered. Preexisting renal dysfunction has been shown to be a risk factor for CKD post-transplant. A decrease of 10 ml/min per 1.73 m in the pre-transplantation glomerular filtration rate was associated with an increase of 9% in the risk of chronic renal failure [32, 33]. However calcineurin inhibitors remain the most important cause of CKD in the SOT population.

Calcineurin inhibitors (CNIs) have become the mainstay of all immunosuppressive regimens in SOT recipients and carry an inevitable risk of renal toxicity by virtue of a number of mechanisms [35] at the cellular level. CNIs can cause acute renal failure due to afferent arteriolar vasoconstriction [36] mediated by chemical metabolites and sympathetic nerve activation and also a chronic nephrotoxicity mediated by angiotensin II [37]. CNIs have been associated with stimulation of renin with juxtaglomerular cellular hyperplasia and angiotensin II and aldosterone led renal vascular injury, micro thrombosis, and finally tubulointerstitial fibrosis and glomerulosclerosis manifesting as CKD [33]. These effects may be additionally mediated by transforming growth factor (TGF) beta 1 [38] and plasminogen activator inhibitor [39]. Local renal factors important for susceptibility to CNI nephrotoxicity include variability in P-glycoprotein and CYP3A4/5 expression or activity, older kidney age, salt depletion, the use of NSAIDs, and genetic polymorphisms in genes like TGF-beta and ACE [35].

Clinical features of CKD are similar to the general population although the use of serum creatinine as a marker for renal function may be misleading in a large proportion of this population who are malnourished and have a decreased muscle mass. The GFR usually stabilizes after an initial accelerated decline and drops at a slower rate thereafter. Proteinuria is usually not a major feature in view of the anti-proteinuric effects of CNIs and may portend development of focal glomerular sclerosis post-cardiac transplant, or IgA nephropathy or membranoproliferative glomerulonephritis (MPGN) post-liver transplantation [40].

Distal renal tubular acidosis type IV associated with hyperkalemia has been described in the setting of CNI use [41, 42]. Cyclosporine associated hemolytic uremic syndrome has been described in association with hemorrhage colitis [43].

A renal biopsy with features of striped atrophy and tubulointerstitial fibrosis with arteriolar hyalinization and glomeruli with sclerosis is consistent with chronic CNI toxicity [44] while as acute CNI toxicity has been associated with lysosomal vacuolization of tubular cytoplasm. Many times renal dysfunction may not have histological correlates being a predominantly functional vascular process [45].

The management of CKD in this population is similar to the general population with some caveats. Prevention and eventually therapy for CNI nephrotoxicity are aimed at lowering total systemic blood levels and renal exposure to the CNIs or their metabolites. The CNI-based immunosuppression may need to be adjusted to achieve lower levels as allowed by the risk of rejection of the allograft. mTOR agents like sirolimus have been used after the initial period of healing post-transplant to decrease the risk of CNI nephrotoxicity.

Calcium channel blockers mainly the dihydropyridine [46] and angiotensin inhibitors [47] have been postulated to block some vasoconstrictive effects and hence improve GFR but have not become the mainstay as the evidence of benefit at this point is not conclusive. Other potential therapies include vasodilatory prostanoids, L arginine, statins, spironolactone, and experimental treatments targeting the mediators like TGF-beta [35].

Optimal control of blood sugars and blood pressure and other cardiovascular risk factors needs to be undertaken.

Finally renal transplantation is an option for this group and has been shown to confer a survival benefit in non-renal transplant patients with ESRD [48]. After the initial transient post-operative increase in mortality, patients who received a kidney transplant had a lower risk of death, which was sustained until 5 years after transplantation [32].

53.4 Neoplastic Complications

The burden of malignancy in SOT recipients is related in part to de novo development of neoplasia and partly to the aggressive course of naturally occurring malignant tumors.

Historically the increase in incidence of malignancies in SOT recipients has run parallel to more robust and multipronged immunosuppression. A surge in the incidence of lymphomas with the introduction of polyclonal antibodies in 1960s and again with the use of cyclosporine in 1980s was a result of this effect [49].

The role of immunosuppression is also corroborated by the data from HIV-infected patients who demonstrate similar increases [50].

The various factors postulated to contribute to this increase in malignancies include oncogenic infectious agents like some viruses (Table 53-3), malignancies from the donor not identified at the time of transplant, direct effects of immunosuppression leading to potential sparing of aberrant cells with malignant potential, and some predisposition from underlying disease.

The spectrum of cancers occurring in this population is wide with an overall two- to fourfold increased risk of cancer compared to general population and an excess absolute risk of 0.7% according to a cohort study using the US Scientific Registry of Transplant Recipients (SRTR) with data on 175,732 solid organ transplant recipients [51].

Non-Hodgkin lymphoma and cancers corresponding to three commonly transplanted organs (kidney, liver, and lung) together comprised 43% of all cancer cases in transplant recipients compared with 21% in the US general population [51].

