Atopic Dermatitis

22

Tetsuro Kobayashi and Keisuke Nagao

Abstract

Atopic dermatitis (AD) is a common skin disease that has received much scientific attention over the recent years. Although disease mechanisms had been difficult to dissect, with multiple factors that seem to affect disease activity, skin barrier, aberrant immunity and the microbiota appear to be the important components in pathogenesis. In this chapter, we will discuss the current concept of AD, its related genetic disorders, and the above pathological components to try to provide cutting-edge understanding on pathogenesis of this disease.

Keywords

Atopic dermatitis • Pathogenesis • AD • Inflammatory skin disorder • Skin leisons • T cells • Dendritic cells • Altered skin microbiota • Dry skin • Immunodeficiency • Genetic skin disorders

Key Points

- Atopic dermatitis is a common chronic inflammatory skin disorder. Patients suffer from eczematous lesions with distinct distribution and dry skin, complicated with progressive development of other allergic diseases, called the atopic march.
- *FLG* gene mutations are a major genetic predisposing factor, suggesting that barrier disruption is prerequisite for eczematous inflammation.
- Several rare genetic disorders manifest eczematous skin phenotype that resembles atopic dermatitis. Netherton syndrome and hyper-IgE syndrome are such prototypes with mutations in well-defined genes.
- *Staphylococcus aureus* colonization is universal in skin of patients with not only atopic dermatitis but also other genetic disorders manifesting eczema.
- Impaired epidermal barrier, immunological abnormalities and altered skin microbiota are three major factors that play a role in atopic dermatitis.
- A variety of helper T cells, such as Th1, Th2, Th17 and Th22, are involved in the pathogenesis of atopic dermatitis.
- Restoring barrier, modulating immune responses and normalizing dysbiosis are three important strategies for the treatment of atopic dermatitis.

Atopy

Atopic dermatitis (AD) is a chronic inflammatory skin disorder and one of the most common skin diseases seen by dermatologists [1, 2]. Defining AD in simple words is rather difficult, but atopy in terminology has been recognized as a personal or familial tendency to become sensitized and produce specific IgE antibodies to foreign

A.A. Gaspari et al. (eds.), *Clinical and Basic Immunodermatology*, DOI 10.1007/978-3-319-29785-9_22

antigens and lead to the development of asthma, rhinitis or eczema [3]. Progressive development of asthma, allergic rhinitis and food allergy in patients with AD is referred to as 'atopic march' [4]. The main clinical feature of AD is eczematous dermatitis with pruritus that has distinctive distributions and that arises upon dry skin [5]. As will be discussed below, it is becoming clearer that barrier disruption, manifesting as dry skin, is attributed to mutations in genes that are necessary for normal epidermal differentiation and function. The role of IgE is not yet clear in eczema formation, and a minor subset of patients exhibit symptoms indistinguishable with AD.

Epidemiology

AD is a prevalent disease that affects 15–30 % of children and 2–10 % of adults. In the past, AD had been more prevalent in highly developed countries. Recently, there has been an increase in the prevalence of AD in relatively under developed countries. A number of population-based prevalence surveys have been conducted to find epidemiological factors for the development of AD and have revealed significant differences in the prevalence of AD between countries. It was suggested that not only genetic factors, but also environmental factors might be pathological factors that contribute to the development of AD. A relatively recently reported environmental factor that had not received much attention is the climate. Based on ecological analysis of AD prevalence, the results, which were adjusted for national per capita income, suggested that AD symptoms correlate positively with latitude, which is attributed to less exposure time to UV light, and negatively with annual outdoor temperature [6].

Consistent with the above finding, a recently performed ecological analysis has also suggested the negative correlation of UV index with decreased prevalence of eczema [7]. AD patients have decreased levels of serum vitamin D, suggesting that low UV exposure time and resulting low serum vitamin D are risk factors for AD [8].

Dry skin is a major clinical manifestation of AD patients and low humidity is a potential exacerbating factor. Consistent with this, AD prevalence was significantly lower with the higher relative humidity [7].

Another prevailing concept is the so-called 'hygiene hypothesis'. It holds that the lack of early childhood exposure to microbes, parasites or other infectious agents increases the risk of allergic diseases due to defects in immune tolerance [9]. Inverse relationship between the risk of AD and endotoxin exposure has been found [10]. Early life exposure to antibiotics can lead to an increased risk of developing eczema [11], which, at a superficial level, is consistent with the report that AD patients harbor low intestinal microbial diversity [12]. The surroundings of homes of atopic individuals are reported to be lower in environmental biodiversity and that such AD patients exhibit significantly lower genetic diversity of gammaproteobacteria on their skin [13], suggesting that natural environment could influence the composition of the human microbiota, and that the reduced contact with such environment could lead to less opportunity to acquire microbes that have the ability to regulate immune functions.

Genetics

Family history of AD or other allergic diseases has been known to be a major risk factor of AD in children suggesting genetic background as a strong risk factor for the development of AD [14]. Recent advances of molecular technologies in genetic analysis have accelerated studies on genetics of patients with AD. Candidate gene approach or genome-wide linkage analysis has identified a number of possible AD-related genes [14]. Since the first genome-wide association study (GWAS) of AD patients reported in 2009, several susceptibility loci for AD have been identified based on GWAS [15, 16].

Although the genome-wide analysis provides a comprehensive and unbiased data set on AD associated-genes, a genetic risk factor stronger than filaggrin gene (*FLG*) has yet to be discovered. The gene *FLG* encodes a large insoluble polyprotein, profilaggrin, which undergoes enzymatic cleavage to generate multiple filaggrin peptides. Such filaggrin peptides function as structural proteins that bind actin filaments to maintain structural integrity, and as so-called natural moisturizing factors, a group of molecules believed to hold moisture within the stratum corneum.

In 2006, two common loss-of-function mutations within the *FLG* gene were found to cause ichthyosis vulgaris [17]. Since ichthyosis vulgaris had been well recognized to associate with AD, investigations of *FLG* mutations were further conducted in the context of AD. As a result, significant associations between AD and two *FLG* null alleles were found in 15 families with ichthyosis vulgaris, and additional AD cohorts from Ireland, Scotland and Denmark demonstrated a strong and highly significant association between *FLG* null mutations and AD [18]. About 40 truncating mutations have been found so far, with distinct mutations in the European and Asian patient populations [19]. Recent meta analyses of multiple studies assessing *FLG* mutations as well as GWAS also confirmed the association of *FLG* mutations with AD [16, 20]. Thus, although some conflicting data exist, most reported studies are congruent with the original finding that *FLG* mutations represent a major predisposing factor for AD.

AD-Like Genetic Disorders with Aberrant Barrier Formation

It is not only *FLG* mutation that results in eczema formation, but several rare genetic disorders also manifest symptoms that resemble AD (Fig. 22.1 and Table. 22.1). Because of their specific and well-characterized genetic defects, these diseases could represent useful prototypes that might allow us to gain deeper insight into the mechanisms of eczematous dermatitis at the molecular level. These diseases could be considered as a part of the extended spectrum of atopic diseases.

Netherton syndrome is an autosomal recessive skin disorder characterized by congenital ichthyosis and severe atopic manifestations including eczematous lesions and staphylococcal skin colonization, food allergy and rhinitis with high serum IgE. It is caused by mutations in *SPINK5*, encoding the serine protease inhibitor LEKTI [21]. LEKTI inhibits several members of kallikreins (KLK) including KLK5, KLK7 and KLK14, the balance of which is crucial to regulate desquamation. Loss of LEKTI leads to aberrant enhancement of multiple proteolytic events in epidermis, and Stimulates proinflammatory signals via protease activated receptor 2 (PAR2). *Spink5*-deficient mice and KLK5-overexpressed mice manifest Netherton syndrome-like, as well as AD-like phenotypes, such as eczematous inflammation, and high serum IgE and TSLP [22–24], which was attributed to PAR2-mediated TSLP up-regulation [23]. A significant association of a *SPINK5* polymorphism with AD has been found, indicating an overlap of disease pathogenesis between NS and AD [25].

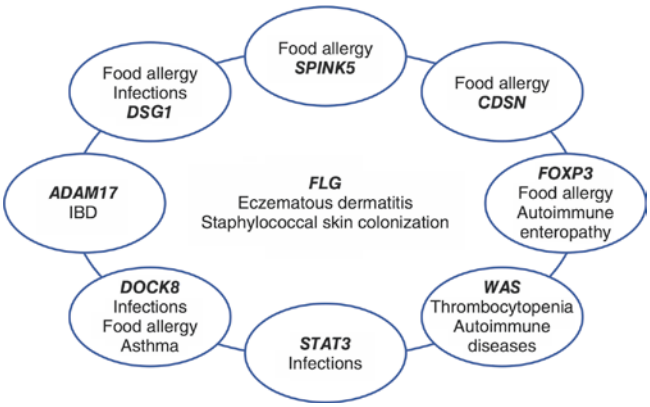

Fig. 22.1 Spectrum of atopic/eczematous dermatitis. List of genes in which mutations can cause eczematous dermatitis associated with staphylococcal colonization bacterial and fungal infections, and other clinical manifestations such as food allergy and asthma

A generalized, inflammatory type of peeling skin syndrome (type B) also manifests as eczematous dermatitis and food allergies. This disease is associated with mutations in *CDSN*, which leads to a complete loss of corneodesmosin [26]. Corneodesmosin is an adhesion glycoprotein located in corneodesmosomes, and deletion of *Cdsn* resulted in hair and skin abnormalities also in mice [27].

Recently, loss-of-function mutations of another important transmembrane structural protein have been reported in patients with eczematous dermatitis. Homozygous mutations in *DSG1*, which encodes desmoglein1, a major constituent of desmosomes, cause a syndrome featuring severe dermatitis, multiple allergies and metabolic wasting (SAM syndrome) [28].

Interestingly, like *FLG*, gene defects in the above diseases and those listed in Table 22.1 directly impair normal differentiation and formation of the upper epidermis to the stratum corneum. Furthermore, it is interesting to note that disease affecting lower parts of the epidermis, such as epidermolysis bullosa, does not result in eczematous dermatitis or asthma and food allergies despite the formation of ulcers or erosions that potentially allow antigen penetration. Existence of upper epidermis ~ stratum corneum with dysfunctional barrier appears crucial for the development of AD and subsequent atopic march.

AD-Like Genetic Disorders with Immunodeficiency

Patients with primary immunodeficiencies, which are caused by mutations in genes mainly associated with the development and regulation of immune cells, can also exhibit

Table 22.1 AD-like genetic disorders

Disease	Causative gene	Staphylococcal infections
Netherton syndrome	*SPINK5*	Skin
Peeling skin disease	*CDSN*	Skin
SAM syndrome	*DSG1*	N.D.
Autosomal dominant hyper-IgE syndrome	*STAT3*	Skin and respiratory tract
Autosomal recessive hyper-IgE syndrome	*DOCK8*	Skin and respiratory tract
Wiskott-Aldrich syndrome	*WAS*	Skin and respiratory tract
ADAM17 deficiency	*ADAM17*	Skin
IPEX syndrome	*FOXP3*	Skin and respiratory tract

SAM severe dermatitis, multiple allergies and metabolic wasting, *N.D.* not determined, *IPEX* immunodysregulation polyendocrinopathy enteropathy X-linked

eczematous dermatitis that closely resembles AD. An autosomal dominant form of hyper-IgE syndrome (HIES) is caused by mutations in *STAT3*, and manifests as eczematous dermatitis with recurrent staphylococcal infections [29, 30]. Staphlycococcal infections not only occur in skin and soft tissue, but also in the respiratory tract. Patients with an autosomal recessive type of HIES caused by *DOCK8* mutations also have eczema and recurrent staphylococcal skin infections [31]. Another rare primary immunodeficiency, Wiscot-Aldrich syndrome, is characterized by eczematous dermatitis with recurrent skin infections, in addition to thrombocytopenia [32]. It is caused by mutations in *WAS*, a protein that is important for proper actin cytoskeleton function during cell motility, and is expressed in most hematopoietic cells.

The hallmark of the above-mentioned diseases is immune dysregulation that leads to increased susceptibility for recurrent infections in skin as well as other organs. Gene mutations responsible for these diseases have not been implicated to be involved in epidermal differentiation. Although it is clear that barrier dysfunction can lead to AD, a pathway that arises from immune dysfunction to barrier dysfunction is also possible. AD-like genetic diseases that result from barrier dysfunction and immunodeficiency might represent opposite ends of the AD spectrum.

A Gene Mutation That Affects Both Immunity and Barrier Formation

A new genetic disorder has been reported that could be fitted within the atopic spectrum. Patients with loss-of-function mutations in *ADAM17* manifest eczematous dermatitis and pustules with *Staphylococcus aureus* skin infections [33]. The function of ADAM17 in skin has been investigated in murine studies, which demonstrated that deficiency of ADAM17 down-stream signaling pathways such as EGFR or Notch are responsible for impaired barrier integrity, immune dysregulation and staphylococcal dysbiosis [34–36]. Note that many of these diseases in the atopic disease spectrum have staphyloccoccal skin colonization in common [37], which may be responsible for the induction of eczematous dermatitis.

Pathomechanisms

Pathophysiology of AD is complex and, as suggested in the above section, multiple pathways can lead to one common clinical phenotype. There are three major drivers that contribute to the pathogenesis of AD: (1) Impaired epidermal barrier (2) immunological abnormalities and (3) altered skin microbiota. Immunological disturbance as the primary cause of AD has been widely investigated because the mainstream of AD has been considered as Th2 type allergic responses against foreign antigens. High serum IgE concentration and eosinophilia are main laboratory features that support the Th2 concept. Barrier function in AD has been a point of focus over the past several years, which gained huge momentum after the discovery of *FLG* mutations. Meanwhile, increased colonization of *S. aureus* in skin of patients with AD has long been known, but was difficult to explain in the context of allergic inflammation. Recent advances in microbiome research are beginning to provide better understanding of interactions between the microbiome and host immunity and highlight the importance of *S. aureus* colonization in AD pathogenesis (Fig. 22.2).

Impaired Epidermal Barrier

Dry skin is caused by barrier alteration followed by increased trans epidermal water loss, and is considered an important underlying condition in AD. Since loss-of-function mutations in *FLG* have been reported in patients with AD, the manner in which filaggrin defects contribute to barrier dysfunction has been intensively studied. Given the fact that filaggrin is a major structural protein in the stratum corneum, filaggrin insufficiency would be expected to result in a number of structural, biophysical and functional changes, and in aggregate result in impaired barrier formation. Filaggrin breakdown products form natural moisturizing factors (NMF), which are thought to be essential for stratum corneum hydration. Although it is widely accepted that *FLG* mutations result in outside-in barrier dysfunction, the mechanism of this defect is yet to be fully elucidated.

Better understanding of filaggrin biology has been gained from murine models of filaggrin deficiency. The spontaneous mutant flaky tail/matted mice exhibit eczematous inflammation and enhanced immune response to cutaneous allergen exposure. A 1-bp deletion mutation of *Flg* was found [38], enforcing the previous finding in humans. Further studies investigating flaky tail (*Flgft*) mice showed clinical AD-like manifestations with barrier abnormalities and Th17-dominated skin inflammation [39–41]. Those studies suggested a crucial role of filaggrin in the maintenance of physical epidermal barrier. Unexpectedly, however, genomic deletion of filaggrin in mice led to altered stratum corneum barrier and enhanced percutaneous sensitization, but did not lead to the onset of spontaneous dermatitis under specific pathogen free conditions [42], demonstrating that filaggrin deficiency alone is not sufficient to induce eczematous dermatitis. In fact, recent studies revealed that the matted (*ma*) mutation, but not *Flg* mutation, is responsible for the dermatitis phenotype in *Flgft* mice [43, 44], which raises the question of whether eczematous inflammation is truly a result of enhanced antigen penetration subsequent to barrier dysfunction.

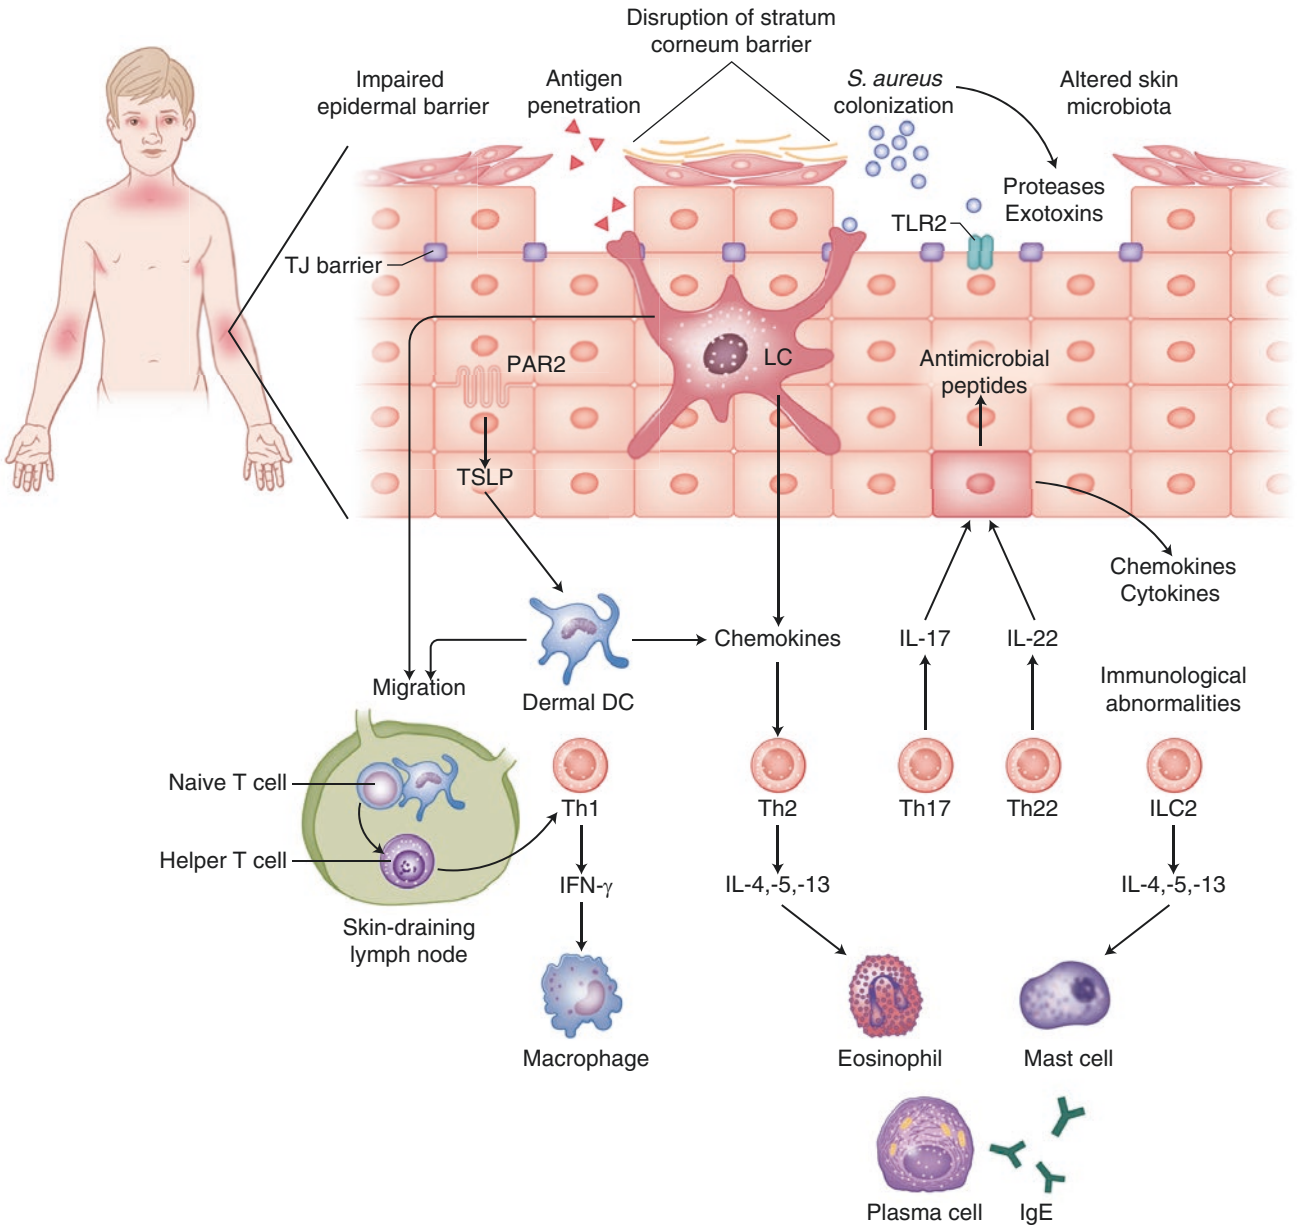

Fig. 22.2 Three major driving forces for the pathogenesis of atopic dermatitis: Impaired epidermal barrier, immunological abnormalities and altered skin microbiota. Loss of barrier integrity is believed to lead to antigen penetration and initiates inflammatory responses driven by a mixed type of cytokine producing T cells. Although the contribution of altered skin microbiota is not yet conclusive, staphylococcus aureus colonization is universal in AD as well as other genetic dermatosis and immunodeficiencies that exhibit eczematous dermatitis

Nevertheless, filaggrin is also reported to play an important role in maintaining pH balance of SC. Acidic conditions caused by filaggrin breakdown products, urocanic acid and pyrrolidone carboxylic acid, have been reported to inhibit the growth of *S.aureus* [45]. Moreover, reduced SC NMF components and consequent increased SC pH result in enhanced cleavage of proinflammatory IL-1 cytokines, which were increased in AD patients with *FLG* mutations as well as filaggrin deficient *Flgft/ft* mice [46]. In light of the matted mutant mice and *Flg* deficient mice, it remains to be clarified whether *Flg* mutation alone is responsible for the above findings.

Immunological Abnormalities

Th2 and Th1

Based on the clinical observation that patients with AD often manifest blood eosinophilia and elevated serum IgE levels, AD was long considered to be a Th2 type allergic disease. Th2 cells produce IL-4, IL-5 and IL-13 and activate eosinophils, basophils and mast cells as well as IgE-producing B cells, which are all involved in allergic reactions. In the 1990s, two studies detected mRNA expression of cytokines via *in situ* hybridization and reported increased

expression of Th2 cytokines in skin of AD patients [47, 48]. In addition, the serum level of the Th2-attracting chemokine, CCL17/TARC, correlates with AD activity [49], indicating contribution of Th2 type response in the disease flare. In contrast, elevation of Th1 cytokines, such as IFN-γ and IL-2, has also been detected in the late phase in patch test reactions of AD patients [50]. Those studies supported the evidence of Th2 cytokine bias as well as involvement of Th1 cytokines in AD.

Findings on TSLP have provided new insights into the mechanism of Th2 biased-pathogenesis in AD. TSLP is a potent activator of dendritic cells and plays an important role in the induction of CD4+ T cell-mediated allergic inflammation. TSLP promotes DCs to induce Th2-chemokines and consequently enhances the production of Th2 cytokines from T cells. TSLP was highly expressed in epidermis of AD patients [51]. Murine models of epidermis-specific overexpression of TSLP (K5-TSLP transgenic mouse) developed T cell-mediated dermatitis [52]. Other murine studies showed that TSLP promotes basophil responses and Th2 cytokine-mediated inflammation [53], and that TSLP induction through PAR2 activation induces dermatitis and basophil accumulation in flaky tail mice [54].

Although a number of studies have been conducted to prove Th2 involvement in the pathogenesis of AD, therapeutic targeting of Th2-mediating factors has not proven effective. Neutralization of Th2 cytokines or IgE and inactivation of B cells has not yielded promising outcomes. True clinical relevance of Th2 has yet to be demonstrated.

Interestingly, epithelial cells directly regulate cutaneous sensory neurons via TSLP activation to promote pruritus, which is dependent on PAR2-triggering Ca influx and NFAT translocation [55], suggesting the contribution of a non-immunological mechanism mediated by TSLP in AD.

Th17 and Th22

Emerging reports suggest the contribution of Th17 and Th22 in atopic skin [56]. IL-17 and IL-22 function to accelerate innate immune responses against extracellular pathogens and are linked to many immune/autoimmune related diseases. IL-17 and IL-22 are overexpressed in skin of AD [57, 58], and infiltrations of Th17 and Th22 cells into lesional skin have been reported [59, 60]. Correlation of serum IL-22 with CCL17 [61] and increase of IL-13/IL-22 producing cells in AD [62] suggest a link between Th22 and Th2 cytokines.

Th17-associated skin inflammation can be observed in several mouse models with AD-like inflammation, such as the flaky tail mice [40], transgenic kallikrein 5 mice [24] and Adam17 conditional knockout mice [36]. Importantly, IL-17 and IL-22 synergistically promote the induction of antimicrobial peptides from keratinocytes [63], and *S. aureus*-derived enterotoxin induces IL-17 production of T cells isolated from AD patients [64], suggesting that production of IL-17 and IL-22 is associated with colonization of *S. aureus* in AD skin (Table 22.2).

Other Cytokines

Overexpression of IL-18, an IL-1 superfamily, in murine epidermis resulted in dermatitis with elevated serum IgE and Th2 cytokines [65]. Epidermal IL-18 levels of patients with AD was correlated with SCORAD and prevalence of *S. aureus* colonization [66]. Transgenic mice overexpressing IL-31, an IL-6 family cytokine that is produced by Th2 cells, developed pruritic dermatitis [67]. Serum IL-31 is also increased in atopic individuals and the production of IL-31 in human PBMCs can be induced by staphylococcal enterotoxin B [68].

Innate Lymphoid Cells

After their recent discovery, innate lymphoid cells (ILCs) have emerged as essential effectors of innate immunity and potent players in the pathogenesis of many inflammatory diseases. ILCs resemble lymphocytes in morphology and function as effector cells through the production of several cytokines, but lack a T cell receptors. ILCs are divided into three groups based on their producing cytokines. Group 2 ILCs produce type 2 cytokines (IL-4, IL-5, IL-9, IL-13) and are implicated in allergic immune responses. The first report in the context of AD revealed that ILC2 are enriched in human AD skin lesions and in mouse skin with Vitamin D3-induced inflammation, and that ILC2 responses were dependent on TSLP [69]. Another report also found accumulation of ILC2 in lesional skin of atopic patients as well as in skin of house dust mite-exposed murine skin with dependency on IL-25 and IL-33 [70]. IL-25 and IL-33 are inducers of ILC2 expansion, and in fact, transgenic mice with epidermis-specific IL-33 overexpression developed AD-like skin lesions with increase of ILC2 [71]. Consistently, the expression of IL-33 receptor is increased in human AD skin [72].

Regulatory T Cells

Regulatory T cells (Treg) are CD25+, Foxp3+ T cell subsets, which play important roles in suppressing T cell responses. Although it is generally accepted that Treg modulate allergic inflammation by suppressing the Th2 response, the exact role of Treg in AD pathogenesis still remains unclear [73]. Treg was absent in AD lesional skin in one study [74], while it existed in other studies [75, 76]. Mutations of the Treg master regulator gene, *FOXP3*, result in the absent or dysfunctional Tregs and cause IPEX syndrome. Importantly, some of IPEX syndrome patients manifest allergic disorders including asthma, food allergy and eczema [77, 78], suggesting a strong link between the loss of Tregs and the onset of allergic diseases.

Table 22.2 Mouse models of AD

Mouse strain	Characteristics	References
Spontaneously developing models		
Nc/Nga	Scratch, increased TEWL, dermatitis, high IgE and increased expression of Th2 cytokines in skin	[126, 127]
Flaky tail (*ma/ma, Flgft/ft*)	Scratch, increased TEWL, dermatitis, high IgE and enhanced percutaneous sensitization to OVA	[38, 43, 44]
Genetically engineered models		
IL-4 transgenic	Scratch, dermatitis, *S. aureus* colonization and high IgE	[128]
IL-13 transgenic	Scratch, dermatitis, high IgE and increased expression of Th2 cytokines in skin	[129]
IL-31 transgenic	Scratch and dermatitis	[67]
TSLP transgenic	Dermatitis, high IgE and increased production of Th2 cytokines	[52]
CASP1 transgenic	Scratch, dermatitis and high IgE	[65]
Foxp3 knockout	Dermatitis and high IgE	[130]
ADAM17 conditional knockout	Scratch, high IgE, increased TEWL, *S. aureus* colonization and increased production of Th2 and Th17 cytokines	[34, 35, 36]
EGFR conditional knockout	Scratch, high IgE, increased TEWL, *S. aureus* colonization and increased production of Th2 and Th17 cytokines	[34, 36]
Notch1 and 2 conditional knockout	Dermatitis, high IgE and increased expression of Th2 cytokines in skin	[131]
Epicutaneous sensitization models		
OVA sensitized	Scratch, dermatitis, high IgE, increased expression of Th2 cytokines and chemokines in skin	[132, 133]
Hapten induced	Th2-associated dermatitis and high IgE	[134]

Dendritic Cells

Specialized antigen-presenting cells (APCs), or dendritic cells (DCs), play pivotal roles in the initiation of immune reactions through activation and modulation of T cells. Although the contribution of Langerhans' cells (LC) in initiating humoral responses against protein antigens that were taken up through the epidermal tight junctions have been established in mice [79–81], the role(s) of DCs in AD pathogenesis still remains enigmatic. It has been reported that human epidermal LCs express the high affinity receptor for IgE (FceRI) [82]. In addition, inflammatory DCs, that expressed CD206, CD209 and FceRI, but did not contain Birbeck granules, were found in lesional epidermis of AD patients, and were termed 'inflammatory dendritic epidermal cells' (IDEC) [83]. IDECs can be found to infiltrate not only epidermis, but also dermis of AD lesions [84].

FceRI on DCs mediate IgE-facilitated allergen presentation [85]. It is therefore possible that FceRI expressed on surfaces of LCs and IDECs are involved in IgE-mediated allergic reactions also in AD skin. TSLP receptor deficient mice reconstituted with normal bone marrow (therefore keratinocytes and LCs are the only relevant cells that lack TSLP receptors) resulted in decrease of clinical manifestations and OVA-specific IgE upon epicutaneous OVA sensitization in mice [86]. Moreover, vitamin D3 analogue-induced eczematous inflammation was decreased in the absence of LCs in mice [87]. Those experimental settings provide evidence that LCs contribute to Th2 as well as eczematous responses in mice, and further suggest that they may contribute to AD pathogenesis.

Altered Skin Microbiota

Skin harbors a diverse community of microorganisms, referred to as the microbiota. Composition of microbiota is greatly influenced by the condition of skin, and possibly, vice versa. Skin resident microbes are implicated in cutaneous immune system development and function and pathology of skin diseases. It has been long known that skin of patients with AD is heavily colonized with *S. aureus* [88]. Density of *S. aureus* colonization correlated with SCORAD [89, 90], suggesting the contribution of *S. aureus* to the mechanism of the disease flare.

Recent technological advances on next generation DNA sequencing have allowed the utilization of culture independent metagenomic approaches to investigate the collective genomes of resident bacteria, the microbiome, and have uncovered the details of bacterial community structure in skin [91]. Bacterial 16S rRNA sequencing analysis

in children with AD revealed temporal shifts in skin microbiome during flares, in which bacterial diversity decreases, and *S. aureus* predominates [92]. A microbiome study in patients with primary immunodeficiencies featuring AD-like eczema revealed that microbial compositions were altered in patients compared with controls, and prevalence of *Staphylococcus* and *Corynebacteirum* were positively correlated with disease severity [37]. Consistent with previously conducted studies with culture dependent detection techniques, these recent studies confirmed the emergence of *S. aureus* in eczematous lesions and provided new insight into bidirectional influences between microbes, particularly *S. aureus*, and atopic skin. However, the cause-and-effect relationship between staphylococcal colonization and eczema formation is still inconclusive, and the clinical studies provide evidence for anti-bacterial therapies only for secondary infections of eczematous lesions, but not for the treatment of eczema itself.

S. aureus is commonly found in healthy human skin, but could cause staphylococcal skin infections such as impetigo, folliculitis and abscesses under certain conditions. *S. aureus* produces a wide array of virulence factors, and it is not clear yet whether such factors contribute to eczema formation. Nevertheless, it is easily imaginable that virulence factors could have direct or indirect contributions, via host immune responses, to eczema formation or aggravation. A major group of virulence factors of *S. aureus*, such as proteases, hyaluronidase, lipase and nuclease, comprise extracellular enzymes. Another group is a family of exotoxins including cytolytic membrane-damaging toxins (mainly α, β, γ, and δ-toxins and Panton-Valentine leukocidin) and superantigens such as staphylococcal enterotoxin (SEA and SEB), toxic shock syndrome toxin-1 and exfoliative toxin A and B. An important characteristic of *S. aureus* is its ability to secrete exotoxins that disrupt host cell membrane. The correlation between the colonization of exotoxin-producing *S. aureus* strains and disease severity of AD has been reported [93].

The mechanism by which superantigens contribute to disease flares in AD has not been completely elucidated. Several reports have suggested effects of staphylococcal exotoxins on immune cells, by activating T cells by specific interaction between TCR and the toxin [94, 95], and by promoting allergic reactions through IgE generated against staphylococcal exotoxins [96–98]. A recent report showed that mast cell degranulation is induced by δ-toxin, suggesting pathological role(s) of secreted toxins in allergic skin disease [99].

Why *S. aureus* is capable of abundantly colonizing skin of AD patients is still another matter of debate, and might represent important mechanisms that could affect future therapeutic strategies. Skin is equipped with innate mechanisms that prevent overgrowth of *S. aureus*. Such mechanisms include protection against adherence of *S. aureus* to corneocytes. Acidic conditioning of skin inhibits the growth of *S. aureus*, and the production of antimicrobial peptide (AMP) by keratinocytes, sebocytes and eccrine glands likely targets *S. aureus*. Neutrophil responses are also promoted by IL-1β produced by keratinocytes [100]. It is possible that one or several of these factors are impaired in skin of AD patients.

One of the initial immune responses against bacterial pathogens is innate immunity via the recognition of pathogen-associated molecular patterns of bacteria through pathogen related receptors, and the most studied family of such receptors are Toll-like receptors (TLRs). Genetic variants of TLR2 have been studied in the context of AD, because it recognizes cell-wall products of *S. aureus*, and its polymorphism has been reported in AD patients with a history of *S.aureus* infections and increased serum IgE [101, 102].

AMPs are evolutionarily ancient innate immune effectors and are thought to contribute in immune defense of epithelial surface. Expression levels of AMPs have been reported in several studies, but the results of those are controversial. Reduced expression of cathelicidins (LL-37) and human β-defensin 2 (HBD-2) in AD skin was first reported in comparison to psoriatic skin [103], and was attributed to Th2 cytokine milieu in AD [104]. However, follow-up studies revealed the expressions of AMPs in lesional skin of AD are not actually decreased, but rather increased, when compared with healthy control skin [105] [90]. Meanwhile, mobilization of HBD-3 appears to be inhibited in keratinocytes derived from AD patients [106].

Increasing number of studies in the recent years has shown that imbalances in the composition of the intestinal microbiota are associated with both intestinal and extra-intestinal diseases. The association of altered gut microbiota with an increased risk of developing AD has been reported in several studies [12, 107–109]. Efforts have been made to "normalize" the imbalance of microbial composition in the intestine via the supplementation of probiotics. A double-blind, randomized placebo-controlled clinical trial demonstrated that taking Lactobacillus GG has a preventative effect in children at high risk of AD [110]. In the era of microbiome, such studies should be corroborated with microbiome analysis via next generation sequencing.

Treatment

Management of AD requires multiple approaches, targeting various aspects of pathogenesis. The cores of such aspects that were discussed in this chapter are barrier disruption, inflammation and, for future perspectives, dysbiosis. While strategic development of novel therapeutics will heavily depend on basic science, treatment strategies at the patient level should be determined based on clinical conditions of individual patients as well as evidence that is provided by

randomized controlled trials (RCTs), optimally supported by data from basic and clinical research.

Dry skin is a fundamental clinical element in AD, and the importance of SC barrier has been highlighted after the discovery of *FLG* mutations in patients with AD. Skin care aimed to maintain barrier integrity, thereby preventing epicutaneous sensitization against environmental allergens, would be a fundamental therapeutic strategy that accommodates most, if not all, disease phases in AD. There is strong evidence that supporting skin hydration by topical application of moisturizers reduces disease severity and prevents flares [111]. Pharmacologic interventions that directly target filaggrin expression that enforce barrier function may be a potential therapeutic approach in the future.

Control of inflammation by the use of anti-inflammatory or immunomodulating agents is another mainstream therapeutic strategy. Topical corticosteroids and calcineurin inhibitors are recommended based on evidence provided by a number of RCTs [111–113]. Systemic application of cyclosporin A is effective but only indicated for patients with AD refractory to conventional topical treatment [114, 115].

Although a large amount of scientific data on immunological pathophysiology of AD has been accumulated, specific therapies for inhibiting specific types of immune cells or cytokines are being studied in clinical trials. The results of clinical trials with new biologics such as monoclonal anti-IgE antibody (Omalizumab) and a chimeric monoclonal antibody against B-cell surface antigen CD20 (Rituximab) had been rather disappointing, although effective in a fraction of patients [112, 116]. Some early clinical trials have shown beneficial effects of recombinant IFN-γ in patients with severe AD [117, 118], but the level of evidence is still of limited-quality. With the variety of helper T cell subsets that have become known, it might be worth revisiting whether modulation and deviation of certain helper T cell subset(s) is a relevant strategy in the treatment of AD.

Inducing immunologic tolerance against specific allergens is an ultimate goal for the treatment of IgE-mediated allergic disorders in which major antigens have been established. There is enough evidence to support the effectiveness of allergen immunotherapy for the treatment of allergic rhinitis, allergic conjunctivitis and allergic asthma, but evidence for AD is still limited [119].

Consistent with epidemiological data that prevalence of AD negatively correlates with exposure time to UV, efficacy of phototherapy has been noted [120]. UV therapy is well established to exert immunosuppressive effects *in vivo*, for example by increasing IL-10 production [121], and can be utilized to attenuate skin inflammation. Meanwhile, specific recommendation of UV for a definitive AD condition has not been made, and its contraindication in patients treated with tacrolimus renders it to be considered a second line treatment.

In addition to initial culture-based studies, microbiome studies in humans have established that *S. aureus* dominates the microbiota during AD flares [92]. Consistently, it has been demonstrated in epidermal Adam17-deficient mice that *S. aureus* is capable of driving eczematous dermatitis, and that intense antibiotic cocktail targeting *S. aureus* nearly eradicates eczematous inflammation [36]. The concept that eczematous dermatitis is driven by *S. aureus* offers novel and attractive therapeutic strategies. However, despite the evidence of *S. aureus* colonization, and despite the longstanding interest in targeting this bacteria to try to improve AD symptoms, the efficacy of anti-bacterial treatment for AD patients remains unclear.

A Cochrane review of RCTs found a lack of quality trials to support the use of anti-bacterial therapies, for both topical and systemic antibiotics [122]. If antibiotics are to be utilized, well-designed randomized studies need to be conducted, considering the presence of Staphylococcal dysbiosis. With the current available evidence, the recommendation for the use of systemic antibiotics for AD patients is limited to those manifesting clear clinical signs of bacterial infections [120], and not for mere colonization. Intensified antibody cocktails might be necessary to target colonizing *S. aureus*, as have been done experimentally in mice. On the contrary, sustained systemic exposure to antibiotics will have adverse effects at distant sites such as the gut [123, 124], thus the approach utilizing systemic antibiotics might not be of practical use. In this context, the use of bleach baths is recommended for moderate to severe AD [125]. It is possible that bleach baths might be targeting Staphylococcal dysbiosis, and such skin microbiome-directed local therapy that normalizes dysbiosis long term, is awaited.

Questions

1. Which of the following genes associated with AD/AD-like genetic disorders have function(s) in barrier formation?
   A. *DOCK8*
   B. *FLG*
   C. *CDSN*
   D. *WAS*
   E. All of the above

2. Which of the following genes associated with AD/AD-like genetic disorders have function(s) in immunity?
   A. *STAT3*
   B. *DSG1*
   C. *SPINK5*
   D. *FOXP3*
   E. All of the above

3. Which of the following immune responses are associated with AD?
   A. T helper type 1 (interferon-γ response)
   B. T helper type 2 (interleukin-4 response)
   C. T helper type 17 (interleukin-17 response)
   D. T helper type 22 (interleukin-22 response)
   E. All of the above

4. Which of the below AD-like genetic disorders are particularly prone to developing food allergy?
   A. Hyper IgE syndrome
   B. Wiskott-Aldrich syndrome
   C. SAM syndrome
   D. Peeling skin syndrome
   E. Netherton syndrome

5. Dysbiosis in lesional atopic skin is overrepresented by:
   A. *Pseudomonas aeruginosa*
   B. *Candida albicans*
   C. *Malassezia furfur*
   D. *Staphylococcus aureus*
   E. All of the above

Answers

1. B, C
2. A, D
3. A
4. C
5. D

Contact Dermatitis

23

Stefan F. Martin and Thilo Jakob

Abstract

Our skin is exposed daily to a large number of chemicals in household products, cosmetics, in the environment and in the workplace. Many of these chemicals can cause irritant or allergic contact dermatitis. Allergic contact dermatitis is an inflammatory skin disease that is mediated by our immune system. In this chapter we summarize current methods for the diagnosis of contact dermatitis and treatment strategies. In addition we review our current understanding of the cellular and molecular pathomechanisms and its implications for the development of novel diagnostic and treatment strategies and of animal-free testing strategies for contact allergen identification.

Keywords

Allergic contact dermatitis • ACD • Antigen presenting cell • APC • Hypersensitivity • Damage-associated molecular pattern • T cell • Mononuclear cell • Local Lymph Node Assay • LLNA • Contact dermatitis • Heterologous innate immunity

Abbreviations

ACD	Allergic contact dermatitis
APC	Antigen presenting cell
CHS	Contact hypersensitivity
DAMP	Damage-associated molecular pattern
DNBS	2,4-dinitrobenzene sulfonic acid
DNCB	2,4-dinitrochlorobenzene
DNFB	2,4-dinitrofluorobenzene
DNTB	2,4-dinitrothiocyanobenzene
FLG	Filaggrin
HA	Hyaluronic acid
hTCPA	Human T cell priming assay
ICD	Irritant contact dermatitis
LLNA	Local Lymph Node Assay
LZT	Low zone tolerance
MAMP	Microbe-associated molecular pattern
MHC	Major histocompatibility complex
PAMP	Pathogen-associated molecular pattern
PBMC	Peripheral blood mononuclear cell
PRR	Pattern recognition receptor
TCR	T cell receptor
TNBS	2,4,6-trinitrobenzene sulfonic acid
TNCB	2,4,6-trinitrochlorobenzene
TLR	Toll-like receptor
Treg	Regulatory T cell

Key Points

- Allergic contact dermatitis affects 5–10 % of the general population and prevalence is increasing
- Contact dermatitis is the most important occupation-related skin disease
- Causative treatment strategies, development of new drugs and of *in vitro* assays to replace animal testing for contact allergen identification are needed and require a detailed mechanistic understanding of the pathomechanisms
- The innate immune response to contact allergens is mechanistically similar to anti-infectious immune responses
- Biomarker panels are being identified for improved diagnostics and distinction of different types of eczema

Allergic Contact Dermatitis: Prevalence, Clinical Presentation and Etiology

Allergic contact dermatitis (ACD) is an eczematous skin reaction to substances (mostly small chemical compounds, so-called haptens) in non-toxic concentrations that requires an immunological cell-mediated sensitization and usually occurs after repeated exposure to the substance, while the same substance does not elicit reactions in non-sensitized individuals.

ACD is caused by activation of the immune system by chemical allergens due to their ability to cause skin inflammation and, consequently, a chemical-specific T cell response. ACD shows increasing prevalence. Roughly 20 % of the general population is sensitized to at least one contact allergen and about 5–10 % develop ACD once per year [1, 2].

The more than 4,000 known contact allergens are found for example in household products, cosmetics, plants, jewelry, clothes and in the workplace. Sensitization does not necessary result in the development of ACD but once the disease has developed, it can become chronic. A major problem is the formation of memory T cells which cause eczema upon re-exposure to the eliciting contact allergen.

Occupational contact dermatitis is the most common occupation-related skin disease [3]. Here, chronic ACD may result from chronic allergen exposure leading to significant damage to the skin. Chronic ACD is difficult to treat and requires complete avoidance of the contact allergen. This often demands that the patients change profession. The socio-economic costs of ICD and ACD are very high and the treatment options are still limited [3–5].

The yearly hitlist of the clinically most relevant contact allergens as presented by the German working group for contact dermatitis (DKG)/German Information Network of Departments of Dermatology (IVDK) consortium has nickel in the first place for many years already, followed by fragrance mix and balsam of Peru [6]. The contact allergen of the year 2013 was the preservative methylisothiazolinone (MI) and sensitization to MI remains a very serious problem [7, 8]. MI is used in cosmetics but also in household products such as paint. Due to the replacement of other preservatives the use of MI and methylchloroisothiazolinone (MCI)/MI (Kathon CG) has increased, and the concentrations used seem problematic. Even airborne exposure to MI can cause severe allergic skin reactions as well as asthma symptoms [9]. Action is now taken to reduce the concentrations of MI in consumer products and to find replacements.

The clinical presentations of ACD can be classified according to the disease kinetics and duration (acute versus chronic ACD), the route of allergen exposure (direct skin exposure, airborne exposure, systemic exposure), the localization (localized e.g., hand, lower leg, face, eyelid, genito-anal, generalized, flexural etc.), the exposure conditions (occupational, accidental, iatrogenic) and the type of contact allergen (e.g., weak, strong, obligatory contact sensitizer).

The acute ACD is characterized by an onset of clinical signs and symptoms within 3–12 h after contact with the allergen. The kinetic of the response depends on the degree of the preexisting sensitization – the stronger the degree of sensitization the faster the onset of symptoms. The initial reaction is characterized by dermal edema, vasodilatation and a beginning perivascular infiltrate of mononuclear cells. Within 6–24 h the infiltrate becomes more prominent and is accompanied by epidermal changes with spongiosis and increasing exocytosis of mononuclear cells into the epidermis. Depending on the type of contact allergen and degree of sensitization the reaction peaks at 24–48 h with a dense dermal mononuclear infiltrate, intra-epidermal blister formation, loss of the granular layer (stratum granulosum) and signs of parakeratosis. The resolution of the acute ACD reaction usually starts around 48–72 h and is characterized by reduction of epidermal spongiosis and blister formation, acanthosis of the epidermis and gradual reduction of the dermal and epidermal mononuclear infiltrate. Clinically, ACD is characterized by infiltrated erythematous pruritic patches and papules with or without vesicular reactions. The histological changes are reflected by the symptoms of acute ACD that initially present as pruritic erythema (stadium erythematosum), pruritic palpable infiltration, with or without formations of small and sometimes confluent larger blisters (stadium vesiculosum), subsequently crust formation (stadium crustosum) and a resolution with eczematous fine lamellar scaling (stadium squamosum). Chronic ACD is mostly characterized by a less prominent spongiosis and a more prominent acanthosis, hyper- and parakeratosis and a less prominent mononuclear infiltrate mostly in the upper

dermis. Clinically, chronic lesions are typically characterized by pruritus, lichenification, erythema, scaling, fissures and excoriations.

Neither acute nor chronic ACD present with histological or clinical changes that definitely allow the differentiation of the type of insult that caused the dermatitis. The only clinical signs that are suggestive of ACD are disseminated small papular eczematous skin reactions that extend beyond the actual area of contact to the allergen. In contrast, irritant contact dermatitis (ICD) is usually sharply demarcated and restricted to the area of direct skin contact with the irritant.

Clinical manifestations of ACD can vary according to the anatomical location in which the contact allergen was encountered. Frequent locations are hands (in particular in occupational ACD), face and eyelids (often associated with use of cosmetics), lower legs (in particular in patients with topical treatment of leg ulcers), and perianal region (in particular in patients with topical treatment of pre-existing perianal dermatosis).

Clinical manifestations of ACD also vary based on the route of allergen exposure. The classical ACD usually begins in the area of direct skin contact. Since some of the contact allergens are volatile components, ACD may also primarily present in areas of airborne exposure such as the face, the neck and extremities. Examples of airborne contact allergens are composite plants allergens (*Asteraceae*), formaldehyde, expoxy resins, isothiazolones, fragrances, drugs and others [10–12].

Also systemic exposure to contact allergens either via enteral or via parenteral application can trigger ACD in sensitized individuals. Clinical examples of systemic ACD are patients sensitized to drugs (e.g., via epicutaneous exposure at the work place) that develop generalized dermatitis upon oral or parenteral application. This often presents with a characteristic clinical pattern as sharply defined symmetrical erythema of the gluteal/perianal area, and/or V-shaped erythema of the inguinal/perigenital area and in flexural or intertriginous folds. Due to the prominent involvement of the buttocks this presentation had previously been designated "Baboon syndrome", a term that was more recently suggested to be replaced by the less derogative and more descriptive acronym SDRIFE, symmetric drug-related intertriginous and flexural exanthema [13]. Allergens reported to induce this drug-induced systemic ACD include betalactam antibiotics such as aminopenicillins, cephalosporins, but also a wide range of other drugs such as clindamycin, macrolides, mitomycin, cimetidine, naproxene, and pseudoephedrine [13]. Other examples of contact allergens that have been reported to induce ACD include oral intake of nickel, chromium and cobalt salts, inhalation of mercury vapours, and-ingestion of balsam of Peru. Clinically systemic ACD presents either as dermatitis flare-up in areas of previous contact with allergen, flare-up of previous positive patch test sites, or as dermatitis in previously unaffected skin [14].

Finally, ACD can also develop to substances that only in combination with exposure to ultraviolet radiation act as allergens/haptens. The mechanism of this photoallergic contact dermatitis involves photochemical reactions that lead to the generation of haptens or full allergens which in turn induce allergic sensitization and classical T cell-mediated hypersensitivity reactions upon subsequent exposure [15]. Examples of photoallergens include systemic drugs such as non-steroidal anti-inflammatory drugs (NSAID), diphenhydramine, phenothiazine and topically applied substances such as halogenated aromatic hydrocarbons (e.g., salicylanilides), hexachlorophene, and chemical components of sunscreens such as 2-hydroxy-4-methoxybenophenone, 4-isopropyl dibenzoyl methane, or para-amino benzoic acid. Photoallergic reactions differ from phototoxic reactions in which exposure to UV radiation leads to the generation of phototoxic substances that cause damage to epithelial, endothelial and immune cells in the vicinity without involving allergic sensitization and hapten/allergen-specific T cell responses. Classical examples of phototoxic substances include furocumarines (psoralens), amiodarone, sulfonamides and certain dyes such as acridine orange. Clinically, both photoallergic and phototoxic reactions are characterized by occurrence in skin areas that are exposed to UV radiation, and sparing of areas that are naturally less exposed such as the skin behind the ear lobes or under the chin. While phototoxic reactions are usually restricted to the area of exposure to the photosensitizer (e.g., bullous dermatitis pratensis induced by giant hogweed) photoallergic reactions may extend beyond the area of exposure.

Conflicting data exist concerning atopy as a potential predisposing factor for ACD [16–19]. The skin barrier defect and bacterial colonization may favor ACD due to enhanced penetration of chemical allergens and enhanced basal inflammation [19, 20]. Infection or tissue damage may facilitate sensitization by providing danger signals that activate the innate immune system (Fig. 23.1, 3) [21]. These danger signals are essential for ACD [22] and such heterologous innate immune stimulation may amplify the contact allergen-dependent, autologous danger signaling or even replace it (Fig. 23.2) [23].

Diagnosis of Allergic Contact Dermatitis

The diagnosis of ACD is ideally based on the patient's history, the clinical presentation and a positive patch test reaction to the suspected contact allergen. In every day practice this ideal situation is rarely present. The clinical presentation, the affected areas and the distribution may be suggestive of ACD, while morphological skin changes and histology

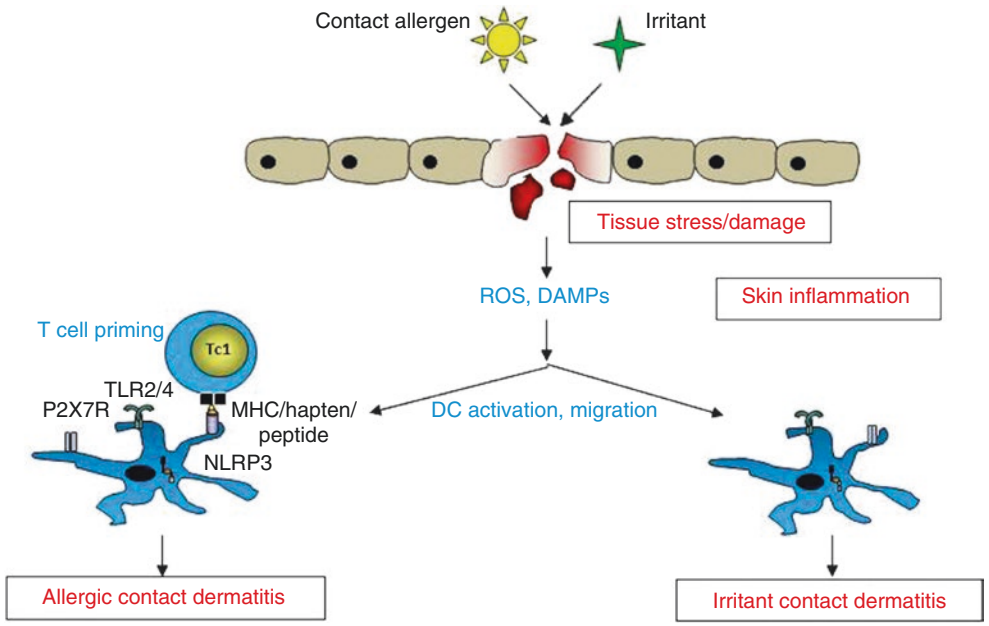

Fig. 23.1 Contact allergens and irritants cause tissue stress and damage. ROS are induced and stressed or damaged cells release and or/produce danger signals such as PRR-activating DAMPs. Additional danger signals are derived from the extracellular matrix. Consequently skin inflammation results and DCs are activated and migrate from the epidermis to the dermis and then to skin draining lymph nodes. Due to the chemical modification of proteins contact allergens form T cell epitopes that are presented on activated DCs in the lymph node and prime contact allergen-specific T cells. This concludes the sensitization phase of ACD. The recruitment of activated effector/memory T cells to the skin upon repeated contact with the contact allergen leads to eczema. Irritants cause eczema without induction of an allergen-specific T cell response

do not allow a definite differentiation between ACD and other forms of dermatitis, such as ICD, atopic dermatitis or seborrheic dermatitis. For the identification of relevant contact allergens a detailed patient history is of utmost importance. This must include detailed information on the work environment, recreational activities, medication, use of cosmetics, emollients, detergents and other substances that the patient has been exposed to prior to the onset of the dermatitis.

The mainstay for the diagnosis of ACD is the patch test in which under standardized conditions contact allergens are applied to the healthy skin of the patient with the goal to reproduce the allergic eczematous skin reaction. Prerequisite for patch testing with suspected contact allergens is that skin reactions during acute or chronic ACD have been sufficiently controlled or even better resolved by topical or systemic anti-inflammatory treatment. Patch testing during ongoing ACD produces increased numbers of false positive patch test reactions and thus should be avoided.

The standard procedure of the patch test involves application of the contact allergen in the corresponding vehicle (vaseline for lipophilic, aqueous solution for hydrophilic allergens) in a Finn chamber to the skin (usually skin of the back) of the patient for 24 h or 48 h. The first reading is taken at 48 h, a second reading is recommended at 72–96 h after initiation of the test. Standardized criteria for reading the patch test reactions have been developed by the DKG and allow a grading and interpretation of the reaction (Table 23.1). Like all test systems the patch test has also a number of pitfalls and limitations and may generate false positive or false negative results. False positive results may occur in patients in whom the ACD has not sufficiently been treated or in patients that display a very strong sensitization. In these situations multiple chemically non-related allergens can induce false positive reactions. This phenomenon is described as "angry back" or excited skin syndrome and most likely reflects the fact that the skin displays reduced thresholds to the irritative capacity of these unrelated allergens.