Risk was increased for 32 different malignancies, some related to known infections (e.g., genital and anal cancer related to human papillomavirus (HPV), Kaposi sarcoma due to human herpesvirus 8 (HHV-8), non-Hodgkin's lymphoma with Epstein–Barr Virus (EBV) and stomach cancer possibly with Helicobacter pylori) and others unrelated to infections (e.g., non-melanoma skin cancers, thyroid, colorectal, and lip cancers). Breast, prostate, ovarian, brain, and testicular cancers were not increased in incidence in this population which may point against an infectious contribution to these cancers [52].

Other population based cancer registries for transplant recipients have also reported similar findings. These include the increased non-Hodgkin's lymphoma and colorectal cancer risk reported in the Canadian liver transplant recipients [53]. Increased risk of head and neck cancers, lymphoma, leukemia, and lung cancer was reported in the Australian cardiothoracic organ transplant cohort [54].

Excess risk for non-melanoma skin cancer, non-Hodgkin's lymphoma, and stomach cancer was observed in Swedish organ recipients [55].

The incidence of specific malignancies does depend on the organ transplanted with two- to threefold higher frequency of non-Hodgkin's lymphoma and lung cancer in lung transplant recipients and more liver and kidney malignancies seen in liver and kidney recipients, respectively.

Variation in cancer risk between recipients of different organs is likely to arise from the degree of immunosuppression maintained in cardiothoracic recipients.

53.4.1 Post-Transplant Lymphoproliferative Disorder (PTLD)

Non-Hodgkin lymphoma is the second most common malignancy in SOT recipients after non-melanoma skin cancer. PTLD is a dreaded complication of organ transplant. It is one extreme of EBV driven monoclonal lymphoid proliferation on a spectrum at the other end of which is seen benign lymphoid hyperplasia with a mononucleosis type syndrome. The most common non-Hodgkin lymphoma subtype amongst both transplant recipients and HIV-infected individuals is diffuse large B cell lymphoma, and most cases have detectable EBV in tumor cells [56].

The pathogenesis of PTLD is hypothesized to be related to B cell proliferation driven by EBV expressing all latent antigens (Type 3 latency program) which remains unchecked because of the T cell suppression related to the immunosuppressive agents in transplant recipients [57]. EBV infected B cells are activated to transcribe proteins from genes like Latent Membrane protein (LMP) and EBNA (Epstein–Barr nuclear antigen). Normally the expression of these proteins leads to activation of the cytolytic T cells and keeps the EBV in check. However in SOT recipients the cytolytic T cell response is suppressed leading to unrestricted EBV invoked B cell proliferation. Other potential mechanisms include IL 10 related suppression of antiviral immunity and a decrease in precursor plasmacytoid dendritic cells which play a role in antiviral immunity [58].

In general, agents that suppress T cell activity appear to be associated with an increased risk of PTLD [59].

Bimodal onset of PTLD (Figure 53-3) following organ transplantation has been described previously [56] and risk factors differ somewhat for early-onset and late-onset PTLD, supporting etiological heterogeneity. Most of the cases were believed to originate from the recipient but further studies have revealed that donor-derived tumors can occur as well [60]. The origin may have implications on the time of disease occurrence and the prognosis. PTLD originating from the donor has been suggested to arise in the first year after transplantation into the graft, and recipient-origin PTLD develops later as an invasive disease and is more aggressive [61]. Early-onset PTLDs tend to be EBV-positive and, when extra nodal, are more likely than late-onset PTLDs to be localized to the transplanted organ. Late-onset PTLD is less likely to be associated with EBV and, overall, is more likely than early-onset PTLD to be extranodal [62].

Non-Hodgkin lymphoma risk was most pronounced amongst young transplant recipients, who are susceptible to primary EBV infection following transplantation and the highest risk was amongst lung recipients, possibly as a result of the high intensity of immunosuppression which needs to be maintained to prevent rejection. Another factor implicated is the larger amount of lymphoid tissue within the lung allograft [63].

The etiology of EBV-negative PTLD has not been fully elucidated, but gene expression profiling studies suggest that

TABLE 53-3. Known infectious associations of cancers in transplant recipients

Post-transplant lymphoproliferative disorder (PTLD)	EBV
Kaposi's sarcoma	HHV8
Anogenital cancers	HPV
Other rarer cancers, e.g., primary effusion lymphomas	HHV 8
Liver cancer	Hepatitis B and C virus

they are biologically distinct from EBV-positive disease. Some may be related to EBV infections that are no longer detectable. Others may be due to unidentified viruses or other causes of chronic antigenic stimulation. As an example, post-transplantation primary effusion lymphoma is associated with HHV-8 infection [64].

An association with CMV has been reported possibly reflecting the immunosuppressive effects of the virus [65].

A donor–recipient mismatch for EBV serostatus with reactivation or primary EBV infection increases the risk of PTLD. In one study, in the absence of the other risk factors, the incidence rate of PTLD for EBV-seronegative recipients was 24 times higher than that for EBV-seropositive recipients [66].

EBV DNA PCR in blood has been advocated as a screening tool in high risk patients and in those with symptoms. However it appears that peripheral EBV PCR may be below the detectable levels in some cases and in these intracellular EBV and other risk factors may play a role. Absence of EBV viremia should not be used to rule out PTLD. On the contrary, EBV DNAemia is very common in all transplant recipients, so that the positive predictive value of EBV DNAemia for predicting the development of PTLD is generally low [67].

The clinical presentation of patients with PTLD is highly variable and depends at least partially upon the type of PTLD and the site of involvement. Non-specific constitutional symptoms such as fever, weight loss, and fatigue are common. Other symptoms may be related to viral infection, lymphadenopathy, dysfunction of involved organs, or compression of surrounding structures. Viral symptoms can resemble those seen in acute infectious mononucleosis, although this is generally seen only in pediatric transplant recipients.

In most cases PTLD presents as a systemic disease involving lymphoid tissue, spleen, central nervous system, or another extra lymphoid tissue [65]. More than half of PTLD presents with extra nodal masses. Extra nodal organs include the gastrointestinal tract (stomach and intestine), lungs, skin, liver, central nervous system, and the allograft itself with symptoms referred to the organ involved. Central nervous system disease (which is rare in the general population) is found as well in about 20% and a similar proportion have infiltrative lesions in the allograft. Involvement of the allograft can lead to allograft dysfunction, including renal failure, heart failure, and respiratory dysfunction. The systemic manifestations may also include unexplained anemia, thrombocytopenia, or leukopenia, elevated level of serum lactate dehydrogenase (LDH), hypercalcemia, hyperuricemia, or monoclonal protein in the serum or urine.

PTLD is further classified according to the subtype of lymphoma. The vast majority of these tumors are B cell lymphomas, most common being diffuse large B cell lymphoma (DLBCL), and less common Burkitt's lymphoma or plasma cell neoplasm (e.g., myeloma or plasmacytoma).

Management of PTLD has varied significantly according to the type of lymphoproliferative disease present, as well as from institution to institution.

Immunosuppression reduction is the cornerstone of therapy. In addition since PTLD is a disorder of CD20 positive B cells effective therapies include rituximab which has become first line treatment. Rituximab a human/mouse chimeric anti-CD20 monoclonal antibody appears to have a survival benefit.

Patients who fail are treated with chemotherapy, radiation therapy, or a combination of these. Other treatments, such as adoptive immunotherapy with EBV specific cytotoxic T cells, are generally reserved for persistent disease despite initial therapy.

A preventive role for anti-EBV agents including ganciclovir and acyclovir has been explored. However at present evidence of long-term benefit appears to be lacking.

Kaposi's sarcoma (KS) is another tumor with increased frequency after organ transplantation. The true prevalence of this tumor depends on the geographic origin of the recipients, being higher in the Mediterranean basin and Africa. In the French GCIF registry a prevalence of 0.52% was seen with higher values in liver transplant recipients (1.24%) than the kidney and heart transplant recipients (0.45% and 0.41%, respectively). Other HHV-8 associated disorders in SOT recipients include multicentric Castleman disease, primary effusion lymphoma, and HHV-8 associated inflammatory cytokine syndrome. Of note, HHV-8 infection can be donor derived; screening for HHV-8 in donor and recipients is not currently recommended because of the poor specificity of current available assays [68, 69].

53.4.2 Skin Cancers

Non-melanoma skin cancers are the most frequent types of cancers seen in post-organ transplant. Out of these squamous cell cancer is the more common pathologic diagnosis with an incidence 65 times the general population followed by basal cell with 10 times the incidence compared to the general population [70].

These tumors are also more aggressive with increased risk of metastases and recurrence. The risk factors for skin can-