The majority of contact allergens has an intrinsic capacity to activate mechanisms of the innate immune response and in this sense can act as irritants. Since this effect is concentration-dependent, using the optimal test concentration of the contact allergen is crucial for the interpretation of the test results. To optimize the performance, test conditions for the most common contact allergens have been standardized. Since relative allergenic and irritative potential of contact allergens can vary a great deal, attempts have been made to classify allergens into those that have a higher irritative than allergenic capacity and those that have a high allergenic and little irritative potency. Calculation of the reaction index (RI) which analyzes the relationship between number of positive patch test reactions and number of questionable or irritant reactions was suggested by the IVDK a parameter to assess the quality of patch test preparations [24, 25]. Similarly, an

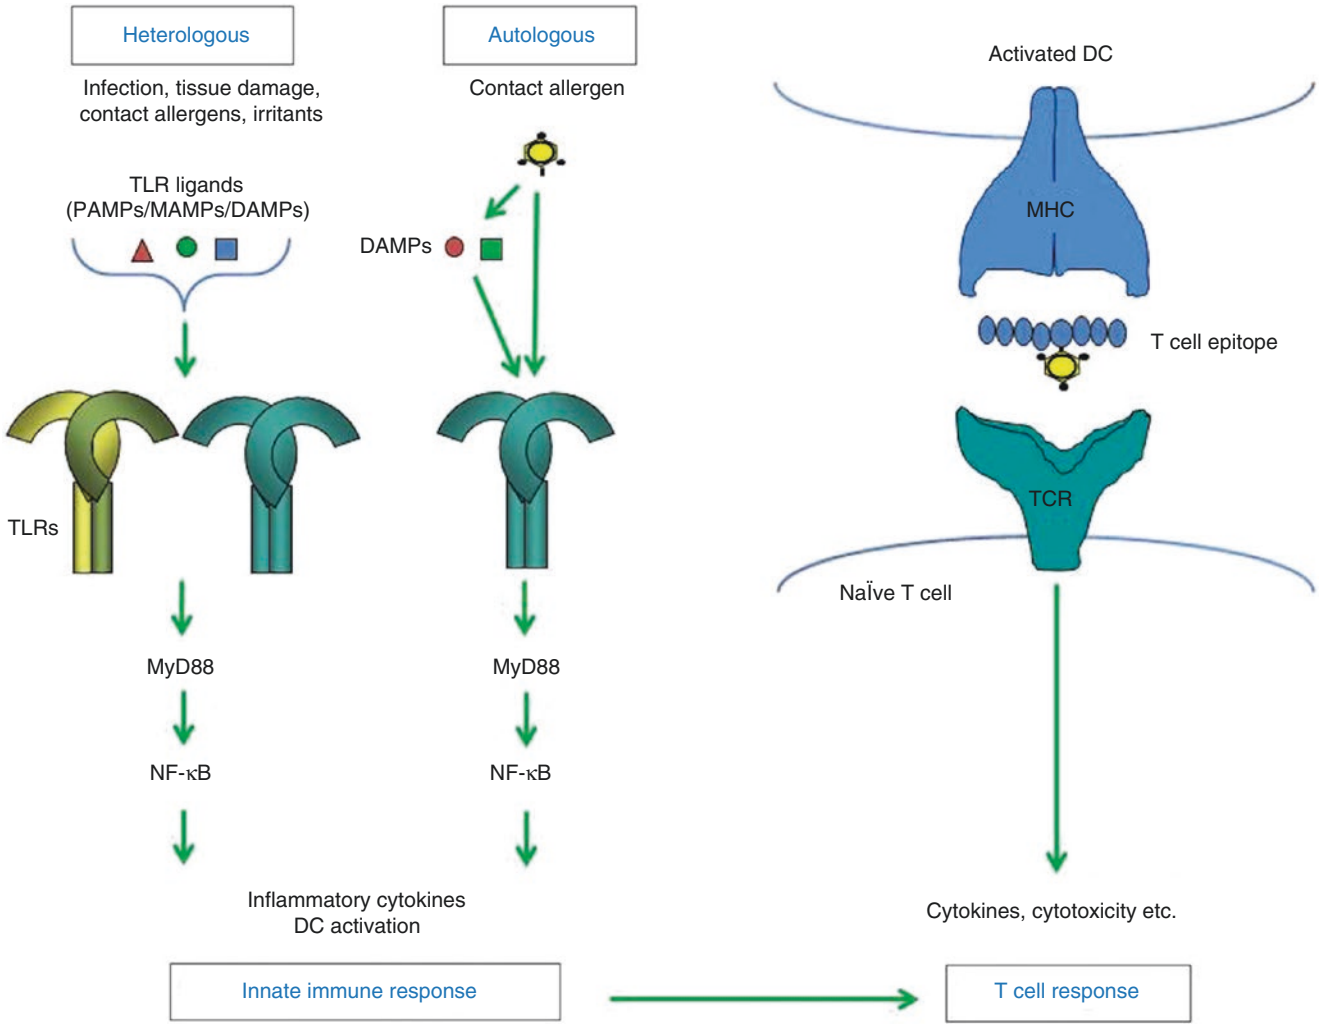

Fig. 23.2 Heterologous innate immune stimulation. Contact allergens can directly or indirectly provide autologous innate immune stimulation for example by triggering TLRs leading to activation of NF-kB and production of inflammatory cytokines and DC activation and migration. Heterologus innate immune stimulation can be provided for example by infection (e.g., PAMPs), tissue damage (DAMPs), irritants and other contact allergens that trigger the same signaling pathways via the same or different TLRs. As a result autologous innate immune stimulation can be amplified or – when absent – be substituted by heterologous innate immune stimulation. Due to T cell epitope formation by the contact allergen a T cell response is induced by activated DC when the innate immune stimulation is sufficiently strong. Upon repeated allergen contact contact allergen-specific effector/memory T cells enter the skin and exert effector function such as cytokine production and cytotoxicity

Table 23.1 Grading of patch test reactions according to the German Working Group for Contact Dermatitis (DKG)

Grading	Morphology	Interpretation
–	No changes	Negative
ir	Sharply demarcated erythema, blister, erosion, necrosis, ulcer	Irritative
?	Only erythema (allergic or irritative)	Questionable
F	Follicular papules, and/or pustules	Questionable
+	Erythema, palpable infiltrate, discrete papules	Positive
++	Erythema, palpable infiltrate, papules, vesicles	Positive
+++	Erythema, palpable infiltrate, confluent vesicles	Positive

Morphological skin changes induced by patch testing form the basis for the grading and interpretation of patch test results

additional parameter, the positivity ratio (PR) which is defined as the frequency of + reactions among the total number of positive patch test reactions (+ to +++), was developed to be used in combination with the RI to identify problematic allergens [26]. Even though subsequent evaluation of both parameters by a Danish group has challenged the general

applicability of this concept [27] it clearly demonstrates that interpretation of the patch test reactions very much depends on the type of allergen tested.

Similarly, false negative reactions may be related to low allergen concentrations in the test preparation or reduced or altered skin permeability. In particular, weak contact allergens that may elicit ACD in sensitive skin areas such as the eyelids, may not be detected when tested on the back skin of the patient. Similarly, weak contact allergens may elicit ACD in areas with a preexisting damage of the barrier function, while they are not strong enough to elicit a reaction on the intact skin of the back. Since the epidermal barrier is crucially involved in determining the level of allergen penetration, modification of the patch test by tape stripping the upper layers of the epidermal stratum corneum prior to allergen application may be used to simulate particularly sensitive or damaged skin areas. Even though this approach has recently been standardized and shown to increase test sensitivity in particular to weak contact allergens [28, 29] interpretation needs to be done very carefully in particular in relation to irritative test reactions which occur more frequently under these conditions.

Both positive or negative test reactions may be re-evaluated by a repeated open application of the suspected substance [30, 31]. Often positive test reactions are observed that are of questionable relevance. They may simply indicate that the patient is sensitized but not necessary allergic to the substance. In this case the substance of interest can be applied twice daily to a 2×2 cm area of the cubital skin for consecutive 7 days after which ACD should develop provided that the contact sensitization is clinically relevant. The same approach can be taken when a strongly suspected substance gives a negative patch test reaction or is not available or suitable for occlusive patch testing.

Finally, when photoallergic reactions are suspected a modified patch (photopatch) test may be applied in which two identical panels of allergens are applied to the back skin for 24 h and subsequently one panel is irradiated with UVA (5–10 J/cm^2), while the other panel is protected from UV radiation. The test readings are performed at 48, 72 and 96 h according to the same criteria as the standard patch test and allow addressing the role of UV light for the elicitation of the ACD [32].

Treatment of Allergic Contact Dermatitis

Since in the majority of the cases ACD presents as a localized skin reaction and the inflammatory skin infiltrate is accessible to topical treatment, the use of topical glucocorticosteriods applied to the affected skin areas is the mainstay of ACD treatment. In cases of extended skin involvement or generalized ACD short term systemic therapy with glucocorticosteriods may be considered. The topical treatment of ACD corresponds to treatment of other forms of dermatitis. The vehicles used for topical glucocorticosteriod treatment should be adapted to the clinical presentation and state of the eczematous skin reaction. Acute dermatitis requires treatment with hydrophilic creams and/or lotions that provide a cooling and anti-inflammatory effect and help to dry acute weeping or blistering skin lesions. In contrast, chronic dermatitis is usually characterized by dry and brittle skin with lichenification and hyperkeratosis and thus requires more lipophilic vehicles such as lipophilic creams or ointments. In cases of prominent hyperkeratosis in particular on palms and soles the keratolytic effects of salicylic acid or urea may be used to reduce the hyperkeratosis and thus allow better access of the topical anti-inflammatory agents. In case of dermatitis with bacterial superinfection, anti-infective agents such as octinidine or polyhexanide may be used. Supportive measures should include minimizing irritative insults to the skin such as chronic exposure to wet conditions at the work place or repeated hand washing. Since allergic sensitization and elicitation of ACD requires for a variety of allergens some sort of adjuvant irritative effect or skin damage as cofactor to fully develop, reduction of this kind of aggravating cofactors will help to improve the skin condition and to avoid relapses. The mainstay of the treatment of ACD is the anti-inflammatory therapy with topical glucocorticosteriods in the correct vehicle. Topical calcineurin inhibitors such as tacrolimus or pimecrolimus can also be effective, and due to an almost absent induction of skin atrophy may be considered in chronic patients that already have steroid-damaged skin. In patients in whom steroid therapy is not appropriate, UVB or PUVA phototherapy may be an effective alternative. In particular in patients with localized chronic hand dermatitis crème PUVA therapy has proven to be a valuable and well standardized therapeutic option.

However the treatment can only be successful if the offending allergen is avoided. So great care should be taken to identify the relevant allergen and large efforts must be taken to explain the necessity of allergen avoidance. In particular in work related contact allergies this may mean leaving the workplace for good and/or changing the profession. The best prophylaxis of ACD is the complete avoidance of the contact allergen, which in many cases is not possible. In addition, risk factors to develop ACD, such as chronic skin damage that leads to a reduced skin barrier function, should be avoided and/or treated. In the same line of thought, consequent basic skin care using rehydrating lipophilic creams or ointments should be recommended to prevent impairment of barrier function. In addition, the use of barrier creams can be recommended for some allergens and irritants that prevent or reduce penetration of the offending agent.

Finally, animal experiments suggest that in ACD specific tolerance can be induced. Attempts to induce contact allergen

specific tolerance in humans have been reported, however only for certain plant allergens like poison ivy [33]. Overall the effects were rather transient and the clinical benefit was not convincing. Similarly oral tolerance induction to nickel has been reported that caused an amelioration of skin manifestation, a reduced skin test reactivity to nickel and a reduced T cell reactivity upon nickel restimulation [34]. Again effects were rather moderate and transient in nature. In summary, so far no effective and lasting allergen specific tolerance induction has been established in humans.

Risk Factors Predisposing to ACD

Many factors may contribute to the susceptibility to ACD. Up to now, genetic studies have not revealed an association of ACD with specific HLA alleles. However, several gene polymorphisms have been identified [35]. These are found in genes regulating skin barrier function, detoxification, innate inflammatory immune responses and T cell responses. Several polymorphisms in the stratum corneum protein filaggrin (FLG) have been found to impact its function and to impair the barrier function of the skin [36]. FLG mutations have been associated with increased susceptibility to atopy [37, 38] but also to ICD and ACD [39, 40]. FLG-deficient mice exhibit increased antigen penetration and exacerbated CHS responses triggered by the irritant croton oil or the contact allergen DNFB [41].

Chemistry and Contact Dermatitis

Contact allergens are low molecular weight chemicals that share one characteristic feature: they are protein-reactive. Due to their small size the chemicals *per se* cannot be recognized by the immune system and are therefore also designated haptens (half-antigens). Their protein binding is essential for their immunogenicity and antigenicity. Organic chemical allergens can covalently bind to proteins, and metal ions form complexes with proteins. Some contact allergens are not reactive haptens but are pre-haptens which require oxidation or pro-haptens which require metabolic conversion to full haptens. Such chemicals are highly problematic in terms of contact allergen identification in patch testing and in *in vitro* assays since an adduct and not the parent compound causes sensitization and ACD [42].

A detailed understanding of the relation between the physico-chemical properties, structure and reaction mechanisms and their biological activity is used to develop *in silico* prediction methods to identify potential contact sensitizers in so-called quantitative structure-activity relationship (QSAR) approaches. Grouping according to so-called mechanistic domains [43, 44] is being analysed with respect to allergenicity and allergenic potency. In a recent study allergenic potency as determined in the mouse local lymph node assay (LLNA) could be correlated with mechanistic domains. The results of that study showed that the more potent contact allergens triggered a broader range of signaling pathways than the less potent ones [45]. These data are encouraging further investigations using QSAR and mechanistic domains to promote our understanding of the relation of the chemistry of contact allergens and its impact on the immune system.

Functional Consequences of Protein Modification by Contact Allergens

The most fascinating question that remains to be solved is how the chemical reactivity of contact allergens is translated into biological responses that can lead to the development of ACD. The interaction of chemicals with biomolecules can alter their function. Since contact allergens are generally chemically reactive electrophiles or complex-forming metal ions, it is to be expected that this reactivity is responsible for their action as allergens. In fact, neutralizing the reactivity of the strong contact allergen 2,4-dinitrochlorobenzene (DNCB) by coupling it to lysine abrogates its ability to induce CHS (our unpublished data). Hypothetically, contact allergens may mimic or interfere with conventional post-translational protein modifications [46].

The chemical reactivity of contact allergens regulates immunity at two levels: the first level is the induction of signaling cascades due to chemical protein modification and the second, resulting level is the regulation of gene expression. Information regarding the identity of the functionally relevant chemically modified proteins is scarce. In one study it was demonstrated that treatment of the human monocytic leukemia cell line THP-1 with the contact allergen DNFB does not modify all cellular proteins but only some which are not necessarily the most abundant proteins [47]. Thus, there is selectivity in the targeting of proteins by contact allergens. New studies begin to analyse contact allergen-modified proteins in 3D skin models. In a recent study high resolution magic angle spinning (HR-MAS) nuclear magnetic resonance (NMR) spectroscopy was used to identify protein modifications by a ^{13}C-labeled electrophile in reconstructed human epidermis (RHE) [48]. Compared to *in vitro* modification of human serum albumin (HSA) which took several days to be detectable, the *in situ* protein modification in RHE was detectable after less than 24 h. The predominant lysine modification of HSA, as observed *in vitro*, was not detected in RHE. This method will be useful to identify contact allergen-modified adducts formed in the skin. Eventually this technique may promote the identification as well as quantitative and qualitative analysis of the contact allergen-modified proteome.

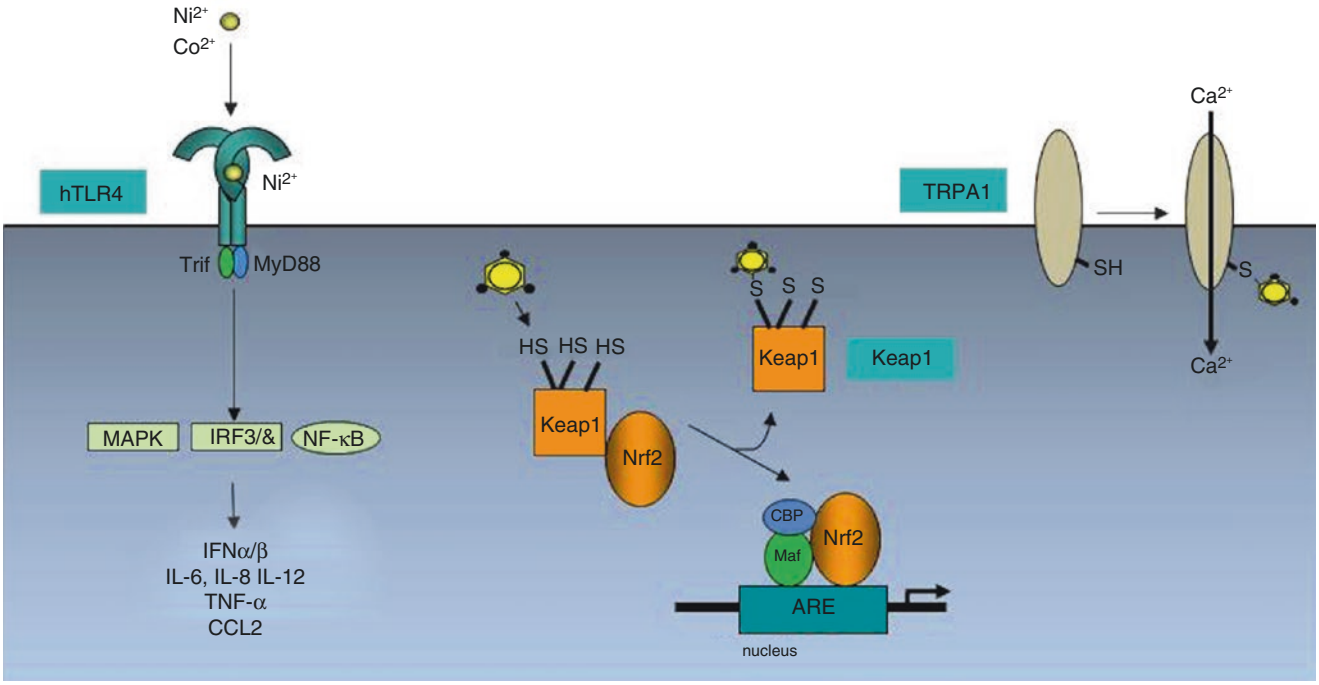

Fig. 23.3 Direct activation of signaling cascades by contact allergens. The metal ions nickel and cobalt form complexes with conserved histidines in human TLR4 resulting in TLR4 dimerization and signaling via NF-kB and MAP kinases and production of inflammatory mediators. Organic chemical allergens such as TNCB or DNCB bind covalently to cysteine residues in the cytosolic protein Keap1. This leads to release of the transcription factor Nrf2, its nuclear translocation and transcriptional activation of the expression of genes containing antioxidant response elements (ARE). These contact allergens can also bind to cysteines in the calcium channel protein TRPA1. Calcium influx activates pathways involved in itch and inflammation

Up to now, only very few proteins, whose modification by contact allergens induce a biological response, have been identified (Fig. 23.3). Human TLR4, the receptor for lipopolysaccharide (LPS, endotoxin) from the cell wall of Gram-negative bacteria, is complexed and dimerized by the metal ions Ni^{2+}, Co^{2+} [49, 50]. Pd^{2+} also interacts with human TLR4 [51]. This results in signal transduction for production of inflammatory mediators in the absence of LPS. The cytosolic, cysteine-rich sensor protein for oxidative or electrophilic stress, Keap1, contains cysteine residues that can be modified by contact allergens. This triggers expression of anti-oxidant phase 2 response- and immune genes due to their activation by the Keap1-regulated transcription factor Nrf2. The promoters of these genes harbor an antioxidant response element (ARE). This pathway limits contact allergen-triggered inflammation. Mice lacking Nrf2 have a much lower sensitization threshold for contact allergens, most likely due to an increased level of pro-inflammatory oxidative stress [52, 53]. A third target for modification by electrophilic contact allergens is the ion channel transient receptor potential ankyrin 1 (TRPA1). TRPA1 also harbors cysteines that are attacked by contact allergens such as cinnamic aldehyde or DNCB [54, 55]. Extracellular Ca^{2+} can then enter the cell. TRPA1 is expressed on a subset of nociceptive nerve fibers, also in the skin, but also on keratinocytes and endothelial cells. The TRPA1 channel is involved in pain but also in itching in inflammatory immune responses [56]. For atopic dermatitis it has been shown that TSLP produced by Th2 cells acts on sensory neurons in the skin to cause itch in a TRPA1 dependent manner [57]. TRPA1-deficient mice show reduced edema, inflammation and itching in cinnamic aldehyde-induced edema in mouse ear skin or in CHS to oxazolone and urushiol [58]. Interestingly, one of the endogenous agonists of TRPA1, 4-hydroxy-2-nonenal (HNE), is produced as a consequence of ROS-mediated oxidation of membrane phospholipids [59]. ROS are important inflammatory mediators in CHS [60].

Innate Immune Responses in Allergic Contact Dermatitis

The induction of ACD requires the priming of contact allergen-specific T cells. This depends on two crucial events: activation of the innate immune system and formation of T cell epitopes (Fig. 23.1). It is a peculiarity of contact allergens that they have this dual function [46]. The activation of the innate immune system results in skin inflammation. The most important outcome of this innate inflammatory response in the sensitization phase is the activation and polarization of

skin DCs allowing their migration to the draining lymph nodes and presentation of contact allergen to T cells in the context of MHC molecules. Naïve, contact allergen-specific T cells are then primed and polarized towards a Tc1/Th1, Tc17/Th17 phenotype. In the elicitation phase, the innate inflammatory response results in the secretion of cytokines and chemokines, up-regulation of adhesion molecules on endothelial cells and eventually the recruitment of effector or memory T cells into the skin where they exert their effector function to produce ACD.

Recent studies in the mouse CHS model have uncovered mechanistic details of the cellular and molecular innate immune response [22, 61, 62]. The emerging picture clearly indicates that the immune system reacts to contact allergens as if they were infectious agents. This is due to the fact that contact allergens activate the same anti-infectious immune response mechanisms as viruses and bacteria.

The innate cellular response to contact allergens is initiated in the epidermis by activation of keratinocytes and Langerhans cells. Here, the innate inflammatory response is essential to abrogate the naturally tolerogenic milieu in the skin as a major immunologic barrier. As a consequence the normally tolerogenic Langerhans cells are switched to an immunogenic phenotype allowing lymph node migration and T cell priming [63, 64]. Despite the fact that Langerhans cells are dispensable for CHS in some experimental models which usually use saturating contact allergen concentrations, they most likely play a role in ACD under physiological conditions, especially at low contact allergen concentrations and absence of spreading to the dermis [65–67]. Further analysis of the orchestration of the cellular innate immune response has identified mast cells as important initiators of skin inflammation [68]. Mast cell deficiency or mast cell depletion before sensitization significantly reduces CHS in mice. This is due to a role of histamine from mast cells in increasing the permeability of the blood vessels in the skin. The absence of mast cells decreases the infiltration of neutrophils and the emigration of DCs from the skin. Neutrophil depletion efficiently abrogates CHS as does the depletion of subsets of skin DCs [66, 67, 69–71]. Both the sensitization and elicitation phase of CHS depend on the presence of neutrophils [71]. The fact that depletion of one or the other cell type has a similar outcome underlines the essential collaboration of the different innate immune effector cells. The same principle is seen in the orchestration of the molecular mechanisms of contact allergen-induced innate immune responses [46].

Pathogens are recognized by the innate immune system via so-called pattern recognition receptors (PRRs) which are triggered by pathogen- or microbe-associated molecular patterns (PAMPs, MAMPs). Examples for families of PRRs are the Toll-like receptors (TLRs), transmembrane proteins in the plasma membrane or endosomal membranes, the cytosolic NOD-like receptors (NLRs), the RIG-I like receptors (RLRs) and C-type lectin receptors (CLRs) in the plasma membrane [72].

PAMPs/MAMPs can be bacterial cell wall components, flagellin, viral and bacterial nucleic acids, lipids and carbohydrates. These are perceived as danger signals by PRRs and induce innate anti-infectious immune responses. Contact allergens can also trigger PRRs by direct or indirect mechanisms [61]. Nickel- and cobalt ions bind to conserved histidine residues of human TLR4 inducing dimerization and signaling [49, 50]. The murine TLR4 lacks these histidines and therefore is not triggered by Ni or Co. This results in resistance of mice to CHS to these metal ions. However, replacement of the murine TLR4 by the human TLR4 in transgenic mice renders these mice susceptible to CHS [49]. Up to now this is the only known case where contact allergens are directly activating a PRR. For other contact allergens, organic molecules such as 2,4,6-trinitrochlorbenzene (TNCB) or 2,4-dinitrofluorobenzene (DNFB) or oxazolone an indirect activation of PRR has been demonstrated [60, 73, 74]. These contact allergens induce endogenous danger signals. A rapid induction of ROS and release of ATP from skin cells has been revealed [60, 74]. Moreover, the degradation of the extracellular matrix (ECM) component hyaluronic acid (HA) results in fragments that can activate TLR2 and TLR4 [60]. Constitutive overexpression or induction of expression of human hyaluronidase 1 in mouse skin under control of the K14 promoter resulted in lack of CHS when expression was induced before sensitization, most likely due to DC depletion from the skin. CHS was enhanced when overexpression was induced at the time of sensitization [75]. HA breakdown resulted in the emigration of DCs from the skin. The HA effects were dependent on TLR4. These data show a TLR4-dependent role of HA fragments for the mobilization of DC from the skin. The pro-inflammatory role of HA breakdown is evident in Shar-Pei dogs who accumulate HA over time due to an overexpression of hyaluronan synthetase (HAS) 2. Periodic breakdown of accumulated HA results in a periodic fever syndrome in these dogs [76]. These findings illustrate the important role of the ECM in innate immunity [77].

The endogenous danger signal high mobility group box 1 (HMGB1) is involved in the *in vitro* induction of IL-18 in the human keratinocyte cell line NCTC2544 [78]. HMGB1 was released upon treatment of the cells with the contact allergens para-phenylene diamine (pPD), DNFB or citral.

While ATP triggers the activation of the cytosolic NLPR3 inflammasome that induces the maturation of immature pro-IL-1β and pro-IL-18 via caspase-1, ROS contribute to skin inflammation for example by triggering oxidative HA breakdown and by promoting TLR signaling and inflammasome activation. Nickel also activates the NLRP3 inflammasome [79].

A recent study [80] demonstrated that mice lacking MyD88 or CARD9 are resistant to CHS to TNCB. Irritant CHS to SLS was normal. While MyD88 is an adaptor protein involved in TLR/IL-1R signaling, CARD9 is an adaptor that plays a role in the signaling of CLRs. The study clearly showed that the contact allergens TNCB/TNBS, DNFB and oxazolone can trigger ITAM-Syk-Card9/Malt10 signaling in DCs *in vitro* resulting in IL-1α and IL-1β production. Signaling was dependent on the ITAM containing adaptor protein DAP12. Syk phosphorylation and CARD9/Bcl-10 mediated NF-kB activation resulted in the production of immature pro-IL-1α and -IL-1β. ROS formation and ROS mediated NLRP3 inflammasome activation for the production of mature IL-α and IL-1β in DCs was Syk-dependent but independent of CARD-9/Bcl-10. The DC-mediated priming and differentiation of contact allergen-specific IFN-γ and IL-17-producing effector T cells was dependent on IL-1β and MyD88. It remains to be determined if and which receptor (e.g., a CLR), couples to this signaling pathway and how it is activated by contact allergens. Moreover, the molecular mechanisms of crosstalk of this signaling pathway with the TLR pathway remain to be determined.

Further important signaling pathways have been identified by genomic or proteomic profiling studies using human cell lines. Two prominent pathways are the aryl hydrocarbon receptor (AhR) and the Keap1/Nrf2 pathway [81]. The AhR is a transcription factor that regulates not only detoxification pathways but also immune processes such as Langerhans cell function and Th17 differentiation. Dietary and endogenous ligands have been identified that modulate immune function [82] and evidence for contact allergen-mediated activation of the AhR has been provided [83].

Disturbed epidermal homeostasis involving keratinocyte death promotes skin inflammation [84] Here, the NF-kB pathway plays an important regulatory role. Mice with an epidermis-specific loss of the NF-kB subunit RelA did not develop spontaneous inflammation. However, DNFB- and oxazolone-induced allergic CHS was aggravated while croton oil-induced irritant CHS developed as in wild type mice [85]. The loss of RelA leads to up-regulation of the small calcium-binding proteins S100A8/A9. These proteins are up-regulated in inflammatory and autoimmune diseases and can have pro-inflammatory, but also anti-inflammatory activity by acting as ligand for TLR4 [86–88]. Increased keratinocyte apoptosis and up-regulation of XIAP associated factor 1 (XIAF1) were observed for contact allergens and croton oil. XIAF1 blocks the anti-apoptotic function of X-linked inhibitors of apoptosis (XIAPs). It was speculated that the selective aggravation of contact allergy may be due to an effect of the contact allergen-specific T cell response on the proliferation of keratinocytes. The nuclear hormone receptor peroxisome proliferator activated receptor (PPAR)-α is involved in the regulation of keratinocyte proliferation and differentiation as well as inflammation. PPAR-α is expressed in keratinocytes but also in Langerhans cells, mast cells and T cells. Its activation can inhibit NF-kB activation [89]. Topical treatment of mice with PPAR-α ligands such as clofibrate counteracts keratinocyte hyperproliferation [90] and reduces TPA-induced irritant CHS and oxazolone-induced allergic CHS. This correlated with a reduction in the levels of TNF-α and IL-1-α [91]. PPAR-α-deficient mice had exacerbated CHS which was associated with impaired IL-2 production in lymph nodes and a decrease in regulatory T cell (Treg) numbers and function [92]. Interestingly, an endogenous PPAR-α ligand, palmitoyl ethanolamide (PEA), is up-regulated along with PPAR-α by contact allergens [93]. These findings underline the importance of dysregulated keratinocyte homeostasis for inflammatory skin diseases.

Many of the mechanisms described above for contact allergens can also be triggered by chemically reactive drugs or drug metabolites. *N*-acetyl-*p*-benzo-quinoneimine (NAPQI), the toxic metabolite of acetaminophen is involved in drug-induced liver injury. It can damage hepatocytes. These release self-DNA which acts as DAMP and activates TLR9 on sinusoidal endothelial cells. ROS and ATP then contribute to activation of the NLRP3 inflammasome [94, 95]. Moreover, NAPQI can also activate TRPA1 [96].

The polarization of the cytokine profile secreted by skin DCs is an essential step in the development of ACD. Polarization of T cells towards a Th1/Tc1 phenotype requires IFN-γ and IL-12 or IL-18, IL-21 and IL-27 whereas the polarization of Tc17/Th17 cells requires IL-6 and TGF-β or IL-6, IL1-β and IL-23 [97]. The innate immune response is certainly instrumental in this polarization process. However, there is also evidence for chemical-intrinsic properties that contribute to that [98, 99]. It was observed that the contact allergens DNFB and DNCB induced a type 1 cytokine profile (IFN-γ^{hi}, IL-4/-5/-10^{lo}) in the skin draining lymph nodes following topical exposure of Balb/c mice. In contrast, the respiratory allergen trimellitic anhydride (TMA) as well as FITC and DNBSCl induced a type 2 profile (IL-4/-5/-10^{hi}, IFN-γ^{lo}). Interestingly, these cytokine profiles correlated with the modification of proteins. *In vitro* studies using human U937 monocytes showed preferential modification of cellular proteins by DNFB and DNCB, but preferential modification of serum proteins by the other chemicals [100].

A modulation of the epigenetic regulation of gene expression has also been discussed in the context of T cell polarization [101]. A first study analyzed genome wide changes in the methylation of DNA from skin draining lymph nodes of Balb/c mice exposed to DNCB or TMA [102]. Characteristic changes were found for both chemicals with differently methylated regions in various pathways including cytokine and chemokine genes. Future studies using T cells or DCs are needed to identify potential methylation signatures that are specific for contact or respiratory allergens.

Mechanisms of Irritant Contact Dermatitis

Unlike ACD, ICD is caused by chemicals that are not covalently binding to proteins or form complexes with proteins like metal ions do. Chemicals such as detergents, acids, bases and solvents with a variety of physico-chemical properties cause a toxic-irritant skin eczema that may evoke pathologically relevant stress or damage to the skin barrier (Fig. 23.1) [103]. Innate inflammatory immune responses also play a role in ICD but adaptive immunity is not involved. The underlying cellular and molecular mechanisms are not well understood. From the CHS model it is known that ICD to the irritant croton oil is absent in mice lacking TLR4 and IL-12Rβ2 or TLR2 and TLR4 (our unpublished data) but is normal in mice lacking P2X7R [74]. SLS induced CHS is normal in mice lacking MyD88 or CARD9 [80]. Addition of croton oil to sub-sensitizing doses of TNCB or oxazolone is not able to compensate the lack of sufficient innate immune stimulation in the CHS model [104]. On the other hand, addition of SLS to the tolerogen/weak contact allergen restores IL-1β production and prevents 2,4-dinitrothiocyanobenzene (DNTB)-mediated tolerance induction to DNFB [105]. These data suggest that there are contact allergen-specific signaling pathways that cannot be triggered by some irritants. In addition, other pathways are triggered by irritants and there may also be irritant-specific pathways not triggered by contact allergens. Due to the essential irritant effect of contact allergens that is required to induce skin inflammation, it is not surprising that there is an overlap of cytokine and chemokine profiles induced by irritants and contact allergens [106, 107].

Differences between contact allergens and irritants are for example the selective up-regulation of CXCR4 on Langerhans cells by contact allergens. This leads to chemokine-selective migration of LCs to the dermis: LC migration in response to contact allergens is driven by CXCL12 while migration in response to irritants is driven by CCL2 and CCL5 derived from dermal fibroblasts [108, 109]. A recent study revealed a role for basophils in attracting eosinophils in a mouse model of croton oil-induced ICD [110]. Eosinophil-deficient mice had impaired, IL-5-transgenic mice exacerbated ICD. In an *in vitro* co-culture model basophils secreted IL-4 and TNF-α, and promoted CCL11 expression from fibroblasts. These data suggest a role for basophils in the maturation and attraction of eosinophils to the skin in ICD. Their contribution to production of pro-inflammatory ROS was discussed. Interestingly, basophils and eosinophils are found in other inflammatory human skin diseases including ACD [111–113].

These findings highlight common principles for the immune response to chemicals. Contact allergens, protein-reactive drugs or their reactive metabolites and irritants cause tissue stress and damage. This leads to oxidative stress and the formation of DAMPs, release of DAMPs from stressed and damaged cells and the activation of downstream signaling events that are in part mediated by PRRs. The chemical reactivity of contact allergens and protein-reactive drugs causes the chemical modification of proteins which can result in the direct activation of signaling cascades as is the case for human TLR4, Keap1 and TRPA1 and in in the formation of T cell epitopes. The former leads to innate immune responses resulting in xenoinflammation which is essential for the subsequent activation of the adaptive immune system and the generation of contact allergen- or drug-specific effector and memory T cells [22].

Heterologous Innate Immunity

Contact allergens and irritants are rarely encountered as pure, single substances. Consumer products such as cosmetics, household products or occupational chemicals such as paints or metal cutting fluids often contain combinations of irritants and contact allergens with other chemicals. This combination is of great relevance. The interaction of the different chemicals may result in enhanced skin penetration or augmentation of sensitization and challenge reactions. Facilitated sensitization may be the result [114–116]. Examples are the augmentation effects by combinations of irritants and contact allergens or several contact allergens [117, 118]. Mechanistically, this can be explained based on the specificity of the innate immune response. Due to the activation of identical signaling pathways by different TLRs or other PRRs, a given contact allergen can generate signals for example via TLR4 and these may be amplified by irritants or other contact allergens that also trigger TLR-dependent inflammation. The result is a T cell response and ACD to this contact allergen. If the autologous innate signals triggered by the contact allergen that elicits the T cell response are too weak, augmentation by heterologous innate immune stimulation by irritants or other contact allergens is possible (Fig. 23.2). Moreover, such heterologous innate stimuli may replace missing autologous stimulation. Heterologous innate immune stimulation can also be provided by infections. This may even break tolerance or abrogate genetically based resistance to contact allergy as shown in the CHS model. Here mimicking an infection renders CHS-resistant TLR4/IL-12Rβ2 deficient mice susceptible to CHS. Injection of contact allergen-modified DCs from these mice fail to induce sensitization in wildtype mice. Stimulation of their TLR9 with CpG-oligodeoxynucleotides (CpG-ODN) *in vitro* restores their sensitizing potential [73]. Likewise, CpG-ODN injection of the CHS-resistant mice at the time of sensitization with contact allergen also abrogates resistance (our unpublished data). Combining nickel which does not trigger mouse TLR4 with LPS allows to efficiently sensitize mice

for CHS to nickel [119] and amplifies patch test reactivity [120]. These data highlight the importance of heterologous innate immune stimulation as a process that significantly impacts the outcome of immune responses to chemicals depending on their context [23].

Adaptive Immune Responses in ACD

ACD develops in two phases. The first, sensitization phase is initiated upon skin contact with a chemical allergen. The contact allergen penetrates into the skin and due to its reactivity binds to extracellular, plasma membrane-associated and intracellular proteins. T cells specific for organic chemical contact allergens such as TNCB recognize hapten-modified peptides on MHC molecules [121]. Metal ions such as nickel are recognized by T cells due to complex formation of the metal ion with histidine residues in the MHC molecule and the T cell receptor. For some T cell clones one coordination site is a histidine residue in the peptide bound to the MHC molecule, for others this not the case [122, 123]. The effector T cells in ACD are CD4+ and CD8+ T cells. In the mouse CHS model the effector T cells are usually cytotoxic CD8+ T cells that produce IFN-γ. Moreover, CD8+ IL-17 producing T cells play a role in ACD [113, 124, 125]. In the mouse CHS model a role for dendritic epidermal T cells (DETC) as producers of IL-17 has been described [126] and the ASK1/p38 MAP kinase pathway was shown to be involved in IL-17 production in the elicitation phase of CHS [127]. In human ACD there is some evidence for early infiltrating CD8+ T cells that may cause initial damage. This is similar to results from atopy patch tests [128]. CD4+ T cells are then also detected later. Other effector cells in ACD are infiltrating NK cells that amplify the response due to their IFN-γ production [129]. In the CHS model evidence for contact allergen-specific NK cell responses and solely NK cell-mediated CHS-like reactions in T-cell deficient mice has been provided [130, 131]. However, these reactions seem to be quite different from T cell-mediated CHS [132].

Down-regulation of the immune response in ACD is determined not only by effector T cell death but also by regulatory immune cells such as Treg. In the CHS model ICOS + CD4 + CD25 + Foxp3+ Treg have been identified and a critical role for Langerhans cells in Treg induction has been identified [63, 133]. Invariant NKT cells (iNKT cells) also have regulatory function in CHS [134]. More recently, PU1 + CD4+ Th9 cells have been isolated from ACD skin biopsies of nickel allergic patients [135]. They may have a regulatory role in ACD by acting on Th1 cells directly or via enhancement of IL-4 production by Th2 cells. Interestingly, IL-9 was increased after skin exposure to nickel, rubber and fragrance in a gene expression profiling study of skin biopsies from allergic patients [136].

Tolerance Induction to Contact Allergens

Induction of allergen-specific tolerance is a major goal of the immunotherapy of allergic diseases. Hyposensitization can re-establish allergen tolerance for some years in type I allergies for example to insect venoms, house dust mite and pollen allergens. Immunotherapy (IT) involves the application of increasing doses of the allergen via the subcutaneous (SCIT) or sublingual (SLIT) route. Allergen peptides or recombinant allergens are now also used [137]. The underlying mechanisms involve a shift in the balance between allergen-specific Th2 cells and Treg as well as other regulatory cells such as regulatory B cells, including the *de novo* induction of such regulatory cells [138]. For ACD there are up to now no established protocols to induce contact allergen-specific tolerance and studies in the CHS model show successful tolerance induction only before sensitization. The clinical problem is therefore not solved, yet [139]. In the CHS model, low zone tolerance (LZT) has been studied for many years. LZT is induced before sensitization and results from the repeated application of contact allergen at doses 100- to 1000-fold below the dose required for sensitization. Recent work has revealed that tolerogenic CD11c + DCs induce contact allergen-specific CD8+ Treg [140]. IL-10 producing CD4 + Foxp3+ Treg were essential for LZT induction and rendered CD11c + DC tolerogenic by direct cell-cell contact via gap junctions. In addition, in the skin draining lymph node, DCs produce TNF-α, which induces the death of effector T cells [141].

The tolerogenicity of contact allergens can be dose-related as in the case of LZT or intrinsic as in the case of DNTB which is a very weak contact allergen and used as a tolerogen. The common principle is most likely the lack of induction of a productive innate immune response. This fails to overcome the homeostatic immunoregulatory default which maintains tolerance and induces active contact allergen-specific tolerance involving DCs and regulatory T cells. The latter occurs due to the fact that T cell epitopes can still be formed by low dose contact allergen or weak contact allergens/tolerogens such as DNTB. The contact allergen is then presented on immature/tolerogenic DCs which results in the induction of CD4+- or CD8+ Treg and the induction of effector T cell anergy and death [63, 140, 141]. The central importance of the innate immune response in shifting the balance between tolerance and immunity was demonstrated by the fact that the irritant SLS was able to prevent tolerance induction by DNTB [105]. The combination of SLS, a heterologous innate immune stimulus [23], with DNTB induced IL-1β. DNTB alone failed to do so.

These findings clearly show that the magnitude of the innate inflammatory immune response is a critical determinant of tolerance and immunity and, most likely, of allergenic potency [142]. It remains to be tested whether tolerogenic

adjuvants may be successful as negative heterologous innate stimuli in the re-establishment of tolerance to contact allergens [23]. A major issue is the tolerization of effector and memory T cells. A combination of anti-inflammatory therapies and strategies targeting effector/memory T cells and inducing contact allergen-specific regulatory T cells should be promising.

Biomarker Identification, Gene Signatures

The identification of changes in gene and protein expression induced by contact allergens and irritants will provide important information regarding the mechanisms of action of these chemicals. Pathway analysis can then be used to validate the pathologically relevant pathways and to identify drug targets for new, causative therapies. In addition, characteristic gene signatures can be identified that allow identification of contact allergens and their discrimination from irritants. The classification of chemicals based on physico-chemical and reaction-mechanistic characteristics will reveal whether the gene and protein expression profiles segregate with these characteristics. Dose-response studies will also be important in this context in order to understand the regulation of the balance between immunity and tolerance by contact allergens.

A recent study has provided such initial results from the genomic profiling of patch test biopsies for nickel, fragrance and rubber [136]. One hundred forty-nine genes were commonly regulated by all contact allergens compared to petrolatum as control. Differences between the allergens were observed for their efficiency in the induction of innate immunity and Th1/Th2/Th17/Th22 responses. Another recent genomic profiling study focused on the intra-individual comparison of skin lesion for psoriasis and non-atopic or atopic eczema in patients with both diseases, but also provided data on nickel-induced contact dermatitis [143]. Induced ACD could be differentiated from naturally occuring eczema by the selective down-regulation of late epidermal differentiation markers such as late cornified epithelial (LCE)1 and LCE2 family members, selective up-regulation of adhesion molecules such as ICAM-1 and of extracellular matrix associated HAS3 and epithelial-stromal interaction 1 (EPSTI1) the expression of which is modulated by inflammatory cytokines. Moreover, inflammasome components and neutrophil attracting chemokines were up-regulated in ACD. These studies mark the beginning of future genomic and proteomic studies that will hopefully identify chemical class-specific biomarker signatures for the identification of drug targets, improvement of diagnostics and development of *in vitro* assays for the identification of contact allergens.

A genome-wide association study (GWAS) with volunteers exposed to the irritants SLS and nonanoic acid revealed differential expression of 883 genes for the two irritants. Only 23 genes were commonly regulated by both chemicals [144].

These data highlight the importance to consider chemical-specific mechanisms. Especially in the case of irritants, it should be rewarding to classify them according to their physico-chemical properties and to analyse their mechanism of action by global technologies as there is little mechanistic understanding regarding the signaling pathways triggered by different irritants. Such studies will not only provide potential therapeutic targets, they will also help to understand the clinically relevant interaction of irritants with contact allergens which may lead to an augmentation of sensitization and of the clinical response, for example due to heterologous innate immune stimulation [23, 117].

In Vitro Assays for Contact Allergen Identification

A great challenge is the replacement of the LLNA (OECD guideline 429) by *in vitro* assays that identify contact allergens. The LLNA measures the proliferation of mouse lymph node cells following repeated topical application of a test substance or the solvent to the ear skin. Stimulation indices are calculated and effective chemical concentrations needed to give an SI = 3 (EC3 values) are used to classify chemicals including the determination of relative allergenic potency.

The current roadmap for the development of such assays is the so-called adverse outcome pathway (AOP) for skin sensitization [145]. It describes the key steps in the sensitization process of ACD that should be addressed by *in vitro* assays. Given the complexity of sensitization, it is clear that a combination of different assays in an integrated testing strategy (ITS) is the most likely strategy for the identification of sensitizing chemicals. Different assays have been developed and are tested for their sensitivity, specificity and accuracy [146]. A recent study demonstrated the advantages of the combination of selected *in vitro* assays covering different mechanistic aspects of the sensitization process of ACD in an ITS [147].

Eventually, the identification of contact sensitizers must also include assessment of their allergenic potency which is currently not possible in *in vitro* assays and remains a major advantage of the LLNA. Potency assessment is relevant to determine concentrations of contact allergens such as fragrances that can be used safely in consumer products or in the workplace. Recently, 131 substances have been categorized solely based on relative human skin sensitizing potency data. Such datasets should be more critical for judging the performance of non-animal methods that aim at measuring allergenic potency than a comparison with LLNA

EC3 values [148]. Eventually, safety levels must be determined for contact sensitizers used in consumer products or in the workplace and the impact on clinical outcome has to be monitored. A comprehensive review of testing strategies and preventive measures and their impact on clinical outcome was published by Thyssen et al. [149–151].

Future Clinical and Research Challenges

Our mechanistic understanding now allows us to develop strategies that decrease or prevent sensitization. Already at the level of the chemistry, steps for primary prevention can be undertaken. For example, the introduction of a methyl group into the allergenic hair dye pPD reduces its skin sensitizing potency [152]. Chemical alteration of epoxy resin monomers can also reduce their skin sensitizing potency [153]. Such efforts reduce the risk of ACD. Moreover, interference with innate immune responses may prevent sensitization or even elicitation as shown in the CHS model [60, 61, 74, 80] and aid in the induction of tolerance. Targeted therapies to blunt the effector/memory T cell response and to induce regulatory T cells are needed. Global technologies will help to identify biomarker profiles for contact allergens and irritants that should improve diagnostics and promote the identification of relevant signaling pathways and novel drug targets as well as the development of mechanistically-based assays for the *in vitro* identification of contact allergens.

Questions

1. What is the outcome of the sensitization to contact allergens?
   A. The primary activation of contact allergen-specific T cells
   B. The recruitment of T cells from the blood into the skin
   C. The induction of skin inflammation by T cells
   D. The reactivation of memory T cells

2. What is a hallmark of contact allergens?
   A. Contact allergens are proteins
   B. Contact allergens have enzymatic activity
   C. Contact allergens bind to proteins covalently or by complex formation
   D. Contact allergens bind to NF-κB

3. Which standard test is used for the diagnosis of ACD?
   A. The Prick test is the current standard test
   B. The Local Lymph Node Assay is the current standard test
   C. The Patch test is the current standard test

4. How do the metal ions nickel, cobalt and palladium activate the human innate immune system?
   A. These metal ions induce penetration of bacterial TLR ligands into the skin
   B. These metal ions bind to and dimerize human TLR4
   C. These metal ions induce extracellular matrix degradation
   D. These metal ions destroy the skin barrier

5. ACD is a T cell-mediated skin disease. Which T cell subsets are the main effector cells of ACD?
   A. CD4+ Th2 cells
   B. Invariant NKT cells
   C. CD4+CD25+ regulatory T cells
   D. CD4+ Th1 and Th17 cells, CD8+ Tc1 and Tc17 cells

Answers

1. A
2. C
3. C
4. B
5. D

Immunology of Acne

24

Galen T. Foulke and Amanda M. Nelson

Abstract

Activation of the immune system is a central event in the development of acne, and our understanding of this process is rapidly expanding. In this chapter, we describe how *P. acnes*, sebaceous glands, and keratinocytes contribute to inflammation in acne and how current acne treatments modulate this immune response. Specifically, we address the role of anti-microbial peptides, Toll-Like Receptors (TLRs), sebaceous lipids as well as cytokines and the role of the inflammasome as driving inflammation in acne. The anti-inflammatory activities of retinoids, tetracyclines and other therapies are discussed.

Keywords

Acne • P. acnes • Inflammation • Innate immunity • Immunology • Cytokines • Inflammasome • Sebaceous gland • Keratinocytes • Anti-microbial peptides

Acne

Clinical Presentation and Etiology

Acne is one of the most prevalent skin conditions encountered by dermatologists, affecting nearly 85 % of the people between the ages of 12 and 24 years including 40–50 million people in the United States each year [1, 2]. Acne has a significant psychosocial and economic impact with an estimated average cost per episode of $690 dollars and a total burden of $12 billion dollars per year in the United States [3–7].

Acne is a disease of the pilosebaceous unit (PSU) and begins with the formation of the microcomedone. The severity of acne is determined by the type, number and distribution of lesions and the presence of scarring. Acne is a multifactorial disease that results from the interaction of four main pathogenic factors: (1) the production of sebum by androgen-mediated stimulation of sebaceous glands, (2) abnormal hyperkeratinization of the follicles leading to comedone formation, (3) colonization of the PSU by *Propionibacterium acnes (P. acnes)*, and (4) inflammation, which is trigged by the interaction of immune cells, keratinocytes, and sebocytes with *P. acnes* after follicle disruption.

P. acnes, a gram positive, anaerobic, pleomorphic diphtheroid is the predominant organism in the follicular flora, although aerobic *Staphylococcus epidermidis* may also be present [8, 9]. *P. acnes* relies on sebaceous lipids, specifically triglycerides, as a nutrient source and metabolizes these into free fatty acids [10].

Experimental Models for Acne Vulgaris

Acne research is limited by the lack of a model system that mimics all aspects of acne pathogenesis. Cell culture, whole organ culture and animal models (mouse, hamster and rat) are used to study the individual features of acne, such as sebum production and hyperkeratinization. However, animal models for inflammation in acne, in which *P. acnes* plays a major role, are not available because *P. acnes* does not

colonize the PSU. One attempt to mimic the microenvironment of acne lesions was done by T. Nakatsuji and colleagues, in which a sebocyte-filled tissue chamber implanted into ICR mice was injected with *P. acnes* and the immune response was measured in the chamber fluids [11]. Thus, studies of acne inflammation rely on *in vitro* methods and acne patient populations.

Activation of the immune system is a central event in the development of acne, and our understanding of this process is rapidly expanding. In this chapter, we describe how *P. acnes*, sebaceous glands, and keratinocytes contribute to inflammation in acne and how current acne treatments modulate this immune response.

Innate and Acquired Immune Systems in Acne

Anti-microbial Peptides (AMPs): Good or Bad?

Increasing evidence indicates that AMPs, produced by neutrophils and epithelial cells, play a pivotal role in acne pathogenesis. The most important skin-derived AMPs are beta-defensins, cathelicidins and S100 proteins. For each of these, both pro-inflammatory and anti-inflammatory activities are reported. In general, the presence of *P. acnes* triggers the production of AMPs, which leads to the direct killing of the microbe and reduction in bacterial burden. However, AMPs also have immunomodulatory properties such as promoting chemotaxis and cytokine release, leading to the outstanding question of whether or not AMPs themselves substantially contribute to inflammation in acne.

Beta-Defensins (BD)

Both human BD-1 (hBD-1) and hBD-2 are expressed within the PSU and hBD-2 is significantly increased in acne vulgaris and hidradenitis suppurativa [12–14]. hBD-2 expression is increased in areas of high sebum secretion including the forehead, nose and chin when compared to the cheeks [15]. *P. acnes* triggers hBD-2 expression in keratinocytes and sebocytes [16, 17]. hBD-2 has antimicrobial activity against *P. acnes* and could limit the *P. acnes*-induced inflammatory response [18].

However, hBD-2 itself likely contributes to inflammation. It induces chemotaxis of immune cells and triggers the release of pro-inflammatory cytokines, histamine and prostaglandins [19]. In addition, hBD-2 enhances keratinocyte proliferation and migration, implying that hBD-2 contributes to possible comedone formation in acne [20].

Cathelicidin

Cathelicidin (LL-37) is increased in acne lesions as well as in hidradenitis suppurativa [21]. The functional LL-37 peptide is present within human sebaceous glands and *P. acnes* induces expression in sebocytes *in vitro* [22]. Similar to hBDs, cathelicidin peptides have direct antimicrobial activity against *P. acnes,* but also initiate cytokine production and inflammation in the host organism [22, 23]. In rosacea, elevated LL-37 expression causes increased inflammation characterized by increases in IL-8, neutrophilic infiltrate and erythema [24]. A similar process may occur in acne.

S100 Proteins

S100A7 (also known as psoriasin) is increased in the overlying epidermis and sebaceous duct of acne lesions and hidradenitis suppurativa [14, 21]. *In vitro*, S100A7 is bactericidal against *P. acnes* and is even more effective when combined with cathelicidin [22]. As with other AMPs, S100A7 may be partially responsible for inflammation in acne, as it is a powerful chemokine for neutrophils and lymphocytes.

Other AMPs

Lactoferrin, lysozyme, RNase 7, and both splice variants of koebnerisin, (S100A15L and S100A15S) are all elevated in inflammatory acne lesions compared to non-lesion control skin [21]. Granulysin, RANTES (CCL5), perforin, CXCL9, substance P, chromogranin B, and dermcidin are not elevated in acne lesions in this study [21], but are reported as elevated in others [13]. The presence of all these AMPs is likely protective and simultaneously pro-inflammatory.

Toll-Like Receptors (TLR)

TLR2 is expressed within sebaceous glands as well as basal and infundibular keratinocytes [25]. Studies have demonstrated increased TLR2 expression within acne lesions and hidradenitis suppuritiva compared to normal skin [26, 27]. Moreover, patients with acne have increased TLR2 expression on peripheral monocytes compared to those unaffected [28]. TLR4 expression is also increased in epidermal keratinocytes of acne skin compared to healthy skin [17].

TLR2 activation by *P. acnes* is an important step in the pathogenesis of acne [27–29]. Activation of TLR leads to activation of NFkB transcription factor and up-regulation of numerous cytokines and chemokines that trigger inflammation through recruitment of immune cells and AMP production. For example, through TLR2, *P. acnes* induces IL-12 and IL-8 cytokine production in monocytes, which likely triggers neutrophil chemotaxis [27].

Sebaceous Glands and Lipids

Sebocytes play a key role in the pathogenesis of acne and actively participate in regulation of the immune system [30]. They express TLRs and have been demonstrated to produce various inflammatory cytokines in response to *P. acnes* [27–29]. Additionally, the synthetic pathways for

the production of prostaglandins and leukotrienes from arachidonic acid are intact within sebaceous glands and sebocytes *in vitro*. These lipid mediators affect lipid synthesis, neutrophil chemotaxis and cytokine production [31].

Increased sebum production, altered sebum and skin surface lipid composition also contribute to inflammatory acne. Triglycerides within sebum are hydrolyzed to free fatty acids (FFA) by *P. acnes* lipase enzymes. These FFA including oleic, palmitic and lauric acids, act as "damage associated molecular patterns (DAMPs)" and can activate TLR2 and TLR4 resulting in inflammatory cytokine and AMP production [32]. The levels of lineolic acid (C18:2) are lower in acne patients compared to controls which may cause changes in keratinization of the follicle and increased neutrophil activity [33–35].