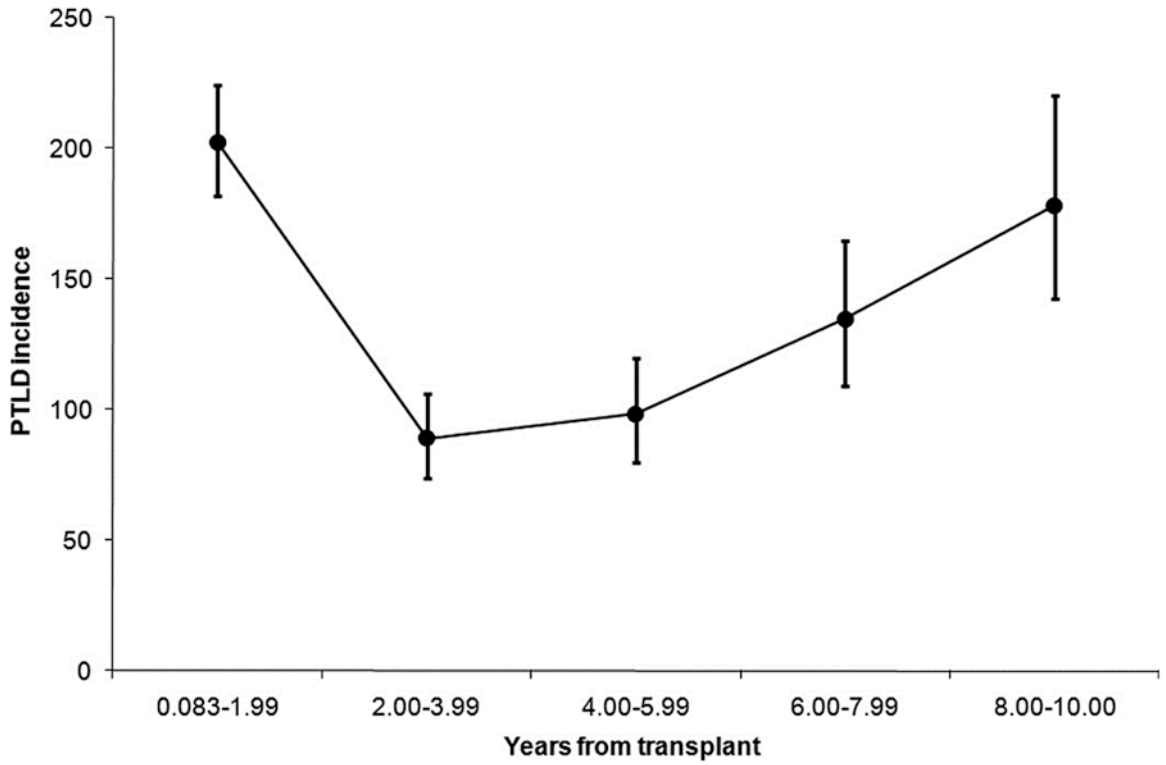

FIGURE 53-3. Bimodal pattern of PTLD incidence in kidney transplant recipients. From Quinlan SC, Pfeiffer RM, Morton LM. Risk factors for early-onset and late-onset post-transplant. lymphoproliferative disorder in kidney recipients in the United States. Am J Hematol. 2011 Feb;86(2):206–9.

cers include Fitzpatrick skin type I to III, photosensitivity, cumulative sun exposure, increasing age, and increased intensity and duration of immunosuppression [71].

The disease is predominantly seen in fair skinned patients and in the sun exposed sites, e.g., head and neck area and the hands. These patients need to have a skin examination before transplant and then follow-up regularly.

The risk of developing skin cancers is higher in lung and heart–lung transplant recipients followed by kidney transplant recipients with the lowest risk seen in liver transplant recipients. This is likely due to lower levels of maintenance immunosuppression in this population and the age at transplantation [72].

There is some data hypothetically linking human papilloma virus (HPV) to the increased incidence of skin cancers but a causal relation is not proven. SOT recipients have been shown to harbor greater quantities of some HPV types in squamous cell cancers and E6/7 transcripts of HPVs 8, 9, and 15 have been found in some squamous cell cancers and predisposing actinic keratosis suggesting a role in pathogenesis [73, 74]. Of note, the impact of HPV vaccination in reducing the incidence of de novo skin cancer after transplantation has not been investigated.

The risk of less common skin cancers like melanomas and Merkel cell carcinoma is also increased in organ transplant recipients [71]. There is a three- to fivefold increased risk of melanomas in the transplant recipients [75]. US Scientific Registry of Transplant Recipients study revealed a standardized incidence ratio (observed/expected cases) of 2.38 [51]. The mean duration to development of melanoma after transplant is 5 years [75]. The risk factors for development of melanoma are multiple nevi, degree of immunosuppression, and fair complexion.

Voriconazole by virtue of causing photosensitivity has been associated with predisposition to development of skin cancers in the SOT recipients. This data comes from the lung transplant population which has the highest incidence of invasive aspergillosis amongst solid organ transplant recipients [76] requiring the use of voriconazole.

The type of immunosuppression is also related to the incidence of skin cancer. Azathioprine has been known to have photosensitizing effects by virtue of its metabolite 6-thioguanine which may result in photocarcinogenesis. The potential etiology could be by formation of highly reactive oxygen radicals [77] and replacing azathioprine has been shown to decrease skin photosensitivity [78].

The anti-angiogenesis and anti-proliferative properties of sirolimus have been hypothesized to be associated with a reduced incidence of malignancy post-transplantation [79]. Conversion to sirolimus based regimen after 6 months of transplant in selected high risk patients with stable graft function may have some value [80, 81].

We suggest regular cancer screening for solid organ transplant recipients in accordance with the age appropriate guidelines for general population with some caveats (Table 53-4). The benefits of screening are likely to be high in the case of malignancies that are noted to be increased after solid organ transplantation. However, more frequent screening may also lead to false positive results and unnecessary further testing. This approach should only be considered as a general guidance since no studies have formally evaluated the value of cancer screening in the transplant population.

53.5 Hypertension (HTN)

A significant proportion of solid organ transplant recipients develop hypertension after transplant with the prevalence ranging from 50% to 80% [82]. The risk factors for this include immunosuppressive treatment mainly the CNIs. The other contributing factors include the use of steroids, chronic kidney disease, weight gain related to steroids, and other factors.