Sphingolipids and ceramides may also play a role in acne. Acid Sphingomyelinase (ASMase) is one enzyme responsible for catalyzing the breakdown of sphingomyelin on cell membranes to ceramide; ceramide, in turn, can induce apoptosis, differentiation and proliferation. Nakatsuji and colleagues demonstrated that *P. acnes* and its release of CAMP factor in combination with host ASMase activity was cytotoxic to keratinocytes *in vitro* and increased inflammation *in vivo* [36]. Interestingly, retinoid treatment of keratinocytes suppressed the expression of ASMase and numerous genes involved in ceramide biosynthesis [37], perhaps explaining some of its potency in the treatment of acne.

Sebaceous lipids are not all bad, some have potent antimicrobial effects. Lauric acid (C12:0) has strong direct antimicrobial activities against *P. acnes* [18]. In addition, lauric acid, along with palmitic acid (C16:0) and oleic acid (C18:1, *cis*-9), enhanced the expression of hBD2 in human sebocytes, suggesting indirect killing of *P. acnes* through hBD-2 [18]. Both palmitoleate (C16:1) and oleic (C18:1), produced by stearoyl-CoA desaturase-1 (SCD1) in the sebaceous gland in a TLR2 dependent manner, are bactericidal against gram-positive, but not gram-negative, organisms [38], although their activity on *P. acnes* has not been exclusively demonstrated.

Cytokines and T-cells

Gene expression studies demonstrate inflammatory acne lesions have increased levels of TNFα, IL-1β, IL-10 and IL-8 as well as increased levels of neutrophils and lymphocytes compared to non-acne skin [13, 39]. Additional cytokines involved in the pathogenesis of acne include IL-6, IL-12, IL-17, IFNγ, TGFα and epidermal growth factor (EGF).

IL-1 Family of Cytokines

Release of IL-1β propagates and perpetuates the inflammatory signal [40–43]. IL-1β release is also mediated by TLR2 activation. Inhibiting monocyte TLR2 activity reduces the secretion of IL-1β by half after stimulation with *P. acnes* [40]. IL-1β has been shown to induce the production of IL-6 and IL-8, a powerful neutrophil attractant, in sebocytes [29, 40, 41, 44]. IL-1β and IL-6, together with Transforming Growth Factor β (TGFβ), induce naïve helper T cells to undergo differentiation into T_h17 cells which can amplify inflammatory signals through the production of IL-17 (See below) [45].

IL-1α is constitutively produced by sebocytes and keratinocytes, but levels increase rapidly following *P. acnes* stimulation early in the formation of microcomedones. High levels of IL-1α results in hypercornification of the follicular infundibulum, mimicking that seen in microcomedones, and may promote keratinocyte terminal differentiation through upregulation of small proline rich protein 1 [43, 46, 47]. IL-1α has been found in high concentration in open comedones, and the production of the cytokine is increased with FGFR2 mutations [30]. FGFR2 mutations underlie Apert Syndrome, a key feature of which is acne [48, 49]. In one study, an uncommon single nucleotide polymorphism (SNP) in the IL-1α gene, a substitution of serine for alanine called the T allele, may be associated with more severe acne [49].

The Interleukins

IL-6 is a marker of activated monocytes, and participates in directing T_h17 differentiation [27, 45]. IL-8 acts to attract neutrophils, whose arrival and degranulation can promote rupture of the PSU [29, 43]. The release of both IL-6 and 8 is promoted by activation of the TLR2, by sebocytes following IL-1β stimulation, and may play a role in stress- induced acne [27, 30, 40]. Corticotropin-Releasing Hormone (CRH) levels rise during stress, and CRH receptor activation on sebocytes promotes IL-6 and 8 secretion [30, 43]. IL-12 is a powerful driver of differentiation toward T_h1 axis responses, is a principal inflammatory mediator in the response to gram positive organisms, and *P. acnes* induces increased secretion of IL-12 via TLR2 binding [27, 43]. IL-17 is involved in the T_h17 axis and will be discussed in depth separately, but promotes the release of TNFα, IL-6, and matrix metalloproteinases [45]. *P. acnes* derived proteases can also stimulate the secretion of IL-1α, IL-8 and TNFα by activation of the protease-activated receptor-2 (PAR2) on the cell membrane of keratinocytes [43].

TNFα, IFNγ, EGF, TGF

Among other roles, TNFα may increase keratinocyte expression of adhesion molecules in the follicular infundibulum and thus may contribute to the formation of the microcomedone through abnormal desquamation [46, 50]. Furthermore, one report suggests that a SNP in the TLR2 gene, Asp299Gly, may increase TNFα secretion following bacterial activation. SNPs in the TNFα promoter region have been studied to varying results, but some hold these polymorphisms may drive acne by increasing production of TNFα in response to NFkB activation [49]. IFNγ is produced by monocytes in response to *P. acnes* and drives differentiation of T cells toward the T_h1

axis [45]. EGF and TGFα together appear to promote rupture of the pilosebaceous unit [46]. TGFβ induces the differentiation of T_{reg} cells in the presence of IL-2 [51].

The *P. acnes* induced cytokine cascade may explain the early perivascular and perifollicular infiltration of lymphocytes seen at the initiation of the microcomedone, prior to clinical evidence of inflammation, and preceding the arrival of neutrophils [46].

T_h1 and T_h17 Cells

Acne is a T_h1/T_h17 associated disease. T_h1 and T_h17 cells are detected within acne lesions [45, 52] and the corresponding cytokine profiles are induced by *P. acnes*.

T_h17 cells are powerful drivers of inflammation and are thought to play a critical role in the development of several immunologically mediated diseases such as multiple sclerosis, psoriasis, and rheumatoid arthritis [45, 51]. This subset of helper T-cells produces IL-6, IL-17, IL-21 and IL-22 which act on tissues to promote degradation of the extracellular matrix and maintain intense chronic inflammation. T_h17 cells are identified by the production of IL-17 family cytokines (IL-17A and IL-17 F) and by the presence of cell markers RORα and RORc. *P. acnes* drives the production of IL-1β and IL-6 through mechanisms discussed above which appear to then promote the differentiation of naïve helper T-cells to T_h17 cells. The bacterium promotes the production and secretion of IL-17, as well as RORα and RORc.

The Inflammasome

Recently elucidated patterns of disease, termed autoinflammatory conditions, manifest from dysfunctional upregulation of innate immunity and several of these disorders share acne as a distinctive feature. Characterization of the inflammasome, an intracellular multi-protein complex capable of activating innate immunity, and its role in auto-inflammatory disease has informed several recent advancements in our understanding of acne [42, 48, 53].

Structure and Function of the Inflammasome

Inflammasome signaling begins with the activation of a Nucleotide-Binding Domain Leucine-Rich Repeat-Containing Protein, also referred to as a Nucleotide Oligomerization Domain-like Receptor Protein (both abbreviated NLRP) and culminates with the secretion of mature, active IL-1β, IL-6 and IL-18 which propagate inflammation [40–42, 53]. The NLRPs are cytosolic, and thought to be non-adaptable pattern recognition receptors, much like TLR's [41, 42, 54]. However, one study has questioned whether NLRPs respond to pattern molecules directly, respond to indirect signals or perhaps both [42]. Four NLRPs are well described: NLRP1, NLRP3 (also termed cryopyrin or NALP3), NLRC4 (also termed IPAF) and AIM2 [41, 42, 54]. These proteins can respond to various threats such as bacterial Pathogen Associated Molecular Patterns (PAMPs), viral and fungal pathogens, and Reactive Oxygen Species (ROS) [40–42, 54]. NLRP activation results in the recruitment of pro-caspase 1 through a Caspase Recruitment Domain (CARD) [41, 42]. In the case of NLRP3, the protein lacks a CARD and instead relies on the Apoptosis-associated Speck-like protein containing a Caspase recruitment domain (ASC) to bind pro-caspase 1 [42, 54]. Binding of pro-caspase 1 results in proteolytic cleavage into active caspase 1 subunits which subsequently convert the precursor of IL-1β into its active form [40, 42, 54]. Caspase 1 has also been shown to increase secretion of IL-1α [41].

P. acnes Activates the NLRP3 Inflammasome

The role of the inflammasome in acne vulgaris is currently being elucidated. First, *P. acnes* has been shown to induce the production of IL-1β and caspase 1 in human monocytes, as well as increasing the production of NLRP1 and NLRP3 [40]. Interfering with the production of NLRP3, but not NLRP1, results in dramatic decreases in the production of IL-1β, as does inhibition of caspase 1 [40, 55]. The production of AIM2 and NLRC4 (IPAF) are not affected by exposure to *P. acnes* [40, 54]. This information suggests that *P. acnes* stimulates the production of IL-1β via activation of the NLRP3 inflammasome in human monocytes *in vitro*, and *in vivo*. Though *P. acnes* is an extracellular pathogen, phagocytosis transmits the bacterium or its products to the cytosol where NLRPs reside [40, 55]. This internalization of bacteria appears to be necessary for NLRP3 inflammasome-dependent IL-1β production [55]. Bacterial muramyl dipeptide has been implicated as an activator of NLRP3, and *P. acnes* produces this molecule [40]. Direct binding of muramyl dipeptide and activation have not been demonstrated in acne.

A recent study shows that sebocytes not only express the constituents of the NLRP3 pathway, but that this pathway is activated upon exposure to *P. acnes*. Exposure to *P. acnes* led to increased levels of active caspase 1 and IL-1β in an NLRP3 dependent manner. The stimulated IL-1β production was dramatically impaired by the presence of N-acetyl cysteine, which the authors suggest as evidence for ROS mediating the activation of NLRP3 in some manner [54]. Other authors have suggested that NLRP3 can be activated by thioredoxin-interacting protein, which is itself released in the presence of ROS.

Autoinflammatory Disorders Involving Acne

The role of the inflammasome in the development of acne is suggested by PAPA (Pyogenic Arthritis, Pyoderma gangrenosum and Acne) syndrome [48, 53]. PAPA syndrome is a monogenic autoinflammatory disorder that involves severe nodulocystic acne as a hallmark feature. The syndrome

develops from a mutation in the Proline-Serine-Threonine-Phosphatase-Interactive-Protein 1 (PSTPIP1) [41, 48, 53]. In PAPA syndrome, the aberrant PSTPIP1 protein develops an increased binding affinity for the protein pyrin, which results in increasing rates of complexation of ASC with the inflammasome and thus recruitment of pro-caspase 1. It is unclear whether PSTPIP1 and pyrin binding activate pyrin to stimulate ASC complexation, or whether PSTPIP1 disinhibits inflammasome assembly by sequestering pyrin [41, 48, 53]. Regardless, as a result of PSTPIP1's increased affinity for pyrin, increased levels of IL-1β and Tumor Necrosis Factor α (TNFα) have been observed in patients with PAPA syndrome, and treatments antagonizing IL-1 or TNFα have been successful in ameliorating disease symptoms [48, 53]. The increase in ASC recruitment to inflammasomes in PAPA syndrome may implicate NLRP3, which appears to play a role in the inflammatory response to *P. acnes* [40, 42, 54]. NLRP3 mutations also underlie the cryopyrin associated periodic fever syndromes such as Familial Cold Autoinflammatory Syndrome, Muckle-Wells Syndrome, NOMID and CINCA syndromes [41, 42].

Other inflammasome components have been implicated in the pathogenesis of pustular autoinflammatory disorders. Pyoderma gangrenosum, Acne and Suppurative Hidradenitis (PASH) syndrome, another disorder involving severe cystic acne, is being evaluated as a separate abnormality of PSTPIP1 that may upregulate inflammasome activity [41, 53]. CARD14 mutations are responsible for certain forms of pustular psoriasis [53].

The Impact of Acne Treatments on Inflammation

The available spectrum of acne treatments impacts acne lesion development at every step. However, most therapies have been shown to have some role in tempering the host's immune response to *P. acnes*. These immunomodulatory effects are crucial, as clinical symptoms arise from host response to the bacterium [28].

Retinoids

The activity of retinoids in the treatment of acne was discovered serendipitously during study of the medication for application in icthyoses [56]. Retinoids are a structurally diverse family of molecules that share the ability to bind retinoic acid receptors and activate the retinoid system [51, 56]. This system influences the expression of an impressively broad array of genes, including those which regulate the immune response [51, 56, 57]. So powerful is the retinoid influence on immunity, that retinoids and their analogues are even showing promise as therapies for autoimmune diseases such as systemic lupus erythematosus [51].

Retinoids bind to nuclear hormone receptors of the steroid-thyroid hormone family which regulate transcription upon activation [46, 51, 56, 57]. These receptors belong to one of two types: the Retinoic Acid Receptors (RARs) and the Retinoid X Receptors (RXR), each of which has three isotypes: α, β and γ. In the inactive state, RAR is sequestered by a co-repressor protein and complexed with thyroid hormone. Upon retinoid binding, RAR is released from its repressor protein, and is obligated to bind with an RXR as a heterodimer to participate as a transcription factor. RXR faces less stringent requirements, and can dimerize with another RXR, or with thyroid hormone, vitamin D3 or peroxisome proliferator-activated receptors. Once the dimer is formed, the complex is capable of binding to Retinoic Acid Response Elements (RAREs) of select genes and modulating their transcription. The activated retinoid receptors may also function to antagonize other transcription factors independent of RARE binding. Retinoids commonly used as therapy in acne include tretinoin (*all-trans* retinoic acid; ATRA), isotretinoin (13-cis retinoic acid), adapalene and tazarotene. The latter 2 are 3rd generation retinoids, also termed arotinoids [46].

Treatment with retinoids, particularly isotretinoin, has been demonstrated to decrease the expression of TLR2 in monocytes, and reduce the levels of IL-1β, IL-6, IL-10 and IL-12 produced in response to *P. acnes* stimulation [28, 46, 56]. This effect is durable and has been shown to persist 6 months after treatment [28]. Though ATRA may play a role in the differentiation of regulatory helper T-cells (T_{regs}), systemic retinoid therapy does not seem to affect the cytokine profiles of peripheral T cells [28]. It appears that retinoids are able to blunt or perhaps normalize the immune response to *P. acnes* by reducing the expression and response of TLR2 to the bacterium.

As discussed above, T_h17 cells are a class of helper T-cells that maintain chronic inflammation and direct tissue mediated destruction of the extracellular matrix. A studies have revealed the ability of *P. acnes* to direct naïve T-cell differentiation to T_h17 cells. ATRA (along with vitamin D3, whose receptor can complex with RXRs) has been shown to inhibit the expression of genes necessary for T_h17 differentiation [28, 45, 51]. These genes include IL-17, RORα and RORc, but isotretinoin had no impact on IL-17 receptor level expression [45]. Retinoids are also shown to promote and maintain the development of $T_{regs.}$ T_{regs} are a class of helper T-cells characterized by FOXP3 expression which inhibit cytotoxic effector T-cells and promote self-tolerance through the secretion of IL-10. ATRA acts to inhibit mRNA expression of IL-2 and IFNγ [51].

In addition to modulating cytokine production, isotretinoin also normalizes expression of many AMPs that are increased in inflammatory acne lesions, including hBD2, cathelicidin, S100A7 [21].

Isotretinoin is able to induce apoptosis in sebocytes both *in vitro* and *in vivo*, which logically reduces the production rate of sebum [44]. Evidence suggests that this process occurs

through up-regulation of the protein NGAL [62]. Though this mechanism is not clearly delineated in sebocytes, NGAL induces apoptosis in some cell lines by altering iron metabolism through the binding of siderophores [44]. NGAL levels rise rapidly during the induction of isotretinoin therapy and precede reductions in *P. acnes* colonization and sebum production. As NGAL is not directly toxic to *P. acnes*, colonization density is likely reduced following nutrient deprivation due to reduced sebum production. NGAL is toxic to gram negative bacteria through the binding of bacterial siderophores [44]. This effect on bacterial iron metabolism probably underlies isotretinoin's activity in gram negative folliculitis.

Knowledge of retinoid action as anti-inflammatories continues to expand. Studies in cancer suggest that retinoids can influence the activity of NFkB, a downstream participant in the TLR2 pathway [51]. Activated retinoid receptors can antagonize AP-1, a proinflammatory transcription factor [56].

Tetracyclines

Tetracyclines act at the 30s subunit of bacterial ribosomes to reduce *P. acnes* burden and thus indirectly inhibit inflammatory pathways. The versatile antibiotics, which include tetracycline, doxycycline, and minocycline among others, also play a direct part in reducing inflammatory cascades. By virtue of ribosomal interference, tetracyclines can reduce the production of bacterial proteins (e.g. lipase) which may serve as neutrophil chemoattractants [50]. This translational interference occurs even at sub-antimicrobial dosing [50, 58].

Recruitment of neutrophils contributes to the development of inflammatory acne lesions. Tetracyclines can inhibit this process in a few ways. First, tetracyclines are well-documented to chelate calcium [58]. Tetracycline sequestration of intracellular calcium prevents proper assembly of microtubules which are critical to neutrophil mobility [50, 58]. Bacterial lipase is itself an attractant to neutrophils, in addition to its ability to cleave free fatty acids. Tetracyclines reduce production of lipase via ribosomal inhibition, and thus reduce the protein's ability to serve as a chemoattractant. IL-8 is a critical cytokine for the attraction and activation of neutrophils. Tetracyclines are shown to reduce IL-8 production in certain study models [50].

There does not appear to be consensus in the way tetracyclines reduce the secretion of cytokines, but studies show clear inhibition of TNFα, IL-1β and IL-8 production. The influence of tetracyclines may be via post-translational modification, as one study presented reduced levels of active cytokines while mRNA levels remained unaffected by tetracycline application [50]. Some posit that tetracyclines inhibit the action of matrix metalloproteinases, which are important in the maturation of certain cytokines to active forms, such as TGFβ [50, 58].

ROS are an important part of immune mediated bacterial killing, but the radicals can damage host tissue and propagate inflammation by many mechanisms including lipid peroxidation and inflammasome activation [40, 43, 50]. Tetracyclines can inhibit the expression of inducible nitric oxide synthase, the products of which can promote free radical formation. Tetracyclines may directly scavenge free radicals, and they also interfere with activation of calmodulin, a mediator in ROS formation and release [50, 59]. Minocycline appears to be the most potent anti-oxidant of the antibiotic class [50]. It is important to note that in other cases, tetracyclines can promote radical formation (such as in doxycycline's phototoxic response), indicating that this anti-inflammatory pathway may need more study.

As discussed above, lipid mediators derived from arachidonic acid can participate in inflammatory signaling. All relevant members of the tetracycline class can inhibit phospholipase A2, the enzyme that cleaves precursors to arachidonic acid. Minocycline can inhibit 5-lipoxygenase by preventing transport of the enzyme to the nuclear membrane [50].

Other Therapies

Benzoyl peroxide has long been a cornerstone in acne therapy. The compound is derived from coal tar, and rapidly penetrates the stratum corneum to reach the follicle where it converts to benzoic acid [60]. Benzoyl peroxide is directly toxic to *P. acnes* and rapidly kills the organism through oxidation of cell membrane components [46, 60]. Five days of treatment with benzoyl peroxide can reduce *P. acnes* populations by 95 %, greatly relieving bacterial influence on inflammation [60]. Benzoyl peroxide is also toxic to neutrophils in clinically relevant doses and weakly inhibits protein kinase C [59].

Dapsone, a sulfonamide antibiotic, has application to a number of pustular disorders. It inhibits myeloperoxidase, hampering the formation of ROS, and decreases production of IL-8 [60].

Summary

Our understanding of the pathogenesis of acne has evolved dramatically through research. Continued discovery has demonstrated the immune response to *P. acnes* as a primary player in the development of acne, rather than subordinate spectator. Once, it was believed that follicular keratinization changes and abnormal sebum metabolism precipitated acne lesions, and immunologic activation was secondary to these physical changes. Now it is evident that immune activation is an early, if not the earliest, event in comedogenesis.

Initial studies of *P. acnes* showed that the organism could elicit the production of cytokines and matrix metalloproteinases from leukocytes. We now know that keratinocytes and sebocytes respond to the organism as well. However, the precise mechanisms of activation were elusive for some time,

and many have questioned how *P. acnes* could influence immunity from within the immune-privileged PSU [61]. How exactly can *P. acnes* activate the immune cells surrounding the follicle if the organism is contained within the intact PSU?

Exciting studies have drawn back the curtain on this mystery. We now know that *P. acnes* can exert its influence through the activation of pattern receptor molecules, specifically TLR2 and the NLRP3 inflammasome. By interacting with these receptors on or in keratinocytes, sebocytes or leukocytes, *P. acnes* can stimulate the production of cytokines. These chemical messengers then activate and recruit immune cells, alter keratinocyte adhesion biology, and influence the behavior of lipid molecules of the PSU. *P. acnes* does not need to escape the PSU to initiate immune signaling, as keratinocytes and sebocytes both express these pattern recognition molecules which are activated independent of leukocytes. Perhaps it is the activation of TLRs and inflammasomes within follicular keratinocytes and sebocytes and the subsequent cytokine production that attracts the lymphocytic infiltrate described in early microcomedones. Once these leukocytes are present, they may then amplify and perpetuate the inflammatory call to arms. As we have seen above, the released cytokines can influence changes in the PSU. IL-1 produced by inflammasome activation may underlie Guy and Kealy's observation that IL-1-like activity can produce follicular hyperkeratinization [47]. Furthermore, the IL-1 and IL-6 produced from pattern receptor molecule activation may help drive Th17 axis differentiation and activation, a recently recognized important feature of acne. Future studies are needed to address whether or not cytokine production by keratinocytes and sebocytes initiate microcomedome formation.

Acne is a complex, multifactorial disease, with inflammation as a key driver of pathology. The rapid and potent immune response to *P. acnes* appears to influence each stage of acne's development, and amplification of the inflammatory cascade results in a self-perpetuating cycle. Bacterial PAMPs activate innate pattern receptors, which produce AMPs and cytokines to recruit inflammatory cells, which themselves produce more cytokines in response to *P. acnes*. With each new advance or discovery of this process comes ever more exciting opportunities to develop targeted therapies that may help interrupt this impressive cycle.

Questions

1. How is *P. acnes* responsible for activation of the immune system ?
   A. Anti-microbial peptides
   B. Tollo Like Receptors
   C. Cytokines
   D. Inflammasome
   E. All of the above
   F. None of the above

Correct Answer: (E) All of the above

2. What role does sebum play in inflammation?
   A. Cleaved triglycerides can act as damage associated molecular patterns for TLR activation
   B. Anti-microbial lipids can inhibit P. acnes
   C. P. acnes sphingomyelinase can augment inflammation
   D. A + C only
   E. All of the above

Correct Answer: (E) All of the above

3. Which of the above statement(s) are true concerning how current acne treatments affect inflammation?
   A. Retinoids decrease TLR2-mediated inflammation
   B. Retinoids decrease P. acnes burden
   C. Dapsone is cytotoxic to P. acnes
   D. Tetracycline increases epithelial differentiation
   E. All of the above

Correct Answer: (A) Retinoids decrease TLR2-mediated inflammation

Adverse Medication Reactions

25

Roni P. Dodiuk-Gad, Wen-Hung Chung, and Neil H. Shear

Abstract

Cutaneous adverse drug reactions (ADRs) are among the most frequent adverse reactions in patients receiving drug therapy. They have a broad spectrum of clinical manifestations, are caused by various drugs, and result from different pathophysiological mechanisms. Hence, their diagnosis and management is challenging.

Severe cutaneous ADRs comprise a group of diseases with major morbidity and mortality, reaching 30 % mortality rate in cases of Toxic Epidermal Necrolysis.

This chapter covers the terminology, epidemiology, pathogenesis and classification of cutaneous ADR, describes the severe cutaneous ADRs and the clinical and laboratory approach to the patient with cutaneous ADR and presents the translation of laboratory-based discoveries on the genetic predisposition and pathogenesis of cutaneous ADRs to clinical management guidelines.

Keywords

Cutaneous adverse drug reactions • Classification • Pathogenesis • Clinical approach • Laboratory tests • Human leukocyte antigen (HLA)

Terminology

The World Health Organization defined an adverse drug reaction (ADR) in 1972 as "a response to a drug that is noxious and unintended and occurs at doses normally used in man" [1]. Edwards and Aronson [2] proposed a different definition in 2000: "an appreciably harmful or unpleasant reaction, resulting from an intervention related to the use of a medicinal product, which predicts hazard from future administration and warrants prevention or specific treatment, or alteration of the dosage regimen, or withdrawal of the product."

The terms 'adverse reaction' and 'adverse effect' are interchangeable, except that an adverse reaction is seen from the point of view of the patient and adverse effect is seen from the point of view of the drug. However, both terms must be distinguished from 'adverse event'. An adverse event is an adverse outcome that occurs while a patient is taking a drug, but is not or not necessarily attributable to it [2].

Differentiating between serious ADR and severe ADR is imperative. Serious ADR is a legal term applied to any untoward medical occurrence that at any dose results in death, is life-threatening, requires inpatient hospitalization or prolongation of existing hospitalization, results in persistent or significant disability/incapacity, or is a congenital anomaly/birth defect [3]. Conversely, the term 'severe' is a clinical term used to describe the intensity (severity) of a medical event, as in the grading 'mild', 'moderate', and 'severe'; thus, a severe skin reaction need not be serious [2].

Epidemiology

ADRs are associated with significant morbidity and mortality and have considerable economic implications. Clinical manifestations of an ADR are variable and may include cutaneous and or systemic features [4].

When analyzing the type of ADRs most encountered, two major groups emerge; **common-mild reactions** and **rare-severe reactions**. Common-severe reactions are not approved for clinical usage and rare-mild reactions are usually not noticed or reported. Cutaneous ADRs are among the most frequent adverse reactions in patients receiving drug therapy [5]. They accounted for 65 % of all reported ADRs in a 4-year retrospective study in Taiwan [6].

The prevalence and incidence of cutaneous ADRs vary greatly among different populations [7–11]. In the USA, a 7-year prospective study found that the prevalence of cutaneous ADRs was 2.2 % in hospitalized patients [7]; and an 11-year retrospective study found the annual incidence of cutaneous ADRs to be 2.26 per 1,000 persons [11]. In Denmark, in a 1-year cross-sectional study the prevalence of cutaneous ADRs was 0.33 % in in-patients and 0.14 % in out-patients [8]. In southern China, in an 8-year retrospective study, the prevalence of cutaneous ADRs was 0.14 % in hospitalized patients [9]. In India, in a 12-month prospective study, the primary incidence of cutaneous ADRs was 2.05 per 1,000 persons [10].

The need to survey ADRs in clinical practice is universally recognized. Various methods may be employed: spontaneous surveillance, prescription-event monitoring (PEM), linkage analysis, case-control surveillance and cohort studies [5]. In 1963, the 16th World Health Assembly reaffirmed the need for early detection and rapid dissemination of information on adverse reactions due to medications. This affirmation led to the creation of the World Health Organization (WHO) Programme for International Drug Monitoring, under whose auspices systems have been created in member states for the collection and evaluation of individual case safety reports (ICSRs) [12]. In 1978 the WHO set up its international drug monitoring programme in Sweden at the Uppsala Monitoring Centre (UMC) http://www.who-umc.org. The US Food and Drug Administration (FDA) provides several options for reporting adverse events. One such option is MedWatch, the FDA Safety Information and Adverse Event Reporting Program http://www.fda.gov/safety/MedWatch/default.htm, founded in 1993 as a system for both consumers and healthcare professionals to report adverse events. MedWatch is intended to detect safety hazard signals for medical products; in the event a signal is detected, the FDA can issue medical product safety alerts or order product recalls, withdrawals, or labelling changes to protect the public health [13].

A number of international research groups are investigating severe cutaneous ADRs (SCARs): the RegiSCAR network, an international registry of SCAR established in 2003, the Japanese Research Committee, J-SCAR, the Asian SCAR consisting of Japan and Taiwan SCAR groups (J-SCAR and T-SCAR) established in 2010, and the Southeast Asia network, SEA-SCAR, with ten member countries: Brunei, Cambodia, Indonesia, Laos, Malaysia, Myanmar, Philippines, Thailand, Singapore, and Vietnam. The International Serious Adverse Event Consortium (iSAEC), a non-profit organization formed in 2007, is a pharmaceutical industry- and FDA-led international consortium that focuses on identifying and validating DNA variants useful in predicting the risk of rare drug-induced serious adverse events [14].

Pathogenesis

Immunologic Versus Non-immunologic Mechanisms

Immunological Mechanisms

Mechanisms of adverse drug reactions (ADRs) can be classified into immunologic and non-immunologic etiologies. There are two common types of immune-mediated drug reactions: immediate-type hypersensitivity (Type I hypersensitivity) and delayed-type hypersensitivity (Type IV hypersensitivity).

1. Immediate-type drug hypersensitivity: Immediate-type drug hypersensitivity reactions usually occur minutes to hours after drug exposure, with clinical manifestations including pruritus, urticaria, angioedema, and bronchospasm to anaphylaxis. The reaction is mediated mainly by drug-specific IgE, the most common causative agents being penicillins, cephalosporins and neuromuscular blocking agents. IgE-mediated reactions to drugs are usually thought to be an immune response to a hapten/carrier complex. In the primary drug sensitization, drug-specific IgE is formed when plasma cells transformed from activated B cells interact with T cells. In an allergic reaction, drug allergens bind to mast cells with high-affinity Fc receptor, to which drug-specific IgE is bound, causing

mast cells to release mediators, such as histamine, leukotrienes, prostaglandins and cytokines [15].

2. Delayed-type drug hypersensitivity: Delayed-type drug hypersensitivity reactions usually take several days to weeks following drug exposure, with variable clinical presentations that may include Maculopapular Eruption (MPE), Fixed Drug Eruption (FDE), Acute Generalized Exanthematous Pustulosis (AGEP), Stevens-Johnson Syndrome (SJS), Toxic Epidermal Necrolysis (TEN) and Drug Reaction with Eosinophilia and Systemic Symptoms (DRESS). T cell receptor (TCR), CD4+ and CD8+ T cells are involved in different delayed-type drug hypersensitivity reactions [16].

Drug Recognition by T Cells in Delayed-Type Drug Hypersensitivity

Drugs are low molecular weight and usually considered not able to bind to TCRs to activate adaptive immunity. In the case of drug allergy, drug interactions with TCRs may involve a drug-peptide complex presented by human leucocyte antigen (HLA) molecules of antigen-presenting cells (APCs). This process is known as the hapten concept; an example is β-lactams that covalently bind to lysine residues [17].

Drugs can also interact directly with TCRs without binding to the peptide/HLA of the APC in what is known as the P-i concept (pharmacological interaction of drugs with immune receptors) [18]. For example, carbamazepine is not able to bind covalently to peptides or proteins, but can associate with low affinity to TCRs and provoke T cell activation [19].

Immunohistologic Characteristics and Functions of Drug-Specific T Cells in Delayed-Type Drug Hypersensitivity

The immunohistologic characteristics of delayed type drug hypersensitivity are summarized in Table 25.1. The skin of MPE is infiltrated by numerous mononuclear cells (CD4 and CD8 T cells, monocyte/macrophages) and some eosinophils. Typically, interface dermatitis is seen with a predominance of CD4+ T cells. These cells are located mainly in the perivascular dermis, and both CD4+ and CD8+ T cells are located at the dermoepidermal junction [20].

Skin manifestations of DRESS may vary from MPE-like to exfoliative dermatitis and are characterized by a heavy infiltration of CD4+ and CD8+ T cells, monocyte/macrophages and eosinophils [21]. MPE and DRESS share many pathological features, but DRESS exhibits more severe dyskeratosis (keratinocyte death in epidermis) and a greater extent of systemic involvement and eosinophilia [26].

Immunohistology of skin lesions in AGEP reveals intraepidermal pustules with infiltration of neutrophils surrounded by IL-8 producing T cells [22].

Despite very diverse clinical presentations, constant features of delayed-type drug hypersensitivity are the presence of high numbers of drug-specific CD8+ cytotoxic T cells and low numbers of innate NK lymphocytes [20, 27, 28].

CD8+ T cells of cutaneous ADRs have classic cytotoxic functions: lysis of autologous lymphocytes or keratinocytes in an MHC class I–restricted and drug-dependent manner [28].

Cytotoxic Immune Cells in SJS/TEN

Drug-induced SJS and TEN are severe cutaneous ADRs in which cytotoxic T lymphocytes (CTLs) and natural killer (NK) cells are activated, and subsequently carry out the cellular immune reactions directed at keratinocytes in a major histocompatibility class (MHC) I-restricted manner. Upon activation of these immunocytes, various cytotoxic signals, including granulysin, perforin/granzyme B, Fas/Fas ligand, and cytokines/chemokines, are relayed to the skin lesions to mediate the disseminated keratinocyte death [23–25]. It is noteworthy that the number of granulysin-positive cells in fixed drug eruptions was found to be similar to that observed in SJS/TEN [27].

Non-Immune-Mediated Hypersensitivity

Non-immune-mediated hypersensitivity is commonly referred to as pseudoallergic reactions because they do not involve a specific immune mechanism – neither IgE-mediated (Type I) nor delayed (Type IV) hypersensitivity. Clinical manifestations, which range from milder erythematous to urticarial reactions to severe lethal anaphylaxis, may be indistinguishable from immune system-mediated hypersensitivity reactions. Common non-immune-mediated hypersensitivity can be caused by contrast media, vancomycin, non-steroidal anti-inflammatory drugs (NSAIDs), opiates, plasma expanders, and drugs used in general anesthesia [29].

NSAIDs-induced pseudoallergic reactions have been attributed to cyclooxygenase-1 inhibition and overproduction of leukotrienes, and may require higher drug doses than are needed for true IgE-mediated reactions [30]. Mast cell

Table 25.1 Summary of immunohistologic characteristics of delayed-type drug hypersensitivity [16, 20–25]

Phenotypes	Major immune cells	Major cytokines or cytotoxic mediators
MPE	CD4+ > CD8+ T cells	IFN-γ, TNF-α, IL-4, IL-5, perforin/granzyme B
DRESS	CD4+ > CD8+ T cells, eosinophils	IFN-γ, TNF-α, IL-4, IL-5, TARC/CCL17
SJS/TEN	CD8+ T cells, NK cells	IFN-γ, TNF-α, Fas-FasL, perforin/granzyme B, granulysin
AGEP	Neutrophils	IL-8

MPE maculopapular drug eruption, *DRESS* drug reaction with eosinophilia and systemic symptoms; *SJS/TEN* Stevens-Johnson syndrome/toxic epidermal necrolysis, *AGEP* acute generalized exanthematous pustulosis

degranulation is involved in some of these pseudoallergic reactions.

The Role of Cytokines or Inflammatory Mediators

Drug-specific T cells mediate skin inflammation in variable clinical presentations of delayed-type drug hypersensitivity through the release and induction of different cytokines and chemokines (Table 25.1) [31]. The heterogeneous cytokines include Th1 cytokines (interferon-γ) and Th2 cytokines (IL-4, IL-5) [22]. Increased expression of IL-5, which is a key cytokine for activation of eosinophils, is commonly seen in delayed-type drug hypersensitivity [32]. The activation of eosinophils can be further enhanced by the chemokines eotaxin and RANTES [33]. Thymus and activation-regulated chemokine (TARC/CCL17) has been reported to be a DRESS specific cytokine [34]. In addition to Th1 and Th2 cytokines, a recent study demonstrated the involvement of IL-17A-producing Th17 in DRESS and SJS/TEN [35]. Elevated expression of the neutrophil-attracting IL-8 has been known to be the key cytokine involved in AGEP.

There are several cytokines involved in SJS/TEN. Numerous studies have shown tumor necrosis factor alpha (TNF-α) strongly expressed in SJS/TEN lesions and correlated with disease severity [24, 36, 37]. TNF-α is a potent cytokine that induces cell apoptosis, cell activation, differentiation, and inflammatory processes [38, 39]. Interferon gamma (IFN-γ) is a common cytokine involved in delayed-type drug hypersensitivity, including SJS/TEN. IFN-γ was intensely expressed in the superficial dermis and epidermis of SJS/TEN lesions [36, 37]. IFN-γ is also known to promote antigen presentation and thus stimulate the cell-mediated immunity by upregulation of MHC molecules [40–42]. In addition to TNF-α and IFN-γ, several cytokines and chemokine receptors that are responsible for trafficking, proliferation, and activation of T-cells and other immune cells have been found elevated in the skin lesions, blister fluids, blister cells, PBMCs, or plasma of SJS/TEN patients. These cytokines/chemokines include IL-2, IL-5, IL-6, IL-10, IL-12, IL-13, IL-15, IL-18, CCR3, CXCR3, CXCR4, and CCR10 [24, 36, 37, 43–45].

Immune Mediators for Cell-Mediated Cytotoxicity in SJS/TEN

The central hypothesis proposed to explain the severe mucocutaneous lesions of SJS/TEN is the CD8+ cytotoxic T cell and natural killer (NK) cell-mediated cytotoxic immune reactions. Three major cytotoxic signals from cytotoxic cells are reported to be involved in the extensive skin necrosis of SJS/TEN, including the Fas–FasL interaction, perforin/granzyme B, and granulysin, which can induce keratinocyte apoptosis [23, 28, 46].

Granulysin is not only a cytotoxic protein; it is also a chemoattractant and proinflammatory activator that can promote monocyte expression of CCL20 [47], and is capable of promoting antigen-presenting (dendritic) cells and leukocyte recruitment, and activating specific immune responses, such as IL-1b,IL-6, IL-10, TNF-a [48].

Genetic Predisposition

Genetic Factors in Delayed-Type Drug Hypersensitivity

Reports on the familial occurrence of severe drug hypersensitivity and cases occurring in identical twins suggest genetic links [49–52]. The HLA genes show strong association with drug hypersensitivity. Examples of strong associations of HLA alleles with specific drug-induced hypersensitivity reactions include abacavir, nevirapine, carbamazepine, and allopurinol (Table 25.2).

The view that HLA alleles are the main genetic determinants of SJS/TEN was first proposed by Roujeau et al. [61], who reported the weak associations of HLA-A29, B12, and

Table 25.2 Recently reported HLA associations with drug hypersensitivity reactions

Methazolamide	B*5901	SJS/TEN	Kim et al. [60]

MPE maculopapular drug eruption, *DRESS* drug reaction with eosinophilia and systemic symptoms, *SJS/TEN* Stevens-Johnson syndrome/toxic epidermal necrolysis

DR7 in sulfonamide-related TEN, and HLA-A2, B12 in oxicam-related TEN in Europeans [61]. Following the immunological hypothesis, the most striking evidence of genetic susceptibility to SJS/TEN was provided by the findings that HLA-B*15:02 is strongly associated with carbamazepine-induced SJS/TEN [53], HLA-B*58:01 with allopurinol-induced SJS/TEN or DRESS [54], and HLA-B*5701 with abacavir hypersensitivity [62].

The HLA association to specific drug-induced hypersensitivity can be ethnic and phenotype-specific. The strength of HLA associations with specific drug-induced hypersensitivity in different populations has been found related to the prevalence of the susceptibility allele in the ethnic population. The association of HLA-B*15:02 with carbamazepine-induced SJS/TEN was replicated in other Asian countries, including Thailand, Hong Kong, Malaysia, China, Vietnam, Cambodia, Reunion, Philippines and Indian ethnicities, which carry high HLA-B*15:02 allele frequency, but not in Europeans, which carry low HLA-B*15:02 allele frequency (<1 %) [63]. In contrast, the strong association of HLA-B*58:01 with allopurinol-induced SJS/TEN is more universal, being found in Han Chinese in China, Thai populations, Korean, Japanese, and European populations; HLA-B*58:01 is the allele common to all these populations [64]. The phenotype-specific characteristics are exemplified by carbamazepine hypersensitivity. While HLA-B*15:02 is strongly associated with carbamazepine-induced SJS/TEN, it is not associated with carbamazepine-induced DRESS; in an international study, HLA-A*31:01was strongly associated with carbamazepine-induced DRESS, but not with carbamazepine-induced SJS/TEN [65].

Phenytoin – an aromatic antiepileptic drug structurally related to carbamazepine – also frequently causes SJS/TEN and DRESS [66, 67]. HLA-B*15:02 has been associated with phenytoin-related SJS/TEN in Asians, although the association is much weaker than that found for carbamazepine-related SJS/TEN [68]. A recent genome-wide association study by Chung WH et al. turned up cytochrome (CYP) 2Cvariants, including CYP2C9*3, that showed a strong association with phenytoin-related SCAR. The significant association between CYP2C9*3 and phenytoin-related severe cutaneous ARDs was replicated in different Asian populations [69].

Genetic Factors in Immediate-Type Drug Hypersensitivity

Similar to delayed-type drug hypersensitivity, genetic predisposing factors have been reported in immediate-type drug hypersensitivity. β-lactam allergy was reported associated with gene variants of IL13, IL4, and IL4RA [70–73]. Several genetic predisposing factors, including gene polymorphisms in cysteinyl leukotriene receptor type 1 (CysLTR1) and leukotriene C4 synthase (LTC4S) [74] and high-affinity IgE receptor (FcepsilonR1) [75], were associated with aspirin.

Classification

Cutaneous ADRs may be classified in terms of their presumed mechanism, severity of the reaction, histological findings, and cutaneous morphological manifestations.

Mechanism of ADRs

The modern pharmacological classification of ADRs differentiates two basic types of reactions; type A, predictable reactions, and type B, unpredictable or idiosyncratic reactions. Type A reactions ('augmented') are dose-dependent, common and predictable based on the pharmacology of the drug; about 80 % of all ADRs are type A. Type B reactions ('bizarre') do not occur at any dose in most patients, but may be dose dependent in susceptible individuals. They are uncommon, affecting a small number of patients based on an individual predisposition that depends on both genetic and environmental factors [76, 77].

The pathogenesis of Type A reaction was described in the sixteenth century by Paracelsus, the Swiss German Renaissance physician who founded the discipline of toxicology: "All things are poison, and nothing is without poison; only the dose permits something not to be poisonous" [78]. The pathogenesis of Type B reaction was designated in the first century BC didactic poem, De rerum natura (On the Nature of Things), by the Roman poet and philosopher Lucretius: "One man's meat is another man's poison" [79].

Type B reactions can be categorized into different subtypes according to Gell and Coombs' classification system [80]. The effector phase of the allergic reaction is classified into four types: Type I mediated by drug-specific IgE antibodies, Types II and III mediated by drug specific IgG or IgM or IgA antibodies, and Type IV induced by drug-specifc T lymphocytes [81]. This classification system may be helpful in daily clinical practice as a guide to diagnostic and therapeutic decisions.

In addition to the basic classification of Type A and B reactions, further types of reactions were subsequently added; Type C- dose and time-related, 'Chronic'; Type D-time-related. 'Delayed'; Type E- withdrawal effects, 'End of use'; and Type F- unexpected failure of therapy, 'Failure' [2].

Severity of Cutaneous ADRs: Skin only (Simple) Versus Skin and Systemic Involvement (Complex)

The diagnosis of a cutaneous ADR must be followed by differentiation between a simple reaction involving only the skin and a complex reaction that includes systemic involvement of organs in addition to the skin [82]. Systemic

involvement should be explored even in a mild cutaneous eruption due to a drug since the severity of skin manifestation does not necessarily mirror the severity of the systemic involvement. Systemic involvement is evaluated by assessing the patient's symptoms, including fever, facial edema, malaise, chills, dyspnea, cough, palpitations, nausea, vomiting, diarrhea, sore throat and arthralgia. Further investigation is based on the patient's symptoms. Basic laboratory screen, conducted in cases of suspected systemic involvement, includes a full blood count, liver and renal function tests, and urine analysis [83].

Histological Classification of Cutaneous ADRs

Skin biopsy is an invaluable diagnostic modality in the assessment of drug eruptions. Histologically, drug eruptions can elicit a variety of inflammatory disease patterns in the skin and panniculus, and overlapping reaction patterns. Ackerman et al.'s basic patterns of inflammatory skin diseases [84] (Table 25.3) are a helpful guide. The most common pattern of drug eruptions is the perivascular type, while psoriasiform and granulomatous patterns are rarely reported [85]. Drug eruptions may also mimic specific skin diseases such as lupus, lichen planus or lymphoma [85]. A single drug may cause a wide range of reaction patterns and no reaction pattern is specific for a particular drug [88]. While the histological changes are not distinctive in many cases of drug eruption, a few important histopathological clues may aid in the diagnosis: (1) Overlapping histological patterns in one specimen (e.g., lichenoid and spongiotic). (2) Presence of eosinophils (although not mandatory); although eosinophils are an important tell-tale sign of a drug-induced reaction, they may also be conspicuous in skin rashes devoid of a drug association and sparse or absent in some drug exanthems. (3) Apoptotic keratinocytes. (4) Mismatch between clinical and histomorphological features [85, 86, 88].

In a study assessing the histological pattern of 104 cases of diagnosed drug eruption during a 5-year period in one institution [89], the majority of the cases (94 %) were morbilliform-type rashes. The most common histological pattern was superficial perivascular and interstitial with interface changes. Eosinophils were present in only 50 % of cases, and approximately half (53 %) of the cases exhibited epidermal-dermal interface changes [89].

In view of the large diversity of cutaneous drug reactions, it is helpful to approach them as clinicopathologic entities and to base the diagnosis on a combination of clinical, histo-

Table 25.3 Pattern analysis of the main types of cutaneous ADRs according to Ackerman et al.'s classification of inflammatory skin diseases [84–87]

Perivascular	Superficial perivascular	Mixed infiltrate	Spongiotic	Psoriasiform	Interface pattern
	Purpuric drug eruption	Urticarial drug eruption	Pityriasis rosea–like eruption Photosensitive drug eruptions: Phototoxic reaction Photoallergic reaction	Psoriasiform drug eruption	Vacuolar: EM SJS TEN FDE Morbilliform drug eruption Lupus erythematosus-like eruption Chemotherapy-induced interface dermatitis Lichenoid drug eruption
Nodular and diffuse	*Lymphomatous*	*Neutrophilic*	*Granulomatous drug eruptions*		
	Pseudolymphomatous drug reaction	Drug-induced Sweet syndrome	Interstitial granulomatous drug reaction (IGDR) Drug-induced accelerated rheumatoid nodulosis Drug-induced granuloma annulare Drug-induced sarcoidosis		
Vesiculobullous	Drug-induced linear IgA bullous dermatosis	Drug-induced pemphigus	Drug-induced bullous pemphigoid	Drug-induced pseudoporphyria cutanea tarda	
Pustular	AGEP				
Vasculitis	Drug-induced vasculitic reaction				
Folliculitis and perifolliculitis	Acneiform drug eruptions	Drug-induced eosinophilic pustular folliculitis (Ofuji's disease)			
Fibrosing dermatitis	Sclerodermoid drug reaction				
Panniculitis	Drug-induced panniculitis				

EM erythema multiforme, *SJS* Stevens-Johnson syndrome, *TEN* toxic epidermal necrolysis, *FDE* fixed drug eruption, *AGEP* acute generalized exanthematous pustulosis

logical and disease course data [89]. Heightened awareness of the possible mimicry of other skin diseases and of the suspicious histopathological clues pointing to drug etiology are key elements to the appropriate histological diagnosis of drug reactions in the skin [85, 88, 89].

Morphological Classification of Cutaneous ADRs

A widely accepted approach to diagnosing the type of drug eruption is a simplified method based on the morphology of the primary lesions. The four main categories are maculopapular, urticarial, pustular and blistering [82]. The diagnosis of the drug eruption can be challenging since the same cutaneous morphology can be manifested in a simple reaction involving only the skin and in a complex reaction including systemic involvement in addition to the skin. Therefore, there are two major steps in diagnosing drug eruptions: determine the morphology and assess systemic involvement [90].

Maculopapular Eruptions – MPE (Synonyms: Morbilliform, Exanthematous)

Terminology The term 'maculopapular' is descriptive. Morbilliform means measles-like, the rash of measles consisting of macules and papules that tends to confluence. The etymon of 'exanthema' is the Greek 'exanthema', which means 'a breaking out'. Thus exanthema merely means 'rash', and 'exanthematous rash' literally means 'rash-like rash'. Therefore, the terminology is redundant [89].

Skin Signs Polymorphous pink-to-red macules and or papules usually in a symmetric distribution that may coalesce to form plaques (Fig. 25.1) [91]. The eruption begins on the trunk and upper extremities and progressively becomes confluent. In addition, purpuric lesions may appear on the ankles and feet [90]. The drug eruption can also manifest in a scarlatiniform pattern of pinpoint-sized pink-red papules coalescing and giving the skin the texture of sandpaper [92].

Maculopapular Eruptions – MPE – Simple (Skin Only)

Frequency The most common drug-induced eruptions, occurring in 1–5 % of first-time users of most drugs [91].

Lag Period 7–14 days [90].

Symptoms Pruritus and low-grade fever are common [91].

Common Sites of Involvement The eruption usually begins on the trunk and becomes generalized. Palms and soles are often involved; mucous membranes are usually spared [90].

Histology Nonspecific changes consisting of mostly superficial but also deep perivascular and interstitial infiltrate of lymphocytes. Eosinophils and epidermal-dermal interface changes appear in approximately half the cases [89].

Differential Diagnosis viral exanthems, scarlet fever, toxic shock syndrome, acute graft versus host disease (GVHD), Kawasaki disease, juvenile idiopathic arthritis [90].

Treatment Identifying and discontinuing the causative drug are the most important steps in management. Symptomatic treatment with antipruritic agents and potent topical glucocorticoids may be helpful [91]. A decision can be made to continue the drug and offer symptomatic treatment if the drug is of paramount importance, but the risk: benefit ratio of this option has to be carefully weighed, and the evolution of the eruption must be meticulously monitored [90].

Prognosis The eruption often fades within 7–14 days of discontinuation of the offending drug and scaling and desquamation may follow. Re-challenge may lead to reappearance of the reaction within a few days [90].

Offending Drugs The most common classes of drugs implicated are penicillins, sulfonamides, cephalosporins, and antiepileptics [90].

Maculopapular eruptions – MPE – Complex (skin + systemic involvement): DRESS – See Severe Cutaneous Adverse Drug Reactions.

Urticarial Eruption

Terminology The term 'urticaria', first introduced by William Cullen in the eighteenth century, is derived from urtica urens (common European stinging nettle). One of the earliest descriptions of urticaria comes from China, and is more than

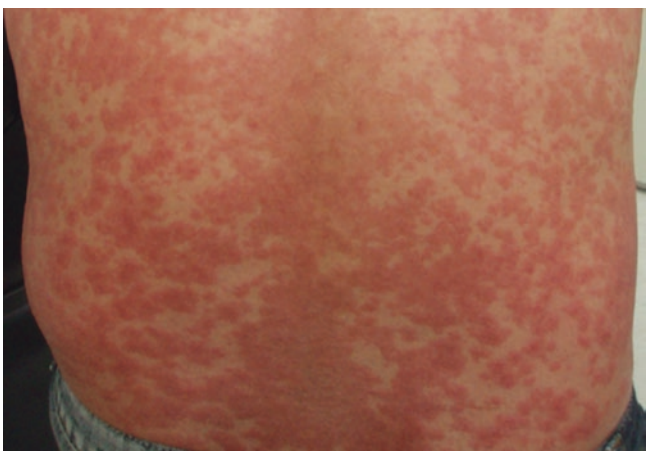

Fig. 25.1 Erythematous macules and papules coalescent into ill-defined plaques on the trunk – maculopapular morphology of cutaneous ADR

2,000 years old. In the Huangdi Neijing, written around 200 BC, urticaria is referred to as Feng Yin Zheng ('wind type concealed rash'). In ancient Latin medical literature, urticaria was called 'uredo' (urere means 'to burn'), and in the old Persian medical texts, 'essera' (meaning 'elevation') [93].

Skin Signs Urticaria is induced by superficial dermal swelling due to plasma leakage and vasodilation triggered by activation of mast cells. The skin manifestations of this process include erythematous and edematous papules and plaques (wheals) of various sizes that may coalesce to form large plaques [94]. Wheals may be characterized by pink or pale center and assume a figurate or polycyclic configuration. Linear lesions can be seen with dermatographism [92, 94].

Urticarial Eruption – Simple (Skin Only)

Frequency Drug-induced urticarial eruptions are the second most common type of cutaneous drug eruption and account for approximately 5 % of all cutaneous drug eruptions [85].

Lag Period Urticaria occurs within minutes to days of drug administration [94].

Symptoms A major clinical feature is pruritus, the lack of which should put the diagnosis in doubt. The lesions can also be painful if they occur on the soles, over joints, or in areas where the skin is tightly adhered to subcutaneous tissue [94]. A single lesion lasts less than 24 h and upon resolution leaves normal skin. However, new lesions may continue to arise for various periods of time. Acute urticaria is defined when a bout of hives lasts less than 6 weeks; when it lasts longer, it is defined as chronic urticaria [95].

Urticaria may be associated with angioedema [93]. Angioedema is defined as a deep, dermal, subcutaneous and/or mucous swelling that may involve the intestinal lining and the upper respiratory tract. Symptoms include slight heat, burning, pain and sensation of pressure or tightness. However, pruritus is minimal or absent. Swelling of gastrointestinal tract mucosa can induce abdominal pain, vomiting and diarrhea. Edema of the respiratory tract may induce various symptoms including life-threatening asphyxia. Drug-induced angioedema is associated with urticaria in approximately 50 % of cases. Some drugs may induce angioedema without urticaria [96].

Common Sites of Involvement Lesions of urticaria can appear anywhere on the skin, including the palms, soles and scalp, but not on mucosal surfaces [94]. Angioedema most commonly occurs in the head, neck and hands, but can occur anywhere and frequently involves mucosal tissue. Swelling may be more prominent in areas of looser skin, such as the scrotum, labia, lips, and eyelids [94].

Histology Urticarial drug reactions are characterised by dermal edema and a superficial and deep perivascular and interstitial dermatitis. The mixed inflammatory infiltrate comprises lymphocytes, histiocytes, mast cells, eosinophils and neutrophils. The presence of neutrophils and deep vascular plexus involvement may be a clue to the drug-induced nature of the urticaria [86].

Differential Diagnosis The wheals with central red halo of urticaria may resemble the target lesions of erythema multiforme. Four clinical signs of urticaria can help distinguish it from erythema multiforme: (1) The central zone consists of normal skin, whereas in erythema multiforme, skin is dusty, bullous or crusted. (2) Each lesion is transient, lasting less than 24 h, whereas erythema multiforme lesions are 'fixed' for a few days. (3) New lesions appear daily and in erythema multiforme all lesions appear within the first 72 h. (4) There may be associated swelling of face, hands and feet and in erythema multiforme there is no edema [97]. Differential diagnosis of urticaria includes also bullous pemphigoid, urticarial vasculitis and serum sickness-like reaction (SSLR). Drug-induced urticaria needs to be differentiated from cases of urticaria induced by other etiologies, such as food, environmental allergens, insects, systemic illness, physical stimuli, genetic and idiopathic [94].

Urticaria and angioedema are the most common symptoms of anaphylaxis (88 % of cases), and are one of the clinical criteria of the National Institute of Allergy and Infectious Disease (NIAID) and the Food Allergy and Anaphylaxis Network (FAAN) for the diagnosis of anaphylaxis [98]. Therefore, all cases of sudden acute urticaria and angioedema should be evaluated for indications of the anaphylactic type of reaction: presence of respiratory compromise, decreased blood pressure, and end-organ dysfunction (collapse, syncope, incontinence) [98].

Treatment The most important step in the management of drug induced urticaria with or without angioedema is withdrawal of the causative agent. In most cases of acute urticaria, when the trigger is removed the rash quickly resolves. H1-receptor blockers are the mainstay of treatment for patients with only cutaneous symptoms. Systemic glucocorticoids are indicated in all cases with upper airway edema and should be considered in cases with extensive cutaneous involvement. Epinephrine is reserved for angioedema with upper airway involvement [94]. The presence or absence of any airway involvement should be specifically investigated.

Prognosis Both urticaria and angioedema fade without visible sequelae. Following resolution, there should be no residual pigmentary changes unless excoriated [94].

Offending Drugs Many drugs can induce acute urticaria, and do so by both immunologic and non-immunolgic mechanisms. The major drugs responsible for immunologically based urticaria are antibiotics, especially penicillins

and cephalosporins [90]. The major drugs triggering mast cell release (non-immunolgic mechanisms) are aspirin, nonsteroidal anti-inflammatory drugs (NSAIDS), opioids and radiocontrast media [90]. Viral infections or connective tissue diseases may induce or augment urticarial drug reactions [86].

Urticarial Eruption – Complex (Skin + Systemic Involvement)

- **Anaphylaxis**

The National Institute of Allergy and Infectious Diseases (NIAID) and the Food Allergy and Anaphylaxis Network (FAAN) defined anaphylaxis as a systemic reaction resulting from the sudden release of multiple mediators from mast cells and basophils, often life threatening, and usually unexpected. The World Allergy Organization (WAO) has divided anaphylaxis into immunologic (further divided into immunoglobulin E [IgE]-mediated and non-IgE-mediated), non-immunologic, and idiopathic causes. Drugs are the second most common cause of anaphylaxis after food, which constitutes 20 % of triggers [98]. Common medications associated with anaphylaxis include penicillins, NSAIDs, and biologic response modifiers [99]. The NIAID/FAAN definition of anaphylaxis has been translated into clinical diagnostic criteria that include an acute onset of illness (minutes to hours) and involvement of the dermatologic, respiratory, cardiovascular, or gastrointestinal systems [98]. Epinephrine is the only first-line treatment for anaphylaxis and is the sole effective treatment for an acute reaction. Delays in administration have been associated with fatalities. Supportive treatment with oxygen, fluids and additional drugs are also necessary according to the cardiopulmonary resuscitation (CPR) anaphylaxis algorithm [98].

- **Serum sickness-like reaction (SSLR) – See Severe Cutaneous Adverse Drug Reactions**.

Pustular Eruptions

Terminology The term pustule originates in classical Latin in which pustule means a blister [100].

Skin Signs Pustular drug eruptions are characterized by monomorphic eruption consisting of erythematous papules (mostly follicular) and pustules at the same location lacking comedones.

Pustular Eruptions – Simple (Skin Only)

Acneiform Drug Eruptions (Acne Medicamentosa)

The term acneiform is applied to eruptions that resemble acne vulgaris.

Frequency Varies, depending on the drug. The highest incidence involves epidermal growth factor receptor inhibitors (EGFRIs), affecting 60–100 % of patients [101].

Lag Period The eruption begins after a variable delay; corticosteroids may induce an acneiform eruption from shortly after their introduction (2–4 weeks) to several months [101]. Acneiform eruptions induced by EGFRIs usually appear after 1–2 weeks of treatment but can also occur after only a few days [102].

Symptoms Pruritus, tenderness and pain may occur. In cases of chemotherapy-related side effects, their appearance and severity are part of the criteria used for the classification of the ADR [103].

Common Sites of Involvement Lesions may be located in and beyond the seborrheic areas, such as the arms, trunk, lower back and genitalia [104].

Histology Drug-induced acneiform eruptions show histopathologic features similar to acne vulgaris. Early lesions most commonly have a corneocytic plug within a widened infundibulum, accompanied by infundibular spongiosis, perifollicular edema, with sparse perivascular and perifollicular infiltrates of neutrophils and lymphocytes. Larger older lesions show similar findings but the infiltrate is denser, with more neutrophils around the involved follicles, and infundibular rupture [85, 88]. In a review of the histological findings of acneiform eruptions induced by EGFRIs [105], all ten cases showed a superficial, predominantly neutrophilic suppurative folliculitis with ectatic infundibula and a rupture of the epithelial lining.

Differential Diagnosis The main differential diagnosis is acne. The following clinical characteristics of acneiform drug eruptions may aid in differentiating between the two entities: (1) Clinical presentation: monomorphic pattern, lack of comedones and cysts and localization on areas beyond the seborrheic area. (2) Patient characteristics: age of onset before or after the teens, and absence of past history of acne. (3) Resistance to conventional acne therapy. (4) Time relationship: onset after recent drug introduction, improvement after drug withdrawal, and recurrence after drug reintroduction [101]. The differential diagnosis also includes folliculitis, rosacea, perioral dermatitis, demodicosis, acne cosmetic, acne mechanica, chloracne, acne necrotica and acneiform presentation of cutaneous lymphomas [104].

Treatment The main treatment is withdrawal of the offending drug and the application of topical treatments as needed (benzoyl peroxide topical antibiotics and topical retinoids) [90]. The management of acneiform eruptions associated

with chemotherapy differs from all other types of acneiform drug euptions, as acneiform eruption is an expected outcome and discontinuation of the medication is not an option in a patient who is responding to therapy [102, 103, 106, 107]. In fact, continuation of EGFRI therapy in these patients may be especially favourable in view of studies that have shown an increased survival with increasing severity of rash [102]. The cutaneous reaction serves as an important clinical tool for determining tumor response and survival [102]. The National Cancer Institute developed a scale for defining the degree of rash and laid down management guidelines for each stage [103]. Other management protocols were suggested by Bachet et al. [107], who recommended that unless contraindicated, a tetracycline should be routinely prescribed for the prevention of acneiform eruption in patients treated with an EGFRI for more than 6 weeks. Chiang et al. [106] reported successful treatment with isotretinoin for high grade and refractory cases.

Prognosis In most patients with acneiform drug eruption, the rash resolves upon discontinuation of the offending drug and the use of topical treatment. In EGFRI-induced acneiform eruption, prophylactic administration of a tetracycline was associated with significantly lower incidence of grade 2–3 folliculitis and improved quality of life of patients [107].

Offending Drugs The drugs responsible for acneiform eruptions include [101]:

- Hormones: corticosteroids and corticotropin – adrenocorticotropic hormone (ACTH), androgens and anabolic steroids, hormonal contraceptives; other hormones – thyroid-stimulating hormone, danazol.
- Neuropsychotherapeutic drugs: tricyclic antidepressants, lithium, antiepileptic drugs, aripiprazole, selective serotonin reuptake inhibitors.
- Vitamins: B1, B6, B12, D2.
- Cytostatic drugs: dactinomycin – actinomycin D, azathioprine, thiourea, thiouracil.
- Immunomodulating molecules:cyclosporine, sirolimus.
- Antituberculosis drugs: isoniazid, rifampin, ethionamide.
- Halogens: iodine, bromine, chlorine.
- Targeted therapies: EGFRIs (cetuximab, panitumumab), multitargeted tyrosine kinase inhibitors (gefitinib, erlotinib, lapatinib,sorafenib, sunitinib, imatinib), vascular endothelial growth factor inhibitor (bevacizumab), proteasome inhibitor (bortezomib), tumor necrosis factor-a inhibitors (lenalidomide,infliximab), histone deacetylase inhibitor (vorinostat).
- Miscellaneous: dantrolene, quinidine, antiretroviral therapy antibiotics.

Drug-Induced Eosinophilic Pustular Folliculitis (Ofuji's Disease)

Few cases of drug-induced eosinophilic pustular folliculitis have been reported [88, 108–111]. Drugs reported include chemotherapy (cyclophosphamide, methotrexate, and 5-fluorouracil) [108], minocycline [109], carbamazepine [110], and allopurinol with timedium bromide [111]. Clinical presentation includes pruritic follicular papules and pustules on the face, scalp, trunk and arms [88]. Histological findings include spongiosis of the follicular epithelium, and an intra- and perifollicular lymphohistiocytic infiltrate with numerous eosinophils that form microabscesses within the follicular epithelium [88]. Topical steroids are the first line of treatment [108].

Pustular eruptions – Complex (skin + systemic involvement)

Acute generalized exanthematous pustulosis (AGEP) – See Severe Cutaneous Adverse Drug Reactions.

Bullous Eruptions

Bullous Eruptions – Simple (Skin Only)

Pseudoporphyria

Terminology The term pseudoporphyria was coined in 1975 by Korting to describe patients with chronic renal failure and a bullous disease resembling porphyria cutanea tarda (PCT) [112].

Frequency The incidence of pseudoporphyria is unknown. However, in a 6-month prospective study, 12% (9/74) of children taking naproxen for juvenile idiopathic arthritis developed pseudoporphyria [113].

Lag Period The skin lesions appear following drug intake combined with exposure to light. Various time durations were reported, weeks to months [114–116].

Skin Manifestations The clinical features of pseudoporphyria may be identical to those of PCT; both exhibit vesicles, bullae, milia, and scarring on sun-exposed skin. In contrast to PCT, however, hypertrichosis, hyperpigmentation, sclerodermoid changes, and dystrophic calcification are rarely reported in pseudoporphyria [117]. Often, fragility and bruising may be the only clinical signs [116]. In children, facial scarring resembling erythropoietic protoporphyria (EPP) may be found [117].

Symptoms Skin fragility and photosensitivity [116].

Common Sites of Involvement The lesions appear on sun-exposed skin, particularly the hands and feet, but also on the face and extensor surfaces of legs [116].

Histology the histological features are identical to those seen in PCT. The blisters are subepidermal and the floor of the blister is typically lined by well-preserved dermal papillae (festooning). There is usually no significant inflammatory component although a light perivascular lymphocytic infiltrate may occasionally be seen in the superficial dermis. Thickening of the superficial vessels (highlighted by a PAS stain) and dermal sclerosis with elastosis may be apparent. In both pseudoporphyria and PCT, direct immunofluorescence reveals granular deposits of IgG and C3 at the basement membrane zone and in the perivascular region [115].

Differential Diagnosis While pseudoporphyria and PCT share clinical and histologic features, they can be differentiated by several features. Most important, by definition, biochemical porphyrin abnormalities are absent in pseudoporphyria. Epidemiologically, pseudoporphyria affects mainly women while there is a male predilection in PCT. Clinically, hypertrichosis, hyperpigmentation, sclerodermoid changes, and dystrophic calcification are frequently evident in PCT and conspicuously absent in pseudoporphyria [117]. The differential diagnosis also includes other types of cutaneous porphyria that manifest with blistering, epidermolysis bullosa acquisita, polymorphous light eruption, and other photosensitive dermatosis [117].

Treatment Treatment entails discontinuation of suspected agents and sun protection, especially against UVA wavelengths, for several months following withdrawal of the drug [114].

Prognosis Blisters may continue to appear for weeks-months after discontinuation of the offending drug [117].

Offending Drugs The most common group of drugs causing pseudoporphyria are NSAIDS [117]. Other groups are antibiotics, diuretics and retinoids. Additional culprits are hemodialysis, renal failure, tanning beds and excessive sun exposure [117].

Fixed Drug Eruption (FDE)

Terminology Fixed drug eruption (FDE) was first reported by Boums in 1889 [118], and the term was coined by Brocq in 1894 [119].

Frequency The incidence is not known, but is suspected to vary greatly by geographic region [120].

Lag Period After initial use of the offending agent, a variable refractory period of weeks, months or years may pass before the lesions first appear on the skin of a sensitized individual [121]. Repeated exposure to the agent typically results in acute lesions within 30 min to 8 h. A refractory phase may occur following an acute flare in which exposure to the offending drug will not exacerbate the lesion for weeks to months [121].

Skin and Oral Membrane Manifestations In its classical form, FDE typically presents round or oval, sharply demarcated, red to livid, slightly elevated plaques ranging from several millimeters to over 10 cm in diameter. Vesicles or even blisters can develop [122]. Usually only a single lesion appears. Sometimes, multiple lesions are present and even lead to generalized FDE characterized by multiple, sharply defined, deep red macules distributed bilaterally and often symmetrically. Generalized bullous FDE is characterized by flaccid blisters arising on these macules. Mucosal lesions are usually bullous and may appear with or without involvement of other areas of the skin [122].

Symptoms Patients often complain of burning and itching in the lesions. General symptoms such as fever, nausea, dysuria, abdominal cramps and diarrhea are rare [122]. Pruritus and burning may be the only manifestations of reactivation in a postinflammatory hyperpigmentation lesion [121].

Common Sites of Involvement The eruption can occur anywhere on the body, but the lips, palms, soles, genitalia (especially male genitalia), groin and occasionally oral mucosa are favored sites [121]. The diagnostic hallmark of FDE is the reappearance of the lesions precisely over the previously affected sites. Studies investigating the predilection areas indicate that some specific kind of drugs cause FDE predominantly at specific sites: examples are tetracycline and location on the male genital area, and naproxen and FDE on the lips [122]. In rare cases, FDE manifests in old trauma sites such as BCG vaccination, burn scar, venipuncture site or insect bite. With each recurrence, additional sites may be affected. The presence of numerous lesions is referred to as generalized FDE [122].

Histology Histologically, the acute phase is characterized by marked basal cell hydropic degeneration, with lymphocyte tagging along the dermoepidermal junction and individual keratinocyte necrosis. Marked pigmentary incontinence is typical, and may be the sole histological finding in late lesions [121].

Differential Diagnosis Skin lesions can imitate various dermatoses, including lichen planus, erythema multiforme, erythema annulare centrifugum, and pityriasis rosea. In generalized FDE, residual pigmentation in healed lesions may be reminiscent of erythema dyschromicum perstans. Involvement of oral and genital mucosa raises the possibility of herpes simplex, pemphigus vulgaris, aphthous stomatitis, Behçet syndrome, and erosive lichen planus [122]. Generalized bullous FDE may resemble SJS/TEN. The following typical

clinical features of generalized bullous FDE may aid in differentiating between conditions: (1) Blistering usually affects only a small percentage of body surface area, and between the large blisters there are sizable areas of intact skin. (2) Erosive mucosal involvement is rare, and when it does occur is rather mild. (3) Patients usually do not feel sick or have fever, and generally are in much better overall health than those with SJS/TEN. (4) Most patients report a history of a similar, often local reaction [123].

Treatment For mild lesions, topical corticosteroids usually suffice. In severe involvement, especially generalized bullous FDE, systemic corticosteroids may be indicated. Strict avoidance of the causative drug and cross-reacting substances is essential for prophylaxis. Successful desensitization was reported [122].

Prognosis The prognosis of localized FDE is good and the lesions fade within a few days to leave a post-inflammatory brown pigmentation [122]. Generalized bullous FDE does not have this benign nature and the mortality rate was 22 % in a recent case control study of 58 patients [120].

Offending Drugs The most common groups of drugs implicated are antibiotics, analgesics, antiphlogistics and hypnotics [122]. There is usually only one causative drug (monosensitivity), but sometimes several drugs can induce FDE in the same patient (multisensitivity). It has also been claimed that recurrences of FDE can be induced in nonspecific fashion by mast cell degranulators such as food, acetylsalicylic acid, bacterial toxins, or physical stimuli [122].

Bullous Eruptions – Complex (Skin + Systemic Involvement)

- **Drug-induced/triggered autoimmune blistering dermatosis (pemphigus, bullous pemphigoid (BP)) and linear IgA bullous dermatosis (LABD)**

Terminology Pemphigus Two Italian dermatologists, Caccialanza and Bellone, were the first to imply activation of pemphigus by a drug (penicillin) in 1951 [124]. However, Degos's publication in 1969 of penicillamine-induced pemphigus in a patient with Wilson's disease is considered the first report of drug-induced pemphigus [125].

BP Bean et al. reported the first case of drug-induced BP in 1970 [126].

LABD Baden et al. reported the first case of drug-induced LABD in 1988 [127].

Cases of autoimmune blistering dermatosis resulting from exposure to drugs present clinical, histologic and immunopathologic features identical or very similar to those seen in idiopathic disease, but are induced by systemic ingestion or local use of certain drugs. There appear to be two main types: drug-induced autoimmune blistering dermatosis proper, the acute and self-limiting type with rapid resolution after withdrawal of the offending agent; and drug-triggered autoimmune blistering dermatosis in which the role played by the drug is only secondary to hereditary and immunologic factors. The drug stimulates a predisposition (hidden susceptibility) to develop the disease and is considered the chronic type in which the disease persists despite withdrawal of the offending agent [128, 129].

Frequency Unknown.

Lag Period Pemphigus Weeks to months [130, 131]
BP Days to weeks [132, 133]
LABD Days to weeks [134, 135]

Symptoms/Common Sites of Involvement/Histology Similar to the idiopathic type of autoimmune blistering dermatosis.

Differential Diagnosis There are no distinctive clinical features that enable differentiation between drug-induced/triggered and idiopathic autoimmune bullous dermatosis. It is obvious that spontaneous remission following withdrawal of the offending drug points to a drug-induced autoimmune blistering dermatosis. However, other clinical findings may also be suggestive of a drug origin in cases of pemphigus and BP: (1) Patients are younger than those with idiopathic disease. (2) Mucous membranes are frequently involved. (3) Combined clinical and immunohistologic features of various immunobullous diseases may exist. (4) Severe general status may appear including high fever. (5) In cases of drug-induced pemphigus, features of pemphigus foliaceus are more common than those of pemphigus vulgaris [130, 133, 136]. Of note, drug-induced LABD patients tend to be older than idopathic type patients [134, 135].

The polymorphic nature of the eruption may mimic other bullous diseases and or drug-induced bullous diseases such as SJS, TEN, and FDE [136].

Treatment Treatment consists of discontinuing the offending agent, and, depending on the severity of the disease, systemic immunosuppressive treatment [129].

Prognosis Drug-induced autoimmune blistering dermatosis remits after the offending drug is withdrawn, while drug-triggered autoimmune blistering dermatosis may persist despite withdrawal of the offending agent and chronic immunosuppressive treatment may be required [129, 130].

Offending Drugs Pemphigus Two major groups of chemical structures were found in the drugs or their metabolites implicated in pemphigus: sulfhydryl radical drugs (thiol drugs or SH drugs) such as penicillamine, and phenol drugs such as aspirin [128, 137, 138].

BP Many drugs were reported [129, 132, 136], the most frequent being NSAIDS, cardiovascular

agents and penicillin-derived antibiotics [136]. In addition, external use of skin and mucous membrane preparations has been documented to provoke cases of either BP or cicatricial pemphigoid [136].

LABD Of the various drugs reported, vancomycin is the most common [134, 135, 139].

Stevens-Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN) – See Severe Cutaneous Adverse Drug Reactions.

Severe Cutaneous Adverse Drug Reactions

Drug reaction with eosinophilia and systemic symptoms (DRESS), Drug-induced hypersensitivity syndrome (DIHS), Drug-induced delayed multiorgan hypersensitivity syndrome.

Epidemiology

The incidence of DRESS remains to be determined because of variable presentations and lack of universally accepted diagnostic criteria [140]. The estimated risk at first or second prescription of an aromatic antiepileptic drug was 1–4.5 in 10,000 [141]. A slight female predominance was found in the RegiSCAR study (male/female 0.8) [142].

Etiology

The drugs most commonly inducing DRESS are anti-convulsants (mainly aromatic anti-convulsants such as carbamazepine), allopurinol, sulfonamides (the anti-infective sulfamethaxazole-trimethoprim, and the anti-inflammatory sulfasalazine), and antibiotics (such as vancomycin and minocycline) [142]. Numerous other drugs have been reported [140, 143, 144].

The role of human herpesvirus (HHV) reactivation in the development of this adverse drug reaction is well recognized, especially HHV-6 [145]. HHV-6 reactivation is among the diagnostic criteria of the Japanese consensus group for DRESS/drug-induced hypersensitivity syndrome [146]. The reactivation of other herpesviruses, including HHV-7, cytomegalovirus (CMV), Epstein-Barr virus (EBV), and human herpes simplex virus was also reported [147].

DRESS is considered to result from complex interactions between genetic predisposition, exposure to drug and viral reactivation [148].

Lag Period

Delayed onset of 2–8 weeks after drug administration followed by a stepwise development of manifestations. Rechallenge can result in a reaction within hours to days [26]. The lag period differs between drugs; carbamazepine tended to show a longer latency (median 29 days) than allopurinol (median 20 days) in the RegiSCAR study [142].

Clinical Features

DRESS has multi-organ involvement with cutaneous, mucosal, hematological and solid organ manifestations.

Skin The cutaneous involvement in DRESS is typically extensive and symptomatic (pruritus, burning and pain) [142, 143]. Various dermatological features were reported. Walsh et al. [143] proposed a classification system based on four distinct patterns: (1) urticated papular exanthema, the most common, (2) morbilliform erythema, (3) exfoliative erythroderma, and (4) erythema multiforme-like (EM-like), which was prognostic of more severe hepatic involvement. The extent of skin involvement varies between studies: it exceeded 50% of the body surface area in most of the patients (79%) according to the RegiSCAR study [142]; head and neck edema observed in most patients [26, 142]; and pustules reported in various studies, predominantly in a facial distribution of the edema [142, 143].

Mucous Membranes Mild mucosal involvement was recorded in 56% of patients with DRESS (66/117 cases) in the RegiSCAR study [142]. Most frequent were oral lesions including lips, oral cavity and throat [142]. The manifestations of oral lesions in DRESS include cheilitis, erosions and dysphagia that may appear before skin lesions, and oropharaynx is considered the first site of herpesvirus reactivation in DRESS [149]. Involvement of eyes and genitalia were also reported in the RegiSCAR study [142].

Systemic Involvement Multi-organ involvement is common in DRESS and may include a wide variety of systems. High-grade fever (38–40 °C) is a typical early manifestation that may last for several weeks; it often precedes the cutaneous eruption by several days [142]. Lymphadenopathy is common and has two distinct types: a benign pattern of lymphoid hyperplasia and a pseudolymphoma pattern [150]. Hematologic abnormalities are frequent and diverse, the most common being marked leukocytosis, eosinophilia and atypical lymphocytes [142]. However, neutrophilia, monocytosis, thrombocytopenia, anemia, pancytopenia and hemophagocytic syndrome were also reported [140, 142, 143, 151]. Hypereosinophilia and activated neutrophils, if persistent, can contribute to organ damage [142]. The liver is the most frequently affected visceral organ in DRESS; hepatitis with isolated elevation of liver enzymes is common and usually anicteric and without cholangitis. However, severe acute hepatitis with liver failure may result and is the primary cause of mortality in DRESS [150]. Renal involvement is common [150]. Involvement of the following organs was also reported: lungs, muscle, heart, pancreas, colon, thyroid, joints, parotid

gland and brain [150]. The type of organs involved was found to be related to the eliciting drug [152].

Histology

The most common pathological changes found in a study of 32 patients with DRESS were basket-weave hyperkeratosis (94%), dyskeratosis (97%), lymphocytic exocytosis (91%), spongiosis (78%), papillary edema (66%), perivascular lymphocytic infiltration (97%), eosinophilic infiltration (72%), and interface vacuolization in the dermoepidermal junction (91%) [26]. The presence of severe dyskeratosis was correlated with a greater extent of systemic involvement [26]. In a different study assessing the histological findings of 27 cases with DRESS [143], the predominant pathological pattern was spongiotic dermatitis with superficial lymphocytic infiltrate (59%); necrotic keratinocytes were noted in 33% of cases, and were associated with a worse hepatic involvement [143].

Diagnostic Criteria

The diverse presentations in DRESS have hampered efforts to define diagnostic criteria. Three diagnostic criteria have been proposed: Bacquet et al. [153], the Japanese study group of severe cutaneous adverse reactions to drugs (J-SCAR) [146], and the RegiSCAR network [154].

Treatment

The first step in the management is immediate withdrawal of the culprit drug. The treatment is tailored according to the severity and extent of systemic involvement, and the diagnosis of viral reactivation of herpesviruses (mostly HHV-6) [150, 155, 156]. Management protocol for DRESS based on the consensus of experts was designed by the French Society of Dermatology [156], and includes four visceral involvement severity categories and corresponding treatment: (1) No severe systemic involvement: topical corticosteroids (potent or very potent), emollients, H1-antihistamines. (2) Severe systemic involvement (transaminases >5 times normal, renal involvement, pneumonia, hemophagocytosis, cardiac, etc.): systemic corticosteroids equivalent to 1 mg/kg/day of prednisone and multidisciplinary evaluation. (3) Life-threatening signs (hemophagocytosis with bone marrow failure, encephalitis, severe hepatitis, renal failure, and respiratory failure): systemic steroids with intravenous immunoglobulin (IVIG) at a dose of 2 g/kg over 5 days. The IVIG should not be used without associated steroids. The treatments are to be conducted under multidisciplinary supervision. (4) Severe systemic involvement and confirmation of a major viral reactivation: combining steroids and antivirals (such as ganciclovir) and/or IVIG.

Counselling both the patient and his family members about drug avoidance is necessary. First-degree relatives have a higher risk of developing the same drug reactions [90]. Increased knowledge of HLA susceptibility genes enables screening patients with DRESS for several high risk drugs [148, 157].

Prognosis

Symptoms are usually present for several weeks even after discontinuation of the offending agent and appropriate treatment [155]. Late complications include the appearance of autoimmune diseases such as lupus erythematosus and autoimmune thyroiditis, with laboratory evidence of autoantibodies [144]. Systemic corticosteroids were found beneficial in the prevention of autoimmune disease. However, this effect needs to be counterbalanced against the higher risk of viral reactivation and infection. [144]. In a 1-year follow-up study of 52 affected patients with DRESS in Taiwan, the overall cumulative incidence of long-term sequelae was 11.5%; four developed autoimmune diseases (Graves disease, type 1 diabetes mellitus and autoimmune hemolytic anemia); and the other two developed renal failure and required lifelong hemodialysis. The author concluded that the sequelae of DRESS can be divided into two major types that appear in different age groups: young patients tend to develop autoimmune diseases; elderly patients are more vulnerable to end-organ failure [158].

Mortality in DRESS has been estimated at 10%, with most patients dying from liver failure [159]. Pancytopenia, leukocytosis, tachycardia, tachypnea, coagulopathy, gastrointestinal bleeding and systemic inflammatory response syndrome were associated with a poor outcome in DRESS patients [159, 160].

Serum Sickness-Like Reaction (SSLR)

Epidemiology

The incidence of SSLR is unknown. Epidemiology studies in children suggest that the overall frequency induced by cefaclor is 0.024–0.2% per course of the drug [76]. Most reactions were reported in children under 5 years old, mainly during the second and third courses of therapy [161].

Etiology

Cefaclor is the most common cause of SSLR in children, inducing 84.1% of cases [162]. Other drugs implicated include other cephalosporins, [163] penicillins, [164] minocycline, [165] insulin, [166] and infliximab [167].

Lag Period

Usually 7–14 days (range 0–20 days) [162, 168].

Clinical Features

Skin The skin is the most frequent finding in SSLR, including erythema that progresses to urticarial lesions (pruritic and migratory), urticarial wheals with dusty to purple centers ('purple urticaria') that morphologically resemble erythema multiforme (EM) [161] and other cutaneous manifestations including morbilliform or scarlatiniform eruptions [82].

Mucous Membranes Mucous membranes are not involved [161].

Systemic Involvement Joint involvement may be prominent, presenting with edema, decreased range of motion, warmth, pain, and difficulty walking. Polyarticular involvement is often observed, with involvement mainly of the wrists, ankles, hips and knees [169]. Some authors suggested that joint involvement may be related in part to increased fluid in the skin around affected joints due to urticarial eruption rather than arthritis [161]. Fever, malaise, myalgia and lymphadenopathy were also reported. Neurologic involvement, gastrointestinal symptoms and renal complications were rarely documented [163]. Notable laboratory abnormalities include elevated erythrocyte sedimentation rate (ESR), C-reactive protein (CRP) and leukocytosis [163, 170].

Histology

The histological findings of SSLR appear to be in the spectrum of urticaria with no vasculitis [171]. Histology can be helpful in differentiating SSLR from acute hemorrhagic edema of infancy, which is characterized by vasculitis [171].

Diagnostic Criteria

There are no diagnostic criteria. The diagnosis is based on clinical findings [161].

Treatment

Withdrawal of the offending agent and symptomatic treatment with oral antihistamines and topical corticosteroids are usually sufficient. A short course of oral corticosteroids may be required in patients with severe symptoms [82].

Prognosis

The disease course is benign and resolves in a few days. However, a few cases lasting several weeks have been described [170]. No long-term morbidity has been reported [172].

Acute Generalized Exanthematous Pustulosis (AGEP)

Epidemiology

The estimated incidence of AGEP is 1–5 cases per million per year [173]. Female predominance was reported in several studies [174–176].

Etiology

The majority of cases appear to be related to drugs (>90 %), mainly antibacterials [4]. In a large multinational case-control study (the EuroSCAR study), the following agents were highly suspected drugs for AGEP: prestinomycin, ampicillin/amoxicillin, quinolones, (hydroxy)chloroquine, anti-infective sulfonamides, terbinafine and diltiazem [176].

Lag Period

Latent periods fall into two categories, according to the offending drug: median duration of 1 day, associated with antibiotics (including sulphonamides), and median duration of 11 days for all other associated drugs [176]. Longer periods of months were reported in a few AGEP cases with an underlying malignancy [177].

Clinical Features

AGEP is a severe acute pustular cutaneous reaction characterized by a rapid clinical course [174].

Skin The typical morphology of AGEP is an acute edematous erythema with burning and or itching sensation, followed by dozens to hundreds of small (pinhead sized) non-follicular sterile pustules with a predilection for the big folds, or with widespread distribution (Fig. 25.2). Sometimes confluence of pustules may mimic a positive Nikolsky's sign [176, 178]. Additional cutaneous manifestations include marked edema of the face, purpura, blisters and target-like lesions [173, 174, 179], all of which overlap with manifestation of AGEP and TEN [180, 181], and acute localized exanthematous pustulosis (ALEP) [179, 182].

Mucous Membranes Mild, nonerosive mucous membrane involvement of one location (mostly oral) occurs in about 20 % of cases [183].

Systemic Involvement Fever (above 38 °C) and leukocytosis with neutrophilia are almost always apparent. Lymphadenopathy, myalgia, headache, mild eosinophilia, elevated CRP, slight reduction of creatinine clearance, and mild elevation of aminotransferases were also reported [173, 175]. A 10-year retrospective review of 58 patients with AGEP [184] turned up 10 patients (17 %) with at least one systemic involvement in the acute phase, 7 with abnormal hepatic function test, 6 with renal insufficiency, two with acute respiratory distress and one patient with agranulocytosis. Mean peripheral neutrophil counts and mean C-reactive protein levels were elevated significantly in patients with systemic involvement [184].

Histology

Biopsy specimen should be obtained from an early pustular lesion [183]. A histopathological study of 102 AGEP cases [185] found the following histopathological features: (1) All cases demonstrated pustules (sub/intracorneal and or intraepidermal). (2) The main epidermal features were spongiosis (80 %), neutrophil exocytosis (77 %) and necrotic keratinocytes (67 %). (3) The main dermal features were mixed superficial (100 %), interstitial (93 %) and mid/deep-dermal infiltrates (95 %) containing neutrophils (100 %) and eosinophils (81 %).

Fig. 25.2 Multiple, pin-head sized, non-follicular pustules on erythematous skin on the trunk in a patient with AGEP

Diagnostic Criteria

The AGEP validation score developed by the Euro- SCAR study group is a standardized scoring system made up of data related to clinical features (morphology and clinical course) and histopathology. Based on this score, AGEP cases can be categorized as no AGEP, possible AGEP, probable AGEP, and definite AGEP [173].

Treatment

Treatment consists of discontinuation of the causative drug and supportive treatment. Although, specific treatment is generally unnecessary, topical and systemic steroids were reported [174, 175]. The treatment of overlapping AGEP and TEN cases is not yet established [180], although successful treatment with infliximab was documented [181].

Prognosis

After elimination of the causative drug, pustules usually spontaneously disappear in a few days with desquamation, and the reaction fully resolves within 15 days [183]. The overall prognosis is good, although high fever or superinfection of skin lesions can sometimes lead to life-threatening situations in patients of old age or poor general condition [173]. The mortality rate is about 5 % [4].

Stevens-Johnson Syndrome (SJS) and Toxic Epidermal Necrolysis (TEN)

Epidemiology

The annual incidence of SJS and TEN is 1.2–6 and 0.4–1.2 per million individuals, respectively [186, 187]. The annual incidence of SJS and/or TEN in HIV patients is estimated at 1–2 per 1000 individuals, approximately 1000-fold higher than that of the general population [188]. The incidence of SJS/TEN increases with age; children less than 15 years of age account for only 10 % of the samples in most studies [189]. Women are two times more likely to be affected by SJS/TEN than men in the adult population, while the male to female ratio is about equal in children [189].

Etiology

Drug exposure is the most common cause of SJS/TEN [190], with more than 200 drugs identified [191]. The groups of medications associated with high risk of inducing SJS/

TEN vary according to the population. In the general population in Europe, high risk drugs for SJS/TEN include allopurinol, carbamazepine, cotrimoxazole and other anti-infective sulfonamides, lamotrigine, nevirapine, oxicam-NSAIDS, phenytoin, phenobarbital and sulfasalazine [192]. In the pediatric population in Europe, they include anti-infective sulfonamides, phenobarbital, carbamazepine and lamotrogone [189]. In Africa, they include antibacterial sulfonamides, nevirapine, tuberculosis drugs, NSAIDs, antiepileptics, aminopenicillin, analgesics and allopurinol [193]. Non-medication triggers, implicated mainly in SJS, include infections, contrast media and vaccinations [194–196]. ALDEN is an Algorithm for the Assessment of Drug Causality in SJS/TEN developed by the RegiSCAR study group and consists of 6 parameters according to which the drug causality is classified as very unlikely, unlikely, possible, probable and very probable [197].

Lag Period

Usually 4–28 days. The median latency was longer (above 30 weeks) for drugs with no associated risk [192].

Clinical Features

SJS and TEN represent different degrees of a severe, acute and life-threatening mucocutaneous reaction. We will refer to this disease spectrum as a single entity, namely SJS/TEN. The classification of SJS/TEN, defined by Bastuji-Garin et al. [198], is based on the extent of epidermal detachment and the findings of characteristic skin lesions (Table 25.4). It should be emphasized that only necrotic skin, which is already detached (e.g., blisters, erosions), or detachable skin (positive Nikolsky sign whereby slight rubbing of the skin results in exfoliation of the outermost layer) should be included in the evaluation of the extent of epidermal detachment [190].

Skin The characteristic skin morphology of SJS/TEN consists of 'flat, atypical target lesions' and 'spots/macules', which are defined as follows. Flat, atypical target lesions are round lesions, with only two zones and/or a poorly defined border, nonpalpable with the exception of potential central blister. 'Spots/macules' are nonpalpable, erythematous or purpuric macules with irregular shape and size, often confluent [198]. Epidermal necrosis, the hallmark process of SJS/TEN, induces flaccid blisters with positive Asboe-Hansen sign (lateral extension of bullae with pressure), erosions, positive Nikolsky sign, and in severe cases extensive skin sloughing [199]. At least 1 % of epidermal detachment is required for the diagnosis of SJS/TEN [83]. In rare instances, extensive epidermal necrosis occurs with only widespread erythema and no evidence of 'flat, atypical target lesions' or 'spots/macules'; these cases were classified as 'TEN without spots' (Table 25.4). A characteristic sign of SJS/TEN is severe pain and tenderness of the skin [83].

Mucous Membranes Mucosal involvement is evident in most of the cases with erythema, erosions and ulceration, due to necrosis of the epithelial lining [199]. SJS/TEN involve more than 2 mucosal sites in 17–71 % of cases [200]. Most common sites are oral (Fig. 25.3), ocular and genital mucous membranes, although any mucous membrane may be involved, such as respiratory, gastrointestinal and urethral [199]. Fuchs syndrome is a unique type of SJS that involves the mucosa without skin lesions and was reported to be associated with mycoplasma pneumoniae, mostly in children and adolescents [201].

Table 25.4 Classification of erythema multiforme major (EMM), Stevens-Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN) according to Bastuji-Garin et al. [198]

	EMM	SJS[a]	SJS-TEN overlap	TEN	
				TEN with spots	TEN without spots/TEN with widespread erythema
Skin detachment (%) detached skin, blisters, erosions and/or detachable skin – positive Nikolsky sign[b]	<10 %	<10 %	10–30 %	>30 %	>10 %
Typical target lesions individual lesions less than 3 cm in diameter with a regular round shape, well defined border, and at least three different zones	+	–	–	–	–
Atypical target lesions Round lesions with two zones and/or a poorly defined border *Raised* – edematous, palpable lesions *Flat* – nonpalpable with the exception of potential central blister	Raised	Flat	Flat	Flat	–
Spots/macules with or without blisters nonpalpable, erythematous or purpuric macules with irregular shape and size, often confluent	–	+	+	+	–

[a]At least 1 % of epidermal detachment is required for the diagnosis of SJS
[b]Slight rubbing of the skin results in exfoliation of the outermost layer

Fig. 25.3 Erosions with hemorrhagic crust on the lips, tongue and skin in a patient with TEN

Systemic Involvement Systemic findings in SJS/TEN include: (1) Flu-like symptoms (malaise, fever, anorexia) that are usually the initial signs of the disease in the prodromal phase prior to the cutaneous involvement. (2) Epidermal barrier breakdown-related symptoms including hypothermia, dehydration and sepsis. (3) Organ involvement induced by necrosis of epithelial lining, including respiratory distress syndrome, colitis, hepatitis and nephritis [199].

Histology

Characteristic histologic features include extensive keratinocyte destruction via apoptosis with separation of the epidermis from the dermis at the dermoepidermal junction. A paucicellular, dermal mononuclear infiltrate has been commonly described. Lymphocytes cross the dermoepidermal junction with moderate infiltration of the epidermis. EM and SJS often demonstrate less keratinocyte destruction on a background of extensive dermal mononuclear inflammation [202]. In a retrospective analysis of the clinical records and histologic material of 37 patients with TEN, the histologic spectrum ranged from sparse to extensive dermal mononuclear inflammation, the extent of which predicts clinical outcome approximately as well as SCORTEN. Increased inflammation correlated with a worse prognosis; a mean cell count of dermal mononuclear >215 cells per high-power field predicted a worse prognosis (65 %) vs 24 % mortality in those with <215 cells in patients with 30 % or more total body surface area sloughing [202]. However, in a retrospective study analyzing clinical records and skin biopsy of 108 patients with SJS, SJS/TEN overlap and TEN, dermal infiltrate severity was not associated with day-1 SCORTEN or hospital death, but full-thickness epidermal necrosis was associated with mortality [203].

Diagnostic Criteria

Diagnostic criteria based on integration of the major clinical characteristics of skin and mucous membrane findings, pathology assessment, lag period and systemic signs remain to be defined.

Treatment

The management of SJS/TEN consists of a multidisciplinary approach that includes the following important aspects:

1. **Identification and withdrawal of the culprit drug**: documenting the medication history during the previous 2 months and withdrawal of all suspected and unessential medications [123].
2. **Transfer of the patient to intensive care, burn unit or other specialty unit**: supportive care including thermoregulation, fluid replacement, nutritional support, monitoring for infection, sedation and pain management, and psychological support [204].
3. **Assessment of skin, mucous membranes and systemic involvement and the SCORTEN score**: Type of lesions in the skin, extent of epidermal detachment, and mucous membranes and systemic involvement. All patients should be evaluated by an ophthalmologist promptly following the diagnosis and at regular follow-up intervals to minimize potential long-term ocular sequelae [205]. Possible acute manifestations include the eyelids, conjunctiva and cornea, and result in the classification of ocular involvement as mild, moderate or severe [206]. Bringing other specialists in on the patient's care is decided in accordance with the relevant findings. The SCORTEN system, a severity-of-illness score for Toxic Epidermal Necrolysis, developed to stratify severity of illness and predict mortality in patients with TEN, includes seven independent risk factors: age, malignancy, tachycardia, initial body surface area of epidermal detachment, serum urea, serum glucose, and bicarbonate [207].
4. **Skin treatment**: There are no clinical guidelines for the skin care of patients with SJS/TEN. Debridement of the necrotic epidermis was recommended in past publications

[187, 204]. Recent publications advise avoiding debridement, which may cause hypertrophic scars, and recommend considering the detached epidermis as a natural biological dressing that favors reepithelialization [14, 205, 208]. Various topical treatments reported include bioactive skin substitutes, semi-synthetic and synthetic dressings, and topical antimicrobials [187, 204]. A recent report on the management of SJS/TEN in an experienced French referral center described the following treatment; wound care once a day with minimal manipulation to prevent skin detachment, including a bath containing a solution of chlorhexidine 1/5000 (morphine is given prior to the bath and/or equimolar mix of oxygen and nitrogen monoxide during the bath); if bathing is not possible, the chlorhexidine solution is sprayed 2–3 times daily on the skin, blister fluid is aspirated while maintaining the blister roof, vaseline is systemically applied over all detached skin areas, topical sulfa-containing medications are avoided, and hydrocellular or absorbent nonadhesive dressings are applied at least once daily to cover pressure points [205].

5. **Mucous membranes treatment**: Specialized care is essential to prevent lifelong complications [208]. Although there is no standardized care for ocular management, the following supportive local treatment is advised: tear replacement solutions, removal of pseudomembranes, lysis of symblepharon, debridement of loosened epithelium, topical antibiotics to prevent secondary infection, topical corticosteroid to prevent scar formation, and cycloplegic drops to relieve pain, photophobia and ciliary spasm [206]. Amniotic membrane transplantation was found effective in the acute and chronic stages of SJS/TEN [209, 210]. A 'Triple-TEN' protocol for severe ocular cases was recently reported [211], comprised of the following: (1) Subconjunctival triamcinolone (Kenalog 20 mg) administered into each of the fornices to curb the local inflammatory response without compromising systemic immunity. (2) Placement of amniotic membrane tissue mounted on a polycarbonate skirt (ProKera) over the corneal and limbal regions to facilitate reepithelialization of the ocular surface. (3) insertion of a steeply curved acrylic scleral shell spacer (Technovent, SC21) to vault the lids away from the globe and provide a barrier to symblephara formation. This treatment offers an effective therapeutic option, without the need for microsurgical equipment, microscope, or sutures in the critical care setting.

   Oral- The mouth should be rinsed several times a day with an antiseptic or anifungal solution and the lips lubricated with an ointment such as dexpanthenol [123].

   Genital- Wet dressings or sitz baths and lubrication with emollient are recommended to avoid adhesions and strictures of genital erosions in females [123, 205].

   A specialist is required in case of involvement of other mucous membranes: respiratory, gastrointestinal and/or urethral.

6. **Systemic immunomodulatory treatment**: The optimal therapeutic regimen has yet to be established, but according to recent publications, the following conclusions can be drawn: the use of IVIg does not yield survival benefits in SJS/TEN [212]; cyclosporine decreased the death rate and the progression of detachment (dosage of 3 mg/kg/day for 10 days) [213]; systemic corticosteroids were associated with clinical benefit according to the Euroscar-study [214] and were reported to be the most common treatment for SJS/TEN in a recent survey of 50 drug hypersensitivity experts from 20 countries [14]. One of the suggested protocols is IV dexamethasone 1.5 mg/kg pulse therapy (given for 30–60 min) for 3 consecutive days [215]. Treatment with anti-TNF biologic treatment was reported to be beneficial [216–218]. A prospective, randomized, open-label trial currently underway in Taiwan [14] comparing etanercept versus systemic corticosteroids in patients with SJS/TEN, reported that the average duration to reach maximal skin detachment and complete skin healing was shorter in the etanercept group. In vitro investigations demonstrated that etanercept, steroids or thalidomide significantly decreased granulysin expression of blister cells. Etanercept did not, however, increase the cytotoxic effect to keratinocytes found with thalidomide [14].
7. **Causality assessment and communication with the patient and his/her family, health-care providers and regulatory agencies**: Recent discoveries of specific HLAs that predict genetic susceptibility to SJS/TEN offer a simple, fast, safe and reliable method for establishing clear causality between a drug and a disease [148]. The HLAs are specific to a drug and an ethnic background [148]. Since these tests are available only for certain drugs and a negative test does not exclude the drug as the offending agent, additional clinical and laboratory methods are available for assessing causality. (**See Practical approach to the diagnosis and management of cutaneous ADRS and Clinical and laboratory assays in the diagnosis of cutaneous ADRs**.) For information on communication with the patient and his/her family, health-care providers and regulatory agencies **see Practical approach to the diagnosis and management of cutaneous ADRS**.

Prognosis

The mortality rates of SJS/TEN are variable. That of TEN may approach 30% [191], and that of children with SJS/TEN is approximately 2–7.5% [189]. In a large-scale, population-based, 1-year follow-up study of 460 SJS/TEN patients, the

6-week in-hospital mortality rate was 23%, and the death rate from 6 weeks to 1 year was 14% [219]. The mortality rate at 1 year in this study was 24% for SJS, 43% for SJS and TEN overlap, and 49% for TEN. Several factors were found to affect mortality: age, severity of reaction, recent malignancy, pre-existing severe kidney or liver disorder, and recent infection. The last two factors were recognized for the first time in this study as being independent risk factors for death. All other factors are part of the SCORTEN [207]. The severity of the reaction was a major risk factor for death in the first few weeks, and severe co-morbidities and older age had major impact on mortality after 6 weeks [219]. Early and late physical complications are common among patients who survive SJS/TEN [219], with some 80% experiencing long-term sequelae [220]. Complications may affect multiple organ systems including skin, nails, hair, oral and genital mucosal sufaces, eyes, kidneys, gastrointestinal tract, and respiratory system [221]. Ocular complications, which can lead to blindness, are the major long-term morbidity [206]. A few studies have dealt with the quality of life of patients surviving SJS/TEN [221–223], which was found to be lower in every domain from before hospitalization to follow-up and a low rate of return to previous employment was documented [221]. Patients reported concerns about social interactions, fear of taking medications, and fear of contracting an illness necessitating medication [223]. Insufficient information and support for patients surviving SJS/TEN was also documented [221–223]. Unfortunately, because of the rarity of SJS/TEN, most physicians are not aware of the long-term complications of the diseases [220].

Practical Approach to the Diagnosis and Management of Cutaneous Adverse Drug Reactions

There are several methods to approach a patient with a cutaneous ADR. The following is the authors' protocol:

Clinical Assessment of Drug-Induced Skin Injury: 4Ds by Dr. Shear

Diagnosis of the Adverse Event

A cutaneous eruption in a patient taking a medication should immediately raise the suspicion of a cutaneous ADR. The physician must then determine whether the patient's clinical symptoms are signs of a cutaneous ADR or of another skin disease not related to a drug. The diagnosis of a cutaneous ADR is based on three key clinical elements (Fig. 25.4): (1) **Appearance**- the morphology of the cutaneous eruption according to four main categories of the primary lesion: maculopapular, urticarial, bullous and pustular (see section "Morphological Classification of Cutaneous ADRs"). (2) **Systemic**- extra-cutaneous signs (fever, dyspnea, lymphadenopathy, etc.) that distinguish between a simple reaction involving only the skin and a complex reaction that includes systemic involvement in addition to the skin (see section "Severity of Cutaneous ADRs: Skin only (Simple) Versus Skin and Systemic Involvement (Complex)") and (3) **Histology**- histopathology and direct immunofluorescence studies of skin biopsies to confirm the clinical impression and to distinguish between a drug-induced eruption and other skin diseases (see section "Histological Classification of Cutaneous ADRs").

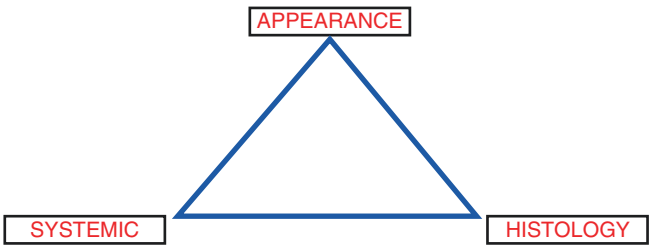

Fig. 25.4 Shear's Diagnostic Triangle of adverse cutaneous drug reactions

Differential Diagnosis

Establishing a differential diagnosis that takes into account all possible diagnoses is essential. Ranking the approximate likelihood of each condition is encouraged.

Drug Exposure (Timing)

All medications, regardless of route of administration, must be considered, especially new drugs taken in the 8 weeks prior to the skin reaction. Drugs taken intermittently, such as vitamins, sedatives, pain relievers, laxatives and natural products, must also be considered. Assessment of the lag period – the time between initiation of the drug and onset of the cutaneous reaction – is crucial in view of the different lag times for different cutaneous drug reactions. A recommended method for drug exposure analysis is to chart a timeline in order to visualize the chronology and facilitate comprehension of the event. The timeline includes the relevant information (starting day, dosage, and discontinuing day) for each drug and the signs and symptoms throughout the period in question [82].

Determine Probabilities

The most important challenge in assessing drug-induced skin injury is establishing whether there is a causal relationship between the suspected drug and the untoward clinical event. The following methods are helpful: (1) Patient history: the patient should be questioned about previous cutaneous reactions to drugs, and whether rechallenge with the drug improved the eruption [82]. These data should also be part of the above timeline. (2) Analysis of the literature: search for information regarding the frequency with which the type of reaction is related to a particular drug. (pubmed

http://www.ncbi.nlm.nih.gov/pubmed/, Litt's D.E.R.M. Drug Eruptions and Reactions Manual and database http://www.drugeruptiondata.com/). (3) Rate the reaction on Naranjo et al.'s adverse drug reaction probability scale, which classifies the drug reaction according to a probability category as definite, probable, possible or doubtful [224], and or on Edwards et al.'s causality assessment criteria [2]. (4) In vitro and in vivo diagnostic assessments including HLA genetic tests. (see section "Clinical and Laboratory Assays in the Diagnosis of Cutaneous ADRs").

Communication with the Patient and Family, Health-Care Providers and Regulatory Agencies

Patient and Family

Good communication strategies will aid in the interactions with the patient and family following a cutaneous ADR and decrease the likelihood of lawsuits, especially in cases of severe reactions such as SJS/TEN. Physicians are advised to follow these steps: (1) Express empathy and say "sorry" according to the "apology laws" in an honest and respectful fashion and in a way that protects the physician from having an apology used against him in case of legal action. http://www.sorryworks.net/. (2) Provide disclosure in a "disclosure meeting" planned according to the acronym CONES: Context – arrange the setting for a quiet, uninterrupted meeting and decide on the participants; Opening shot – the first sentence in the meeting explains the aim of the conversation; Narrative – lay out the facts; it is advised to avoid using the words "error" and "mistake" since the ADR is a result of multiple factors, particularly when the facts are not completely known; Emotions – provide an empathic environment; Summary (3) Provide the patient with clear information on his cutaneous ADR, the name of the offending drug, potential cross-reacting drugs, and drugs which can be safely taken as an alternative to the offending drug. In addition, advise the patient to wear a medic-alert bracelet. (4) Family counselling is part of the management plan since the predisposition to some cutaneous ADRs may be genetic [191].

Health-Care Providers

Information on the adverse event must be provided to the family physician and entered in the patient's records.

Regulatory Agencies

Report the cutaneous ADR to the manufacturer and regulatory agencies [225]. International reporting systems: MedWatch, the FDA Safety Information and Adverse Event Reporting Program http://www.fda.gov/safety/MedWatch/default.htm, and WHO Uppsala Monitoring Centre (UMC) http://www.who-umc.org.

Clinical and Laboratory Assays in the Diagnosis of Cutaneous ADRs

Pharmacogenomic Aspects of Drug Reactions

The strong associations found between HLA alleles and specific drug-induced hypersensitivity reactions have fostered pharmacogenetic testing to prevent the development of life-threatening drug-induced hypersensitivity reactions, such as SJS/TEN and DRESS. The usefulness of such testing is dependent on a number of factors, including the incidence and severity of the adverse event, the sensitivity and specificity of the predictive markers, and the availability of equally effective, alternative medications for individuals who test positive.

HLA-B*1502 Test for Prevention of Carbamazepine-Induced SJS/TEN

Although the incidence of SJS/TEN is relatively low, it is life-threatening and many patients who survive have long-term sequelae, such as ocular complications. HLA-B*1502 is a useful and strong predictive marker with high sensitivity and specificity for carbamazepine-induced SJS/TEN in Asian populations. This genetic association is strong enough that it prompted the USFDA and many countries to relabel the genetic information for carbamazepine, and to recommend screening for HLA-B*1502 before prescribing the drug for subjects of Asian descent. The HLA-B*1502 test for carbamazepine-induced SJS/TEN has very high sensitivity (near 100 %) and specificity (97 %). With the 0.25 % prevalence rate of carbamazepine-induced SJS/TEN among Chinese, the HLA-B*1502 test has a 7.7 % positive predictive value and 100 % negative predictive value for detecting [226]. In view of the serious consequences of SJS/TEN and the availability of alternative drugs, withholding carbamazepine from screened patients who test positive for HLA-B*1502 and switching to alternative antiepileptic drugs is reasonable and feasible in the high risk populations, including Chinese and South-East Asians.

HLA-B*5701 Test for Prevention of Abacavir Hypersensitivity

Abacavir is used in the treatment of HIV infection, and has been associated with drug hypersensitivity syndrome in 8 % of patients [227]. HLA-B*5701 is a strong and useful predictive marker with high sensitivity and specificity for abacavir hypersensitivity in Caucasians, prompting the USFDA and many other countries to recommend screening for it before prescribing the drug. The HLA-B*5701 test for immunologically-mediated abacavir hypersensitivity has very high sensitivity (100 %) and specificity (97.4 %) as well as positive predictive value (55 %) and negative predictive value (100 %) [55].

Other Potential Genetic Tests in Drug Hypersensitivity

HLA-B*5801 is a potentially useful predictive marker for allopurinol-induced SJS/TEN or DRESS, with 3 % positive predictive value and almost 100 % negative predictive value for detecting allopurinol-induced SJS/TEN or DRESS in Chinese (Table 25.2). This association was significant in Caucasian and other Asian populations as well. The recent American College of Rheumatology guidelines for the management of gout recommend HLA-B*5801 screening for populations with high frequency of the allele [228].

Other recently discovered HLA alleles related to drug hypersensitivity of potential usefullness in clinic practice are HLA-B*1301 for dapsone hypersensitivity [58], HLA-A*3101 for carbamazepine-related DRESS [65], and CYP2C9*3 for phenytoin hypersensitivity [69].

In Vitro Assessment

Lymphocyte Transformation Test (LTT) and Lymphocyte Activation Assays

The lymphocyte transformation test (LTT) is a widely used in vitro assay for the diagnosis and identification of offending drugs with T cell-mediated drug hypersensitivity [229]. LTT is based on the activation and proliferation of T cells from PBMC obtained from drug-sensitized patients after stimulation, and incubation with the culprit drug in vitro [230]. Following in vitro stimulation by specific drugs, drug-specific T cells are activated and release several cytokines that promote proliferation of T cells. This in vitro proliferation of specific drug-activated T cells can be detected by the incorporation of 3H-thymidine during DNA synthesis after 6 days of culture. The results of LTT are expressed as the stimulation index (SI): the relationship between the 3H-thymidine uptake in cells (counts per minute (c.p.m.)) with and without the drug antigen [229]. The general sensitivity of the LTT is 50–80 %, varying with different drugs and different phenotypes of delayed-type hypersensitivity reactions; thus, a negative result does not exclude the possibility of drug hypersensitivity. Extensive studies on LTT for beta-lactam drugs report even higher sensitivity [230–234]. The specificity of the LTT is 85–100 % in different studies [231–233, 235].

LTT for the diagnosis of drug hypersensitivity has limitations. Because it is measured by radioisotopes, the sensitivity can be very low and negative results are commonly observed for specific drugs (e.g., allopurinol, lamotrigine) and specific phenotypes (e.g., SJS/TEN) [236, 237]. Several non-radioactive methods have been developed for measuring lymphocyte proliferation or activation in in vitro tests for diagnosis of delayed-type drug hypersensitivity, including the use of carboxyfluorescein succinimidyl ester (CFSE) cell staining dye [238, 239], and measuring cytokines or cytotoxic proteins expression, such as INF-γ, IL-2, IL-4, IL-5, IL-13, granzyme-B, and macrophage migration inhibitory factor [240–244].

Basophil Activation Test (BAT)

Flow cytometry-assisted basophil activation test (BAT), which measures specific cell makers such as CD69 or CD203c to quantify basophil activation after antigen-specific stimulation, has been widely used in the diagnosis of immediate-type drug hypersensitivity [245]. BAT directly measures basophil responses instead of IgE sensitization. It has been applied to the diagnosis of different drugs implicated in immediate-type hypersensitivity, including beta-lactam antibiotics, neuromuscular blocking agents, aspirin, NSAIDs and radiocontrast media [246–248]. The sensitivity of BAT varies in different types of drugs: that for beta-lactam antibiotics ranged from 28.6 to 55 % [249, 250]; that for NSAIDs ranged from 30 to 70 % [251, 252].

Computational Analysis for HLA Alleles

Recent data have shown that the unique interaction between drug, T-cell receptor and HLA molecule is a key factor in the development of immune-mediated adverse reactions to drugs. The discovery of strong association of specific HLA alleles with specific drug-induced hypersensitivity (e.g., HLA-B*1502 to carbamazepine-SJS/TEN, HLA-B*5801 to allopurinol-SJS/TEN/DRESS, and HLA-B*5701 to abacavir hypersensitivity), and studies of the functional role of HLA-B* allele (e.g., HLA-B*1502) directly interacting with a specific drug (e.g., carbamazepine) and unique T-cell receptor support the hypotheses of the ‘pharmacological interaction with immune receptors’ (p-i) [18, 19, 253].