A variety of mechanisms have been postulated to explain CNI related HTN. These include endothelial dysfunction with imbalance between vasoconstrictor endothelin [83] and vasodilator substances like prostacyclin, reduced GFR with increased sodium reabsorption [84], renin angiotensin aldosterone level increases particularly later in the course [85], and possible sympathetic activation.

HTN should be aggressively managed in this population according to the usual guidelines. Anti-hypertensive agents should be used as needed with monitoring of renal function and counseling about weight loss strategies and other metabolic risk factors. There may be some use of changing cyclosporine to tacrolimus or decreasing the target levels of CNI as allowed by the allograft function if the HTN is recalcitrant (http://m.srtr.org/2011/chapters/lung/images/12%20LU%20s5%20fig%207-01.png).

53.6 Diabetes Mellitus

Ten to fifteen percent organ transplant recipients develop de novo DM post-transplant. Some studies have shown that the cumulative incidence of this condition in heart transplant recipients may reach 32% at 5 years [86] similar to that reported in kidney and liver transplant patients. The 12-month cumulative incidences of new-onset diabetes after transplantation were found to be 13% for heart, 11.4–11.9% for liver, and 1.8–21.7% for kidney transplantation [87].

This is mainly related to the mainstays of immunosuppression which are CNIs and steroids. In addition underlying factors like age, family history, and obesity play a role as well. CNIs are diabetogenic by decreasing the secretion due to pancreatic β-cell apoptosis and synthesis of insulin and possibly calcineurin related insulin resistance [88].

Steroids cause DM via multiple mechanisms including insulin resistance, weight gain, and increased appetite. Most of these effects are pronounced in the first year of transplantation when the doses of these medications are quite high [89, 90].

53.7 Hyperlipidemia and Cardiovascular Disease

Hyperlipidemia is common after SOT and about half of the organ recipients develop some form of dyslipidemia with the incidence of hypertriglyceridemia and hypercholesterolemia after liver transplant reported as being over 60% [91]. The main factors predisposing to this are the immunosuppressant meds including steroids, mTOR inhibitors, and CNIs and other comorbid conditions like diabetes and obesity, diet and genetic predisposition. It has been suggested that cyclosporine may inhibit the enzyme 26-hydroxylase thereby decreasing the synthesis of bile acids from cholesterol and subsequently the transport of cholesterol to the intestines. Cyclosporine is also reported to bind to the low-density lipoprotein (LDL) receptor, which results in increased serum levels of LDL cholesterol [92]. Corticosteroids are reported to contribute to hyperlipidemia via several mechanisms. These include enhancing the activity of acetyl-coenzyme A carboxylase and free fatty acid synthetase, increasing hepatic synthesis of VLDL, down-regulating LDL receptor activity, increasing the activity of 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase, and inhibiting lipoprotein lipase [93].

Hypercholesterolemia in organ transplant recipients may be associated with an increased risk for allograft vasculopathy. In cardiac transplant recipients, transplant vasculopathy takes the form of transplant coronary artery disease (CAD); in renal transplant recipients, vasculopathy manifests as chronic rejection; in hepatic transplantation, vascular involvement of biliary epithelial blood supply can manifest as vanishing bile duct syndrome. Atherosclerotic vascular disease in non-transplant vessels is another possible consequence. It has been reported that 55% of deaths in renal transplant recipients with functioning allografts were cardiovascular related. Peripheral vascular disease has been reported in 10% of heart transplant recipient [94, 95].

Cardiovascular disease (CVD) is a common cause of morbidity and mortality after solid organ transplantation. Both preexisting cardiovascular risk factors in recipients and immunosuppressive drug toxicity may contribute to CVD. In a study of 126 patients by 3 years after transplantation, 90% of patients had developed at least 1 cardiovascular risk factor and 40% developed ≥2 risk factors. The cumulative prevalence of new-onset hypertension at 1, 3, 5, and 7 years was 45%, 65%, 67%, and 72%, respectively. The corresponding

Table 53-4. Suggested screening for malignancies in organ transplant recipients

Organ	Recommendation
Skin	Monthly self-examination with a yearly skin examination by specialist. Early resection of suspicious lesions
PTLD	Periodic clinical assessment for symptoms or signs. In EBV mismatched patients viral titers in blood/plasma have been followed early post-transplant
Breast	Periodic self-examination and annual age appropriate mammograms
Colorectal	Colonoscopy every 10 years above 50 years of age. Earlier and more frequent if high risk. Fecal occult blood yearly but less specific
Lung	Yearly low dose CT in patients with native lung and over 30-pack year smoking. Need to consider alternate etiologies for findings
Cervical	Annual pelvic examination and pap smear for >18-year-old females. Role of HPV DNA testing unclear
Renal and urogenital	Low threshold for imaging (annual ultrasound) with high risk factors including analgesic abuse, cytotoxic chemotherapy, multicystic renal disease, and hematuria
Hepatocellular	Consider periodic screening with ultrasound and alpha fetoprotein if recipient is hepatitis B or C infected
Prostate	Consider yearly PSA and digital examination for patients over 50 years

prevalence for hypercholesterolemia was 16%, 33%, 48%, and 58%, and for diabetes 6%, 7%, 7%, and 10%, respectively, [96].