In recent years, bioinformatics and computer modeling have been applied to elucidate how drug molecules interact with specific HLA in drug hypersensitivity. HLA alleles have been associated with liver injury induced by different drugs (such as flucloxacillin). Using silico strategies to examine HLA haplotype relationships, and bioinformatics tools, Alfirevic et al. [254] demonstrated a connection between the different HLA alleles associated with drug-induced liver injury caused by therapeutically and structurally different drugs, suggesting a mechanism of peptide binding of one of the associated HLA alleles [254]. Computer modeling of the molecular interaction between HLA-B*1502 and carbamazepine predicted a favorable drug-binding position in the B pocket of the HLA-B*1502 protein, where the side chain of Arg62 could form a hydrogen bond with the ketone group of 5-carboxamide of carbamazepine (Fig. 25.5) [253].

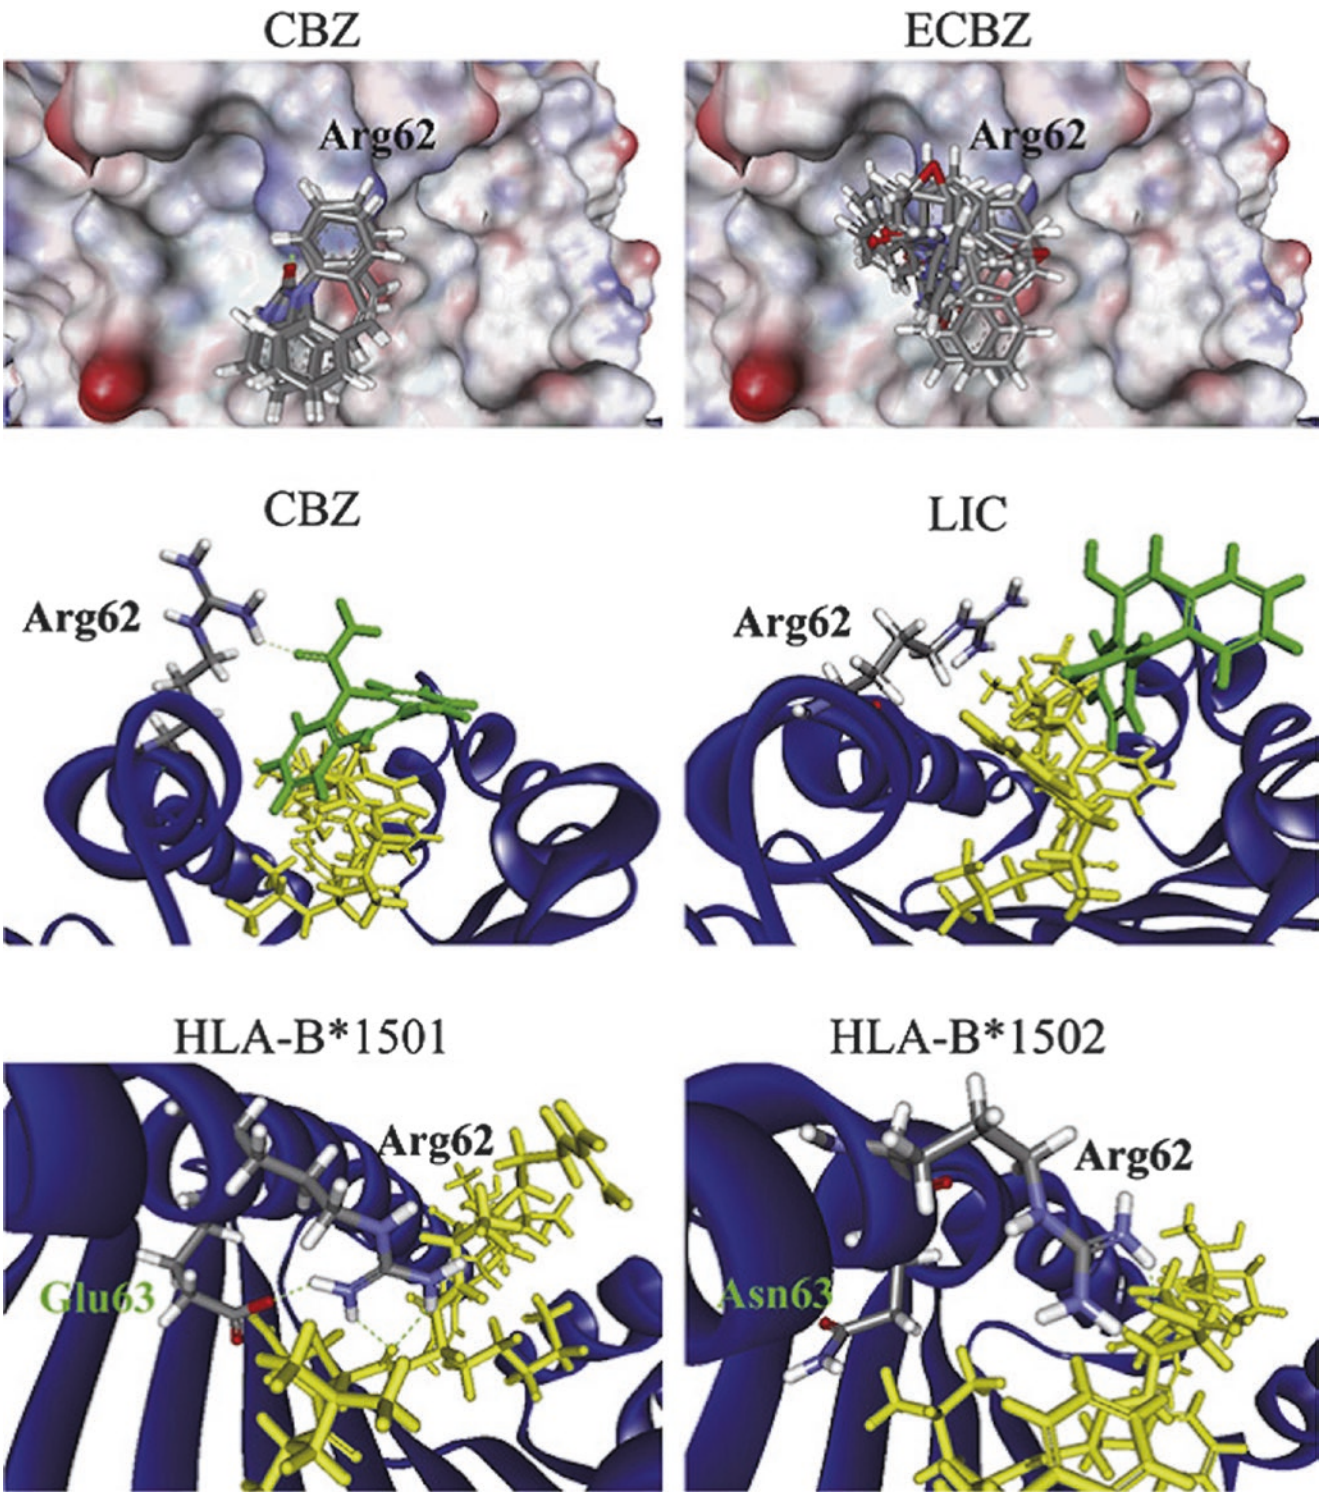

Fig. 25.5 Computer modeling of the molecular interaction between HLA-B*1502 and carbamazepine and its derivatives (Figure from Wei et al. [253])

Conclusion

Cutaneous ADRs have a wide spectrum of clinical manifestations that may be caused by multiple drugs and different mechanisms. In this decade, our understanding of the pathogenesis of cutaneous ADRs had progressed greatly. Understanding how a drug can possibly cause reactions in the skin has led to an understanding of the cellular immunology, cytokines and immunogenetics. These key insights can help mitigate the risk of reactions by testing for genetic factors, and to understand the treatment of drug reactions by better understanding the pathways involved. The future will depend on better genetic screening and directed approved therapies.

Review Questions

1. What is the major immune cell in acute generalized exanthematous pustulosis (AGEP)?
   A. CD4 T cells
   B. CD8 T cells
   C. Eosinophils
   D. Neutrophils
   E. NK cells

2. In which of the following delayed-type hypersensitivity reactions is interleukin (IL) 8 known to be involved?
   A. acute generalized exanthematous pustulosis (AGEP)
   B. drug reaction with eosinophilia and systemic symptoms (DRESS)
   C. maculopapular drug eruption (MPE)
   D. Stevens-Johnson syndrome (SJS)
   E. Toxic epidermal necrolysis (TEN)

3. The HLA gene B5701 and hypersensitivity reactions MPE/DRESS are associated with use of which of the following drugs?
   A. Abacavir
   B. Allopurinol
   C. carbamazepine
   D. Dapsone
   E. Nevirapine

4. What is the most common group of drugs causing pseudoporphyria?
   A. Antibiotics
   B. Diuretics
   C. NSAIDS
   D. Protease inhibitors
   E. Reverse transcriptase inhibitors

5. Which drug is most closely associated with fixed drug eruptions on the male genitalia?
   A. Allopurinol
   B. Carbamazepine
   C. Minocycline
   D. Tetracycline
   E. Vancomycin

Answers

Cutaneous Vasculitis: A Clinical Approach

26

Carlos H. Nousari and Michael R. Baze

Abstract

Vasculitis, an inflammatory condition of blood vessel walls, varies in severity from a self-limited disorder to a life-threatening disease, and can be caused by many different mechanisms. This condition can be an idiopathic primary process or a secondary manifestation of certain triggers such as infection, malignancy or systemic inflammatory conditions. Vasculitis can present many challenges to the clinician, including diagnosis and classification, necessary diagnostic studies and appropriate treatment. Depending on the organs and caliber of blood vessels involved, vasculitis can manifest with a wide spectrum of clinical and histopathologic findings. In cases of suspected vasculitis, the laboratory and histolopathologic studies yield invaluable information beyond the history and physical examination. Confirmation of vasculitis should prompt a search for potential underlying systemic disorders. Treatment for vasculitis is driven by the severity of symptoms and extent of organ involvement. Most cases of vaculitis are isolated occurrences and can be managed conservatively with rest and elevation of affected limb, and nonsteroidal anti-inflammatory drugs for symptom control. For disease that is recalcitrant or with evidence of systemic involvement, more aggressive therapy, including immunosuppressive agents is necessary. Traditional agents for treating vascultis include corticosteroids, cyclophosphamide, azathioprine, methotrexate, colchicine, dapsone and mycophenolate mofetil. Newer modalities include rituximab and TNF-α inhibitors. This chapter reviews the classification and diagnosis of cutaneous vasculitic conditions and current treatment options.

Key Points

- Vasculitis can be caused by many different mechanisms.
- Skin biopsies for hematoxylin and eosin and direct immunofluorescence are the cornerstones of diagnosing vasculitis.
- Serology, histories, and physical examinations can help determine the type of vasculitis.
- Treatments can include traditional agents such as corticosteroids, cyclophosphamide, azathioprine, methotrexate, colchicine, dapsone and mycophenolate mofetil, as well as newer modalities that include rituximab and TNF-α inhibitors.

Vasculitis is defined as inflammation of blood vessel walls. With inflammation of the vasculature, there is resultant wall destruction and increased permeability, which can lead to aneurysm formation, extravasation of blood cells, and stenosis. Clinically, these processes present as hemorrhage, tissue ischemia, or infarction of the affected organ. Depending on the organs and caliber of blood vessels involved, vasculitis can manifest with a wide spectrum of clinical findings, from a benign, self-limiting course, to death. Vasculitis of any organ can be a primary process (idiopathic) or a secondary manifestation of other triggers such as trauma, infection, malignancy, systemic inflammatory conditions, connective tissue disease, and drug hypersensitivity.

The skin in particular is among the most common organs affected by vasculitis due to its rich vascular supply, exposure to cold temperatures and trauma, and predisposing hemodynamic conditions (e.g., venous hypertension, stasis in the lower extremities).

Because lesions of the skin are readily visible to the clinician, often they are the first indication of potentially life-threatening vasculitic processes occurring elsewhere in the body. As such, it is critical to develop a systematic and thorough approach to the patient with suspected vasculitis. Cutaneous signs are varied and are primarily a reflection of the size of the affected vessels. Involvement of small, superficial vessels results in erythema and purpuric macules, whereas deeper involvement of larger vessels presents with increasingly severe lesions including livedo, palpable purpura, vesicles, ulcers, urticaria, subcutaneous nodules, distal gangrene, and necrosis. In this regard, the morphology of lesions can be a clue to the underlying vasculitic process; however, multiple lesion types are often present, as a range of blood vessel sizes may be involved. While the majority of cases of vasculitis restricted to the skin are self-limited, the physiologic response to inflammation from blood vessels results in the release of chemical mediators that may give rise to a variety of systemic findings, such as malaise, fever, weight loss, arthralgias, arthritis, myalgia, night sweats, and laboratory abnormalities [1–3]. Therefore, a complete history, physical exam, review of systems, and laboratory workup are necessary to further classify suspected vasculitis and identify extracutaneous involvement. In all cases, biopsy and clinical histologic correlation provide the gold standard for diagnosis. Herein, features common to most, if not all, variants of cutaneous vasculitis are described, including workup, common etiologies, and specific presentations.

Cutaneous Vasculitides

Cutaneous vasculitis most often manifests as palpable purpura in dependent areas and under tight-fitting clothing [4]. These lesions may be asymptomatic, tender, or pruritic, and, depending on the disease process and the size of the affected vessels, there may be varying degrees of involvement of other organs such as the kidneys, gastrointestinal (GI) tract, or lungs [5]. While accompanying signs and symptoms may give hints to systemic disease, there are no pathognomonic indicators of extracutaneous involvement, although tools have been proposed that may identify patients with more extensive disease [6, 7]. Furthermore, because different vasculitic processes can present with the same skin findings, and because many conditions can mimic vasculitis, prognosis cannot be determined from physical examination alone [8–11].

The annual incidence of biopsy-confirmed cutaneous vasculitis has been reported from 40 to 60 cases per million [12, 13]. Approximately 40 % of vasculitides limited to the skin are idiopathic and typically self-limited [12–14]. Other etiologic factors have been described (Table 26.1), with infection and drug reaction being most common among these [12–14]. There is a slight predilection in women over men, and all ages can be affected (mean adult onset = 47 years, mean pediatric onset = 7 years), with 90 % of pediatric cases represented by HSP. [12]

Initial Workup of Cutaneous Vasculitis

In cases of suspected vasculitis, the laboratory results and the histologic workup provide invaluable information beyond the history and the physical examination in determining the degree of systemic involvement and uncovering underlying causes for the vasculitic process. While physical findings can afford initial clues as to the types of vessels involved, the diagnosis of vasculitis can only be confirmed histologically. As the histopathologic diagnosis does not lend information regarding the degree of extracutaneous involvement, a clinicpathologic correlation is necessary in the evaluation of these

[b]Other tests to consider based on the individual case

patients. Recommended initial laboratory workup for all patients and other tests that should be considered on a case-by-case basis have been described (Table 26.2) [13–15]. Taken together, these data ultimately contribute to decisions regarding prognosis and treatment modalities. For example, serum complement is a known mediator of vascular inflammation, and low levels indicate excessive consumption, suggesting more extensive or systemic involvement [16]. An elevated erythrocyte sedimentation rate (ESR) has been described in approximately 50% of patients with limited cutaneous vasculitis [17]. An ESR of 40 mm/h or greater is associated with a high probability of systemic involvement [14].

Skin biopsies sent for both routine hematoxylin and eosin (H&E) staining as well as direct immunofluorescence (DIF) are the cornerstones in determining whether physical findings represent true vasculitis or other conditions that can clinically mimic vasculitis. Decisions as to which lesions should be biopsied have direct impact on the diagnostic information elicited. Tissue should be acquired from lesions between 24 and 48 h after their appearance, as sampling before or after this time range may result in false-negative results. Biopsies with thrombosis or perivascular lymphocytic inflammation are characteristic of older lesions. In cases where suspicion of vasculitis is high but histology does not correlate with clinical findings, biopsy should be repeated. Likewise, if a medium-vessel vasculitis such as polyarteritis nodosa (PAN) is suspected, the biopsy must be of sufficient depth to include the subcutaneous tissue where these vessels are found. In general, ulcerated lesions should be avoided [1].

The diagnosis of vasculitis is confirmed unequivocally by the presence of an inflammatory infiltrate around and within the walls of vasculature with fibrin deposition. These areas of fibrinoid necrosis are accompanied by swelling and necrosis of endothelial cells, as well as secondary changes such as erythrocyte extravasation and necrosis leading to purpura and infarction, respectively [1, 12]. Apoptotic cells are seen

Table 26.3 Agents commonly reported

Medication

Carbamazepine	Montelukast
Hydralazine	Infliximab
Isoniazid	Etanercept
Propylthiouracil	Rituximab
Allopurinol	Ciprofloxacin
Metformin	

Reported to cause vasculitis [28–40]

frequently as well as overlying ulceration. Determination of vessel size, type of cellular infiltrate, depth, and degree of involvement on H&E stains helps in classification and generation of differential diagnoses.

The pathogenic features of vasculitis in the skin are related to vessel wall injury, which can be toxin mediated, immune mediated, or from direct infection, and all three mechanisms can result in the histologic pattern of fibrinoid necrosis. It is critical to identify those patients in which pathogenesis is caused by antibody-mediated toxicity and immune complex formation, as they are more likely to have extracutaneous involvement [1].

Deposition of immune complexes leads to complement activation, further recruitment of inflammatory cells and cytokines, and expression of adhesion molecules such as E-selectin, P-selectin, and intercellular adhesion molecule 1 (ICAM-1) [12]. With endothelial cell retraction, there is vascular deposition of immune complexes, neutrophil infiltration, edema, hemorrhage, and thrombosis [12].

Immunofluorescence is an essential diagnostic tool in the evaluation of cutaneous vasculitis, especially in the small-vessel group. This technique consists of the detection of immunoglobulins (Igs) and complement deposited within tissue. Deposition of IgA, IgG, IgM, and C3 in or around vessels identified by DIF characterizes antibody and immune complex–mediated vasculitis, and the patterns of deposition further classify disease. Lesion age is critical to evaluation, as up to 30 % of immune-mediated vasculitides are negative on DIF by 72 h and only C3 is detected after this point [17, 18]. Tissue samples are transported in Michel's medium and stored at 4 °C prior to processing at specialized laboratories. Samples are washed, flash frozen, sectioned, and then stained to detect antibodies and complement in and around blood vessels. Certain diagnoses cannot be made without characteristic DIF patterns, which will be discussed with their associated conditions below.

Serologic testing has become routine in evaluation of vasculitis. In particular, antineutrophil cytoplasmic antibodies (ANCAs) have established clinical utility in dermatology [19]. Initially described in patients with rheumatoid arthritis, ANCA-associated vasculitides include small and medium-sized involvement such as Wegener's granulomatosis, microscopic polyangiitis, Churg-Strauss syndrome, and many drug-induced cases of vasculitis, as well as systemic inflammatory conditions and connective tissue diseases [20]. It is believed that vasculitides associated with ANCAs have a distinct mode of pathogenesis [20, 21]. Antibodies can be directed against cytoplasmic (c-ANCA) and perinuclear (p-ANCA) neutrophil-derived products. C-ANCA antibodies are directed against proteinase 3 (PR3) and p-ANCA antibodies are directed toward myeloperoxidase (MPO), elastase and lactoferrin [20, 21]. Inflammatory cytokines are believed to induce the translocation of these targets to the surface of neutrophils, allowing binding of ANCAs and adherence to endothelial cells, ultimately causing damage to vessel walls [22]. Titers may predict clinical relapse or disease activity, and serial testing is recommended, as transient elevations in ANCAs can be seen with acute infections [23, 24]. Because c-ANCA is represented by only one antigen (PR3), enzyme-linked immunosorbent assay (ELISA) is a more sensitive and specific assay. Since several antigens are responsible for the p-ANCA pattern, immunofluorescence is preferred.

Drug–Induced Vasculitis

Medications from virtually every pharmacologic class (including herbal supplements) have been linked to drug-induced vasculitis, resulting in a range of clinical presentations (Table 26.3) [25–40]. In a MEDLINE database search for published cases of drug-induced vasculitis by ten Holder et al. [41], vasculitis was more often associated with propylthiouracil, hydralazine, colony stimulating factors, allopurinol, cefaclor, minocycline, D-penicillamine, phenytoin, isotretinoin, and methotrexate. The onset of findings after exposure to the causative agent is typically 5–20 days [1], and while withdrawal is often sufficient to reverse the vasculitic process, there have been cases of fatal drug induced allergic vasculitis in previously healthy patients [42]. There have also been reports of cutaneous vasculitis stemming from vaccines [43]. Ironically, many

Table 26.4 Immunoglobulin A (IgA) vs. non–immunoglobulin A vasculitides [46–51]

IgA predominance?[a]	No IgA or IgG/IgM predominance?[a]

	Microscopic polyangiitis
	Behçet's syndrome
	Paraneoplastic vasculitis

[a]Predominance seen on direct immunofluorescence
[b]*HUVS* hypocomplementemic urticarial vasculitis syndrome

of the medications used for the treatment of systemic inflammatory conditions have also been linked to the development of cutaneous vasculitis [37–39]. Although the precise pathogenic mechanisms are varied, there appears to be a combination of cell-mediated and humoral immune responses contributing to the development of the observed vasculitis. As such, a thorough medication history is critical in the initial evaluation of the patient with suspected vasculitis, and all recently added medications should be discontinued. In those patients with both p-ANCA and c-ANCA, as well as eosinophilic infiltrates, the notion of drug-induced vasculitis should be entertained [44, 45]. Finally, one should keep in mind that the vast majority of drug-induced small-vessel vasculitis falls into the category of cutaneous leukocytoclastic angiitis (hypersensitivity vasculitis) or IgA vasculitis (Henoch-Schönlein purpura).

Vasculitis Associated with Systemic Conditions

Cutaneous vasculitis may result from a number of systemic triggers such as infectious, inflammatory, autoimmune, and malignant diseases, as well as pregnancy, and be of varying severity (Table 26.4) [46–51]. The workup of patients may reveal an underlying condition. Vasculitis can present prodromally or at any time during the disease. Among malignant diseases associated with vasculitis, hematologic cancers are seen most frequently. Bachmeyer and colleagues [52] found that of 95 hospitalized patients with hematologic malignancies, 23 (24 %) had biopsy proven cutaneous vasculitis. Skin findings developed before (26 %), during (39 %), and after (35 %) the diagnosis of malignancy. A thorough history, physical, and laboratory workup often point to the underlying disease processes, and in cases where there is failure to respond to treatment, investigation for occult malignancy should be considered.

Treatment

If systemic conditions are excluded and potentially causative agents discontinued, treatment for vasculitis is driven by the severity of symptoms and extent of extracutaneous involvement. Many cases are isolated occurrences and can be managed supportively with rest, warming, compression and elevation of affected lower extremities. Symptomatic treatment for pain and inflammation can often be accomplished with nonsteroidal anti-inflammatory drugs, and pruritus with antihistamines. For recalcitrant disease or with evidence of systemic involvement, more aggressive therapy, including immunosuppressive agents, is necessary. Therapeutic decisions are based on the experience of the clinician and the details of the specific patient. Initially, systemic corticosteroids alone or in combination with steroid-sparing immunosuppressants are often employed. Long-term, steroid-sparing medications are used for control with systemic corticosteroids limited to disease flares, as to avoid the well known adverse effects of chronic corticosteroids. Each medication has certain adverse effects (i.e., bone marrow toxicity, impaired renal function and drug-induced bladder complications) and regular and frequent laboratory evaluations are necessary to screen for these. Corticosteroids, cyclophosphamide, azathioprine, methotrexate, colchicine, dapsone and mycophenolate mofetil have been reported to treat vasculitis [14].

Corticosteroids demonstrate great utility across the spectrum of autoimmune and inflammatory disorders by suppressing effects of cytokines (IL-1, TNF-α), T-cells and B-cells. Circulating T-cell depletion occurs from corticosteroid enhanced circulatory emigration, induction of apoptosis, inhibition of T-cell growth factors, and impaired release of cells from lymphoid tissues [53]. Higher corticosteroid doses render significant B-cell effect and reduced immunoglobulin production.

Cyclophosphamide is an alkylating agent first developed to treat malignancies and has been used in the treatment of certain autoimmune diseases. Having potent immunosuppressive effects it depresses B-cell function more than T-cell function. Cyclophosphamide is used often in combination with corticosteroid therapy, considered the first-line treatment for Wegener's granulomatosis [54]. Cyclophosphamide is also used for remission induction with less toxic medications (i.e., methotrexate or azathioprine) for maintenance therapy.

Azathioprine, initially used in transplantation medicine for immunosuppressant properties, is also often used for its anti-inflammatory qualities. Azathioprine's active metabolites are 6-thioguanine monophosphate and other metabolites [55]. The exact mechanisms by which these purine analogs lead to immunosuppressive and anti-inflammatory effects are not clear.

Methotrexate is an antimetabolite chemotherapeutic agent with immunosuppressive effects used for inflammatory and immune-mediated processes. This drug is a potent competitive antagonist of dihydrofolate reductase, thereby inhibiting DNA synthesis and cell division. The immunosuppressive effects of methotrexate stem from inhibition of DNA synthesis in immunologically competent cells, suppressing antibody responses [56]. The anti-inflammatory effects are predominantly mediated by adenosine [57].

Colchicine has both antimitotic and anti-inflammatory properties and has demonstrated utility in dermatologic diseases characterized by polymorphonuclear leukocyte infiltration. Within leukocytes, colchicine binds to the dimers of tubulin, preventing the assembly of tubulin subunits into microtubules, thereby leading to arrest of mitosis [58].

Dapsone is useful in treating many skin diseases, primarily those characterized by neutrophilic infiltrates in the skin. Dapsone has been thought to accomplish this by altering neutrophil chemotaxis and respiratory burst, thereby leading to reduced oxidative damage in tissues [59]. The exact mechanisms are not clear, however.

Mycophenolate mofetil has demonstrated efficacy in multiple types of autoimmune and inflammatory skin diseases. MMF is a prodrug which first must be converted to the active drug form mycophenolic acid (MPA). MPA inhibits inosine monophosphate dehydrogenase, thus depriving the T- and B-lymphocytes of purine metabolites necessary for growth and replication and subsequent immunosuppression [60].

Often, these treatment regimens are sufficient to control disease activity with few adverse effects when appropriate monitoring is performed. Some patients, however, may be refractory to these treatments or develop intolerable side effects from therapy. These factors have ushered in an era of alternative treatment modalities with less toxicity and greater efficacy. More recently, effective treatments with tumor necrosis factor-α (TNF-α) inhibitors [61, 62] and anti-CD20 antibodies have been described [63, 64]. Rituximab is a chimeric monoclonal antibody directed against the B-cell lineage specific CD20 antigen, yielding B-cell depletion activity and subsequent inhibition of antibody production. Originally developed for the treatment of B-cell non-Hodgkin's lymphoma, rituximab has increasingly been used to treat a variety of immune-mediated disorders.

Clinical Mimickers of Cutaneous Vasculitis

A variety of conditions are capable of clinically simulating cutaneous vasculitis and have been termed pseudovasculitides [65]. Many of these conditions can be excluded by biopsy, and are typically associated with conditions that cause hemorrhage or vessel occlusion, and should always be in the differential diagnosis for vasculitis. Vessel wall dysfunction or incompetence from infiltrative processes, nutritional deficits such as scurvy [66], infection, embolism, vasospasm, and trauma can all present with varying degrees of purpura, petechiae, ecchymoses, ulcers, and necrosis. Likewise, hypercoagulable states such as antiphospholipid syndrome and factor V Leiden can lead to similar clinical pictures and need to be excluded [8].

Classification of Cutaneous Vasculitis

Classification of vasculitis in the skin is typically based on the size of predominantly affected blood vessels and type of inflammatory response, which when interpreted with DIF examination and laboratory workup, correlate with disease etiology and affect the treatment decisions. Vessels of varying sizes are frequently involved, however, as vasculitic processes do not always recognize arbitrary boundaries of vessel size. Most texts refer to the classification schemes outlined by the Chapel Hill Consensus Criteria (Table 26.5) or the American College of Rheumatology, although it is often difficult to characterize individual patient variations [67–69].

Small blood vessels are ubiquitous in the skin. They include arterioles, capillaries, and postcapillary venules. They are typically 50 μm or less in diameter, and may not have a fully developed muscular layer. Clinical lesions of cutaneous small-vessel vasculitis (CSVV) are most commonly nonblanchable and purpuric, and are found in dependent areas (buttocks, back, lower extremities). When urticarial lesions are present, they are less pruritic, short-lived (<24 h), and can occur anywhere on the body. They include Wegener's granulomatosis, Churg-Strauss syndrome, microscopic polyangiitis, Henoch-Schönlein purpura, essential cryoglobulinemic vasculitis, and cutaneous leukocytoclastic angiitis.

Table 26.5 Classification of cutaneous vasculitis according to the Chapel Hill Consensus Conference [67]

Large vessel vasculitis	Medium vessel vasculitis	Small vessel vasculitis
Takayasu arteritis	Polyarteritis nodosa	Microscopic polyangiitis
Giant cell arteritis	Kawasaki disease	Granulomatosis with polyangiitis[a]
		Eosinophilic granulomatosis with polyangiitis[b]
		Cryoglobulinemic vasculitis
		IgA vasculitis[c]
		HUVS (anti-C1q vasculitis)[d]

[a]Wegener's Granulomatosis
[b]Churg-Strauss syndrome
[c]Henoch-Schönlein purpura
[d]Hypocomplementemic urticarial vasculitis

Medium-sized blood vessels are larger than 50 μm, have fully developed muscular layers, and are located deeper within the dermis or subcutaneous fat. Clinically, these processes present with livedo, nodules, ulcerations, or digital infarcts. Wedge biopsy is typically needed for sufficient diagnostic yield, and biopsy of necrotic or ulcerated areas is of low yield. Included among this group are polyarteritis nodosa and Kawasaki disease. Vasculitis of these vessels is commonly referred to as necrotizing vasculitis, reflecting the hyalinization, coagulative necrosis, and degeneration of muscular layers, where it is more readily visible. Occasionally nerve or muscle biopsy can provide additional diagnostic information if histology is inconclusive.

Large-vessel vasculitides rarely have cutaneous manifestations and include giant cell (temporal) arteritis and Takayasu's arteritis, and will be mentioned only briefly.

Cutaneous Leukocytoclastic Angiitis

As defined by the Chapel Hill Criteria, cutaneous leukocytoclastic angiitis (CLA) is the term applied to patients with hypersensitivity vasculitis. Exogenous chemicals, infectious agents, cytokines, and circulating immune entities that do not strongly activate complement can cause CLA by inducing an inflammatory cascade in endothelium of CSVV. Most commonly triggered by infections or drugs, the onset is acute with both palpable and nonpalpable purpuric and urticarial lesions on the lower extremities appearing 5–20 days after initial exposure, and 2–4 days after repeat exposures (Fig. 26.1) [70]. These cases tend to be single episodes, and relapsing cycles can result from systemic inflammatory conditions, infection, and malignancy. Extracutaneous involvement is rare, with the exception of constitutional symptoms caused by mediators of inflammation released locally [71]. Serum sickness resulting from the injection of nonhuman serum can present with a similar picture, but is rarely seen in modern practice.

Routine laboratory tests are usually normal, as extracutaneous disease is rare. The ESR is elevated in up to 50% of cases, while complement levels and urinalysis are normal. There are no specific serologic markers for CLA, making it largely a diagnosis of exclusion, and normocomplementemic urticarial vasculitis is likely to be a clinical variant of this condition [72].

On histology, there is a neutrophil predominant vasculitis of superficial vessels with varying numbers of surrounding eosinophils (Fig. 26.2). Direct immunofluorescence is positive in roughly half of these biopsies, displaying mild to moderately intense granular IgM deposits with weak or absent C3. The lack of complement involvement may correlate with the relatively benign course of this condition and low level of systemic involvement. Although DIF is frequently negative, it is a key factor in discriminating CLA from IgA vasculitis, which shares the same triggers and clinical presentation [73, 74].

Up to half of the cases of CLA are idiopathic and resolve spontaneously. In cases with a known trigger, treatment consists of removal of the offending agent or resolution of underlying systemic condition. Immunosuppressive treatment is largely unnecessary in CLA, with the exception of the most severe cases, and is aimed at reducing constitutional symptoms and synovitis. Moderately dosed corticosteroids (0.5 mg/kg/day) are a reasonable option until symptoms resolve. Recalcitrant cases warrant more extensive investigation. Rituximab therapy has demonstrated efficacy in the treatment of cutaneous angiitis refractory to high dose corticosteroids and cyclophosphamide [75].

Henoch-Schönlein Purpura

Henoch-Schönlein purpura (HSP) is defined as an IgA-mediated syndrome presenting with a tetrad of purpura, abdominal pain, arthralgias, and hematuria [76]. It is most commonly seen in children, but there have been increasing reports of HSP in adults [76, 77]. HSP runs a more severe

Fig. 26.1 Acute palpable purpura of cutaneous leukocytoclastic angiitis (hypersensitivity vasculitis)

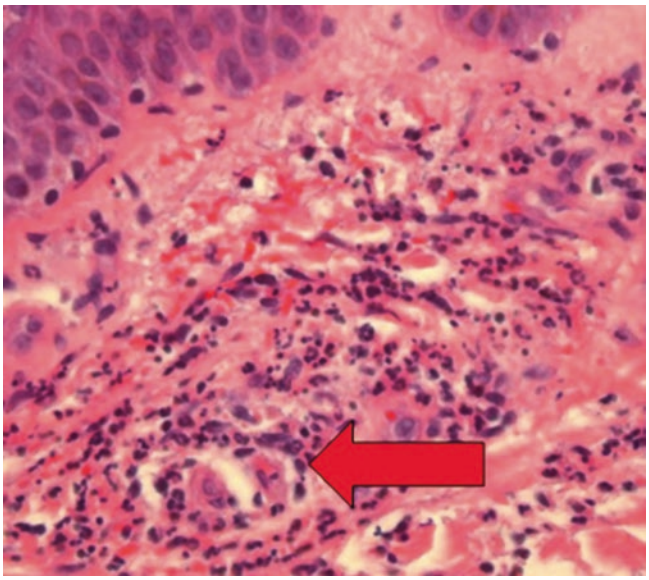

Fig. 26.2 Hematoxylin and eosin (H&E) staining of skin biopsy from a patient with cutaneous small-vessel vasculitis. This is a leukocytoclastic vasculitis involving small, superficial vessels, rich in neutrophils (*arrow*)

course and is more likely to cause long-term renal disease in adults compared to children [78, 79].

As with CLA, HSP is often preceded by medications or infection, most commonly upper respiratory, gastrointestinal (GI), and genitourinary (GU). When associated with GI and GU infections, it can be difficult to discern findings related to infection from those caused by the vasculitic process itself. Approximately 50 % of those affected develop systemic involvement such as nephritis, neuropathy, and GI symptoms. [80] Skin lesions are seen in all patients and are typically palpable purpura or urticaria of the lower extremities and buttocks that turn into purpura with annular configuration (Fig. 26.3). Koebnerization is known to occur in HSP. A subset of patients displays only urticarial lesions, and lesions above the waist have been associated with renal disease, as are elevated ESR, fever, and adult onset [81]. Women have an increased risk for the development of proteinuria or preeclampsia in future pregnancies [82, 83].

Extracutaneous involvement can appear in any organ, with the kidneys, GI tract, and joints being most common. Renal failure secondary to glomerulonephritis is the most serious complication of HSP.

Renal involvement occurs in about 33 % of children and 63 % of adults with HSP. [84] The risk of progression to renal insufficiency ranges from 5 to 15 % in children and seems to be much higher in approximately 30 % in adults [77]. Children with renal involvement have a higher incidence of hypertension and renal failure as adults, and 15 % of children on hemodialysis have renal failure secondary to HSP. [85] Urinalysis is an absolute requirement for the patient with suspected HSP, with hematuria providing the most sensitive measurement for renal involvement. Recent studies have revealed abnormalities of IgA1 glycosylation and formation of autoantibodies to aberrantly glycosylated IgA1 molecules with subsequent mesangial deposition and renal disease [86, 87]. New noninvasive disease activity markers (aberrantly glycosylated IgA1 and its immune complex) may aid in the diagnosis and help guide therapy. Gastrointestinal involvement can range from pain to hemorrhage and necrosis of the bowel from mesenteric vasculitis, and pulmonary hemorrhage has also been reported [88]. However, it is difficult to determine if involvement of these organs is the result of a prodromal infection or from the vasculitic process itself.

There is mounting evidence that acute hemorrhagic edema of infancy (AHEI) is a variant of HSP, although in contrast with HSP, extracutaneous involvement is rare and IgA deposition is rarely seen with DIF. [89] AHEI is frequently seen after bacterial infection, and lesions appear on the face and extremities. There are no specific serology associations with HSP, although up to 40 % of adult patients demonstrate some degree of IgA gammopathy [81]. When appropriate, additional workup should include serum and urine protein electrophoresis (SPEP and UPEP), total immunoglobulin quantitation, and immunofixation.

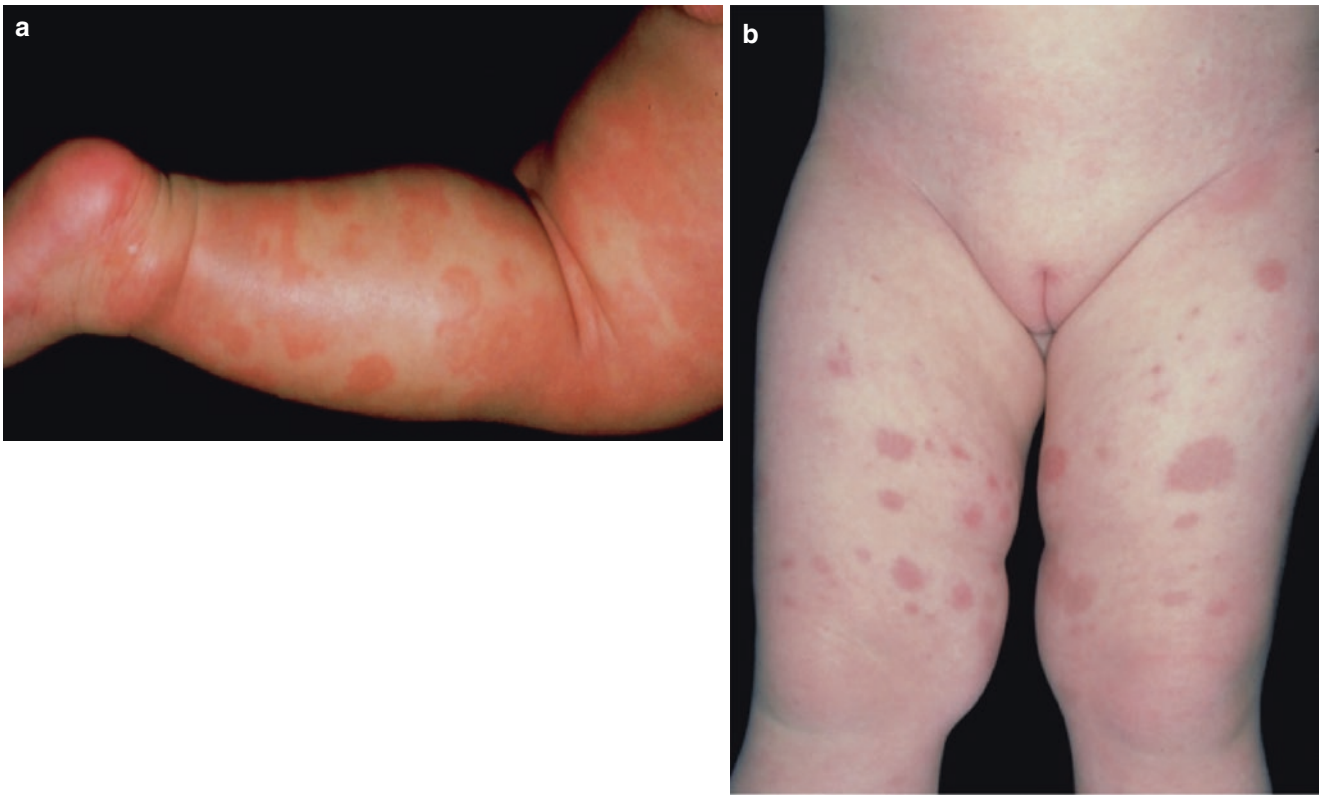

Fig. 26.3 (**a**, **b**) Infants with typical lesions of Henoch-Schönlein purpura. Lesions above the waistline are associated with a worse prognosis (Courtesy of Dr. M. Mercurio)

Routine H&E staining reveals a neutrophil-rich small-vessel vasculitis of the superficial dermis with leukocytoclasia and few eosinophils (Fig. 26.2). DIF provides the gold standard for diagnosis, with IgA deposits in small, superficial vessels found in virtually all biopsies. Granular deposits of other Ig classes are occasionally seen, with IgA being the most prominent [87].

As with any of the vasculitides, treatment decisions hinge on the degree of involvement and constitutional symptoms. While the cutaneous findings are largely refractory to therapy, synovitis and GI symptoms are quite responsive to moderate doses of oral corticosteroids. Skin lesions frequently have an initial response to steroids, followed by rapid relapse upon completion of treatment. Antimetabolites such as azathioprine and mycophenolate mofetil, as well as alkylating agents can be effective for treating glomerulonephritis. However, there is little evidence that any other immunosuppressive therapy beyond corticosteroids is effective in HSP nephritis [90].

Urticarial Vasculitis

Urticarial vasculitis presents clinically as urticaria of the trunk and proximal extremities, and histologically as vasculitis (Fig. 26.4). It occurs in two forms differentiated by serum complement levels. The normocomplementemic variant is a subset of CLA, while the hypocomplementemic type (HUVS) is a subset of systemic lupus erythematosus (SLE) [72, 91]. Patients with low levels of C3, C4, and total serum hemolytic complement (CH50) have dramatically increased rates of complement consumption. CH50 is a more sensitive predictor of HUVS since C3 and C4 are acute-phase reactants and may be normal in mild disease or early-stage disease. Thorough workup of patients with urticarial vasculitis

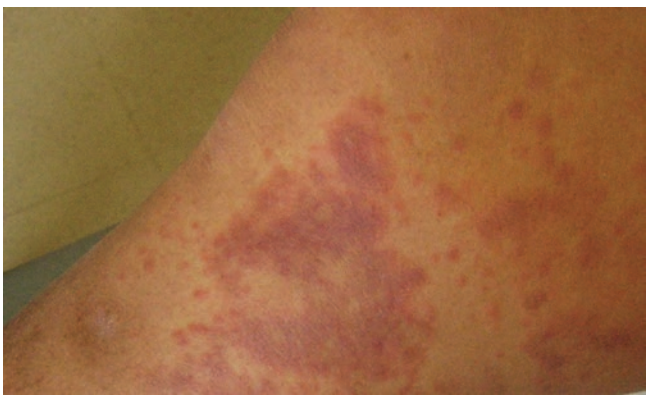

Fig. 26.4 Urticarial vasculitis. These lesions are difficult to distinguish clinically from traditional urticaria and can occur on the face and upper extremities (Courtesy of Dr. F. Tausk.)

should include the quantitation of C3a, C5a, and C3bi when available [72, 74].

Ninety percent of normocomplementemic urticarial vasculitis (NUV) are triggered by infection or medications, and are self-limited without indication of systemic involvement [73]. The clinical differential includes urticarial HSP, neutrophilic urticaria, Schnitzler's syndrome, and urticarial cryoglobulinemia II and III.

Neutrophilic urticaria, also known as polymorphonuclear predominant urticaria (PPU) is a subset of chronic urticaria [92]. Lesions are typically pruritic, and mild constitutional symptoms can be present. Histologic features of PPU can be confused with NUV, as perivascular neutrophilic infiltrates can be dense, with occasional karyorrhexis; however, there is no definite disruption of vasculature and DIF is consistently negative in PPU. Chronicity and no obvious underlying cause argue against NUV. Treatment consists of antihistamines, leukotriene antagonists, dapsone, or colchicine. In cases of PPU it is important to rule out Schnitzler's syndrome, which is characterized by NUV, fever, lymphadenopathy, hepatosplenomegaly, peripheral neuropathy, bone pain, and monoclonal IgM gammopathy [93]. In contrast to patients with NUV, the hypocomplementemic variant of urticarial vasculitis presents as a chronic, relapsing syndrome (HUVS) with signs and symptoms typically seen with SLE, including fever, arthralgias, and myalgias [73, 91].

In contrast to lesions of NUV, HUVS lesions tend to have a purpuric component upon careful examination. Synovitis, GI involvement, and scleritis are not uncommon associated findings. A subset of HUVS patients with more overt symptoms of SLE will display angioedema, thought to be mediated by a high rate of consumption of C1 esterase caused by autoantibodies to C1q. In both variants of urticarial vasculitis, histology reveals a dense neutrophilic infiltrate in and around the walls of small vessels that disrupts normal architecture. In HUVS, dermal edema and neutrophils extend to the dermal-epidermal junction (DEJ), resulting in vacuolar changes and clefting of the basement membrane zone (BMZ). The only serologic marker associated with NUV is an elevation in ESR in up to 70% of patients, while essentially all patients with HUVS have high ESR and an antinuclear antibody (ANA) titer greater than 1:320 at some point in their disease course [1].

As with CLA, 50% of patients with NUV have immune deposition within and around blood vessel walls seen with DIF. IgM is seen more frequently than IgG, and C3, if present, is weak and patchy. In contrast, essentially all patients with HUVS show significant IgG and C3 intravascularly and perivasculary within superficial dermal vessels extending to the BMZ (Fig. 26.5). It has been reported that this latter finding resembles the lupus band test, further linking HUVS with SLE [74, 94].

Treatment of NUV is similar to that for CLA— conservative and directed toward alleviation of mild symptoms. HUVS, however, frequently requires systemic immunosuppressive therapy such as corticosteroids, azathioprine (3–4 mg/kg/day), or mycophenolate mofetil (40–50 mg/kg/day); these medications are usually sufficient. Anti-inflammatory agents such as dapsone, colchicine, methotrexate, and calcineurin inhibitors are not typically effective, as they have no effect on the production of immune complexes or anti-C1q synthesis.

Cryoglobulinemia

Cryoglobulinemic vasculitis affects both small and medium-sized skin blood vessels. Cryoglobulins are antibodies that precipitate with cold, and three types of cryoglobulinemia exist as defined by the type of antibodies present. Type I is a monoclonal gammopathy that commonly presents as a hyperviscosity syndrome and thrombotic events in the context of myeloproliferative disorders, and does not represent true vasculitis. Type II is mixed, with an IgM monoclonal component (usually an IgM rheumatoid factor) in conjunction with polyclonal gammopathy. Type III consists of polyclonal cryoglobulins. Because types II and III readily form immune complexes, they are more likely to cause vasculitis, as opposed to the thrombotic vasculopathy seen with type I cryoglobulins [1, 95, 96]. Cryoglobulinemia type II has antibodies that form immune complexes with much higher avidity and levels of complement fixation, resulting in more significant clinical syndromes. Hepatitis C is by far the most common cause of type II cryoglobulinemia, representing essentially all cases previously labeled as essential mixed cryoglobulinemia (Fig. 26.6) [95, 96]. It is felt that the virus stimulates the immune system chronically, causing B-cell expansion and production of autoantibodies. Other associated infections include endocarditis, hepatitis B, and

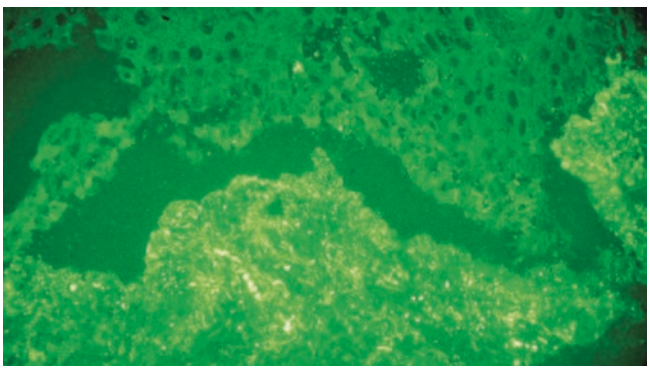

Fig. 26.5 Direct immunofluorescence of biopsy from a patient with hypocomplementemic urticarial vasculitis syndrome (HUVS) revealing granular immunoglobulin G (IgG) in and around superficial vessels

HIV. Connective tissue disease, other autoimmune conditions, and malignancy have been associated with both types II and III cryoglobulinemic vasculitis [97].

Clinically, skin lesions associated with cryoglobulinemia type I are indistinguishable from those seen with type II, and resemble the palpable purpura and urticarial findings seen with any CSVV. As with most vasculitides other than urticarial vasculitis, lesions most commonly appear on the lower extremities. Cryoglobulin-associated nonpalpable purpura can also present as the capillaritic eruption seen in Schamberg's disease. The benign hypergammaglobulinemic purpura seen in Waldenström's (lymphocytic vasculitis) is clinically, serologically, and histologically indistinguishable from that seen with cryoglobulinemia type III, and, as such, is generally believed to belong to the same spectrum of disease [97]. Pigmented purpura above the waistline or involving the soles of the feet favor cryoglobulinemic vasculitis over Schamberg's, as do lesions seen at different stages of evolution, ulcerative lesions, and constitutional symptoms. Ulceration signals the involvement of medium-sized vessels and can help differentiate from other CSVV. As mentioned, medium-sized vessels can also be seen with cryoglobulinemia.

Fig. 26.6 Clinical image of patient with known hepatitis C presenting with the CSVV (purpura) and medium-sized vessel vasculitis (livedo) lesions associated with cryoglobulinemia type II

These patients also tend to have systemic symptoms such as nephropathy, neuropathy, arthralgias, and gastrointestinal involvement [1, 98].

Serologically, cryoglobulin type II patients demonstrate monoclonal IgM rheumatoid factor (RF) and polyclonal IgG. All patients have an RF greater than 1:320, and over 90 % have decreased C4 but essentially normal C3. Therefore, a negative cryoglobulin assay and negative RF in the setting of low C4 virtually excludes cryoglobulinemia type II, whereas a low titer cryoglobulinemia in the absence of vasculitis is common after many infections. A positive cryoglobulinemia with negative RF activity likely represents an incidental finding and not vasculitis. Cryoglobulinemia type III demonstrates a polyclonal gammopathy without any specific monoclonal spike, and low levels of both C3 and C4 [1].

Histology demonstrates findings consistent with CSVV or both CSVV and medium-sized vessel vasculitis (MSVV), but not MSVV alone. Some texts report the deposition of a nonspecific, homogeneous intravascular infiltrate associated with cryoglobulinemic vasculitis; however, this likely represents thrombotic vasculopathy seen with type I cryoglobulinemia and not true vasculitis [97].

Direct immunofluorescence in cryoglobulinemia type II usually reveals significant granular IgM and C3 deposition in and around small and medium sized vessels, while type III has both IgG and IgM in addition to C3. In practice, it is often difficult to distinguish between types II and III cryoglobulinemia by DIF.

Because types II and III cryoglobulinemias are difficult to distinguish histologically and clinically, treatment decisions should hinge on the serologic workup and be directed toward the underlying etiology (e.g., hepatitis C) as well as the vasculitis. Treatment of the latter is similar to that of other vasculitides and is based on combinations of steroids and steroid-sparing agents that are used in an effort to target antibody and immune complex–mediated inflammation. Differences do exist, however, when treating the underlying condition in type II as opposed to type III cryoglobulinemia. For instance, in the setting of hepatitis C–induced type II cryoglobulinemia with high titers of cryoglobulins and RF and low complement, antiviral treatment with interferon-γ could potentially result in massive formation of immune complexes, exacerbation of vasculitis, and multi-organ failure [98]. This group of patients should be treated with immunosuppressive agents of low hepatotoxicity for at least 6 months prior to antiviral therapy [99].

An additional difference in the management of type II versus type III cryoglobulinemia is with plasmapheresis aimed at removing pathogenic immunoglobulins. Because antibodies in type II cryoglobulinemia are intravascular as opposed to the intra- and extravascular deposition seen in type III cryoglobulinemia, plasmapheresis is much more effective in the prior condition, as extravascular antibodies are not affected by plasmapheresis. Rituximab is a newer therapeutic option that has demonstrated its utility by its B-cell depletion activity and subsequent inhibition of antibody production such as that which occurs in cryoglobulinemia. Studies have demonstrated the efficacy of rituximab as monotherapy in the treatment of cryoglobulinemia vasculitis, or when used in combination with corticosteroids [100]. Rituximab plus corticosteroids appears to provide better efficacy in patients with relapsing disease or disease refractory to other therapies [101, 102].

Antineutrophil Cytoplasmic Antibody (ANCA)–Positive Vasculitis

ANCAs are antineutrophil cytoplasmic antibodies and are found in varied autoimmune disorders. In the setting of vasculitis, they are associated with three conditions: Wegener's granulomatosis (WG), microscopic polyangiitis (MPA), and Churg-Strauss syndrome (CSS). Skin findings of these three conditions are those of CSVV or cutaneous medium-vessel vasculitis (CMVV), with palpable purpura being most common. [103, 104] Papules and nodules are occasionally seen on extensor surfaces and can be ulcerated or necrotic, occasionally with overhanging borders as seen with pyoderma gangrenosum [105, 106]. However, primary cutaneous disease in these conditions is essentially nonexistent, as all patients with WG, MPA, and CSS have varying degrees of extracutaneous involvement. Wegener's granulomatosis has significant associated extracutaneous involvement including upper and lower respiratory, renal, and nervous system manifestations, and almost all of these patients are c-ANCA positive. Churg-Strauss syndrome is hard to distinguish from WG except for the presence of significant tissue and blood eosinophilia, higher levels of p-ANCA, and associated atopy in CSS [107]. The diagnosis of CSS requires eosinophil predominance in a mixed infiltrate. Some patients with CSS describe pruritus as a symptom preceding the development of vasculitic lesions, and this is thought to be related to the high number of eosinophils. Microscopic polyangiitis is the most common cause of vasculitis associated with pulmonary-renal syndrome, and almost all of these patients are p-ANCA positive [71, 108].

Histologically, lesions from the ANCA-associated vasculitides demonstrate classic findings of vasculitis or Churg-Strauss (cutaneous extravascular necrotizing) granulomas (CENG) [105, 109]. The latter is a misnomer, as the blood vessels in these infiltrates demonstrate clear evidence of vasculitis. Originally observed in CSS, but later seen in several vasculitides, CENG lesions contain four components: (1) a central area of degenerated extracellular substance surrounded by (2) a palisaded mononuclear infiltrate; (3) variable polymorphonuclear interstitial infiltrate; and (4) variable degrees of vasculitis or vasculopathy of small or medium sized vessels [106, 109, 110]. This fact helps differentiate CENG seen in systemic vasculitides from the palisaded granulomas of rheumatoid nodules. Both the histologic and clinical appearances are similar to those of rheumatoid nodules. Oscillating titers of pathogenic antibodies cause sustained damage to the endothelial lining, leading to slow death and degeneration of the extracellular matrix, resulting in a palisading inflammatory reaction. Because extensor surfaces of the extremities are prone to trauma and injury, they tend to be a common site for their location. Whether typical vasculitis or CENG is present, marked levels of eosinophils seen on biopsy (>60 %) are pathognomonic for CSS. Direct immunofluorescence in all types of ANCA vasculitis is positive in approximately 80 % of cases for IgG and IgM deposition, but not C3. Cutaneous extravascular necrotizing granuloma is also referred to as CSG, Winkelmann's granuloma, interstitial granuloma, palisaded neutrophilic and granulomatous dermatitis of connective tissue disease, superficial ulcerating rheumatoid necrobiosis, and rheumatoid papule [1, 107, 109].

Because ANCA-associated vasculitis occurs in the setting of extracutaneous disease, treatment of the primary vasculitis treats the cutaneous findings. Standard management involves combinations of steroids and steroid-sparing immunosuppressive agents [20, 22, 23].

Cyclophosphamide and glucocorticoids have been standard therapy for remission induction in severe ANCA-associated vasculitis but they are associated with high rates of adverse events and death. Rituximab was thought to be a potentially more effective and safer treatment than cyclophosphamide. Two recent randomized control studies, RITUXVAS (rituximab-based regimen versus cyclophosphamide in ANCA-associated renal vasculitis) [111] and RAVE (rituximab for ANCA-associated vasculitis) [112], have demonstrated similar efficacy of rituximab to cyclophosphamide for the induction of remission in ANCA-associated vasculitis. Results also revealed that sustained-remission rates were high in both groups, and the rituximab-based regimen was not associated with reductions in early severe adverse events, compared to cyclophosphamide. These findings could suggest that the nature of the disease and prolonged high-dose glucocorticoid therapy and are the main contributors to the adverse events.

Remission ANCA-associated vasculitis is a relapsing condition, for which cyclophosphamide has been used for

prolonged periods to maintain remission. Given the potential adverse effects of high cumulative cyclophosphamide toxicity (bladder cancer and myeloproliferative disease) safer maintenance therapeutic options are needed. In a prospective multi-center study, Pagnoux et al. [113] randomized 126 patients to receive either methotrexate or azathioprine as maintenance therapy after successful induction of remission with cyclophosphamide. The authors found no difference in efficacy and safety of these two agents. Mycophenolate mofetil (MMF) is an alternative to azathioprine for remission maintenance therapy in AAV. Results from a small pilot study in 11 patients were promising, with only one relapse occurring after 14 months of follow-up [114]. However, the IMPROVE randomized study comparing MMF and azathioprine as maintenance agents after cyclophosphamide induction in 174 patients, found an increased hazard ratio of 1.7 for relapse in the MMF group, and a shorter time to relapse [115]. Both treatments had similar adverse event rates. MMF may have greatest utility in azathioprine intolerant renal failure patients for whom methotrexate is contraindicated.

The utility of TNF blocking agents has been mixed. Etanercept was shown not effective for the maintenance of remission in patients with Wegener's granulomatosis when added to glucocorticoids and cyclophosphamide or methotrexate [116]. Further, a high rate of serious adverse events and an excess of solid organ tumors were seen. Infliximab demonstrated effectiveness for inducing and maintaining remission when used with conventional therapy, although there was an increased rate of severe infections [117].

Connective Tissue Disease–Associated Vasculitis

Essentially any cutaneous vasculitic syndrome can be triggered by connective tissue disease (CTD). Furthermore, these patients are more prone to infections and drug exposure, resulting in higher rates of CLA or IgA-mediated vasculitides. Three vasculitic entities in particular are associated with CTD: CTD-associated vasculitis, HUVS (discussed above), and lymphocytic vasculitis (LV) [118]. Connective tissue disease–associated vasculitis is most frequently seen with SLE, but can also happen with other CTDs such as Sjögren's syndrome, dermatomyositis, systemic sclerosis, and mixed connective tissue disease [118, 119].

Clinically, these diseases can present as CSVV of the lower extremities. Although they may resemble the lesions of cryoglobulinemia, CTD vasculitides may present as a pure CMVV without small vessel involvement, whereas small vessels will always be involved in cryoglobulinemia. Systemic involvement is present in essentially all patients, with the kidneys being the most affected organ. Central and peripheral neuropathies and GI and cardiac involvement can also occur at varying rates.

Serologically, high titers of antinuclear antibodies (ANAs) and low complement are present. Different combinations of ANA are commonly seen including anti–double-stranded DNA (anti-dsDNA), ribonucleoprotein (RNP), Ro, and Sm, further increasing the chance for vasculitis.

Histologically, CTD-associated vasculitis shows CSVV or CMVV without any distinguishing features. Lymphocytic vasculitis is rare and more commonly seen in SS and SLE; however, it can occur in association with other CTDs as well. Lymphocytic vasculitis is also known as benign hypergammaglobulinemic purpura (BHP) of Waldenström. Most experts believe that both LV and BHP of Waldenström are type III cryoglobulins associated with CTDs [118, 119].

As opposed to cryoglobulinemia, however, DIF reveals IgG in and around small and medium-sized vessels as the predominant immunoglobulin. C3 is usually very strongly deposited. Interestingly, in vivo ANA is very commonly present. This reflects the high titer of ANA, especially RNP in keratinocytes and dermal cells in these patients [1].

As the development of vasculitis in CTD is often associated with an ominous prognosis, aggressive treatment of the underlying CTD is mandatory. Combinations of corticosteroids, with high doses of antimetabolites or alkylating agents and occasionally plasmapheresis, are necessary to control the progression of this disease.

Rheumatoid Vasculitis

Rheumatoid vasculitis (RV) is a rare but severe complication in patients with advanced, usually otherwise quiescent seropositive rheumatoid arthritis (RA) [120]. It can affect virtually any sized vessel, with palpable purpura being the most common presenting sign, but ulcerations, livedo reticularis, digital infarcts, or cutaneous nodules can also be seen. Isolated, fluctuating periungual splinter hemorrhages, known as Bywater's lesions, are caused by digital small-vessel vasculitis. Cutaneous medium-vessel vasculitis involvement typically presents as deep geographic ulcers at the malleoli. As with cryoglobulinemia, these patients frequently have accompanying mononeuritis multiplex. [98]

Serologically, high titers of RF often with low levels of both C3 and C4 are characteristic of RV. This often helps in distinguishing RV from cryoglobulinemia since RF is elevated in both, and, even in RA patients with higher titers of RF, low levels of cryoglobulins are not uncommon. Thorough exclusion of other causes of CMVV in RA patients with cryoglobulins is mandatory (e.g., viral hepatitis, lymphoma, HIV) [120–122].

Histologic findings in RV are indistinguishable from those in other CSVVs and CMVVs. Direct immunofluorescence is indistinguishable from cryoglobulinemia, with heavy granular IgM and variable degrees of C3 in and around small and medium vessels [120].

The aim of therapy in RV is to reduce IgM immunocomplexes with combinations of corticosteroids with antimetabolites or alkylating agents. Methotrexate is effective for the synovitis and T-cell–mediated symptoms of RA, but is not effective for RV. Because of the IgM RF, plasmapheresis in combination with steroids and alkylating agents is a good choice in patients with life- threatening disease (as with cryoglobulinemia type II) [122]. Bywaters lesions alone do not necessitate aggressive systemic therapy.

Evidence supporting the use of biologic agents consists of case reports and case series. Puéchal et al. [123] described nine patients with rheumatoid vasculitis refractory to cyclophosphamide treatment that were subsequently treated with anti-TNF therapy. Remission was achieved in two-thirds of patients, with a significant decrease in prednisone dose. Severe infection occurred in three patients. Other reports describe patients intolerant or refractory to cyclophosphamide therapy with successful treatment of rheumatoid vasculitis with infliximab [124, 125]. An additional benefit of anti-TNF therapy is the treatment of synovitis, which is not contained with cyclophosphamide. Rituximab improves articular symptoms in rheumatoid arthritis and has been shown to be effective in ANCA-associated vasculitis. In a recent study of 17 patients with RA-associated vasculitis, nearly three-fourths of patients receiving rituximab achieved complete remission with a significant decrease in daily prednisone dosage and an acceptable toxicity profile [126]. Other reports also describe the successful use of rituximab to treat RA vasculitis [127, 128].

Polyarteritis Nodosa

Polyarteritis nodosa (PAN) is the prototype of a pure medium-sized vessel vasculitis (Fig. 26.7), often presenting as a systemic illness with multi-organ involvement. It is a diagnosis of exclusion when other causes of CMVV such as RV, ANCA vasculitis, and cryoglobulinemia have been ruled out. While the etiology of PAN is unknown, the hepatitis B virus has been implicated as an etiologic agent. Guillevin et al. [129] found that over a 30-year period the frequency of HBV-PAN was roughly 50 % to about 17 %. The authors attributed the decline to factors such as widespread use of the hepatitis B vaccine and increased safety of blood transfusions and products. HBV-related PAN is an acute disease, occurring shortly after infection and sharing the characteristics of classic PAN.

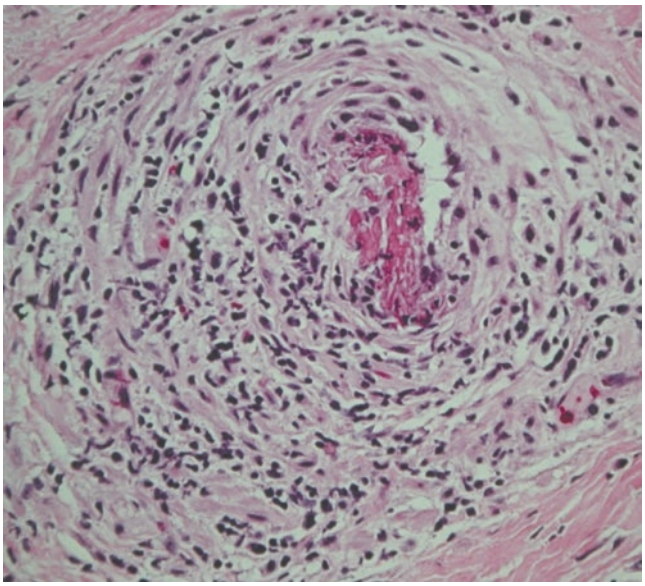

Fig. 26.7 H&E staining of a skin biopsy from patient with polyarteritis nodosa. Note involvement of medium-sized vessel

The most common presentation is with painful cutaneous nodules and ulcerations with a predilection for the malleoli [130], but since PAN is a pure CMVV, other lesions can include nodules, ulcers, livedo (Fig. 26.8), and digital infarcts (Fig. 26.9), and less frequently papulonecrotic lesions on extensor surfaces (CENG) [131]. Ulcerations heal with stellate, atrophic, ivory-colored scars or hyperpigmentation, designated as atrophie blanche or livedoid vasculitis in the past, or even Degos' like lesions. They are often accompanied by neuropathic pain resulting from involvement of the vasa nervorum. Focal synovitis and arthralgia may be present in the joints close to areas of cutaneous involvement, particularly the ankle, as opposed to erythema nodosum, where generalized arthralgias may be present. Disease limited to the skin occurs in less than 10 % of those affected, and PAN can occur in children after streptococcal infection [132].

Differential diagnosis for nodular lesions includes erythema nodosum, nodular vasculitis, and erythema induratum [133–135]. The latter two are most likely variants of this disorder, with a prominent component of panniculitis present. Infectious causes of ulceration, pyoderma gangrenosum, calciphylaxis, and other causes of medium-sized vessel vasculitis must be included in the differential. Patients with nodules limited to around the ankles may have cutaneous PAN, and even these patients require close and long-term follow-up for progression to systemic disease [136, 137]. Systemic disease is present in virtually all patients with extensive nodulo-ulcerative disease. Synovitis, hypertension, and mononeuritis multiplex are the most common systemic findings.

Fig. 26.8 Livedo reticularis in a patient with polyarteritis nodosa

Fig. 26.9 Digital infarct in a patient with poyarteritis nodosa

Kawasaki's disease is an equivalent of PAN in children with a predilection for the coronary arteries, leading to coronary aneurysms and myocardial infarction [132, 136–139].

Serologic testing may reveal elevated ESR with hypocomplementemia. ANCA, ANA, and RF are typically negative, but may be present at insignificant titers.

By definition, small-vessel involvement should rule out the diagnosis of PAN. Because PAN is a pure CMVV, shallow biopsies that do not sample deeper skin vessels will lead to frequent misdiagnosis. Therefore, multiple, deep biopsies are recommended. The diagnostic yield in PAN is the following: nodules (90–100 %), ulcers (50–80 %), livedo (0–20 %), and digital infarcts (0–5 %). Direct immunofluorescence shows granular IgM in and around medium-sized vessels and weak C3 in approximately 60 % of cases [1].

The approach to treatment of PAN requires consideration of disease severity and whether the patient is infected with HBV. Corticosteroids alone may be sufficient for mild nodular disease, while ulcerative disease without significant systemic involvement may respond to prednisone in combination with azathioprine. Severe cutaneous disease with digital infarcts and systemic involvement should be treated with corticosteroids and alkylating agents. Plasmapheresis is not effective in PAN since IgM immune complexes and RF do not play a prominent role in this disease in contrast to the high titers of these factors seen in RV and cryoglobulinemia [131]. In HBV-associated PAN, the potential risk of accelerating viral replication complicates the use of corticosteroids and cytotoxic agents. In this patient population, studies have shown favorable outcomes with a combination of short-term steroid therapy, antiviral agents, and plasma exchanges [129, 140].

Cutaneous Large-Vessel Vasculitis

Cutaneous large-vessel vasculitis (CLVV) is rare, as there simply are not large vessels found in the skin. These disorders typically target the great vessels of the body such as the aorta and its major branches and include giant cell (temporal) arteritis and Takayasu's arteritis. Giant cell arteritis is more likely in Caucasian patients over 50 years,

with a predilection for the extracranial branches of the carotid artery, while Takayasu's arteritis is more common in persons of Far Eastern descent under age 50, affecting the thoracic aorta and branches supplying the upper extremities [2]. Involvement of large vessels can occasional manifest as lesions of the scalp and tongue [134].

Paraneoplastic Vasculitis

Cutaneous vasculitis is most often associated with relatively benign conditions, but can be part of a paraneoplastic syndrome. The incidence of paraneoplastic vasculitis is unclear, as most information has come from case reports and small series of patients. Difficulty in distinguishing between vasculitis from a malignancy or other causes (chemotherapy, infection), are factors which can confound determination of epidemiologic data. Recommended guidelines have been suggested that would better establish a vasculitis as being part of a paraneoplastic process. These include establishment of a temporal relationship between vasculitis and malignancy and a relationship between effective treatment for malignancy and vaculitis [141]. The reported frequency of cutaneous vasculitis associated with malignancy varies in the literature from about 2 to 5 %, with the vast majority affecting adults [142–144].

The pathogenesis for the development of paraneoplastic vasculitis remains unknown. Tumor antigen induced antibodies directed at normal vessel endothelium, cytokines causing endothelial injury, and impaired clearance of immune complexes injuring endothelial cells are thought to be contributing factors [141, 145].

Paraneoplastic vascultis is seen more commonly with hematologic malignancies (multiple myeloma, T-cell leukemia), as compared with solid tumors [143, 146]. The cause for this stronger association between vasculitis and hematological malignancies is unclear. Solid tumors more commonly associated with vasculitis include those arising from the urinary tract, lung, prostate, colon, renal, breast, and head and neck cancer [143, 144, 147].

The signs and symptoms of paraneoplastic vasculitis will vary depending on the type of vasculitis and the organ system(s) affected. Cutaneous small vessel vasculitis generally occurs with palpable purpura mainly in the dependent areas of the body. Polyarteritis nodosa (PAN) predominantly affects medium-sized arteries and can appear clinically as livedo reticularis, ulcers, and subcutaneous nodules. Other clinical features of the vasculitides also are dependent on the size of the vessel affected, but can include constitutional symptoms, arthralgias, myalgias, paresthesias, abdominal pain and hematuria. Leukocytoclastic angiitis is the most common type of paraneoplastic vasculitis [143, 144]. Malignancy-associated cryoglobulinemic vasculitis, Henoch-Schonlein purpura, polyarteritis nodosa, and giant cell arteritis have also been described [142, 144]. There is no variation in the histologic features between paraneoplastic vasculitis and vasculitis without an associated malignancy.

Vasculitic skin manifestations may represent the initial sign of a neoplastic disease [148]. Most often vasculitis precedes the diagnosis of malignancy, but can be found simultaneously or after the malignancy has been found [149]. In patients with unexplained vasculitis, a malignancy should be considered, particularly in those with advanced age, and when vasculitis becomes chronic, recurrent or is no longer effective to treatment. Infection, medication or connective tissue diseases are much more common causes of cutaneous vasculitis and should be ruled out. Work-up should include a comprehensive medical history and physical exam, as well as appropriate cancer screening. Persistent constitutional symptoms should raise the clinician's index of suspicion for malignancy. Enlarged lymph nodes or viscera palpated on physical exam should necessitate the search for malignancy. In the setting of hematologic abnormalities, a peripheral blood smear and bone marrow biopsy should be considered. Serologies remarkable for anti-neutrophilic or ds-DNA antibody suggests potential presence of a connective tissue disease. Appropriate imaging should be performed, such as a chest radiograph or computed tomography scan to exclude lung cancer. Electrophoresis should be performed to evaluate the presence of abnormal immunoglobulins in serum or urine. In the presence of hematuria, kidney cancer should be excluded. A positive hemoccult or anemia could be an indicator of blood loss from the gastrointestinal tract, requiring endoscopy to rule out a malignancy.

Treatment and prognosis of paraneoplastic vasculitis is generally related to the underlying malignancy. Often times, treatment of the underlying malignancy leads to complete resolution of the vasculitis [145, 147]. Paraneoplastic vasculitis may also require treatment with glucocorticoids alone or in combination with immunosuppressive agents, particularly when a curative treatment of the neoplasm is not possible [145, 147]. A flare of vasculitis can mark the return or progression of the malignancy [144].

Conclusion

Vasculitis, or inflammation of the vasculature, can be caused by many different mechanisms that ultimately result in varying degrees of vessel wall destruction, hemorrhage, ischemia, or infarction of affected organs. Any sized vessel in any organ can be affected and will determine the clinical and pathologic findings, with fibrinoid necrosis being the pathognomonic feature. The patient with vasculitis can present initially to dermatologists,

rheumatologists, or primary medical service, as a wide range of initial presenting signs occur. Because even mild cutaneous disease does not rule out severe and significant systemic involvement, thorough workup including history and physical, serology, histology, and immunofluorescence is mandatory for these patients.

Questions

1. Which of the following statements is true regarding Henoch-Schonlein purpura (HSP) and renal disease?
   A. End-stage renal disease (ESRD) occurs in 50% of patients
   B. Pupura above the waist is associated with the development of renal disease
   C. Azathioprine is not an effective treatment of nephritis
   D. Renal insufficiency is more likely to occur in children than in adults

2. Which of the following regarding Polyarteritis nodosa is correct?
   A. Hepatitis B virus has been implicated as an etiologic agent
   B. Shallow biopsies that sample superficial dermis are sufficient for diagnosis
   C. Is the prototype small-vessel vasculitis
   D. Plasmapheresis is the mainstay of therapy

3. Each of the following distinguishes Churg-Strauss syndrome from Wegener's granulomatosis except
   A. Eosinophilia
   B. Associated atopy and asthma
   C. Higher levels of p-ANCA
   D. Granulomatous inflammation

4. The following therapeutic agents have been shown effective for induction of remission in ANCA-associated vasculitis except
   A. Corticosteroids
   B. Rituximab
   C. Cyclophosphamide
   D. Dapsone

5. All of the following characterize Cryoglobulinemic vasculitis except
   A. Cryoglobulin type I represents a true vasculitis
   B. Palpable purpura of the legs is the most common lesion seen
   C. Cryoglobulin type II patients demonstrate monoclonal IgM rheumatoid factor and polyclonal IgG
   D. Cold enhances most of the lesions

Answers

1. B
2. A
3. D
4. D
5. A

Allergic Urticaria

27

Eric T. Oliver and Sarbjit S. Saini

Abstract

Urticaria, commonly known as hives, is characterized by the episodic appearance of pruritic, erythematous papules or plaques with superficial swelling of the dermis. Urticaria is classified as either acute or chronic based on symptom duration. Acute urticaria, which is defined as having hives for less than 6 weeks, is estimated to occur in 15–23 % of the population, although cases are likely to be underreported due to the short-lived nature of the disease. Chronic urticaria, defined by symptom duration of greater than 6 weeks, can be further classified as physical urticaria or chronic idiopathic urticaria (CIU). Physical urticarias are comprised of many subtypes in which a specific trigger can quickly induce hives, while the majority of hives in CIU do not occur as a result of a known trigger. The prevalence of physical urticaria is not well-established, but it is thought to account for 20–35 % of all cases of chronic urticaria. CIU, which has been renamed as chronic spontaneous urticaria (CSU) in recent guidelines, occurs in approximately 0.1–3 % of the population and, like many forms of chronic urticaria, has a female predominance.

Key Points

- Urticarial lesions, commonly known as hives, are produced in the skin by the degranulation of mast cells.
- Urticaria can be acute or chronic (lasting greater than 6 weeks), and may be allergic (mediated by immunoglobulin E) or nonallergic (mediated by pharmacologic effects of drugs such as aspirin).
- There are a multitude of causes of urticaria, including food or medication allergies and infections.
- There are subsets of chronic urticaria that are caused by physical factors such as exposure of the skin to pressure, vibration, cold, or even water (aquagenic urticaria).
- In most cases of chronic urticaria, it is not possible to identify an etiology. One theory is that a subset of these cases may have an autoimmune basis.
- Urticaria can be a presenting sign of vasculitis. Urticaria may also be associated with autoimmune diseases such as Hashimoto's thyroiditis.
- Treatment is based on identifying a trigger factor. Antihistamines are a cornerstone of treatment. For more severe cases, immune modulating drugs or biologic agents such as omalizumab (Xolair) may be necessary to control signs and symptoms of this process.

Overview of Urticaria

Urticaria, commonly known as hives, is characterized by the episodic appearance of pruritic, erythematous papules or plaques with superficial swelling of the dermis (see Fig. 27.1). Urticaria is classified as either acute or chronic based on symptom duration. Acute urticaria, which is defined as having hives for less than 6 weeks, is estimated to occur in 15–23 % of the population, although cases are likely to be underreported due to the short-lived nature of the disease [1]. Chronic urticaria, defined by symptom duration of greater than 6 weeks, can be further classified as physical urticaria or chronic idiopathic urticaria (CIU). Physical urticarias are comprised of many subtypes in which a specific trigger can quickly induce hives, while the majority of hives in CIU do not occur as a result of a known trigger [2]. The prevalence of physical urticaria is not well-established, but it is thought to account for 20–35 % of all cases of chronic urticaria [3, 4]. CIU, which has been renamed as chronic spontaneous urticaria (CSU) in recent guidelines, occurs in approximately 0.1–3 % of the population and, like many forms of chronic urticaria, has a female predominance [1, 5–7].

Clinical Features of Urticaria

Clinically, urticarial lesions are intensely pruritic and can appear anywhere on the body, typically appearing quickly and lasting 1–24 h [8]. Unlike other pruritic skin diseases such as atopic dermatitis, patients with urticaria find relief from rubbing the skin versus scratching, making excoriated skin a less common finding in CSU [9]. Lesions can vary in size and can be confluent (see Fig. 27.1). The swelling observed with urticaria results from the movement of plasma from small blood vessels into adjacent connective tissue [4]. Angioedema often coexists with urticaria, and develops from a deeper, swelling of the dermis, subcutaneous, and submucosal tissues. Angioedema is described as painful or burning in quality, and is rarely pruritic [10]. It frequently involves mucous membranes with common locations being the face, lips, tongue, pharynx, and extremities (see Fig. 27.2) [9].

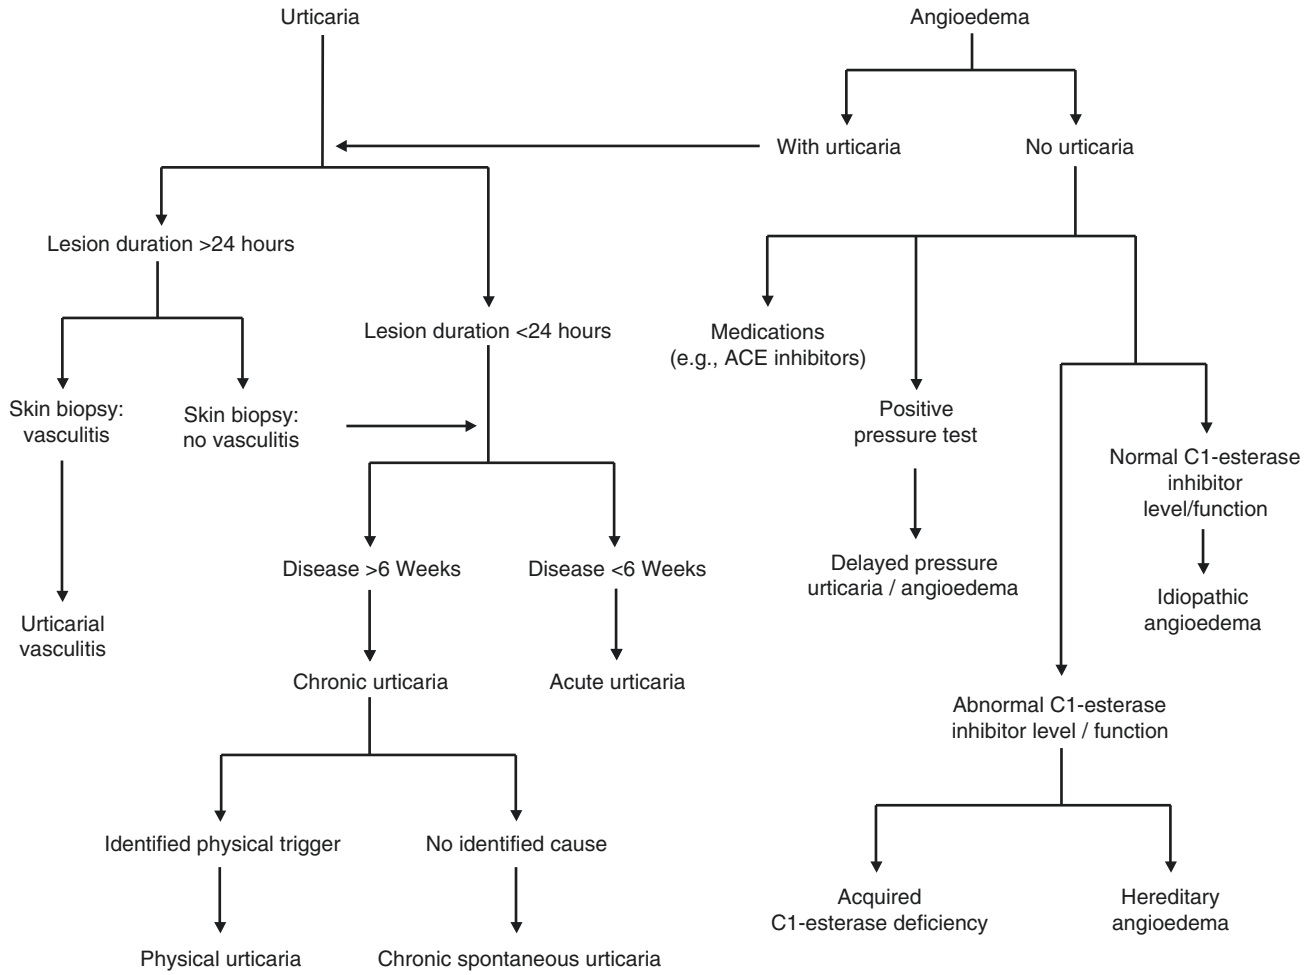

Fig. 27.3 Diagnosis algorithm for urticaria

In contrast, urticaria, both acute and chronic, rarely involves mucosal surfaces [10]. Angioedema typically has a slower resolution time than hives, often greater than 24 h and larger areas may take longer to resolve [9, 10].

History and Physical Exam

In diagnosing either acute or chronic urticaria, a good history is the most critical element (see Fig. 27.3). It is important to assess the time of onset of hives, as some patients may experience diurnal variation, as well as the temporal association with certain environmental exposures or stressors. The most important aspect of history-taking is to identify the inducing agent for the patient's urticaria and/or angioedema. This involves questions regarding recent use of medications, including antibiotics, nonsteroidal anti-inflammatory agents, and aspirin. A history of food ingested shortly prior to symptom occurrence, recent changes in environment, and possible insect stings should also be sought.

Patients should provide a description of lesions including elements such as shape, size, distribution, color, pigmentation, and the quality of pain or itch. Urticarial lesions are typically pruritic and usually demonstrate complete resolution without skin pigment changes. A clinician must also assess for the presence of angioedema in association with urticaria. In patients with isolated angioedema without urticaria, family history is critical to assess for hereditary angioedema (HAE), an autosomal dominant condition resulting from a defect in C1 esterase inhibitor function [10].

Additional questions should include recent infections, thyroid disease symptoms, surgical history of implantable devices, and for females, the relationship of hives to their menstrual cycle or pregnancy. Further evaluation of exposures, including patient's work, may assist in understanding the timing or exacerbation of lesions. It is also important to evaluate how the patient is coping and what therapeutics, including nonprescription medications and dietary regimens, are being used and if they are providing any relief.

Along with the detailed history, the physical exam in a patient with urticaria can be helpful in excluding other

Fig. 27.4 Dermatographism (By permission of B Cohen and CU Lehmann, DermAtlas, Johns Hopkins University, 2000–2007)

disorders. It is important to do a complete exam as well as assess for dermatographism, wheals brought out by stroking of the skin (see Fig. 27.4). The size, distribution, and color of lesions should be noted. Wheals are characteristically pink or red due to histamine-induced dilatation of vessels in the skin while vasculitic lesions have a darker red or purple appearance resulting from vascular damage and leakage [6]. Urticarial lesions can be easily blanched. The physician should also inspect mucous membranes for the presence of angioedema (see Fig. 27.2). Patients should also be assessed for thyroid gland abnormalities on physical exam. Physical urticarias may require additional maneuvers, such as an ice-cube test to evaluate cold urticaria, and should be tailored to the suspected type of urticaria (see Fig. 27.5 and Table 27.1) [1]. No specific laboratory testing is needed for all patients with urticaria and should be dependent on the subtype of urticaria: acute, chronic idiopathic/spontaneous, or physical [11].

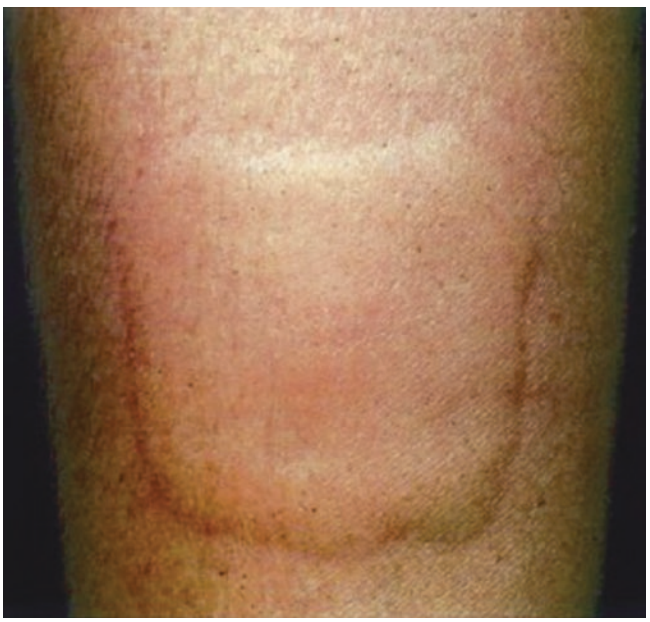

Fig. 27.5 Ice-cube test for cold urticaria (By permission the Department of Dermatology, University of Iowa College of Medicine)

Acute Urticaria

Acute urticaria is classified as hives of less than 6 weeks duration and accounts for up to 56 % of cases of urticaria [12]. Lesions are short-lived, lasting less than 24 h but can return [12]. Clinically, acute urticaria cannot be distinguished from chronic urticaria by physical exam alone. No routine laboratory testing should be done unless used to identify the trigger, such as in suspected food or drug reactions.

Acute urticaria can be classified as allergic (IgE-mediated) or nonallergic. IgE-mediated urticaria may occur in allergic responses to foods, insect stings, and drugs. Non-IgE mediated urticaria may occur in response to a "pseudoallergen" like aspirin, or result from other immunologic responses as seen with blood transfusions, serum sickness, and febrile illnesses [7].

Urticaria related to an IgE-mediated food allergy should occur within 30 min to 2 h following exposure. Testing for food allergies is appropriate in acute urticaria if the patient's history reveals urticaria associated with other symptoms such as nausea or vomiting, however food allergies are not a common cause of acute urticaria in adults. In children, food allergy plays a larger role in acute urticaria, such as with milk, egg, soy, peanuts, and wheat [13].

Drugs can also be responsible for acute urticaria, through either IgE or non-IgE mediated processes. Drugs have been implicated as a cause of acute urticaria in 9.2–27 % of cases [12]. Penicillin is an example of an allergen, which can elicit urticaria through an IgE-dependent mechanism, while acetyl salicylic acid (aspirin) is a frequent non-IgE mediated stimulus for histamine release [12]. ACE inhibitors have also been implicated as triggers for angioedema through effects on the bradykinin pathway [10].

Viral infections are the most common reason for acute urticaria with onset of hives typically occurring a few days after the start of viral symptoms. The coexistence of acute urticaria and upper respiratory infections reported between 28 and 63.4 % [13–16]. Surprisingly, no identifiable trigger is found in 30–50 % of cases of acute urticaria [12].

Chronic Urticaria

Chronic urticaria by definition is wheals occurring at least 2 days per week of at least 6 weeks duration [17]. In contrast to acute urticaria, chronic urticaria is unlikely to be the result of IgE-mediated allergic reactions [18, 19]. Chronic urticaria can be divided into two subtypes: chronic idiopathic/spontaneous urticaria and physical urticaria. Chronic spontaneous

Table 27.1 Classification of physical urticaria

Type	% of all urticaria	Pathogenesis	Features	Reaction times	Provocation test	Differences on biopsy	Treatment
Dermatographic	7–10 %	Unknown, but elevated plasma histamine levels and positive passive transfer experiments, indicate an IgE-mediated process.	Mechanical shearing forces lead to lesions. Koebner's phenomenon, a wheal and flare reaction at pressure sites (e.g. waistband), is present. Higher frequency in young adults.	(1) Immediate – within 2–5 min; lasting 30 min (2) Intermediate – within 30 min to 2 h; lasting 3–9 h (3) Late onset (rare) – within 4–6 h; lasting 24–48 h	Stroke forearm or back with tongue blade	Scant leukocytic infiltrate in upper dermis.	Nonsedating H_1 blocker.
Delayed pressure	3–5 %	Unknown	Constant application of pressure to skin results in erythema and superficial and deep swelling. Pressure areas commonly affected. Male predominance.	Within 3–12 h; lasting up to 48 h	Application of weight to one area for minimum 10 min	Infiltrate typically located in mid- to lower dermis. Neutrophils may be seen in lower dermis.	Nonsedating H_1 blocker. Short course of corticosteroids, leukotriene antagonists may also be used.
Vibratory	Rare	Unknown, but elevated histamine levels and mast cell degranulation reported following application of stimuli. Familial cases have autosomal dominant inheritance.	Occurs after vibratory stimuli (e.g. lawn mowing or motorcycling).	Within minutes; lasting up to 24 h	Challenge with vibratory stimuli (e.g. vortex mixer) for 5 min		Avoidance of trigger.
Familial cold		Gene alteration at CIAS1 on chromosome 1q.44. Autosomal dominant inheritance.	Immediate type characterized by burning papules or macules and systemic symptoms such as arthralgias and fever. Delayed type follows cold exposure.	Delayed occurs within 9–18 h of cold exposure, lasting 2–3 days.		(1) Immediate – Polymorphonuclear infiltrates. (2) Delayed – Mononuclear infiltrates.	

(continued)

Table 27.1 (continued)

Type	% of all urticaria	Pathogenesis	Features	Reaction times	Provocation test	Differences on biopsy	Treatment
Cold contact	3–5 %	IgE-mediated histamine release with IgM and IgG antibodies reported.	Occurs with skin cold exposure. May have angioedema. Rare cases of anaphylaxis after total body exposure to cold.	Within 2–5 min as skin re-warms.	Ice cube placement to area for 10–20 min	Loose lymphocytic and leukocytic infiltrates. Platelet infiltrates and vascular changes may also be present.	Nonsedating H_1 blocker. Leukotriene antagonist may be added.
Heat contact		Unknown, but complement system is afffected.	Occurs at sites of heat application. Divided into immediate nonfamilial and delayed familial.	(1) Immediate – within 5 min; up to 1 h (2) Delayed – within 6–18 h; lasting 12–24 h	Local contact with hot water or object		Avoidance of trigger.
Solar	Rare	Unknown, but thought to be IgE-mediated with increased serum histamine levels, mast cell and eosinophil degranulation, and photoallergen production. Secondary solar urticaria is characterized by a porphyrin metabolism abnormality leading to complement activation.	Induced by sunlight or indoor lighting exposure (wavelengths 280–760 nm). Most common in third and fourth decades of life, commonly affecting young adults.	Within 2–3 min; lasting 3–4 h	Expose to UV light		Avoidance of sun exposure and skin protection. Nonsedating H_1 blocker.

Type	% of all urticaria	Pathogenesis	Features	Reaction times	Provocation test	Differences on biopsy	Treatment
Cholinergic	2–7 %	Unknown, but acetylcholine, released by exercise, can release histamine. Elevated histamine and eosinophil and neutrophil chemotactic factors reported.	Due to a rise in core body temperature. Usually start on face and neck, then spreading. The pruritic wheals are small (1–5 mm) with "fried egg" appearance. More common in young adults.	Within minutes; lasting less than 1 h	Physical activity (e.g. running in place for 5 min)	Loose lymphocytic and leukocytic infiltrates in upper dermis.	Nonsedating H_1 blocker. Increase dose if necessary. In addition, danazol can be used.
Aquagenic	Rare	Unknown, but a proposed mechanism is that water induces formation of histamine-releasing substances.	Contact with water induces small hives similar to those seen in cholinergic urticaria. More common in young adults.	Within 2 min; lasting up to 1 h	Apply water compress for 30 min	Mast cell degranulation noted in challenged skin.	Avoidance of trigger.
Contact		May be IgE-mediated.	Inciting triggers are plants, foods, drugs, and chemicals.	Within minutes; lasting less than a few hours.			Avoidance of trigger.
Adrenergic		Unknown	Pin-sized wheals elicited by stress.	Within minutes; lasting less than 1 h			Propanolol

Source: Data from Zuberbier [6], Kaplan [10], Haas et al. [46], Kontou-Fili et al. [211]

urticaria (CSU) usually lacks an identifiable and consistent trigger, whereas physical urticaria is categorized into subtypes based on the specific trigger(s) which directly elicit hives within minutes. Lesions in physical urticaria generally do not last longer than a few hours, while CSU lesions typically are present for at least 6–8 h [4, 9, 17]. Some crossover exists between CSU and physical urticarias with 40 % of CSU patients displaying dermatographism [20].

Physical Urticaria

Physical urticaria is defined by the ability of a physical stimulus to reproducibly elicit urticarial lesions and accounts for 20–35 % of all cases of chronic urticaria [4]. Physical urticaria can be further divided into many subtypes depending on the physical stimulus (Table 27.1), and more than one subtype can exist simultaneously in one individual [17]. Evaluation of physical urticaria is strongly guided by the patient's history and provocative testing.

Mechanical shearing forces, such as rubbing or scratching the skin, are the catalyst for *dermatographic urticaria*, the most frequent type of physical urticaria, where lesions arise a few minutes following application of the trigger [2, 7]. Features of physical urticarias can be common in the general population with dermatographism reported in approximately 2–5 % of subjects with no history of chronic urticaria [21]. *Delayed pressure urticaria* and angioedema result after vertical pressure is applied to the skin with lesions, often painful, appearing several hours after application and persisting for up to 48 h; this subtype of urticaria predominantly affects the palms, soles, buttocks, and back and has a male predominance [7, 22]. *Vibratory urticaria* is instigated by vibratory forces, is quite rare, and can be described as familial with autosomal dominant inheritance or may occur in sporadic pattern [21, 23].

Familial cold urticaria is an autosomal dominant disease mainly affecting young adults and is due to gene alteration CIAS1 at chromosome 1q.44. This gene locus is also involved in Muckle-Wells syndrome and autosomal dominant periodic fever syndrome, both are diseases that demonstrate cold-sensitivity [24, 25]. *Cold contact urticaria*, which occurs after direct contact of skin to a cold object or air, also occurs predominantly in women, younger adults, and cold climates. This subtype can be idiopathic or can be incited by bacterial or viral infections [22]. *Heat contact urticaria* is rare and results after the skin directly comes in contact with a hot object or warm air [21, 22]. Ultra violet light is the trigger for *solar urticaria*, an IgE-dependent subtype that occurs at wavelengths of 280–760 nm and more commonly affects females and young adults [21, 22].

Cholinergic urticaria is aggravated by a rise in body temperature and thus is triggered by exercise, bathing, emotions, and less with alcohol or spicy food consumption [21, 22]. Cholinergic urticaria typically involves young adults and is characterized by small, pin-sized wheals (1–5 mm diameter), sometimes with a white halo, that last for less than an hour. The symptoms of cholinergic urticaria can be so mild that an estimated 80 % of people with this urticarial subtype do not seek medical advice [7, 22]. Cholinergic urticaria should be distinguished from exercise-induced anaphylaxis which involves the development of systemic symptoms [21]. *Adrenergic urticaria* is also described as pin-sized wheals but unlike cholinergic urticaria, it is elicited by stress and can by treated with propanolol [21, 22]. *Aquagenic urticaria*, which is elicited by any exposure to water regardless of its temperature, mimics cholinergic urticaria in the appearance of its lesions, has a female predominance and more often affects young adults [21, 22].

Contact urticaria can be IgE-mediated or non-IgE-mediated, with the inciting triggers ranging from plants such as grass, foods like peanut, drugs, cosmetics, chemicals, and textiles. Contact urticaria has a short-lived duration like cholinergic and adrenergic urticarial subtypes, occurring within minutes of exposure, and resolving within a few hours [21]. Systemic symptoms can be present with contact urticaria, especially if IgE-mediated [22].

Chronic Spontaneous Urticaria

CSU accounts for approximately 80 % of all cases of chronic urticaria [11]. CSU is episodic and persistent in nature with typical disease duration of 3–5 years [26]. One prospective study of CSU subjects demonstrated that at 6 months, 94 % of patients were still active, 75 % at 12 months, 52 % at 24 months, 43 % at 36 months, and 14 % at 5 years [3]. Likewise, 18.5 %, 54 %, and 67.7 % of children were in remission at 1, 3, and 5 years, respectively, after the onset of symptoms [27]. Disease duration was directly correlated to the presence of severe disease, angioedema, and the presence of anti-thyroid antibodies [3]. Angioedema coexists with urticaria in approximately 40–50 % of CSU patients [26, 28]. The most common and bothersome symptom for patients with CSU is pruritus, which frequently adversely affects their sleep. Fatigue and gastrointestinal symptoms have been previously described with exacerbations, however respiratory complaints and arthralgia also noted [9, 29].

CSU can be a socially and financially disabling disease with an impact on quality of life, comparable to that of coronary heart disease [30]. One study of 170 chronic urticaria patients reported individuals with CSU alone experience a moderate impairment in their quality of life as measured by the Dermatology Life Quality Index (DLQI), while those with CSU and angioedema and/or delayed pressure features had significantly greater quality of life impairment [31]. Compared to other debilitating dermatological diseases, the quality of life impairment in chronic

urticaria is similar to patients with severe atopic dermatitis and worse than patients with psoriasis, acne, and vitiligo [31]. Part of the frustration patients experience results from the lack of an identifiable trigger for urticarial exacerbations, leading to an unpredictable disease. CSU also carries an economic burden for patients with multiple medications, medical evaluations, work absence, and use of the emergency department [32, 33].

Aspirin and nonsteroidal anti-inflammatory agents (NSAIDs) can substantially aggravate urticaria and angioedema in CSU subjects via inhibition of prostaglandin synthesis. Selective cyclooxygenase-2 (COX-2) inhibitors lead to less symptoms than aspirin and traditional NSAIDs and provide an alternative choice for analgesics in CSU patients [34]. One study of chronic urticaria patients challenged with aspirin demonstrated that approximately 20 % of CSU subjects had a reaction, while those with physical urticaria were unaffected [35]. Patient history of suspected aspirin sensitivity correlates very well with reactions during aspirin challenges, as one study found that 92 % of patients with a history of reaction reacted during an aspirin challenge [36]. Patients should be advised that aspirin and traditional NSAIDs have the potential to exacerbate their disease, and should be informed that salicylates may be an occult ingredient in medications or supplements. Studies to assess the role of salicylates in foods demonstrated inconclusive results, and "low salicylate" diets are not generally recommended [11].

There is a higher prevalence of thyroid disease in CSU than in the general population. Hashimoto's thyroiditis and, less commonly, Graves' disease are the only reported systemic diseases with a correlation to CSU [37–40]. It has been reported that 27 % of CSU subjects have thyroid autoantibodies, nearly twice the rate observed in the normal population. Typically, the majority of those with thyroid autoantibodies are euthyroid and some may be hypothyroid, but it is rare for these individuals to be hyperthyroid [40–42]. Currently, these autoantibodies are not thought to be pathogenic in urticarial [43] but lend support to an autoimmune basis for a subset of CSU [44]. Studies of thyroid hormone replacement in patients with concomitant CSU and thyroid autoantibodies have yielded mixed results [43, 45]. The current recommendation is to screen patients for underlying thyroid disease and to treat any underlying thyroid disease, but no clear evidence exists for the use of thyroid hormone in euthyroid patients who present thyroid autoantibodies.

Histology

The classic wheal observed in both acute and chronic urticaria represents dermal edema with dilatation of postcapillary venules and lymphatic vessels (see new Fig. 27.6a, b) [46]. In biopsies, the leukocyte infiltrate is characteristically perivascular and classically consists of lymphocytes, neutrophils, macrophages, basophils, and occasionally eosinophils (see Fig. 27.6a, b) [47, 48]. Degranulated mast cells are also noted in urticarial lesions [48]. Histologically, CSU shares lesional features with acute urticaria consisting of a lymphocytic-predominant perivascular infiltrate. Occasionally, neutrophils are seen within capillary or post-capillary venule walls, but unlike the neutrophilic infiltrate seen in urticarial vasculitis, there is no evidence of vascular damage, nuclear debris, or red cell extravasation (Fig. 27.6b, c) [1]. The presence of intradermal CD3+, CD4+, CD8+, and CD25+ T-cells, as well as eosinophils, neutrophils, basophils, and macrophages is significantly higher in CSU skin lesions as compared to skin of nonatopic individuals [48]. A survey of basophil numbers in the skin biopsies from 24 skin diseases revealed that CSU had among the highest numbers of infiltrating basophils [49].

Although the cellular infiltrate of CSU resembles that seen in allergen-induced late phase skin biopsies, the cytokine profile in CSU is T_H1 and T_H2 with higher expression of IFN-γ, as well as IL-4 and IL-5 in the skin [48]. By immunohistochemistry, TNF-α and IL-3 protein expression are increased in acute and chronic urticarial lesions [50]. TNF-α is a cytokine produced by epithelial cells, leukocytes, and mast cells [51, 52]. TNF-α can induce mast cell mediator release and increase endothelial adhesion molecule expression, thus an increase of this cytokine in urticaria may contribute to the leukocyte infiltrate observed [51, 53, 54]. IL-3 is a cytokine produced by mast cells, T-cells, monocytes, and granulocytes, and can increase expression of the endothelial adhesion molecule P-selectin [55–59]. P-selectin expression is elevated in both the skin and serum of chronic urticaria patients [60]. Two endothelial adhesion molecules, integrins ELAM-1 and ICAM-1, were upregulated in acute and chronic urticarial lesions [61]. The persistent expression of ELAM-1 and ICAM-1 in lesions older than 6 h may help to explain the long duration of urticarial wheals [61].

Pathophysiology of Urticaria

Whereas the pathophysiology of allergic urticaria supports a specific allergen interacting with IgE bound on skin mast cells, chronic urticarias do not appear to involve IgE binding to allergen [4]. The pathophysiology of both physical urticaria and CSU is unknown. Although mast cell degranulation is a clear component in some subtypes of physical urticaria (dermatographic, cholinergic, cold, and solar urticaria), serum IgE may also play a role as demonstrated by passive transfer experiments [9, 22, 42]. An acute rise in serum histamine and PGD2 levels has been observed in cold urticaria following cold exposure [62]. In CSU, there is also evidence for mast cell degranulation observed on skin biopsies [48]. Mast cell number appears to be similar in nonlesional and

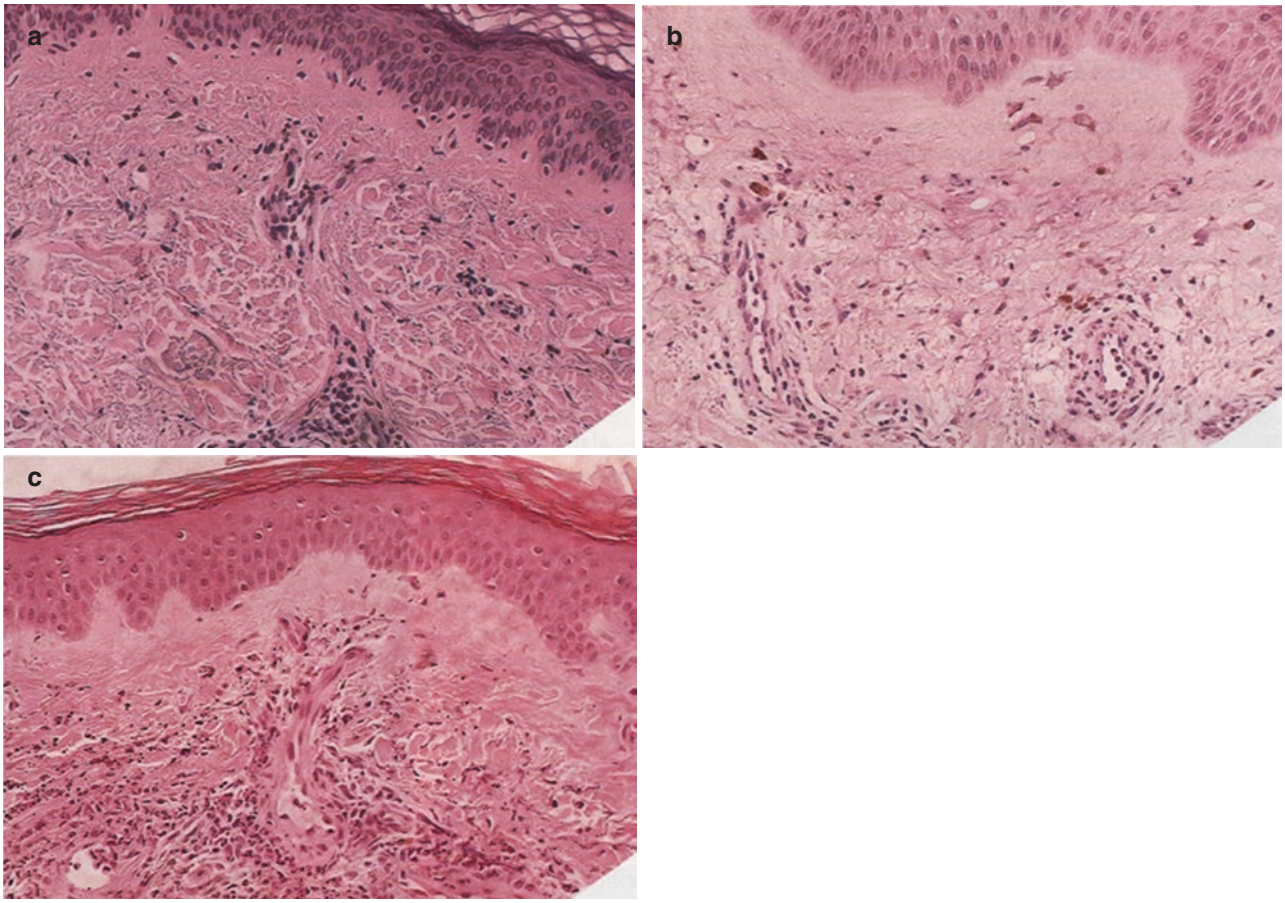

Fig. 27.6 Biopsy of urticarial lesion. (**a**) Representative of acute urticaria with dermal edema and a perivascular mononuclear infiltrate. (**b**) Chronic urticaria is may also have infiltration of neutrophils and/or eosinophils without evidence of vasculitis. (**c**) Urticarial vasculitis is shown with a large perivascular infiltration of neutrophils, and even some neutrophilic damage (By permission of Fireman and Savin [212])

lesional CSU skin and normal skin, using tryptase and chymase staining [63]. Although mast cell number is not altered, increased mast cell releasability has been demonstrated in patients with CSU with active disease, which resolves with disease remission, suggesting that the mast cell alteration is reversible [64]. Cultured peripheral blood mast cells from CSU patients have been found to have higher levels of spontaneous histamine release compared to healthy controls [65]. In contrast, another study found higher levels of total tryptase (a reflection of the body burden of mast cells) in the sera of chronic urticaria patients compared to controls, but no difference was found in mature tryptase levels (reflects mast cell degranulation) [66].

There has been accumulating evidence that basophils play a role in CSU [67]. Basophils have been reported in both lesional and nonlesional CSU skin using BB1 staining [48, 49, 68]. Blood basopenia is a feature of active CSU disease, and the reduction in basophil number correlates inversely with disease severity [69, 70]. As seen with allergen late-phase reactions, basophils that have migrated to the skin may play a role in duration as well as magnitude of urticarial lesions [71]. Select basophil surface markers correlate to basophil activation and have been measured in CSU, in particular, CD63, CD69, and CD203c [72–75]. CD63 is a member of the transmembrane-4 superfamily is rapidly mobilized onto the basophil surface by IL-3, allergen, anti-IgE and other stimuli of degranulation while CD69 is slowly induced following IL-3 stimulation [72, 76]. CD203c, also known as ectonucleotide pyrophosphatase, is unique to basophils, mast cells, and their progenitors and is mobilized by allergen, anti-IgE, and IL-3 [77–81]. CSU subjects demonstrate enhanced basophil surface expression of CD63, CD69, and CD203c when compared to non-allergic controls [49, 75].

Furthermore, CSU basophils demonstrated a decreased functional response to IgE receptor stimulation but not to other stimuli [67, 82–85]. Early studies showed that histamine release mediated via the basophil high affinity IgE receptor, FcεRI, was diminished in subjects with CSU versus controls [84, 85]. This finding is paradoxical since anti-histamines are used to treat CSU, and pruritus, the predominant symptom in CSU, is histamine-dependent. A later study has shown that

basophils in CSU have altered FcεRI-mediated histamine release and have found two patterns of histamine release within subjects with active CSU disease [83]. Approximately 50% of subjects with CSU tested were found to be "responders," releasing greater than 10% of cellular histamine content when triggered with a polyclonal anti-IgE stimulus, and 50% were "nonresponders", releasing less than 10% of cellular histamine content [83]. Also, these two basophil phenotypes appear to be stable over time as subjects maintain active disease, but this altered basophil function improves with disease remission [84, 86].

In a subset of CSU referred to as "autoimmune urticaria," histamine-releasing autoantibodies have been reported and hypothesized to be pathogenic, although this remains controversial [44, 87–92]. These IgG autoantibodies are thought to activate mast cells and basophils via complement and act by C5a to potentiate histamine release [93]. These autoantibodies are detected in 30–40% of patients with CSU, and the majority of these autoantibodies are directed against the alpha subunit of the high affinity IgE receptor, FcεRI, while the remainder directly target IgE [29, 89]. In favor of autoimmune mechanisms in CSU is the increased incidence of thyroid autoantibodies, specifically anti-microsomal and anti-thyroglobulin, as well as reports of higher frequencies of certain HLA class II alleles (DR4, DQ8) in CSU patients [37, 38, 40, 41, 94]. The autoantibody theory is also supported by the observation that autologous serum injected into a CSU patient's skin can result in a wheal-and-flare response [95, 96]. However, a recent study demonstrated that healthy controls and patients with allergic rhinitis can also have a positive ASST, raising doubt about the usefulness of the ASST in the diagnosis of urticaria [11, 97, 98].

Since the presence of an ASST response alone does not prove that autoantibodies are present, further studies were done and demonstrated that sera from ASST-positive CSU subjects also had histamine-releasing activity (HRA) from healthy donor basophils [89, 99]. A large study found that 40% of CSU subjects' sera exhibit HRA when performed *in vitro* on donor basophils [88]. Although HRA is reported to indicate the presence of autoantibodies, the presence of HRA and the presence of autoantibodies by Western blotting in CSU subjects do not agree [100, 101]. The presence of serum HRA had no effect on the character of the leukocyte infiltrates of new (<4 h) or established (>12 h) skin lesions even though autoantibody presence has been previously linked to increased disease severity [48, 101, 102]. In addition, serum HRA has been demonstrated in healthy patients' sera, and there is no correlation between HRA and CSU basophil FcεRI function [83, 103].