53.8 Bone Disease

Bone loss after SOT is a common and significant problem and can develop within months of transplantation [97]. Osteoporosis develops in a significant proportion of SOT recipients. The prevalence of osteopenia and osteoporosis can reach up to 50% in renal transplant recipients and is associated with increased incidence of fractures. 25% of liver and kidney transplant recipients develop pathological fractures. Osteoporosis at the lumbar spine (LS) has been reported in approximately 28% and at the FN in approximately 20% in cardiac transplant and up to 73% in lung transplant recipients [98] with fracture rates from 18% to 65% most commonly effecting the spine and ribs.

The bone loss is related to several pre- and post-transplantation factors including steroid use and dose, renal disease and osteodystrophy, vitamin D disorders, lack of exercise, hypogonadism, parathyroid hormone levels, malnutrition, older age, and female gender are other predisposing factors. Cyclosporine may be associated with bone loss by direct effects on calcineurin genes in osteoclasts [99] or indirectly via T cell mediated effects. Rapid bone loss with FK506 has been reported in both cardiac [100] and liver [101] transplant recipients.

There is some data that patients with osteoporosis or osteopenia showed worse graft function at 1 and 8 years compared with patients with normal bone mass density [102]. The most rapid rate of osteoporosis occurs during the first year of transplantation [103] most likely due to higher doses of immunosuppression, less weight bearing, and higher metabolic and other comorbid disturbances.

Careful monitoring of patients with bone densitometry both pre-transplant and periodically post-transplant and use of calcium and Vit D supplements along with resistance training and exercise is very important in risk assessment and in preventing and treating bone loss and pathological fractures. The management focuses on prevention by modifying the risk factors outlined above and treatment as indicated.

Bisphosphonates are the treatment of choice for preventing transplant bone loss particularly in patients with evidence of bone loss, history of fragility fractures, and other risk factors. Calcitriol is an alternate agent for preventing bone loss.

53.9 Obesity in Organ Transplant Patients

Obesity is a significant problem in the organ transplant population and in the setting of other cardiovascular risk factors common in this group, including hypertension and diabetes, can have deleterious consequences. The use of steroids and other immunosuppressive medications predisposes to obesity and other cardiovascular issues. An accelerated weight gain of about 20 bounds has been described within the first year of transplant in liver, heart, and kidney recipients [104–106].

The rate of post-transplant metabolic syndrome in liver transplant recipients is more than twice that reported for the general population and has been associated with cardiovascular morbidity [107]. Obesity has also been recognized as a risk factor for post-transplant fatty liver [108]. Metabolic syndrome has also been noted to be more common in kidney recipients and associated with coronary artery disease [109]. Cardiac transplant recipients with BMI > 35 at the time of transplant had significantly higher morbidity and mortality [110]. Obesity is recognized as an independent risk factor for primary graft dysfunction after lung transplantation [111]. Obesity has also been observed to be a risk factor for death after lung transplantation [112].

As the long-term survival from organ transplant increases it is conceivable that the consequences of obesity and the metabolic syndrome will become more noticeable and important to address.

53.10 Chronic Allograft Dysfunction

Chronic allograft dysfunction has been a significant long-term issue in organ transplant recipients not succumbing to other processes. It is known by different names depending on the organ: chronic allograft nephropathy (CAN), transplant glomerulopathy, or chronic renal allograft dysfunction in kidney transplant recipients; chronic allograft vasculopathy (CAV) in heart transplant recipients; vanishing bile duct syndrome (VBDS) in liver transplant recipients, and bronchiolitis obliterans syndrome or chronic lung allograft dysfunction (CLAD) in lung transplant recipients.

Chronic allograft dysfunction points to a variable and usually slow decline in the organ function beginning within months of transplant. It is difficult to differentiate this process from other contributing processes or diseases and usually is a diagnosis of exclusion with some support provided by histopathology from a biopsy. The clinical significance of chronic allograft dysfunction depends also on the organ transplanted. While CLAD is the main cause of allograft loss and death after lung transplantation (50% at 5 years), the incidence and outcomes of VBDS in liver transplant recipients have not completely been established.

The histopathology of CAN is characterized by fibrous intimal thickening of arteries, glomerulosclerosis, interstitial fibrosis, and tubular atrophy [113]. It is common at 10 years after transplantation being present in over 50% of patients [114]. It is manifested by decline in kidney function, hypertension, and proteinuria [115].

The pathophysiology of this process is unknown and is most likely multifactorial with contributions from immunological factors like antibody-mediated rejection and non-immunologic factors. Drug toxicity, bacterial or viral infection, hypertension, obstruction, recurrent or de novo renal diseases, and acute and chronic cell- and/or antibody-mediated rejection need to be addressed and some cases remain as "interstitial fibrosis and tubular atrophy, no specific cause (IFTA)" [116].

Infection significantly contributes to the development of chronic allograft dysfunction in kidney transplant recipients, and in particular in case of viral infections (Figure 53-4). The mechanisms as to why infection contributes in the impairment of allograft function include, on the one hand, the development of direct allograft injury (for example, in case of BK virus associated nephropathy or by inflammation associated with CMV disease or by bacterial urinary tract infection) and, on the other hand, by immunological factors triggered by viral replication, such as the activation of the innate and adaptive immune systems, leading to the development of acute and chronic rejection. This has particularly been observed after CMV infection [117]. The impact of CMV replication in impairing allograft outcomes has significantly been reduced with the introduction of universal preventive strategies against CMV, mainly with the use of antiviral prophylaxis, which has been associated with a decrease in the rate of acute rejection [118] and graft loss [119]. However, studies assessing long-term outcomes (i.e., > 10 years) in kidney transplant recipients receiving antiviral prophylaxis are lacking.

Similarly in the lung transplant recipients a majority of recipients develop a relentless dysfunction to varying degrees called CLAD which encompasses the commonly recognized bronchiolitis obliterans syndrome (BOS) an obstructive process and other recently recognized processes including restrictive allograft dysfunction (R-CLAD) and a neutrophilic variant which is azithromycin responsive allograft dysfunction (ARAD) [120]. The pathophysiology of these processes remains obscure. Recurrence of some native disease processes like sarcoidosis needs to be ruled out. Infection appears to play an important role in the development of CLAD after lung transplantation. In addition to CMV, other viral infections such as influenza and RSV infection have been associated with both transient and progressive decline in lung allograft function. Influenza vaccination may reduce the burden of influenza-associated allograft dysfunction. Also, some studies have identified de novo colonization of the respiratory tract with *Pseudomonas aeruginosa* [121] and colonization/infection with *Aspergillus fumigatus* [122] as significant risk factors for the development of CLAD. The role of antibiotic and antifungal prophylaxis in reducing the incidence of CLAD has not yet been established.

In heart transplantation, this disease process is referred to as cardiac allograft vasculopathy (CAV) contributed to by immunologic factors and non-immunologic processes like hyperlipidemia, cytomegalovirus infection [123], baseline coronary artery disease, and the mechanism of brain death in the donor [124]. CAV affects over 30% of patients within 5 years of cardiac transplantation [125].

Histological abnormalities are commonly present in late post-transplant biopsies, including protocol biopsies from patients who appear to be well with good graft function. Recurrent disease is the commonest recognized cause of abnormal graft histology, but may be modified by the effects of immunosuppression or interactions with other graft complications, resulting in complex or atypical changes [126].

53.11 Neurotoxicity

CNIs are associated with neurotoxicity in a significant number of organ recipients. The manifestations of this toxicity lie along a wide spectrum with the most common manifestation being tremor related to tacrolimus or cyclosporine. This tremor may range from mild to disabling in which case a change in immunosuppression may be warranted. CNIs also have other minor non-specific CNS effects including