Another issue with the autoantibody hypothesis is that anti- FcεRIα autoantibodies are also found at a similar frequency in other autoimmune diseases like systemic lupus erythematous (SLE) and dermatomyositis as well as in normal subjects [104]. Similar frequencies of positive results have been found between CSU and SLE patients using a commercial test which measures the ability of a patient's serum to trigger histamine release from donor basophils [105]. This lack of diagnostic specificity of the HRA assay raises concern about its usefulness in determining disease pathogenesis in CSU patients [103]. Also, anaphylaxis is rarely seen in CSU, which is a skin-limited disease, but would be expected to occur more often if autoantibodies directed against basophils and mast cells IgE receptor are present.

Laboratory Evaluation

In most cases of urticaria, history and physical examination are sufficient for diagnosis [6], and a thorough history may identify potential triggers such as medications. Patients with chronic urticaria who are resistant to conventional therapies or experience atypical lesion features (i.e., hyperpigmentation, bruising, prolonged duration) may need further evaluation to exclude secondary causes for hives. Laboratory testing should be limited because previous studies have shown extensive testing provides low yield [11, 106]. Patients who have symptoms or a family history of thyroid disease would warrant thyroid screening by measuring thyroid stimulating hormone and possibly thyroid autoantibodies.

For physical urticarias, patients are unlikely to benefit from further laboratory testing [107–109]. The physical exam can assist substantially in defining the type of physical urticaria that is present based on provocative tests (see Table 27.1). Patients with significant angioedema without urticaria should have complement levels checked along with C1 inhibitor testing (functional and quantitative levels) to screen for *hereditary and acquired angioedema* due to C1 esterase inhibitor deficiency which would result in low complement C4 levels [10].

Infections have been implicated in urticaria. As previously mentioned, viral infections, especially viral upper respiratory infections are a common cause of acute urticaria. A study in a Japan, which has a high prevalence of hepatitis C, demonstrated that this infection may manifest with chronic urticarial lesions, but further work in areas with lower prevalence has not supported this finding [110, 111]. It is recommended that individuals with risk factors for infectious hepatitis should have the appropriate testing. In recent years, Helicobacter pylori has been implicated to CSU but controlled studies have not been able to establish this link [112–115]. Parasitic infections are a rare cause of urticaria that should be investigated by stool examination for ova and parasites. Bacterial cultures are rarely necessitated as bacterial infections are not a common cause of urticaria [116].

Allergy testing may be of limited use in acute urticaria. Serum specific IgE testing (ImmunoCAP) or skin testing may be beneficial when a Type-I hypersensitivity reaction is strongly suspected. Skin testing is often difficult to perform in chronic urticaria patients due to the high prevalence of dermatographism and delayed pressure features in this group as well as their dependence on anti-histamines. ImmunoCAP testing is not affected by medications. A careful history can help to identify which allergens to test. Extensive food or inhalant allergy testing should not be performed blindly in patients with chronic urticaria as this does not improve patient outcomes and is not a cost-effective approach [11].

Another skin test used in the past to define autoimmune urticaria is the autologous skin serum test (ASST). Since the presence or absence of the ASST or autoantibodies does not alter treatment options in patients, the ASST should not be used as a diagnostic tool for chronic urticaria [7, 11]. Newer basophil-based assays to check for serum histamine releasing activity (HRA) also lack specificity and validation for clinical use [103, 105, 117, 118].

Other Conditions Associated with Urticarial Lesions

Urticarial vasculitis (*UV*) must be excluded in patients with chronic urticaria unresponsive to conventional therapy. UV is a Type-III hypersensitivity reaction mediated by antigen-antibody complexes deposited on vascular endothelium, and may be precipitated by infections, medications or neoplasms [119]. The duration of UV lesions is characteristically greater than 24 h and may be painful and purpuric, leaving residual skin changes [120]. These patients may also complain of systemic symptoms and have laboratory findings consistent with an inflammatory process, such as an elevated ESR or C-reactive protein or low complement levels [120]. To rule out urticarial vasculitis, the definitive test is a skin biopsy. The features of urticarial vasculitis on biopsy are leukocytoclasia, extravasation of red blood cells, fibrin deposition, leukocyte invasion of the vascular endothelium, and endothelial edema, of which the latter three features may also be observed in chronic urticaria (see Fig. 27.6) [1, 120].

There are other diseases associated with urticarial lesions, and patients presenting with appropriate symptoms should be evaluated for these disorders. *Urticaria pigmentosa* (*UP*), a subtype of mastocytosis, may mimic urticarial lesions with the exception that these are pigmented and typically longer-lasting lesions than those in urticaria. These lesions typically urticate with scratching (Darier's sign), however, the diagnosis must be confirmed by biopsy and histology in each case [121, 122]. UP is often limited in children, as there is generally a spontaneous regression of the condition by puberty [123]. Adult mastocytosis, however, is an aggressive disease, and all adults with UP should have a total tryptase level measured and undergo a bone marrow biopsy [121].

Bullous pemphigoid (*BP*) is an autoimmune blistering skin disease which, in its early stages, may also present with urticarial lesions. The primary lesions of BP result from IgG autoantibodies are directed primarily against the BP 230 and BP 180 antigens, which are components of the hemidesmosome adhesion complex and allow the basal cells of the epidermis to adhere to the basement membrane. BP primarily affects older patients, and should be considered in urticaria develops in elderly individuals [120].

Subacute cutaneous lupus erythematosus (*SCLE*) can present with urticarial-like lesions which can be mistaken for CSU. SCLE is characterized by nonscaring lesions that typically burn more than they itch. These lesions tend to fluctuate in appearance and occur predominantly on sun-exposed areas of the body, often hours to days following significant sun exposure [120].

The presence of systemic symptoms along with urticaria should raise concern for additional conditions. *Schnitzler's syndrome* is associated with recurrent urticarial lesions and dermatographism, fever, arthralgia, bone pain, lymphadenopathy, a high ESR, and IgM gammopathy. Patients with Schnitzler's syndrome generally have a pale rose or red eruption consisting of macules papules, and plaques which tend to occur in crops, last <24 h, and are usually not significantly pruritic [124]. Angioedema is not a common is not feature of this condition. There is a delay in diagnosis (usually 5 years or longer) because most patients are instead labeled as having antihistamine-unresponsive CSU, and patients with these symptoms warrant a serum protein electrophoresis [120].

Sweet's syndrome (acute febrile neutrophilic dermatosis) was first described in 1964 by Robert Sweet [125]. It is characterized by fever, neutrophilia (with blood polymorphonuclear leukocyte level greater than 10,000/mm^3), and painful, erythematous papules or plaques (dense dermal neutrophilic infiltrate) on the extremities, face, and neck [125]. Classic Sweet syndrome is associated with infection of the respiratory or gastrointestinal tract, or may occur after vaccination. There is also a paraneoplastic variant of Sweet syndrome which is most commonly associated with lymphoproliferative disorders, and occasionally associated with solid malignant tumors [126].

Also presenting with fever and urticaria are *serum sickness* (*SS*), *serum sickness-like reactions* (*SSLR*), and *urticaria multiforme*. Both SS and SSLR present with fever, rash and arthritis 7–21 days after exposure to the offending antigen, which is most often a medication. It is critical that a medication history be elicited from these patients, and that

suspected medication be promptly discontinued. Unlike classic SS, SSLR does not have detectable circulating immune complexes or hypocomplementemia, and its pathogenesis remains poorly understood. Urticaria multiforme primarily affects children, and involves urticarial plaques with a hemorrhagic pattern which appear 1–3 days following an acute viral illness [119].

Treatment

Acute Urticaria

For acute urticaria the most important step is to eliminate the trigger if identified. Patients can use antihistamines to help with symptom alleviation until resolution of the episode. Approximately 44–91 % of all urticaria patients treated with H1-antagonists found a benefit [127, 128]. Typically, non-sedating H1-antagonists are utilized although classic sedating H1-antagonists, such as diphenhydramine or hydroxyzine, may be used. The major risk associated with administration of first-generation H1-antagonists is somnolence [12]. For severe cases of acute urticaria, a short course of systemic corticosteroids may provide more prompt control [12]. One study reported that acute urticaria exacerbations lasted only 3 days in approximately 94 % of studied patients compared to only 66 % of patients not receiving steroids [129]. Topical steroids play no role in the treatment of urticaria since application would involve a large area of skin with minimal benefit [7].

Chronic Urticaria

The treatment of CSU is a greater challenge than that of acute and physical urticarias. The physician should explain to the patient the natural history of CSU and the lack of a cause as this may lessen patient frustration. Patients should avoid triggers, but these are rarely identified in CSU. Avoidance of certain potential triggers such as aspirin, nonsteroidal anti-inflammatory drugs, ACE inhibitors, and codeine-containing products that can directly stimulate skin mast cells is also recommended [7].

Second-generation antihistamines are first-line therapy for chronic urticaria [130]. H1-antagonists are used to control the intense pruritus associated with the CSU. One study reported that 94 % of patients with CSU had some itch relief with use of H1-antagonists, with the majority on the sedating type [131]. In patients with CU who do not respond adequately to second-generation antihistamines at FDA-approved doses, doses can be provided at higher than licensed doses, often with additional therapeutic benefit [130]. Similarly, the treatment of physical urticaria involves second-generation antihistamines and avoidance of triggers [132–137]. Some past studies in CSU patients demonstrated an improvement in dermatographism and pruritus with the simultaneous use of an H1-antagonist and H2-antagonist versus a H1-antagonist alone. *Doxepin*, a tricyclic antidepressant with some H1- and H2-receptor antagonist properties, may be useful for nighttime itch and has been shown to be more effective than diphenhydramine in the treatment of CSU [138]. Doxepin should not be used with MAO inhibitors due to a risk for Long QT Syndrome [7]. However, approximately 50 % of chronic urticaria patients do not respond to antihistamines and require additional agents to achieve symptom control [139, 140].

Success with *leukotriene receptor antagonists* has been reported for physical urticaria of the cold-induced and delayed pressure types, aspirin-sensitive urticaria, and food-induced acute urticaria [141–143]. However, there is conflicting results regarding the efficacy of leukotriene receptor antagonists in CSU. Various randomized, placebo-controlled studies reported that montelukast provided symptom alleviation in CSU patients when used as a monotherapy or in conjunction with cetirizine or desloratidine, but another placebo-controlled study demonstrated that montelukast plus desloratidine was equal to desloratidine alone while montelukast monotherapy offered no benefit over placebo [141, 144–146]. Another leukotriene receptor antagonist, zafiruklast failed to show benefit over placebo in CSU [147]. Some studies have only shown a benefit with leukotriene receptor antagonists in a subset of CSU patients with a positive ASST [148, 149]. Overall, leukotriene receptor antagonists may be added to anti-histamines in urticaria patients as a limited trial and have a side effect profile similar to placebo.

Systemic corticosteroids also have a role in severe, antihistamine-resistant CSU when rapid control is warranted or with episodes of significant angioedema. The mechanism for disease alleviation with corticosteroids is not known, but CSU patients treated with steroids have a transient rise in peripheral basophil counts perhaps suggesting decreased recruitment of basophils to the skin [70]. The use of systemic corticosteroids should be sparse due to the side effect profile with prolonged use including a greater risk for osteoporosis, peptic ulcer disease, diabetes, and hypertension, to name a few [150].

More recently, anti-inflammatory drugs have been used for the treatment of antihistamine-unresponsive and steroid-dependent CSU. In various case reports, *sulfasalazine* has shown some benefits in CSU as well as delayed pressure urticaria [151–154]. One recent study of patients with antihistamine-unresponsive CSU reported that 74 % of

patients treated with sulfasalazine had significant improvement in disease and with an additional 21 % showing minimal improvement, and in additional all patients treated either discontinued or decreased their steroid use [155]. Although the mechanism of action is unknown, it is hypothesized that sulfasalazine may alter IgE-mediated mast cell histamine release, with one study demonstrating reduced release in mast cells and two prior studies demonstrating enhanced release in mast cells as well as basophils [156–158]. *Dapsone*, which exhibits anti-inflammatory properties and inhibits neutrophil function, showed promising results in one open-label study and may be beneficial for patients with neutrophil-predominant infiltrates on skin biopsy [159, 160]. More recently, a small randomized placebo controlled trial showed benefit in patients with antihistamine-refractory CSU [161]. This medication should be avoided in individuals with G6PD deficiency, which places patients at risk for hemolytic anemia [150].

Hydroxychloroquine has also shown some benefit in chronic urticaria. A randomized, double-blind, placebo-controlled study showed a significant improvement in quality-of-life scores in patients treated with hydroxychloroquine, but only a marginal change in urticaria activity scores [162]. Hydroxychloroquine has a number of immunologic effects, which include inhibition of endosomal TLR signaling resulting in reduced B-cell and dendritic-cell activation, as well as inhibition of antigen presentation [163]. *In vitro* studies have shown that hydroxychloroquine can decrease the production of TNF-α, IL-6, and IFN-γ by mitogen-stimulated peripheral blood lymphocytes [163, 164]. When compared with other immunomodulatory agents, antimalarials have a favorable safety profile [163]. Although rare, there is a risk of retinopathy with prolonged use (>5 years) of hydroxychloroquine [150].

Cyclosporine, a calcineurin inhibitor, has shown some success in small series and randomized control trials in CSU patients [165–167]. Cyclosporine reduces the Th1 lymphocyte response, inhibits antibody formation, and inhibits basophil and mast cell anti-IgE induced histamine release [165, 168]. One of these studies reported that cyclosporine treatment did not change the presence of the ASST in patients who entered drug remission [167]. Blood pressure, kidney function, and liver function should be monitored regularly during the treatment period, which is generally 3–6 months [150, 169]. After the treatment course has been completed, remission may last up to 9 months in about 50 % of patients [150, 170].

Methotrexate is an anti-inflammatory agent with immunosuppressant activity, and has a number of actions ranging from increasing adenosine levels, inducing apoptosis in activated $CD4^+$ T cells, and decreasing neutrophil chemotaxis [171]. The most frequent adverse effects are nausea and vomiting (both dose-related) [172]. Methotrexate is also a known abortifacient and teratogen, and should be avoided in women capable of conceiving [172]. Small studies and case reports involving the use of methotrexate for CSU have shown conflicting results [173, 174]. One retrospective review reported a beneficial role for methotrexate for the treatment of steroid-dependent chronic urticaria [175]. However, a prospective study showed that a 3 month regimen of methotrexate (15 mg weekly) failed to provide any additional benefit over H1-antagonists [173].

Mycophenolate mofetil functions as a reversible inhibitor of inosine monophosphate dehydrogenase, which is involved in the synthesis of purines and unique to lymphocytes [139]. In a study of 9 CSU patients, mycophenolate provided a significant improvement in the individual urticarial activity scores at the end of a 12-week treatment period [139]. *Azathioprine*, which inhibits lymphocytes by also suppressing purine nucleotide biosynthesis, has been investigated in chronic urticaria in a limited number of cases with success [176].

Small case reports of *cyclophosphamide* have shown a potential role for these agents in CSU [177, 178]. Cyclophosphamide results in a differential cytotoxicity to various lymphoid cell populations, with selective suppression of B cells [172, 179]. Because of the risk of bladder toxicity, gonadotoxicity, myelosuppression, and malignancy, some recommend that its use be reserved for serious and potentially life-threatening disorders in which the benefit outweighs the risks [172].

Rituximab, a monoclonal anti-CD20, has had success in the treatment of SLE, and due to CD20's role in B cell development, it may decrease autoantibodies thus making it a potential therapeutic for CSU [180, 181]. This treatment has been associated with a number of adverse events, including supraventricular arrhythmias, acute coronary syndrome, interstitial lung disease, myelosuppression, infections, sepsis, anaphylaxis, and neoplasms [140]. Although promising, further controlled studies including needed to determine the safety and efficacy of this treatment.

A therapeutic option recently FDA-approved for CSU (ages 12 and above) is *omalizumab* (*Xolair*), a monoclonal antibody directed against IgE. Omalizumab is known to alter mast cell and basophil anti-IgE induced histamine release as well as decrease free IgE levels and FcεRI expression on mast cells and basophils [182]. A number of controlled studies have demonstrated that a significant improvement in disease activity occurs much earlier than the expected decline in skin mast cell IgE receptors [140, 183–185]. The response rate to omalizumab is approximately 65 %, when one includes only those patients who cannot be managed satisfactorily with high-dose antihistamines [140]. Similar response rates have been observed between in CSU subjects independent of autoimmune status [183, 184]. Taken together, these studies demonstrate an

excellent side effect profile with mild side effects (in 1–10 % of patients) such as local injection site reactions (swelling, redness, itching), sinusitis, headache, arthralgia and upper respiratory tract infections [140]. Despite its success, the mechanism of action of omalizumab in CSU is currently not clear.

TNF-α inhibitors, which have known anti-inflammatory properties, may be a potential therapeutic for CSU as they have been successfully used in autoimmune diseases such as rheumatoid arthritis and inflammatory skin diseases like psoriasis [186, 187]. There are two methods for neutralizing the activity of TNF-α: a neutralizing antibody (infliximab, adalimumab) and a fusion protein of a TNF-α receptor (etanercept) [186]. Among 20 patients treated with either adalimumab or etanercept, 12 obtained complete or almost complete resolution of symptoms and 3 received a partial response; however 6 patients experienced side effects [188].

Other therapies, although less studied, have also been used in chronic urticaria. *Plasmapheresis* has been used with the intended purpose of removing autoantibodies with temporary effects on disease activity [9]. One study in HRA-positive CSU patients demonstrated a reduction in ASST in patients treated with plasmapheresis, but these patients continued to have a positive ASST during clinical remission [189]. *Intravenous immunoglobulin* (*IVIG*) infusions were studied in patients with reported functional anti-FcεRI or anti-IgE autoantibodies and had a reported benefit [190, 191]. However, a subsequent study demonstrated that the improvement with IVIG was temporary, indicating that IVIG is likely not an effective therapy for CSU [192]. *Androgen therapy* with danazol was shown to be beneficial in one randomized controlled trial 17 male patients with cholinergic urticaria [193]. The anti-inflammatory effects of androgens may stem from their ability to interfere with endogenous sex steroid production and suppress leukocyte activation [178, 194, 195], but such agents should be avoided or used with extreme caution in females due to their strong androgenizing effects [178]. *Zileuton*, a 5-lipoxygenase inhibitor, inhibits leukotriene B4 and C4 production and has shown success in a small case study of chronic urticaria patients [196, 197]. Oral *ketotifen*, which has both antihistamine and mast cell stabilizing properties, has been widely used in Europe, Canada, and Mexico but is not approved by the FDA for use in the United States [198]. *Warfarin* therapy was studied due its ability to alter proteases of the complement, kinin, clotting or fibrinolytic systems which may potentially be activated in CSU, leading to vasoactive mediator release in CSU [199]. *Heparin* and *tranexamic acid* therapy may be effective in treatment-resistant chronic urticaria patients with elevated d-dimer levels [150, 200]. *Psoralen UVA or UVB phototherapy* has not proven beneficial in CSU in past studies, although PUVA is known to reduce skin mast cell number [201–205]. However, a more recent study of PUVA-and narrow band UVB treatment, demonstrated a significant decrease in symptoms in both treatment groups [206]. *Colchicine* has been suggested as a therapeutic option for delayed-pressure urticaria [207]. A recent retrospective study of 36 chronic urticaria patients treated with colchicine found that 56 % reported as complete or partial response [208]. *Interferon-alpha* has also been studied and does not appear to be an effective therapy [209, 210].

Conclusion

Urticaria is produced by the degranulation of mast cells in the skin, and has immunologic and nonimmunologic mechanisms. Chronic urticaria is a troublesome condition that can adversely affect the quality of life of this affected. Evaluations to identify and remove trigger factors are critical to the management of this condition. Treatments range from the H1 receptor antagonists with or without H2-antagonists, leukotriene receptor antagonists, tricyclic antidepressants, and systemic corticosteroids. In severe cases, immunosuppressive drugs and biologic agents have been successfully used.

Questions

You see a 43-year-old female with chronic hives that occur daily and disrupt her sleep. She has no other systemic disease aside from hypertension. She has failed updosing with cetirizine (20 mg bid) montelukast, and required 2 steroid courses in the last 4 months. Her physical exam is consistent with urticarial. Routine clinical labs are within normal (CBC WESR, Chemistries, and TSH

1. Which of the following add-on agents has regulatory approval for the treatment of chronic idiopathic urticaria refractory to H1 antihistamines?
   (A) Cyclosporine
   (B) Hydroxychloroquine
   (C) Omalizumab
   (D) Dapsone

   Answer: (C) Among the listed choices, only omalizumab and cyclosporine have been studied in randomized controlled trials. In 2014, the US Food and Drug Administration approved the use of omalizumab, a monoclonal antibody against immunoglobulin E, in adolescents and adults (12 years of age or older) with chronic idiopathic urticaria refractory to H1 antihistamines

   Given the evidence of hypertension, omalizumab therapy is a better choice given the side effect profile of cyclosporine

2. After discussion with you and reading further about omalizumab, the patient agrees to proceed with omalizumab therapy. Which of the following assessments prior to starting treatment would be most appropriate?
   (A) Pulmonary function tests
   (B) Blood or skin prick tests for environmental allergy
   (C) Total IgE level
   (D) Urticaria activity score
   (E) None of the above

   Answer: (E) Rationale for correct answer: At present, no testing for IgE or specific IgE levels is needed for chronic hives patients. In contrast, such IgE testing is needed prior to ordering omalizumab for asthma. Likewise, measuring PFTs or the urticaria activity score is not needed. Dosing and treatment response for omalizumab in chronic idiopathic urticaria are not dependent on serum IgE level or atopic history. Approved dosing for omalizumab for chronic urticarial are as follows: omalizumab 150 or 300 mg subcutaneously every 4 weeks

3. Approximately what percentage of patients with chronic idiopathic urticaria can have concomitant angioedema?
   (A) 5 %
   (B) 10 %
   (C) 20 %
   (D) 40 %

   Answer: (D) 40 %. Patients with CIU can have concomitant angioedema that occurs either simultaneously or separately from episodes of urticaria. The incidence has reported to be 40–80 % in different series. Swellings may involve the face or extremities. Life-threatening laryngeal edema is rare

Vitiligo

28

Jillian M. Richmond and John E. Harris

Abstract

Vitiligo is an autoimmune disease of the skin that affects approximately 1 % of the population. It is mediated by self-reactive $CD8^+$ T cells that target and kill melanocytes in the basal epidermis. Patients present with patchy depigmentation, which commonly appears on the face, hands, feet and genitals, but may affect any part of the body. Depigmentation is typically progressive and chronic, slowly developing over the life of the patient. There are currently no FDA-approved treatments for vitiligo, and while some therapies are effective for disease, they primarily work through general immunosuppression. Like most autoimmune diseases, both genetic and environmental factors contribute to the risk of developing vitiligo. These factors promote immune dysregulation, which then initiates depigmentation and disease progression. Genes that confer susceptibility to vitiligo have been identified in Genome-Wide Association Studies (GWAS), implicating both innate and adaptive immunity. Environmental triggers for vitiligo include a number of common household commercial products that contain chemical phenols, which act as tyrosine analogs and induce stress responses in the melanocyte. Several recent studies connecting cellular stress and innate immune activation have shed light on possible mechanisms by which vitiligo is triggered through exposure to these environmental insults. Studies of the "effector" phase of vitiligo reveal that disease is driven by IFN-γ and its target genes, including chemokines. Here we will outline the clinical presentation and treatment options, immunopathogenesis, basic and translational research strategies, and future prospects for the treatment of vitiligo.

Key Points

- Vitiligo is an autoimmune response against melanocytes that results in patchy depigmentation
- Autoimmune responses in vitiligo can be triggered by combinations of genetic and environmental factors
- Melanocyte-intrinsic defects confer susceptibility to vitiligo and may make melanocytes more susceptible to environmental triggers
- Treatment options are limited to narrow-band UVB and topical steroids, though current research favors the development of more targeted immune suppression combined with factors that promote melanocyte regeneration

Clinical Presentation

Symptoms/Signs

Vitiligo is a disfiguring disease of the skin that results in prominent white patches, or depigmentation (Fig. 28.1a). It is due to a gradual loss of the melanin-producing cells, melanocytes, from the epidermis. Depigmentation in vitiligo most commonly affects the face, genitals, hands and feet, followed by the trunk. Vitiligo is a lifelong disease, such that progression can be observed for decades. Lesions begin as small, pinpoint macules (Fig. 28.1b), and grow into large patches that often coalesce with the potential to cover the entire skin surface, usually in a symmetrical distribution (Fig. 28.1c). Hairs are often spared from depigmentation (Fig. 28.1d), but may also be affected (Fig. 28.1e). Most patients are asymptomatic, while ~20 % report itching in affected skin [1], and small numbers experience redness and scaling, a subtype described as "inflammatory" vitiligo [2, 3] (Fig. 28.1f). While melanocytes are present in the epidermis, hair, eyes, inner ear, and brain, depigmentation is almost always limited to the epidermis and hair, with involvement of the hair less common than epidermis. Very rarely, patients experience inflammation in multiple organs, a variant labeled Vogt-Koyanagi-Harada Syndrome. Such patients are highly symptomatic, complaining of meningitis (nausea, vomiting, photophobia) from brain involvement, tinnitus and hearing loss from inner ear involvement, and eye pain, visual changes, and loss of vision from eye involvement [4].

A subset of patients have segmental vitiligo, which is characterized by depigmentation only on one side of the midline (Fig. 28.1g). During embryonic development, keratinocytes (ectoderm) and melanocytes (neural crest) emerge from the dorsal midline primitive streak, proliferate (keratinocytes) or migrate (melanocytes) ventrally, and generally meet at the midline, without crossing to the contralateral side [5]. This unilateral pattern of skin formation in the embryo is readily apparent in diseases of somatic mosaicism, where affected skin is unilateral and limited by the midline [5–8]. T cells, which are bone marrow-derived and recruited to the skin from the circulation, are thought to move freely through tissues, unlimited by the midline (reviewed in [9]). Therefore, the unilateral nature of segmental vitiligo should most likely be attributed to skin cells, rather than immune cells, and a form of somatic mosaicism could induce a unique susceptibility of melanocytes within a unilateral, focal segment to autoimmune attack. A recent study compared patterns of segmental vitiligo to those of known diseases of somatic mosaicism, and found that patterns of segmental vitiligo most resembled those of melanocytic origin [10, 11].

Disease Course

While it has a primarily progressive course, vitiligo can wax and wane, or even arrest altogether. Trauma to the skin may induce depigmentation at the site, a phenomenon known as koebnerization (Fig. 28.1h). Rapid spread of disease may occur, which has been associated with the trichrome variant in which three colors are evident, including the normal skin, depigmented skin, and an intervening zone of hypopigmentation that typically progresses to depigmentation (Fig. 28.1i). The inflammatory variant described above also typically marks rapidly progressive disease. Arrest of depigmentation, either spontaneous or induced, enables melanocytes to regenerate from pigmented hair follicles, a potential reservoir of melanocyte stem cells (Fig. 28.1j). Over time, these melanocytes can repigment the epidermis and erase any evidence of its existence [12] (Fig. 28.1k). In the segmental variant, depigmentation is usually limited to a focal, unilateral area, but may rarely spread beyond this initial site, a variant described as "mixed" vitiligo (Fig. 28.1l) [13].

Epidemiology and Diagnosis

Vitiligo affects approximately 0.5–1 % of the general population [14], although isolated populations where their genetics are more homogenous report higher rates [15]. The average age at diagnosis is 24 years [16], and half the patients who develop vitiligo do so before the age of 20. The segmental variant of vitiligo comprises ~30 % of childhood disease and 10–15 % of adult vitiligo, because childhood onset is more likely to be segmental [17]. The inflammatory variant of vitiligo is uncommon, and Vogt-Koyanagi-Harada Syndrome is very rare, although it appears to be most prevalent in Japan.

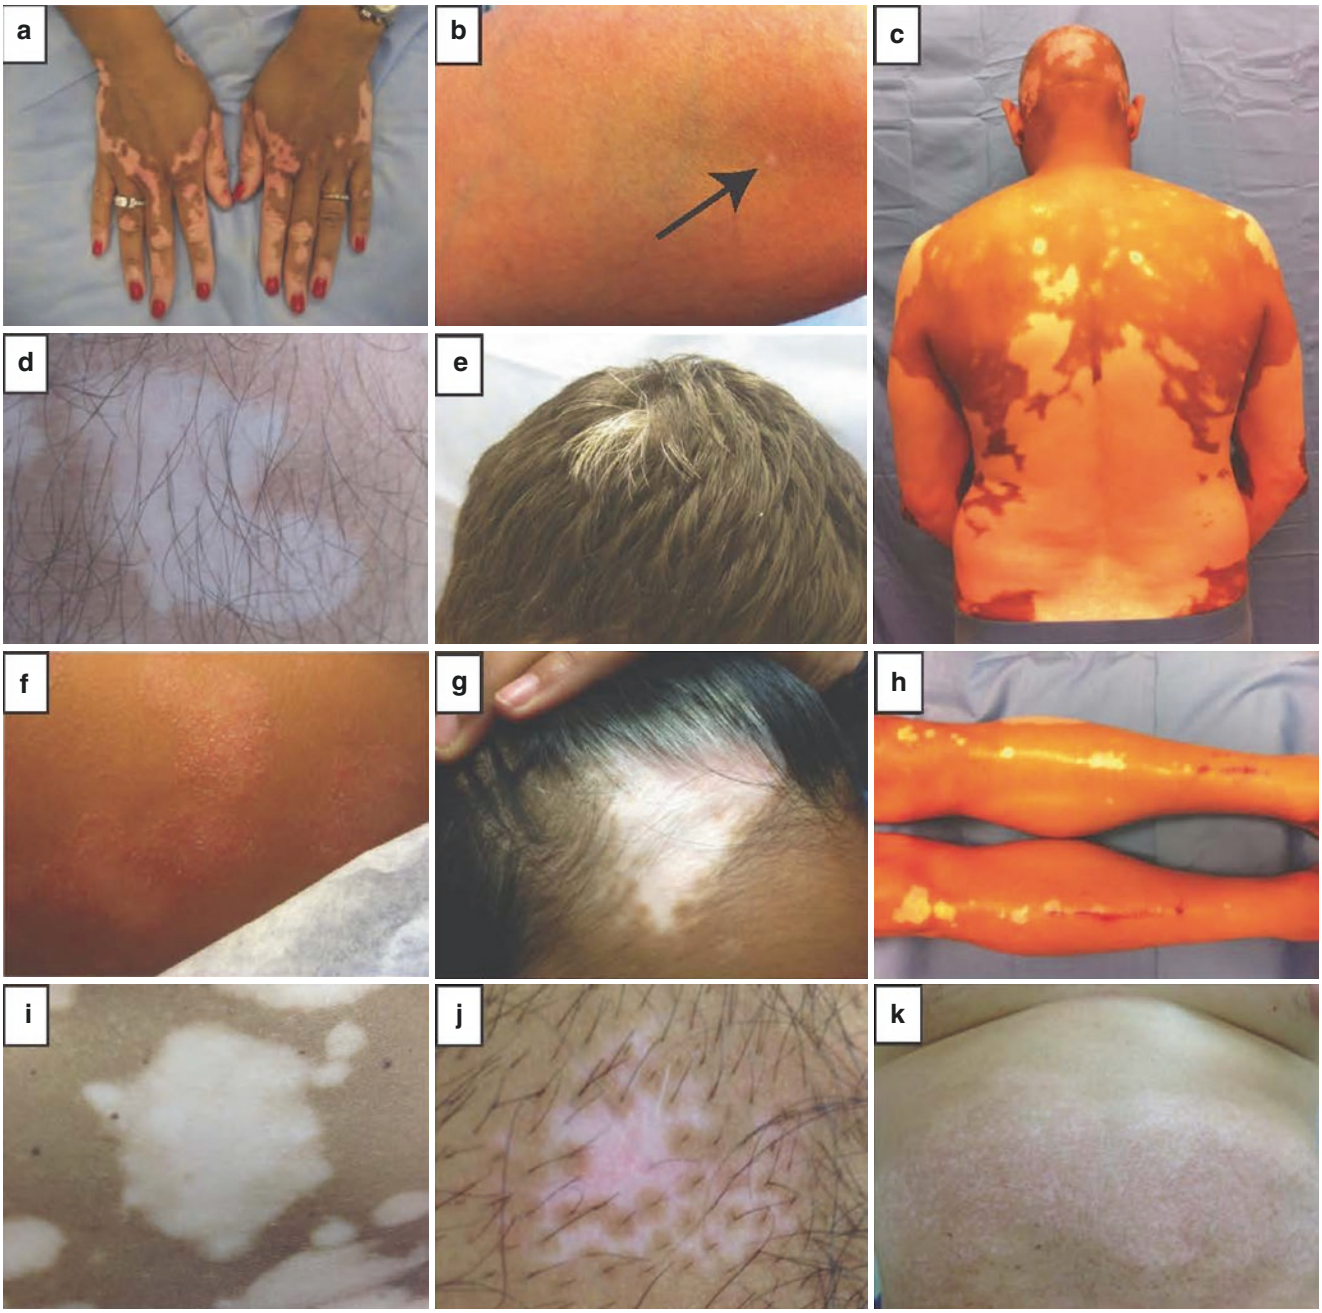

Fig. 28.1 Clinical manifestations of vitiligo. (**a**) Patchy depigmentation on the hands. (**b**) Early macule of vitiligo on the arm. (**c**) Large, coalescing patches of vitiligo on the trunk. (**d**) Epidermal depigmentation on the knee, with sparing of the hair. (**e**) Poliosis from vitiligo on the scalp. (**f**) Erythema and scaling in a depigmented patch in a young girl with inflammatory vitiligo. (**g**) Unilateral depigmentation on the forehead of a young woman with segmental vitiligo. (**h**) Depigmentation on the shins of an avid mountain-biker, reflecting koebnerization of skin trauma. (**i**) Trichrome pigmentation in a patch of vitiligo that includes normal skin and depigmented skin with a hypopigmented border. (**j**) Perifollicular repigmentation from pigmented, but not depigmented, hairs on the abdomen of a patient receiving nbUVB phototherapy. (**k**) Near-complete repigmentation in a large patch on the abdomen of a patient receiving nbUVB phototherapy. (**l**) Mixed vitiligo with depigmentation in a well-defined unilateral segment on the right chin as well as remote areas of depigmentation on the left chest and right hip

Fig. 28.1 (continued)

Vitiligo is typically a clinical diagnosis, and Woods lamp examination helps to distinguish the depigmentation of vitiligo from hypopigmentation of other conditions. The differential diagnosis of depigmentation is limited, and includes nevus depigmentosus, piebaldism, idiopathic guttate hypomelanosis (IGH), and trauma-induced depigmentation (burns and other scars). Nevus depigmentosus and piebaldism are present at or shortly after birth and grow with the child. IGH is characteristically limited to macules of small size on sun-exposed surfaces, and trauma-induced depigmentation is typically geographic-appearing and often recalled by the patient. If the diagnosis is not clinically clear, the lack of melanocytes can be confirmed through biopsy of the lesion using normal skin for comparison, although biopsy is rarely necessary. The differential diagnosis of hypopigmentation is extensive, and thus distinguishing depigmentation from hypopigmentation via Woods lamp examination is very helpful. Important hypopigmented conditions not to miss include hypopigmented mycosis fungoides due to the need for more intensive monitoring, lichen sclerosus et atrophicus (LSetA) due to the need for aggressive treatment to avoid permanent sequelae, as well as tinea versicolor, pityriasis alba, and progressive macular hypomelanosis due to simple alternative treatment strategies.

The risk of developing vitiligo in first-degree relatives of patients is 6.1 %, and in an identical twin is 23 % [16], implying a moderate *genetic* contribution to disease. The remainder of the risk has been described as *environmental* [18], which will be discussed below. A third possible explanation for twin disconcordance in vitiligo and other autoimmune diseases that is often not considered is a *stochastic* contribution, or risk conferred by chance during development. Stochastic influences occur during cell replication, differentiation, and migration during embryogenesis [19], the generation of T cell receptors through VDJ recombination and nucleotide insertion/deletion [20], and central tolerance induction in the thymus [21].

Psychological Impact

Vitiligo is a disfiguring condition, as skin color is an important component of identity. The porcelain-white lesions are brandished on the skin as if a public announcement of disease. Maybe for this reason, or for its similarity in appearance to tuberculoid leprosy (hypopigmented patches), vitiligo sufferers in India are frequently bypassed as candidates for arranged marriage [22]. Psychological consequences of vitiligo are severe, leading to depression, anxiety, sleep disturbances, sexual dysfunction, feelings of discrimination, and even suicidal thoughts and attempts. These emotional disturbances are comparable to those suffering from psoriasis and eczema [1, 23]. Public concerns over transmissibility of vitiligo make understanding its pathogenesis not only critical for the development of effective treatments to help our patients, but also for public education and acceptance of those who have been ridiculed and ostracized from their communities, beginning over 3500 years ago and continuing to this day [22].

Current Treatments

Treatments for vitiligo can be very effective for some patients, although they are all used "off-label", as there are currently no treatments that are FDA-approved to promote repigmentation of vitiligo. Options include topical steroids, topical calcineurin inhibitors, and narrow-band ultraviolet light B (nbUVB) [24].

Studies reveal that nbUVB is the most effective single therapy for vitiligo, followed by ultrapotent topical steroids and calcineurin inhibitors [25]. Combined therapy with nbUVB and topicals has greater efficacy then either one alone. In a head-to-head comparison, nbUVB showed similar efficacy to psoralen with ultraviolet light A (PUVA), however nbUVB resulted in a better color match of repigmented skin to normal skin [26], and long-term treatment with nbUVB appears to be safe, while PUVA increases the risk of

skin cancer [27]. Therefore, PUVA therapy is best avoided for vitiligo in favor of nbUVB. The frequency of treatment for nbUVB is most efficacious at 2–3 visits per week, as once weekly treatment has only modest efficacy. It appears that visits 3 times weekly induces repigmentation more rapidly than twice weekly, however over the long-term both schedules appear to have equal efficacy. Therefore after 2–3 months of treatment, those receiving therapy 3×/week typically have more repigmentation, while after six months of therapy either 2 or 3×/week have similar repigmentation. If possible for the patient, we often treat 3×/week for the first three months, and then decrease to 2×/week for the remainder of treatment.

Ultrapotent topical steroids appear to have slightly better efficacy than topical calcineurin inhibitors; however, they also have increased risk of epidermal atrophy, striae, and steroid-induced acne. Tacrolimus ointment does not induce atrophy, but may burn shortly after application and, in some patients, results in flushing of the skin after alcohol consumption. Burning seems to go away with repeated treatment. Skin flushing in public may be avoided by taking a small amount of alcohol to induce the flushing in a private environment, which then resolves and may not reappear with additional consumption. We often suggest patients treat with an ultrapotent topical steroid twice daily for one week, followed by tacrolimus ointment twice daily for one week. The patient then alternates treatment with steroid and calcineurin inhibitor each week, which appears to have good efficacy with significantly reduced risk of side effects.

In select cases where depigmentation is stable, autologous melanocytes can be harvested from uninvolved skin and transplanted to depigmented skin, resulting in repigmentation, a procedure called melanocyte-keratinocyte transplantation (MKTP) [17]. This approach may be curative for patients with highly stable disease, and is most useful for those with segmental vitiligo, a variant in which depigmentation is highly stable.

Avoidance of environmental triggers may prevent or reduce the severity of vitiligo. This includes avoiding exposure to phenol-containing products such as hair dyes, cleaning products, adhesives, and treated rubber products. Patient history can be helpful to identify exposures, though difficulty with recall and the large number of common household products involved can make this approach difficult. One study reported that patients with chemical-induced vitiligo often present with confetti-like macules of depigmentation, which may help to identify those patients in whom a detailed exposure history should be taken [28].

Monobenzyl ether of hydroquinone, or monobenzone, was first implicated as a risk factor for vitiligo through occupational exposure in a group of factory workers in 1939 [29]. It is now the only FDA-approved treatment for vitiligo, used for removing the remaining pigment in a patient with widespread disease. Its mechanism is through the exacerbation of vitiligo, described below. For clinical use, the chemical is compounded as a 20 % ointment and should be applied daily to pigmented skin. Successful depigmentation can take up to 12 months, and should be considered irreversible. In addition, pigmented skin remote from the application site may also depigment, so this strategy should not be used for localized depigmentation. A subset of those who use this approach exhibit allergic contact dermatitis to the chemical, which may be treatment-limiting. The majority of those who successfully undergo depigmentation with monobenzone topical therapy are very pleased with the results [30].

Pathophysiology of Vitiligo in Humans

Historically it has been debated whether vitiligo is an autoimmune disease or a melanocyte-intrinsic degenerative syndrome [31]. Like most other autoimmune diseases, vitiligo is multifactorial, requiring both genetic and environmental factors for melanocyte destruction. Melanocytes from vitiligo patients are difficult to grow *in vitro*, are more susceptible to oxidative stress, and have elevated cellular stress responses [32]. Autoimmunity plays a key role in pathogenesis as well, evident by the fact that the majority of genes that confer susceptibility to vitiligo play central roles in immune responses, and "adoptive transfer" of vitiligo has been observed in patients receiving bone marrow/stem cell transplants from donors with vitiligo [33–35]. In this section we will outline the pathophysiology of vitiligo with an emphasis on the recent literature.

Melanocyte Stress

Melanocytes are particularly susceptible to cellular stress, due to their exposure to UV irradiation and other environmental stressors, as well as the production of melanin, which generates reactive oxygen species (ROS) and activates the unfolded protein response (UPR). Electron microscopy of cellular substructure revealed that the endoplasmic reticulum (ER) in melanocytes from vitiligo patients was dilated compared to healthy controls [36], a characteristic that implicates cellular stress. Elevated levels of H_2O_2 and oxidative byproducts are present in vitiligo patients' epidermis compared with controls, suggesting uncontrolled generation of reactive oxygen species (ROS) [37]. In addition the enzyme catalase, which reduces H_2O_2 to O_2 and H_2O and thereby relieves oxidative stress, is

decreased in lesional skin [38], which may be either a cause or an effect of increased H_2O_2. Treatment of vitiligo with topical exogenous catalase has been attempted, with variable results [39].

Tyrosinase facilitates a number of steps that convert the amino acid tyrosine to melanin. Tyrosine is a phenol, containing a hydroxyl group attached to a benzene ring. Monobenzone was the first chemical reported to induce vitiligo in a group of factory workers exposed to the chemical through acid-cured rubber gloves. Distant spread of depigmentation to areas beyond the exposure sites (hands and forearms) suggested that monobenzone is not simply directly cytotoxic to melanocytes, but induces autoimmunity during exposure. Monobenzone treatment of vitiligo patients, used to depigment their skin to induce an even tone, also induces depigmentation at sites remote from the site of application, supporting this concept. Like tyrosine, monobenzone and other depigmenting agents are phenols, which act as tyrosine analogs but bind irreversibly to tyrosinase and thereby interrupt the melanin synthesis pathway [40]. This induces cellular stress through the induction of ROS and activation of the UPR, which then results in activation of innate immunity to induce inflammation [40–42]. Many household products contain other chemical phenols, including hair dyes and cleaning products, which have both been reported to induce chemical leukoderma, or chemically-induced vitiligo [28]. It is likely that phenols used as ingredients in these products act in a similar way as monobenzone, producing cellular stress through interaction with tyrosinase.

Initiation/Innate Immune Activation

There is evidence that the initiation of vitiligo requires innate immune activation. Several studies have implicated innate immune sensing of cellular stress, including dendritic cell (DC) activation by stress-induced release of exosomes [40], the heat shock protein HSP70i [43] and an apparent increased recruitment of natural killer (NK) cells into the skin of vitiligo patients [44]. Melanocyte stress is therefore linked to innate immune activation, and thus initiation of inflammation that may lead to adaptive autoimmunity; however, more studies will be required to identify the precise signaling pathways involved [45]. Innate immune gene polymorphisms in vitiligo have been identified through genome-wide association studies, though their functional roles in disease are still being defined (see section "Genetic Contributions"). Environmental triggers that induce melanocyte stress have been identified, and patients may be counseled to avoid these exposures (see section "Melanocyte Stress").

Adaptive/Autoimmune Response

Vitiligo is driven by $CD8^+$ T cell-mediated killing of melanocytes. This has been demonstrated *ex vivo* using a human skin culture system in which melanocyte-specific T cells isolated from affected skin migrated into an unaffected skin explant from the patient and induced melanocyte apoptosis. $CD8^+$ T cells were both necessary and sufficient for this effect [46]. Increased frequencies of melanocyte-specific $CD8^+$ T cells in the blood and skin correlate with disease severity [47]. The antigen specificities of the T cell receptors (TCRs) in vitiligo have been identified and are shared with melanoma, including MART-1, gp100, tyrosinase, and tyrosinase-related proteins 1 & 2 (TRP1 & 2) [48]. These T cells produce IFNγ which, in addition to inducing T cell recruitment, may be directly cytotoxic to melanocytes [49]. It is possible that vitiligo results from an overzealous antitumor response [50]. Patients with vitiligo are at a three-fold lower risk for melanoma, and those with melanoma who spontaneously regress or who are cured following treatment frequently develop vitiligo [51].

$CD4^+$ helper T cell responses may also play a role in vitiligo via IFNγ production, although functional evidence for their role is lacking [52, 53]. There is growing evidence that vitiligo is dependent on IFNγ and downstream genes including IFNγ-inducible chemokines [52, 54]. There are several case studies of patients who were treated with IFNα for hepatitis who developed vitiligo [55–64], suggesting that type I interferons can induce disease, though it is unclear what their role is in spontaneous vitiligo. Several studies have questioned whether T_H17 cells and IL-17 drive pathogenesis, but their functional role in vitiligo remains unclear. It is possible that a subset of vitiligo patients, such as those with inflammatory vitiligo, also have an IL-17 component in their disease pathogenesis, but studies to date have not classified T_H1 versus T_H17 in different vitiligo subtypes. Autoantibodies against melanocytes have been identified in patients [65], though it is uncertain whether they play a direct role in pathogenesis or are merely a biomarker of disease. A role for regulatory T cells (Tregs) have also been implicated in vitiligo through genetic studies [66] and the fact that patients with immune dysregulation, polyendocrinopathy, enteropathy, and X-linked (IPEX) syndrome, who lack Tregs, have an increased incidence of vitiligo [67]. However evidence is conflicted regarding whether their numbers are normal or fewer, whether they have difficulty homing to the skin, and whether or not they are functionally impaired [68–72].

Hair depigmentation is not commonly observed in vitiligo, most likely due to hair follicle immune privilege. Immune privilege is defined as tissue that is not readily inflamed, possibly due to limited access by the immune system and/or the expression of immunoregulatory proteins

or cell populations [73–75]. Melanocyte stem cells reside in hair follicles, which migrate out into the epidermis to repigment the skin [76]. When repigmentation occurs in patients, it usually begins around pigmented hair follicles and spreads outward, indicating that the stem cell populations in the hair follicles may be maintained through immune privilege. Little is known about the mechanisms of repigmentation, though this is critical for effective therapy (see also section "Future Perspectives into Vitiligo Treatment Strategies"). A summary of vitiligo pathogenesis is presented in Fig. 28.2.

Genetic Contributions

Genetic contributions to vitiligo are well-established, based on familial associations of the disease, as well as the increased concordance in identical twins [16, 66]. It is likely that inherited factors affect all pathways involved in vitiligo pathogenesis, including melanocyte stress, innate inflammation, and adaptive autoimmunity. The earliest genetic associations with vitiligo were with the HLA-A haplotypes, required for T cell recognition of their target cells [77]. The first non-HLA gene found to confer risk for vitiligo was NACHT, LRR and PYD domains-containing protein 1 (NLRP1). NLRP1 is a component of the innate immune response, confirming a causative role of innate immunity in vitiligo [78]. A recent study using functional genomics demonstrated that NLRP1 haplotypes associated with vitiligo cause increased IL-1β secretion by monocytes, potentially predisposing patients to innate immune activation and lowering the tolerance threshold [79].

Genome-wide association studies (GWAS) have revealed a large number of additional genes, the majority of which also play roles in immune responses (PTPN22, TSLP, HLA class I/II/III, CCR6, IL2RA, UBASH3A, and FOXP3), including specifically cytotoxic T cell responses

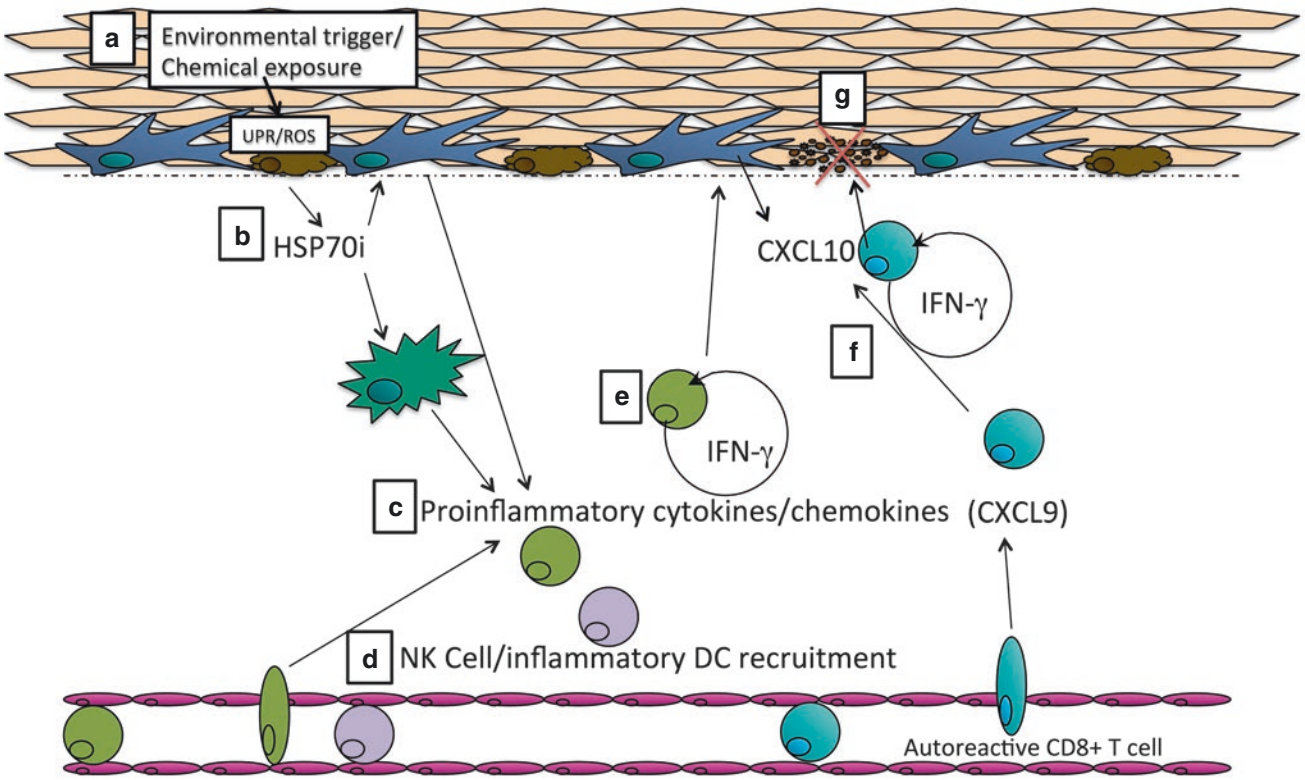

Fig. 28.2 Vitiligo pathogenesis: linking melanocyte stress, innate immune triggering and adaptive immune responses. (*A*) Exposure to an environmental insult, such as a phenol, may induce stress responses in melanocytes through activation of the unfolded protein response (*UPR*) or production of reactive oxygen species (*ROS*). (*B*) This results in release of stress/danger signals such as HSP70i, which are detected by other skin resident immune cells such as Langerhans cells or dermal dendritic cells. (*C*) These cells secrete proinflammatory cytokines and chemokines to recruit more immune cells to the skin, including natural killer (*NK*) cells or inflammatory dendritic cells (*DCs*). (*D*) NK cells produce IFN-γ, which stimulates CXCL10 production by skin resident cells (*E*). (*F*) Established gradients of CXCL9 and CXCL10 from the dermis to the epidermis direct autoreactive $CD8^+$ T cell recruitment to the skin and up to the epidermis, where they kill melanocytes either through cell contact dependent mechanisms or through IFN-γ production, which induces additional chemokine production to promote the cycle (*G*)

(GZMB), supporting earlier histologic and *in vitro* mechanistic data [18]. An allele of tyrosinase, the enzyme responsible for creating melanin, is protective against melanoma but causes an increased risk of vitiligo [80, 81]. X-box binding protein 1 (XBP1) variants were also identified as risk factors for vitiligo [82]. XBP1 promotes class II HLA expression (important for antigen presentation to CD4 T cells) [83], IL-6 and IL-8 production [84], and it is also a member of the UPR that protects the cell from stress-induced apoptosis [85].

In addition to a proinflammatory role in vitiligo, XBP1 may also participate in the stress response, as decreased expression or impaired activity of the protein may increase stress levels of the melanocyte [85], indirectly leading to activation of autoimmunity. Consistent with this hypothesis, studies in inflammatory bowel disease have identified two hypomorphic variants of XBP1 that contribute to a proinflammatory state of the intestine as a result of increased cellular stress [86]. To date, only a hypermorphic variant has been described in vitiligo [87], which may induce an exaggerated inflammatory response to cellular stress [41]. Another stress-related genetic factor that has been identified is tyrosinase-related protein 1 (TRP1). Mutations in TRP1 have been identified in vitiligo patients, and have been shown to activate cellular stress responses in melanocytes via chaperone proteins such as calnexin [32]. Further studies will be required to determine the functional role of other identified genetic factors in disease pathogenesis (Fig. 28.3).