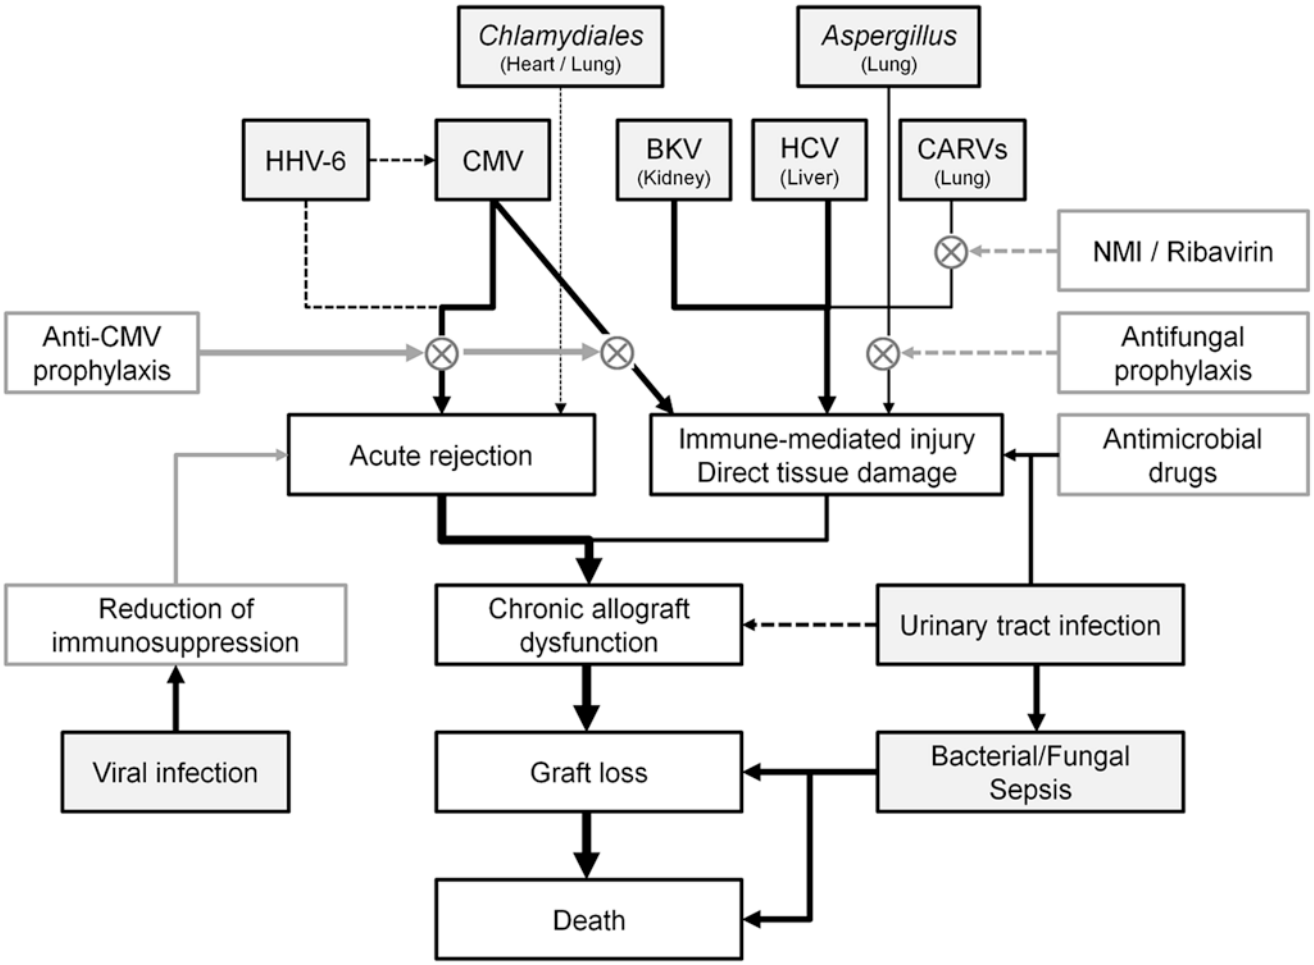

FIGURE 53-4. Potential interaction between infections and transplant outcomes. From Martin-Gandul, C., Mueller, N. J., Pascual, M. and Manuel, O. (2015), The Impact of Infection on Chronic Allograft Dysfunction and Allograft Survival After Solid Organ Transplantation. American Journal of Transplantation. doi: 10.1111/ajt.13486.

headaches, confusion, mild encephalopathy [127], memory issues, and insomnia or major complications, as neuropathy, reversible posterior leukoencephalopathy syndrome, and seizures. Some of the effects have been related to the hypomagnesemia and hypertension related to tacrolimus.

These effects are usually seen early on after initiation but can happen after long-term immunosuppression [128].

Beta blockers and primidone have been used for the tremor if stopping the medication is not an option.

53.12 Hematological Toxicity

The common effects include anemia, leukopenia, and thrombocytopenia. The factors predisposing to this include medication effects on bone marrow from drugs like mycophenolate and sirolimus used for immunosuppression, valganciclovir or acyclovir used for treatment or prophylaxis of CMV or HSV, and trimethoprim and sulfamethoxazole used as prophylaxis for *Nocardia* and PCP. In cases of liver transplant some degree of pre-transplant hypersplenism may contribute to this issue.

53.13 Psychiatric Complications

The process of organ transplantation takes a toll on the recipient psychologically with anxiety and depression being common problems after surgery. The effects of the intensive care stay, the need for an intensive post-transplant management, fear of complications, and social and economic impact require a psychological resilience and coping that can lead maladjustment. About 20–63% organ transplant recipients develop anxiety or depressive disorders post-transplant [129]. The number seems to be higher for cardiothoracic transplants.

53.14 Conclusion

In general as the life expectancy of solid organ transplant recipients improves, the care of these patients needs to be all encompassing addressing community-acquired viral and bacterial infections, metabolic and cardiovascular complications, and a wider range of neoplasia with a focus on preventive maintenance as well. The periodic screening of this population for the late complications discussed will likely have an impact on morbidity and outcomes.

Erratum to: Special Considerations for Long-Term Survivors After Solid Organ Transplantation

Hakim Azfar Ali, Scott M. Palmer, and Oriol Manuel

Erratum to:
Chapter 53 in: P. Ljungman et al. (eds.), *Transplant Infections*,
https://doi.org/10.1007/978-3-319-28797-3_53

The original version of this chapter Table 53-2 had the wrong headings--duplicated one year events. This has been corrected and the correct heading has been updated to Five year events 2004-06 tx in the last column.

The updated online version of this chapter can be found at
https://doi.org/10.1007/978-3-319-28797-3_53