Basic and Translational Approaches for Studying Vitiligo

Basic Science Approaches: Animal Models of Disease

One of the earliest models of vitiligo identified was a spontaneous mouse model caused by a point mutation in the microphthalmia-associated transcription factor (MITF) gene, which caused melanocyte degeneration as the mouse aged. However due to its monogenic nature and lack of autoimmunity [88, 89], this strain (mi^{vit}) does not appear to accurately model human vitiligo pathogenesis. Several other mouse models have been developed to study vitiligo, including models induced through exposure of the skin to melanocyte antigens plus adjuvant to induce depigmentation [90], or through adoptive transfer of transgenic T cells engineered to react against melanocyte antigens. Early models were developed from animal models of melanoma immunotherapy [91–95] in which TCR transgenic mice responding to gp100 (called PMEL for pre-melanosome protein were used to mediate tumor clearance. The mice spontaneously developed white hair, and several studies have used these PMEL host mice to study spontaneous hair depigmentation [43]. We developed a model through the adoptive transfer of PMEL T cells into hosts that have epidermal melanocytes [95], which resulted in progressive epidermal depigmentation with sparing of the hair (Fig. 28.4a). Studies using this

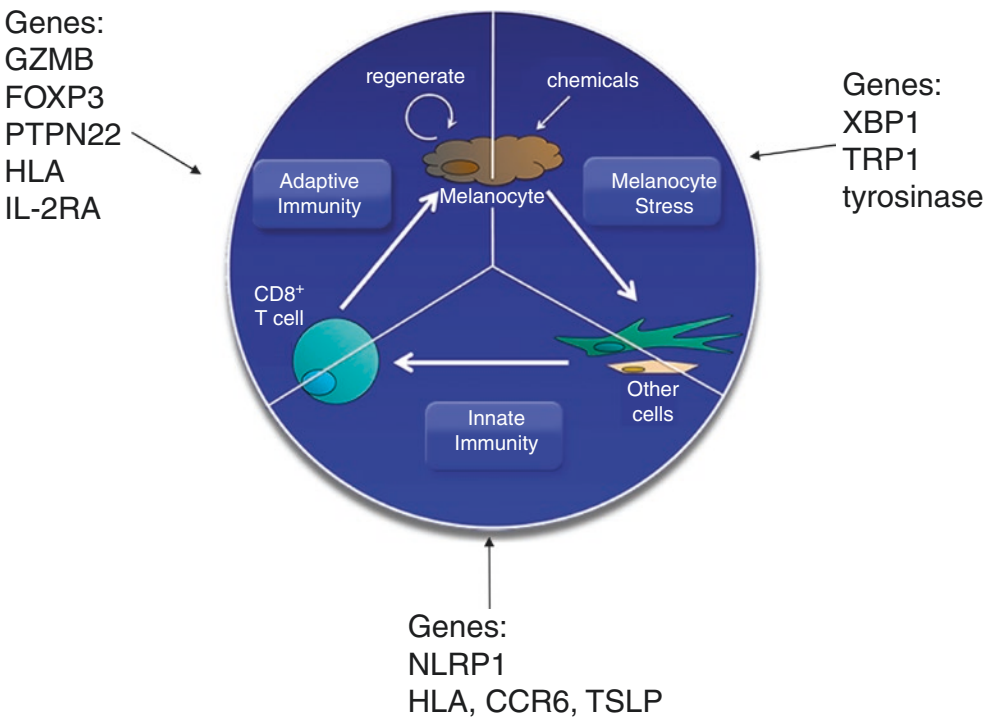

Fig. 28.3 Multiple pathways contribute to vitiligo pathogenesis. Melanocyte stress can be induced by chemicals and other environmental insults, resulting in release of stress signals that are detected by other cells in the skin. This can trigger activation of the innate immune system, resulting in production of chemokines required for autoreactive $CD8^+$ T cell recruitment to the skin. These $CD8^+$ T cells target and kill melanocytes, resulting in release of more proinflammatory signals in the skin, thereby re-activating the cycle. As melanocytes try to regenerate, they may continue to be targeted by CD8+ T cells in the skin, resulting in maintenance of clinical depigmentation. Examples of genes that may directly affect these three major pathways in disease are highlighted

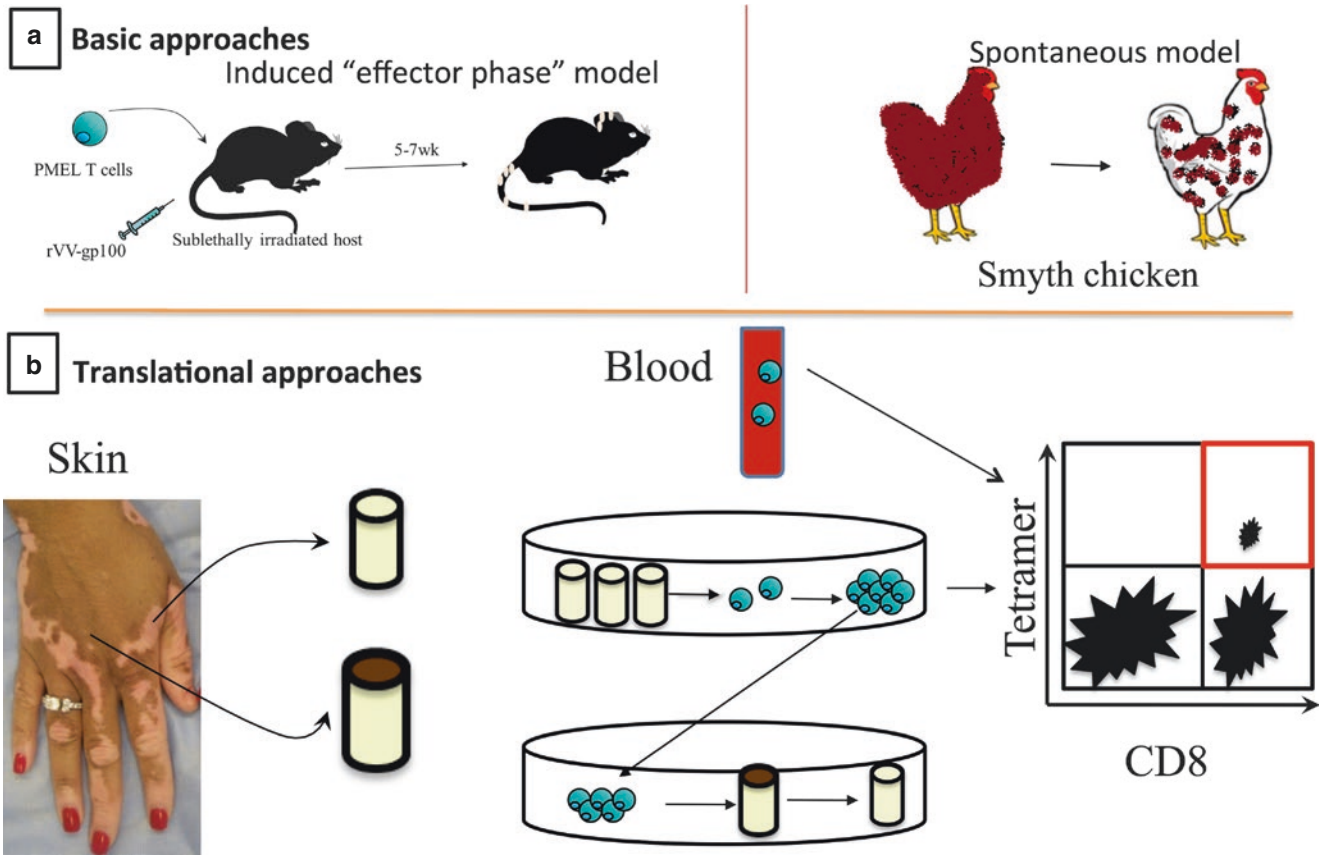

Fig. 28.4 Experimental approaches for studying vitiligo. (**a**) Basic science approaches for studying vitiligo: animal models. Adoptive T cell transfer model for studying the effector phase of vitiligo in mice. Melanocyte antigen-specific T cells (*PMEL*) are adoptively transferred into hosts and activated *in vivo* with an attenuated recombinant vaccinia virus expressing their cognate antigen gp100 (*rVV-gp100*). After 5–7 weeks, mice develop patchy depigmentation. This model is most useful for studying the "effector phase" of vitiligo. Alternatively, the Smyth Line Chicken spontaneously develops vitiligo, and is a more appropriate model for studying induction of vitiligo. (**b**) Translational approaches for studying vitiligo. Human samples can be analyzed *ex vivo* to examine elements involved in disease pathogenesis. Using skin biopsies, antigen-specific T cells can be isolated from lesions, cultured, expanded, and used to examine killing ability in normally pigmented skin cultures [46]. Antigen specificities of these skin T cells as well as T cells isolated from peripheral blood of vitiligo patients can be analyzed with tetramers, which are fluorescently labeled reagents comprised of MHC:peptide complexes. Most of the melanocyte tetramer reagents available are for CD8+ T cells, though it is possible that reagents for CD4+ T cells will become available in the future

model implicated IFN-γ and the IFN-γ-induced chemokine CXCL10 as required for both disease progression and maintenance [54]. This model is most useful for studying the effector phase of vitiligo, as loss of tolerance through innate immune activation is largely bypassed.

Perhaps the most representative animal model of vitiligo is the Smyth Line (SL) chicken, which develops spontaneous depigmentation of its feathers over time (Fig. 28.4a). Affected brown SL chickens develop white feathers with age and produce anti-melanocyte antibodies. Depigmentation is due to melanocyte loss by apoptosis induced by cytotoxic T cells. Interestingly, the SL chicken also has melanocyte defects, including autophagocytosis of melanosomes and increased generation of ROS. Consistent with the theory that vitiligo pathogenesis is multifaceted, these melanocyte defects are not sufficient for depigmentation in the absence of a functional immune system [96]. While the SL chicken appears to model vitiligo in a way that is most similar to human disease, the paucity of tools and expertise for investigation of chicken cells limits its use. Recent studies determined that IFNγ, IL-21 and IL-10 are expressed in evolving lesions [97], and microarray analysis has been conducted to begin to address gene signatures in the model [98].

Translational Approaches Using Patient Samples

Histology and immunohistochemistry were the earliest methods used to study inflammatory infiltrates in vitiligo. Histologic analysis of vitiligo patient biopsies revealed a lack of epidermal melanocytes with accompanying lymphomonocytic infiltrates. Immunohistochemistry revealed infiltrates of CD8 and CD4 T cells that are most often detected perilesionally [3, 99, 100]. CD8 T cells have been

observed infiltrating the epidermis and may be found proximal to dying melanocytes. Innate immune populations including CD11b+ CD11c+inflammatory DCs [43] and NK cells [44] have also been identified in vitiligo lesions.

Van den Boorn et al. used human skin organ culture and autologous T cells to demonstrate that $CD8^+$ T cells are necessary and sufficient to induce melanocyte apoptosis in human skin, consistent with a causative role for adaptive immunity in vitiligo [46]. This approach models processes that occur within the skin, and provides the normal 3D architecture and maintains most of the microenvironment. Punch biopsies of lesional skin from vitiligo patients were cultured *ex vivo*, T cells migrated out of the explant, and were expanded *in vitro*. Expanded populations can then be analyzed, manipulated, and re-exposed to punch biopsies of normally pigmented skin from the same patient to determine their effects on melanocytes *in situ* (Fig. 28.4b). Disadvantages of this approach include the inability to model recruitment of T cells from the blood to the tissue, and the fact that over time culture of skin results in the loss of resident immune cell populations through emigration [101].

Immune responses can be categorized by the cytokines that are expressed during the response. For example, in general T_H1 responses target tumors and intracellular pathogens and are characterized by the expression of interferons, including IFN-α, IFN-β, and IFN-γ. T_H17 responses target extracellular pathogens and are characterized by IL-17, IL-23, and TNF-α. T_H2 responses are involved in protection against parasites, and utilize IL-4 and IL-13. Autoimmune responses like vitiligo are mediated by inappropriate immune responses to self-tissues, and are often characterized by the cytokines that drive them as well. Enzyme-linked immunosorbent assays (ELISAs) have been used to measure cytokines in peripheral blood, serum, and/or plasma from vitiligo patients in an effort to characterize immune responses in vitiligo and to serve as potential biomarkers. We found that CXCL10 is elevated in the serum of vitiligo patients compared to controls [54], and others have been reported as well, although with variable results [102–106]. One caveat of studying cytokines present in serum in vitiligo patients is that the autoimmune process occurrs in the skin rather than the blood. Presumably serum chemokines have diffused from lesional skin, and so will likely be dilute, and detection will vary according to their magnitude and location of expression in tissue, solubility, and binding to other proteins in the serum.

Studies to detect the expression of cytokines directly in human lesional skin include quantitative reverse-transcriptase PCR (qRT-PCR), gene expression microarray, histology, and flow cytometry on T cells isolated from lesional skin. We used microarray to determine that the IFN-γ-induced chemokines CXCL9, CXCL10, and CXCL11 are significantly elevated in human skin [54], consistent with a previous report that IFN-γ is induced using qRT-PCR [107]. Other studies have reported other cytokines as well, including small amounts of IL-17, TNF-α, and IL-1β [104, 107–109]. Immunofluorescence on fixed vitiligo lesions revealed a number of infiltrating $IL\text{-}17^+$ cells, although other cytokines were not analyzed, and therefore it is difficult to say whether the number detected is the predominant population [108]. Flow cytometry on T cells isolated from lesional skin reveal some heterogeneity among individual patients, but included IFN-γ, TNF-α, IL-17, and IL-4 [46]. While cytokine detection directly in lesional skin appears to be more relevant to disease than serum cytokines, their functional roles are difficult to determine without the use of animal models.

Tetramers, which are comprised of fluorescently tagged, peptide-bound HLA molecules, can be used to detect melanocyte antigen-specific $CD8^+$ T cells in blood using flow cytometry (Fig. 28.4b). This approach has revealed that melanocyte-specific $CD8^+$ T cells are elevated in vitiligo patients compared with controls, and the numbers in the blood correlate with disease activity [47]. We found that they express high levels of CXCR3, and therefore have the capacity to respond to the high levels of CXLC9, CXCL10, and CXCL11 expressed within the skin [54]. Healthy donors also have melanocyte-specific T cells in the blood, although at frequencies much lower than that of vitiligo patients [47, 54]. It is likely that these melanocyte-reactive T cells also play a role in protection against melanoma. One study demonstrated that a large proportion of T cells isolated directly out of lesional vitiligo skin are positive for tetramer staining, thereby demonstrating melanocyte-specific T cells directly within lesions [46].

The combination of human correlative studies with mechanistic studies in representative preclinical animal models is a powerful approach to study disease pathogenesis and develop new treatments, and it is likely that the complimentary use of both basic and translational strategies to understand vitiligo pathogenesis will be necessary to develop badly needed new treatments for the disease.

Future Perspectives into Vitiligo Treatment Strategies

In general, new vitiligo treatments may address any key aspect of vitiligo pathogenesis and repigmentation, which includes melanocyte stress, autoimmune destruction, and melanocyte regeneration (Fig. 28.5). Approaches to normalize melanocyte stress have included the administration of antioxidants orally (Vitamin E, etc) to counteract ROS, as well as the topical administration of pseudocatalase to help break down ROS. To date, these approaches have not demonstrated consistent efficacy in clinical trials, and their use as

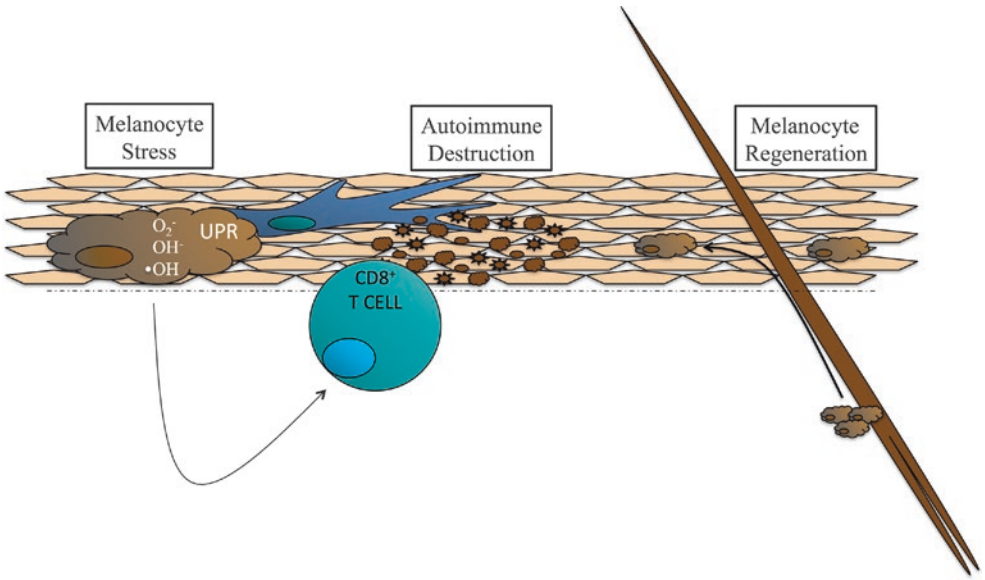

Fig. 28.5 Treatment goals for vitiligo: Target all three aspects of disease. Ideally, treatments for vitiligo will reduce melanocyte stress, suppress autoimmune destruction, and promote melanocyte regeneration

treatments remains controversial [39, 110]. Further study into these approaches is warranted however, and a holistic approach to treatment, including stabilizing melanocyte stress, is an attractive strategy.

Current first-line treatments for vitiligo include nbUVB, topical steroids and topical calcineurin inhibitors. While their precise mechanisms of action are not known, general immunosuppression is likely, and therefore they primarily address the autoimmune component of disease. Future treatments may be developed that provide more targeted immunosuppression, such as interfering with key cytokines and chemokines, or their signaling pathways. For example, based on translational studies with human tissues as well as functional studies in our mouse model, we suspect that interfering with the IFN-γ-CXCL10-CXCR3 axis could be a highly effective strategy for the development of new treatments [54, 95]. CXCL10 and its receptor CXCR3 are particularly attractive candidates, and a number of pharmaceutical companies have developed antibodies and/or small molecules that target these proteins. Janus kinase (JAK) inhibitors, which are currently being developed as well, block signaling through the IFN-γ receptor and may also prove to be effective treatments for disease. It was recently reported that a mutant form of the chaperone protein HSP70, called HSP70i, could prevent depigmentation in a mouse model of vitiligo [43]. This may also be an effective future therapy, and likely helps to uncouple chronic melanocyte stress from innate immune triggering.

Melanocyte regeneration is critical for reversing vitiligo through repigmentation, which often occurs spontaneously when autoimmunity is addressed. Melanocytes typically regenerate and migrate out of pigmented hair follicles, presumably supplied from a protected pool of stem cells within the follicle [76]. Therefore, promoting melanocyte regeneration may improve treatments that target autoimmunity. In addition to the immunosuppressive effects of phototherapy, melanocytes are stimulated as well, promoting repigmentation. Additional approaches to repopulate epidermal melanocytes include the melanocyte-keratinocyte transplant procedure (MKTP), which directly transplants melanocytes and keratinocytes from uninvolved areas of skin to affected areas. However it is only effective in stable conditions, where the autoimmune response has presumably stabilized, as in the segmental variant [111]. Afamelanotide, an analog of α-MSH, is a novel treatment that has been tested in open-label clinical studies. The hypothesis is that stimulating melanocytes through the MSH receptor will promote their regeneration and growth, improving repigmentation. Because it does not address ongoing autoimmunity, clinical studies paired its use with nbUVB with promising results. Repigmentation indeed appeared to occur faster in subjects treated with afamelanotide, although placebo-treated controls were not included in initial pilot studies, and whether the overall quantity of repigmentation was increased is not clear [111]. Additional studies will be required to determine how afamelanotide, and other strategies to support melanocyte regeneration, will contribute to overall clinical treatment strategies of the future.

Conclusion

Vitiligo is a common autoimmune disease in which melanocytes are targeted for destruction. Disease pathogenesis is dependent on genetic susceptibility and environmental triggers related to both the melanocytes and the immune system. Current treatment options focus on general immunosuppression, though investigational procedures and

new research supports targeted treatments combined with therapies that promote melanocyte regeneration. In addition to developing a deeper understanding of the contributions of melanocyte stress, innate immunity, and adaptive immunity in vitiligo pathogenesis, future studies should seek to understand the interactions among them, as well as functional genomics to understand the role of specific genes that affect these pathways. New treatments are on the horizon, and will be exciting to watch as they enter clinical trials in vitiligo patients.

Questions

1. Briefly describe the clinical presentation of vitiligo. What is required for a definitive diagnosis?

   Vitiligo presents as patches of depigmentation, most commonly on the hands, feet, face, and genitals, followed by the trunk/back. Depigmentation may be bilateral or unilateral, and is thus classified as either non-segmental or segmental, respectively. Signs for highly active vitiligo include confetti or trichrome depigmentation, as well as the koebner phenomenon. A definitive diagnosis of vitiligo requires biopsy demonstrating a lack of melanocytes by immunohistochemical staining, although this is not commonly required.

2. What are current treatment options and how do they work? How would future treatment options improve upon these?

   Current treatment options for vitiligo include general immunosuppressants, including topical steroids and calcineurin inhibitors like tacrolimus, and narrow band UVB, which is thought to both suppress autoimmune inflammation and promote melanocyte differentiation/melanin production in the skin. Melanocyte transplantation surgery, or MKTP, often works for patients with stable disease such as segmental vitiligo patients. Future treatment options would improve upon these by more specifically targeting the immune cells responsible for vitiligo maintenance and progression, and through direct stimulation of melanocytes to better promote repigmentation.

3. Briefly describe the pathophysiology of vitiligo. Be sure to discuss cellular stress, innate immunity, adaptive immunity?

   Vitiligo is caused by a combination of genetic susceptibility and environmental exposures that lead to immune activation. Melanocyte stress is thought to be the first step in vitiligo pathogenesis. Genetic factors may cause increased basal melanocyte stress, and/or exposure to phenolic chemicals would cause increased melanocyte stress through interaction with tyrosinase. This stress is likely sensed by innate immune cells that reside in tissues, such as dendritic cells and macrophages, who in turn present melanocyte antigens to T cells in skin draining lymph nodes. These T cells then infiltrate the skin to target and kill melanocytes.

4. What are some genetic contributions to vitiligo? Please describe the functions of these genes in relation to disease pathogenesis.

   Some genetic contributions to vitiligo include HLA-A2, which is important for presentation of melanocyte antigens to T cells; innate immune genes such as NLRP1, which may play a role in sensing melanocyte stress; XBP-1, a chaperone that may contribute to melanocyte stress; genes affecting Treg function including PTPN22, IL2RA, FOXP3; and genes affecting effector T cell function such as granzyme B.

5. Name two research tools currently being used to better understand mechanisms of vitiligo. How does each tool help to identify new potential treatments?

   Two research tools currently used to better understand vitiligo are animal models and translational studies using human skin biopsies. Animal models help identify disease mechanisms and potential treatments, as T cell responses may be assessed in skin and lymphoid tissues following experimental treatments at specific time points, which cannot be assessed in humans. Skin biopsies, however, provide insight into human disease and may be assessed for inflammatory markers and cellular phenotypes.

Alopecia Areata

29

Ali Jabbari, Lynn Petukhova, and Angela M. Christiano

Abstract

Alopecia areata (AA) is an autoimmune disease characterized by targeting of the hair follicle. Clinically, patients exhibit nonscarring hair loss with varying presentations across all age groups and follow an unpredictable course. Our understanding of the pathogenic mechanisms underlying AA has been greatly enhanced by recent large scale studies of genetic associations of disease. Descriptive studies in humans in tandem with mechanistic experiments in mice have helped define cellular and soluble disease drivers at the level of the end-organ target, the hair follicle, as well as the immune system. In AA, those mechanisms that protect the hair follicle from immune attack and maintain the immune privileged status of this site become disrupted and allow autoreactive cytotoxic immune cells to recognize and respond to self-antigens associated with the hair follicle. Our enhanced understanding of the disease has led to the identification of new therapeutic targets for AA. In particular, targeting of JAK molecules, proximal intermediates that transduce ligand binding signals for a wide variety of cytokine receptors, have shown promise in the treatment of this disease in animals models and humans.

Introduction

Alopecia areata (AA) is an autoimmune disease characterized by targeting of the hair follicle. Clinically, patients exhibit nonscarring hair loss with varying presentations across all age groups. The most common form of the disease, patchy AA, is characterized by well-defined, coin-shaped or ovoid patches of alopecia that typically involve the scalp or beard area (Fig. 29.1), although any part of the body can be affected. These areas may resolve spontaneously or with treatment, or may be persistent. In approximately 1 in 20 cases of patchy AA, the alopecic areas will grow and coalesce, resulting in a more severe form of AA [1]. AA that involves the entire scalp (Fig. 29.2) is called alopecia totalis (AT), and AA that involves the entire body is called alopecia universalis (AU). The course of disease in patients with AT and AU can vary, although a much higher percentage of these patients exhibit persistent disease when compared with patients with patchy or localized AA. These more severe forms of the disease are also largely recalcitrant to long-term treatment. In addition, specific patterns of hair loss can be observed in patients with AA. In the ophiasis pattern, first described by Aulus Cornelius Celsus circa 30 AD, a band-like area of hair loss is observed extending from the occipital scalp bilaterally to the temporal scalp [2]. The inverse of this pattern has been described; in the sisaipho pattern, the vertex

and frontal scalp are affected with relative sparing of the band of hair between the occiput and bilateral temporal scalp. Like the severe forms of AA, both of these variants are usually recalcitrant to currently available therapies.

Genetic Architecture of AA

Human genetic studies in AA have played a pivotal role in understanding its etiology. Initial evidence for a genetic basis to the disease arose from family studies that demonstrated increased risk of disease in first degree relatives [3, 4], twin studies [5, 6], and studies in animal models [7]. The earliest genetic studies, limited by the availability of high throughput cost-efficient technologies for genotyping or sequencing, utilized a candidate gene approach testing only a few variants in pre-selected genes, utilizing small cohorts. These initial genetic studies demonstrated associations to several immune related genes, including genes within the human leukocyte antigen (HLA) complex such as HLA-DQB1, HLA-DRB1, HLA-A, HLA-B, HLA-C, NOTCH4, MICA, as well as PTPN22 and AIRE, which are located outside the HLA. While these studies provided consistent support to the theory of an autoimmune basis for the disease, they were limited in generating new etiological insight. With the advent of commercial single nucleotide polymorphism (SNP) genotyping arrays, it became feasible to query the entire genome in large cohorts of patients and controls, enabling unbiased testing in well-powered studies. The first genome-wide association study (GWAS) conducted for AA identified eight regions in the genome with statistically significant evidence for association [8]. Of these, only the HLA had previously been implicated in AA. A subsequent replication study utilizing this GWAS data and genetic data in an independent cohort identified two additional loci in the genome [9]. Most recently, the first meta-analysis GWAS was performed in AA in a cohort of 10,000 samples. The substantial increase in sample size increased the power to detect association, and four additional loci were at or near genome-wide statistical significance [10].

GWAS loci typically contain multiple genes, but the technique does not allow individual genes within loci to be prioritized for etiological significance. In order to gain mechanistic insight from GWAS evidence, pathway analysis

Table 29.1 GWAS loci in AA implicate biological processes perturbed in disease

Pathway, GWAS locus (pathway gene)
T cell activation, co-stimulation, and differentiation 1p13.2 (PTPN22), 2q33.2 (CD28, CTLA4), 4q27 (IL2, IL21), 5q31.1 (IL13, IL4, IL5, IRF1), 6p21.32 (HLA-DMA, HLA-DOA), 10p15.1 (IL2RA, PRKCQ), 11q13.1 (BAD), 12q13 (IL23A, IKZF4 (Eos)), 16p13.13 (CIITA)

There are 14 regions in the genome that demonstrate significant association with AA by GWAS, which range in size from 30 Kb up to 500 Kb and can contain many genes, in addition to regulatory elements that influence genes proximal to GWAS loci [10]. Pathway analysis of the 228 genes within 1 Mb of a GWAS loci implicates several molecular pathways. Genes contributing to pathway evidence are listed by region

is used to identify sets of functionally related genes. In AA, the 14 GWAS loci contain 226 protein coding genes and pathway analysis demonstrates enrichment of genes involved with a small number of biological processes (Table 29.1). For instance, pathways that implicate specific immune perturbances include T-cell activation/differentiation, JAK-STAT signaling, and viral defense response. There are additional pathways implicated by GWAS that suggest disease mechanisms that could be operating in either cells of the immune system, or alternatively, within the hair follicle itself, including oxidation-reduction, apoptosis, and steroid hormone signaling.

Of clinical relevance, some of the etiological pathways that came to light as a result of these genetic studies are targeted by therapeutics already in use to treat other autoimmune diseases, but had not previously been considered within the context of AA treatment. For example, the costimulatory pathway is targeted by abatacept, and JAK-STAT signaling is therapeutically targeted by ruxolitinib and tofacitinib, discussed further below. Trials to test these interventions in the treatment of AA have yielded promising early results [30]. Thus GWAS in AA have rapidly realized the initial promise of the human genome project, to improve the care of patients.

Hair Follicle Immune Privilege

An 'immune privileged' (IP) site was initially defined as a body site to which foreign grafts could be placed without being rejected [11]. This concept was first described by Peter Medawar, after conducting experiments in rabbits demonstrating relative resistance to rejection of allogeneic skin grafted into the anterior chamber of the eye [12]. IP was extended to describe not only sites or organs but also tissues, which were so defined by their relative resistance to rejection if transplanted onto conventional, non-immune privileged sites [13, 14]. Immune privileged sites include the eye, brain, gametes, pregnant uterus, as well as the hair follicle. Indeed, early experiments in which black skin from guinea pigs was grafted onto immunologically nonreceptive white skin of a different guinea pig strain showed rejection of donor skin but prolonged retention of the donor hair follicles [13, 15, 16]. More recently, hair follicle cells from a human male donor were implanted into the skin of an unrelated female, without evidence of rejection [17].

Many factors contribute to IP in the hair follicle. HLA expression is minimal in the hair follicle [18, 19] below the level of the isthmus, preventing recognition of cell-associated antigens by T cells. The hair follicle also employs various methods to avoid or minimize recognition and attack by natural killer (NK) cells, which may be expected due to low HLA expression, including the expression of macrophage migratory inhibitory factor and relative absence of ligands of NK cell stimulatory receptors [20, 21]. Evidence exists that the local environment is comprised of other immunoregulatory proteins, such as TGF-β1 [22], α-MSH [23, 24], and cell-associated PDL1 [25] that may be serving to inhibit immune responses to hair follicle-associated antigens [26]. Lastly, there is an alteration and overall diminution in immune cells that may be contributing to inflammation. Langerhans cells, an immune component of the skin epidermis, are relatively deceased in numbers below the level of the isthmus [19, 27], as are T cells [19]. The contribution of these cells to pathologic states where IP is altered is currently an active area of research.

AA is associated with a collapse of the immune privileged status of the hair follicle [26]. Hair follicles within and adjacent to alopecic patches in AA patients exhibit marked expression of HLA molecules [28], and infiltration of the hair follicle with CD4 and CD8 T cells is observed in AA

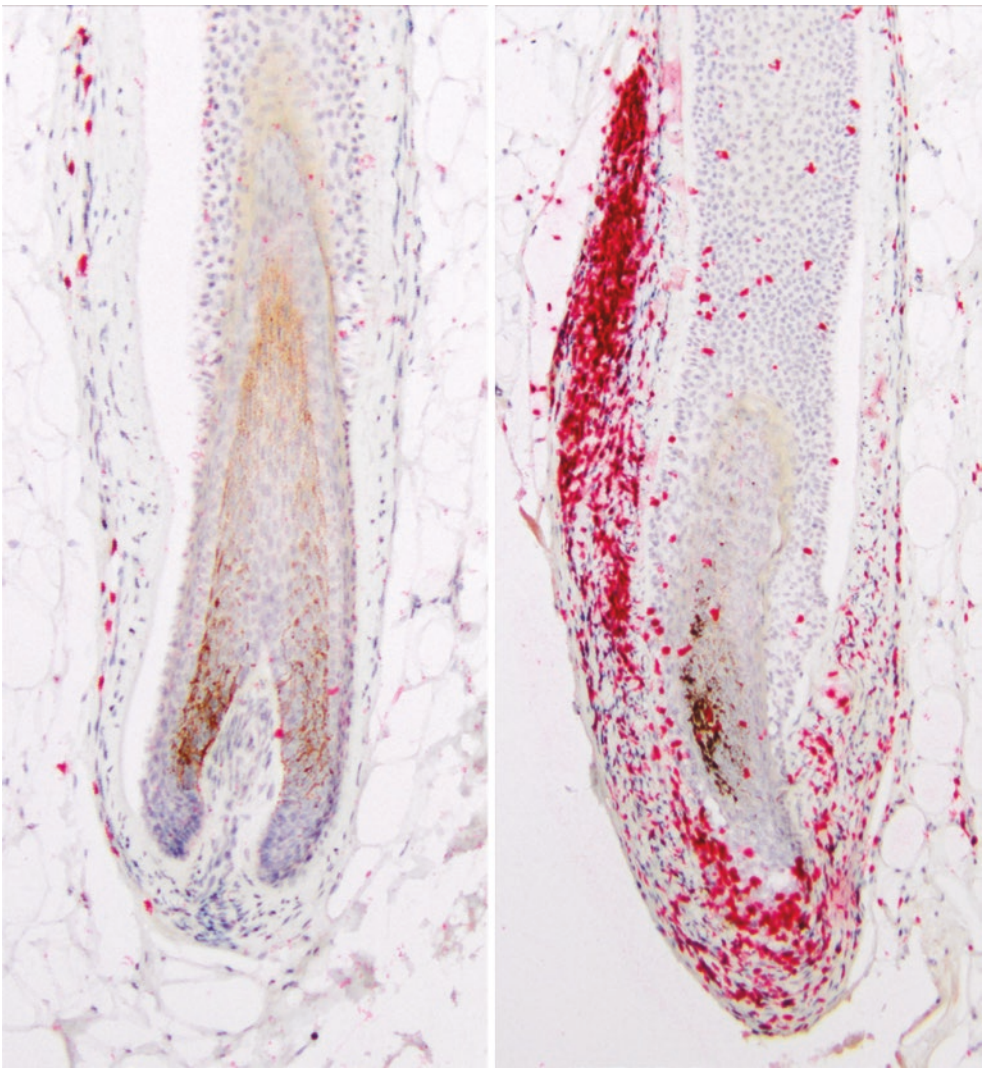

Fig. 29.3 Peribulbar CD3 infiltrate in AA. CD3 immunohistochemical staining of hair follicles in a normal patient (*left panel*) and AA patient (*right panel*). The peribulbar infiltrate has been likened to a "swarm of bees"

lesions (Fig. 29.3), in a pattern termed the "swarm of bees" [1, 29]. Furthermore, the hair follicle begins expressing ligands for NK cell stimulatory receptors, including MICA [20] and several ULBP molecules [8]. The cytokine milieu is also skewed toward a proinflammatory profile, exemplified by the marked increase in the expression of interferon (IFN)-response genes as well as common γ-chain (γ_c) receptor cytokines in AA lesions [30]. This loss of IP in the hair follicle is likely a necessary step for antigenic responses by the immune system and clinical disease in AA.

Cellular Immune Effectors in AA

Much of the work to identify the cellular pathogenic mediators of AA has been conducted in animal models. The C3H/HeJ mouse is a murine model of spontaneous AA development, wherein approximately 10–20 % of mice develop nonscarring alopecia that replicates many features of the human disease [31]. Subcutaneous injection of unmanipulated lymph nodes cells from alopecic C3H/HeJ mice to unaffected mice resulted in hair loss after 5 weeks, implicating the presence of an immune effector mediating the disease [32]. Another model of alopecia, in which human punch biopsy samples from normal patients are grafted onto immunodeficient recipient mice, requires the subcutaneous injection of peripheral blood mononuclear cells after culture in IL-2, corroborating the necessity of a cellular immune effector [33]. More recently, spurred by multiple lines of evidence including (1) the recognition of increased expression of NKG2D ligands in AA skin biopsies [8, 20], (2) our identification of a genetic association between AA and NKG2D ligands [8], and (3) the presence of $CD8^+NKG2D^+$ cells surrounding the hair follicle in patients with AA, adoptive transfer studies were performed demonstrating that $CD8^+NKG2D^+$ cells from skin draining lymph nodes of alopecic C3H/HeJ mice were necessary and sufficient to induce systemic disease in previously unaffected

C3H/HeJ mice [30]. Several lines of evidence support the NKG2D-NKG2D ligand interaction as a critical component of disease, including the upregulation of NKG2D ligands in the hair follicle of AA patients [8] and affected C3H/HeJ mice [30] as well as the known capacity of NKG2D to potentiate antigen-induced T cell responses [34, 35]. These identify $CD8^+NKG2D^+$ T cells as critical players in AA pathogenesis.

Other T cell populations are also likely influencing the development of AA. CD4 T cells comprise part of the peribulbar infiltrate seen in lesions from AA patients [20], and the strongest AA genetic associations have been with HLA Class II molecules [8], which present peptides to CD4 T cells. Adoptive transfer studies in the C3H/HeJ model indicate that CD4 T cells from the lymph nodes of affected mice were sufficient to induce the disease in unaffected, AA-prone mice [36]. Experiments in which the CD4 T cell population have been segregated based on CD25 expression, putatively separating regulatory T cells and conventional CD4 T cells, indicate that the $CD4^+CD25^-$, or conventional T cell, population is the more potent subgroup of this population, whereas $CD4^+CD25^+$, or Treg, cells have a protective role and act to prevent the development of AA [36]. In humans, analyses of serum cytokines in AA patients show reduced levels of circulating TGF-β1 and elevated levels of IL-2, IFN-γ, IL-13 and IL-17, supporting a reduction in the ratio of Treg/conventional T cell activity [37].

The role of NK cells is currently less clear. Although the expectation may be that NK cells would be playing a pro-inflammatory role in AA pathogenesis, data exists supporting an immunoregulatory role for NK cells [38]. The mechanisms of this immunoregulation have not yet been elucidated. It has become challenging to interpret prior studies interrogating the role of NK cells in AA, and the recent discovery of a CD8 T cell population that co-expresses NK markers in AA invites a re-evaluation of prior studies examining NK cells.

Mast cells have also been described in increased numbers around the hair follicle and in the perifollicular dermis in patients with AA [39]. However, studies of mast cells in AA have been limited, although mast cells are able to act as professional antigen presenting cells [40, 41] and elaborate T cell chemotactic molecules [42]. While the mast cells in AA lesions exhibit a pro-inflammatory profile skewing [39], their contribution to AA pathogenesis is unclear.

Macrophages also make up part of the peribulbar infiltrate in AA. In the normal murine hair cycle, the transition from telogen to anagen is marked by a decrease in the number of macrophages, and experimental depletion of macrophages hastened the transition from telogen to anagen [43]. The heightened presence of these cells in AA may indicate that macrophages may be playing in a role in regulating the hair cycle in AA, although this has yet to be substantiated.

Cytokines in AA

IFNs have been implicated in the induction of AA in human disease and in mouse models. Scalp lesions in AA exhibit a strong IFN signature [30], with both type I and II IFNs likely contributing. In particular, IFN-γ, the sole member of the type II IFN family, appears to strongly influence the immune status of hair follicles. Injection of IFN-γ into C3H/HeJ mice reverses the IP status of the hair follicle, demonstrated by increased MHC Class I and II expression, T cell infiltration, and hair loss [44], although some studies of this effect have shown contrasting results [45]. Genetic ablation of IFN-γ prevented the development of spontaneous AA in C3H/HeJ mice [46]. Furthermore, in a modified murine AA model in which alopecic C3H/HeJ skin has been grafted onto previously unaffected C3H/HeJ recipients, which induces hair loss in 90–100 % of graft recipients, neutralizing antibodies to IFN-γ prevented the development of AA [30].

Evidence that type I IFNs, including IFN-α and IFN-β, contribute to the development of AA can be inferred from studies in which patients were treated with IFN for other medical conditions. IFN-α is used as a treatment for chronic hepatitis C, and case reports exist exhibiting the development of AA with treatment and subsequent resolution after the treatment course is completed [47, 48]. Examinations of lesional biopsies from patients with AA demonstrate expression of MxA [49], an IFN-stimulated gene. However, more extensive studies examining the necessity and sufficiency of type I IFNs in AA pathogenesis, for example in mouse models, are lacking.

The participation of certain γ_c receptor cytokines, especially IL-2 and IL-15, has also been implicated in the development of AA. IL-2 and IL-15 function in many ways in the immune system, including providing survival and proliferative signals to T cells. IL-15 can also induce the expression of NKG2D on T cells and can prime NKG2D signaling [50]. IL-2 haploinsufficent C3H/HeJ graft-recipient mice were relatively protected from developing AA, compared to IL-2 sufficient control graft recipients [51]. Antibody treatment targeting IL-2 or the shared β subunit for the IL-2/IL-15 receptor prevented the development of AA in a mouse model of the disease [30]. In AA patients, IL- 15 is expressed at high levels on the hair follicle [30] and has been implicated in another autoimmune disorder, celiac disease [52–54]. Both IL-2 and IL-15 are likely crucial to the development of AA.

Putative Antigens in AA

It is currently unknown whether a shared specific antigen or set of antigens is the target of autoimmune attack for patients with AA. Several lines of evidence support the notion that an

antigen-specific response is involved, including the genetic association between AA and HLA alleles [8], the congregation of T cells around hair follicles in skin samples of affected patients [1], and the ability to induce disease from one mouse to another by adoptive transfer of T cells [30, 36]. Attempts at identifying target antigens in AA have mostly focused on autoantibodies in patients with AA, and the role of antibodies in AA has not been defined. Autoantibodies against a hair follicle-associated antigen have been detected at higher levels in AA patients compared with normal controls, although the identity of this antigen is not known. Trichohyalin has been identified as an autoantibody target in patients with AA [55], although whether autoantibody formation to this or other putative antigens is critical to the pathogenesis of AA or a marker of hair follicle damage remains an open question.

Immunointerventions in AA

There are currently no US FDA approved drugs for the treatment of AA. A Cochrane systematic review conducted in 2008 concluded that there is no convincing trial evidence that any treatments provide long-term benefit to patients with any form of AA [56]. Interventions for AA have, for the most part, consisted of local or systemic immunosuppressive regimens that are relatively nonspecific in their effects and have included topical or intralesional glucocorticoids or steroid-sparing agents.

Glucocorticoids are likely the most commonly used treatment for AA. Glucorticoids inhibit the production of pro-inflammatory cytokines and chemokines and induce the apoptosis of dendritic cells and lymphocytes. Localized treatments are often performed using topical or intralesional delivery methods, and systemic treatment is usually performed only in the context of severe disease. No double blind, randomized controlled trials exist of these treatments, and it is unknown whether these treatments alter the long-term disease course.

Prolonged treatment with systemic steroids has the potential to cause many adverse effects. Steroid-sparing immunosuppressive agents are usually used in the context of severe disease and in cases where the need for a prolonged treatment course are suspected. These treatments include methotrexate, cyclosporine, azathioprine, and sulfasalazine. Only case reports exist of the use of these treatments for AA [57].

Topical immunomodulation is another treatment strategy used for AA. The rationale for these treatments is that the end-organ inflammatory milieu may be redirected to a different, non-hair follicle associated target or can be changed in such a way that it is no longer permissive for continued attack of the hair follicle by the immune system. Anthralin has been cited as a topical immunomodulator, likely due to its proinflammatory effects causing a dermatitis to applied areas. The time that anthralin is allowed to remain on the skin is often titrated to a maximum of 1 h or until a dermatitis is achieved. The mechanism by which AA is inhibited by this drug, however, is unknown.

Topical sensitization to either diphenylcyclopropenone or squaric acid dibutylester is another form of topical immunomodulation that is used for severe cases of AA. These treatments consist of a sensitization phase, in which an allergic response is generated to the drug, and a treatment phase, in which the drug is applied to the affected area with the intent of causing a low-level dermatitis and, secondarily, allowing hair regrowth. Studies in which half the head had been treated with the topical immunomodulator while the contralateral side was left untreated demonstrated some efficacy for these treatments in severe forms of AA, although the hair regrowth is often not sustained long-term [58]. The proposed mechanisms by which these drugs effectively treat AA include antigenic competition, in which an immune response to a separate antigen is elicited with accompanying regulatory/suppressor cells that quell responses to competing antigens [59]. Other studies have shown that DPCP also increases the number of infiltrating CD8 T cells in perifollicular and epidermal areas [60] and decreases the CD4:CD8 ratio [61], but it is unclear how this contributes to ameliorating hair loss in AA since CD8 T cells are thought to be the primary cellular effectors of disease.

Targeted treatments, specifically identified for AA or for immune pathways active in AA, have been lacking. The identification of candidate therapeutic targets for drug development have been recently spurred by results from a GWAS for AA in 2010 as well as gene expression profiling of affected skin from human AA patients and the C3H/HeJ mouse model [62]. Many of these treatments have been tested in the C3H/HeJ model, with a few beginning to be assessed in human AA patients. Antibodies to IFN-γ, IL-2, and the IL-2/15R β chain have shown their utility in the prevention of AA onset in the C3H/HeJ murine model. The efficacy of blocking these cytokine pathways in the murine model led to investigation into whether inhibiting the signaling pathways activated by these cytokines is also an effective treatment strategy.

Notably, γ_c receptors and IFN receptors signal through JAK molecules, with the γ_c cytokines signaling predominantly through JAK1 and JAK3 and the IFN-γ receptor signaling through JAK1 and JAK2. Ruxolitinib and tofacitinib are tyrosine kinase inhibitors with selectivity for JAK molecules that have been approved for use by the US FDA in myelofibrosis and rheumatoid arthritis, respectively. Both of these drugs were able to prevent the development of AA and effectively treat established disease in the C3H/HeJ graft model [30]. Furthermore, topical formulations of these inhibitors reversed established disease in the C3H graft model [30].

Experience with these drugs in the treatment of AA has been limited to a very small number of patients. A single patient with psoriasis and AA universalis treated with tofacitinib experienced partial scalp hair regrowth at 2 months when treated with 5 mg twice daily. Complete scalp hair regrowth with regrowth of eyelashes, eyebrows, axillary hair and pubic hair was observed after an additional 3 months of taking 10 mg in the morning and 5 mg at night. No adverse symptoms or laboratory abnormalities were reported for the patient.

The use of ruxolitinib has also been reported in a series of three patients with moderate to severe AA [30]. All three patients experienced striking hair regrowth after 12 weeks of treatment. Adjunctive studies performed on these patients demonstrated diminished skin infiltration by CD4 and CD8 T cells, and resolution of the observed IFN and cytotoxic T lymphocyte signatures, which were elevated at baseline prior to treatment. Open label pilot studies of ruxolitinib and tofacitinib in patients with AA are currently underway. Larger placebo-controlled studies are needed to determine whether JAK inhibitors are a safe and efficacious treatment for AA, to validate the striking results reported to date.

Conclusions

AA is a common autoimmune disease in which the hair follicle is the target of immune attack. Genetic studies support the immune-related etiology of AA and have been critical in the identification of cellular effectors in AA and pathways that underlie the pathogenesis of the disease. $CD8^+NKG2D^+$ cells, which were first implicated by the genetic association between AA and NKG2D ligands, have since been found to be necessary and sufficient for the development of AA in mouse models. The IFN and γ_c cytokine circuits, identified in the AA GWAS and/or gene expression analyses in humans and mice, play critical roles in the collapse of immune privilege and the development of AA in mouse models and warrant further investigation as targets of biologics in humans for treatment development.

JAK inhibition, resulting in ablation of these cytokine signaling pathways, is a strategy showing promise in effectively treating AA but will likely require further studies.

Cutaneous Lupus Erythematosus

30

Christopher B. Hansen, David F. Fiorentino, and Richard D. Sontheimer

Abstract

Cutaneous lupus erythematosus is a heterogeneous skin disease that is identified based on histopathological and clinical features. It can exist in the presence or absence of systemic manifestations of lupus erythematosus. Classification of cutaneous lupus into subtypes is clinically useful in predicting clinical course and potential association with systemic disease. Pathogenesis involves a genetic susceptibility and environmental triggers. An increasing number of therapeutic options are available.

Keywords

Lupus • Cutaneous • Epidemiology • Therapy • Photosensitivity

Lupus erythematosus (LE) is a broad term referring to disease phenotypes that are characterized by a particular form of aberrant immune activation. Disease presentation is heterogeneous, ranging from a single organ (i.e., skin) disorder to a multi-systemic disease. As such, the term LE should be used with certain modifiers to specify more precisely the type of clinical illness that is being discussed. Systemic LE (SLE) refers to a unique medical diagnosis that is characterized by involvement of multiple organ systems and, although heterogeneous, is bound by certain commonalities of immune dysfunction. The term cutaneous LE (CLE) describes the spectrum of skin disease that has a pathophysiology that is related to LE and is bound by common histopathological and/or molecular criteria. After accepting this definition of CLE, it is paramount to understand that the same lesions can also be found as isolated cutaneous findings in an otherwise healthy individual.

When considering the patient with SLE, one must remember that CLE is not the only form of skin condition related to the underlying disease. It is useful to consider the classification scheme developed by Gilliam and Sontheimer [1] in which the skin findings in a patient with SLE are further characterized as either "LE specific" or "LE non-specific". LE-specific skin disease refers to CLE. LE-specific skin disease generally has one or more of the following histologic features: lichenoid tissue reaction with or without basal keratinocyte vacuolar change; hyperkeratosis; thickening of the epidermal basement membrane; pervivascular and/or perifollicular mononuclear cell infiltrate; and dermal mucin deposition.

In contrast, LE non-specific disease refers to those cutaneous findings that, although driven by the underlying SLE, do not possess the typical histologic features of CLE and can also seen in other disorders. LE non-specific disease includes vascular abnormalities (i.e., vasculitis, vasculopathy, Raynaud's), mucosal ulceration, alopecia, and photosensitivity [2]. This chapter will only concern itself with LE-specific skin disease (i.e., CLE). However, it should be noted that LE non-specific skin disease is of paramount importance to the clinician, as its presence can be an indicator of systemic disease and can reflect SLE disease activity.

Classification

LE-specific skin disease can be classified in various ways—clinically, serologically, or histopathologically. We will employ the scheme of Gilliam and Sontheimer [1], which relies heavily on clinical manifestations and divides lesions into acute (ACLE), subacute (SCLE), and chronic (CCLE). It should be noted that these terms refer both to the morphologies and pace of the cutaneous lesions themselves. The fact that some forms of LE specific skin disease such as ACLE are strongly associated with SLE disease activity is one reason why it is so vital to categorize carefully LE-specific disease, as this can give a clue if the findings are isolated or are occurring in the context of SLE. As with any classification system, there are cases that do not fit neatly into a group or are considered indeterminate. In addition, these categories are not mutually exclusive; that is, patients may have more than one type of LE-specific skin lesion, either at the same time or during the course of their disease.

Epidemiology

There are few population-based data concerning the epidemiology of CLE, particularly isolated forms of CLE such as SCLE and classical discoid LE (DLE) that typically are not associated with clinically significant SLE. A retrospective population based study over 40 years suggested that the incidence of CLE is comparable to the published incidence of SLE [1].

In the context of SLE, the skin appears to be second only to the joints as the most frequently affected organ [5–7]. For ACLE, the association is so strong with SLE that the epidemiology of ACLE would be expected to be similar to that of patients with SLE [3]. Assuming that ACLE is synonymous with "malar rash" as well as "maculopapular rash", facial ACLE appears to occur in 20–60 % of large LE patient cohorts, while the "maculopapular rash" of SLE occurs in 35 % of SLE patients [6]. Malar rash/ACLE is more common in whites than blacks, women, and younger patients [6, 8, 9].

SCLE occurs predominately in white females of all ages. The original cohort of Sontheimer et al. showed that 70 % were female and 85 % were white, with a mean age of 43.3 years [10]. These patients have been shown to comprise 7–27 % of the total LE cohort in several studies [3]. A study using an anti-Ro/SSA registry followed by patient reported photosensitive skin disease estimates an incidence and prevalence of 4.8 (per year) and 6.2–14 per 100,000 persons, respectively, for SCLE [11].

Chronic cutaneous LE (CCLE) can occur with or without systemic disease. There are no reliable population-based data for CCLE, as these patients are underrepresented in studies from rheumatologists and internists and over represented by dermatologists. It appears that DLE lesions, the most common form of CCLE, can be found in 15–30 % of SLE patients at some point in time during their disease course [12]. Approximately 5–10 % of SLE patients will present with DLE skin lesions [13]. Female:male ratio of DLE is between 3:2 and 3:1 (much lower than SLE); males and females are equally affected, and typical age of onset is between 20 and 40 years [2, 14].

Cutaneous Manifestations

Acute Cutaneous Lupus Erythematosus

ACLE can either be localized to the face or generalized. The classic "butterfly rash" consists of confluent or patchy macular erythema with or without papules, edema and induration, scattered across the malar eminences and bridge of the nose. The forehead, chin, and V-area of the neck can be involved (Fig. 30.1a). The nasolabial folds are typically spared. Although usually symmetrical, this is not always the case. There can be some mild degree of hyperkeratosis.

Generalized ACLE is less common and presents as a widespread morbiliform eruption, often accentuated in a photodistributed pattern over the extensor aspects of the arms, forearms, and dorsal hands and fingers. Over the dorsal fingers during the early phase of the disease, the hair-bearing interphalyngeal areas are especially targeted while the knuckles are spared. Some patients experience an extreme form of ACLE that simulates toxic epidermal necrolysis (TEN), due to the intense lichenoid inflammation [15]. Of note this is one mechanism for the development of vesicular lesions in CLE.

LE patients can experience several types of vesiculobullous skin disease. In "bullous SLE," patients typically with active SLE can present with vesicles (which appear similar to dermatitis herpetiformis) or bullae on the face, arms, and trunk [3]. Histopathological examination of the skin often reveals papillary dermal neutrophilic microabcesses as well as deposition of multiple immunoreactants at the dermal-epidermal junction. In some cases, these antibodies have been shown to bind type VII collagen, while in others the multiple immunoreactants are more consistent with nonspecific immune complex deposition. Thus, these lesions clinically and histologically simulate dermatitis herpetiformis or epidermolysis bullosa acquisita, but the clinical distribution and multiplicity of immunoreactants and the presence of other features of LE help to distinguish these cases.

As "bullous SLE" does not share the histopathologic findings that are typical of CLE, it can be considered as a form of LE-nonspecific vesiculobullous skin disease. Vesiculobullous annular SCLE is an example of vesiculobullous LE-specific

Fig. 30.1 Lupus-specific skin disease. (**a**) Acute cutaneous LE. (**b**) Drug-induced subacute cutaneous LE secondary to rabeprazole (Aciphex) (personal unpublished observation, R. D. Sontheimer). (**c**) Classical discoid LE affecting the chin and lips. (**d**) Classical discoid LE affecting the scalp and external ears with scarring alopecia and postinflammatory hypopigmentation

skin disease. Of note, vesiculation can also result from other blistering disorders, such as bullous pemphigoid, dermatitis herpetiformis, porphyria cutanea tarda, and pemphigus vulgaris that have rarely been reported to occur concordantly with LE [79–82].

Superficial ulceration of the oral or nasal mucosa can also occur in ACLE. These lesions are often asymptomatic, transient, and tend to occur on the hard palate (although virtually any area of the oral mucosa can be involved) [2, 16].

The lesions of ACLE are typically photosensitive and transient, usually lasting several days or weeks. Patients can concurrently develop SCLE, or, less commonly, DLE lesions. ACLE lesions do not scar but can result in predominate post-inflammatory pigmentary alteration, especially in dark-skinned patients.

The differential diagnosis for ACLE includes any dermatosis that can produce a red face, with common diagnoses being acne rosacea, dermatomyositis, seborrheic dermatitis, contact dermatitis, polymorphous light eruption (PMLE), and drug eruptions. Rosacea deserves special mention as a mimic of ACLE. In a study of patients referred to a dermatology clinic with a presumptive diagnosis of cutaneous LE, there were 21 that in fact had a different dermatological condition. Sixteen of these 21 patients had rosacea based on biopsy or diagnostic clinic features [2].

Subacute Cutaneous Lupus Erythematosus

First described as a distinct entity by Gilliam in 1977, SCLE is the prototype of a LE-specific skin disease that is defined by clinical, serological, and genetic features [10]. Clinically, these lesions present as either scaling papules or small plaques (“psoriasiform type”) (Fig. 30.1b) or scaling, annular and/or polycyclic plaques (“annular type”)—these forms are equally prevalent [2]. In general, one

individual presents with one or the other type, though both forms can occur in a patient.

Lesions are characteristically photodistributed on the chest, back, extensor arms and V-area of the neck—it is the experience of the authors and others [92] that these lesions occur less commonly on the face compared to ACLE and DLE [2, 17]. Eighty-five percent of all SCLE patients report photosensitivity [18]. The inactive central portion of the radially spreading annular lesions is often hypopigmented. As in ACLE (see above), intense basovacuolar degeneration of epidermal keratinocytes can result in vesiculation and/or crusting, which usually occurs at the active edge of annular lesions. This can resemble TEN in its extreme form [19]. Lesions of SCLE typically heal without scarring, but permanent hypopigmentation and/or telangiectasias can occur. SCLE patients can also develop the lesions of ACLE or classic DLE. Localized facial ACLE has been reported to occur in 20 % of patients [3], while various reports document DLE lesions in 0–30 % of SCLE patients [11, 18]. In contrast to ACLE, SCLE lesions tend to be less transient, more scaly, less edematous, associated with more pigmentary change, and, as previously mentioned, less commonly affect the face. The absence of induration in SCLE lesions can serve as a clinical distinguisher from DLE and LE tumidus.

The differential diagnosis for SCLE includes psoriasis, dermatophyte infections, pityriasis rubra pilaris, polymorphous-light eruption (PMLE), nummular eczema, dermatomyositis, and mycosis fungoides. Annular lesions can be confused with granuloma annulare, erythema multiforme, and gyrate erythemas. However, the inactive centers of SCLE lesions are typically hypopigmented while those of other annular disorders are typically pigmented normally or hyperpigmentated.

Chronic Cutaneous Lupus Erythematosus

Classic DLE is the most common form of CCLE. These lesions begin as erythematous papules, which then develop scale and evolve into larger plaques covered by adherent scale that are usually associated with follicular plugging and peripheral hyperpigmentation. When the adherent scale is peeled back, follicle-sized keratotic spikes can be seen to project from the underside (the so-called "carpet tack sign"). The lesions expand slowly leaving central atrophy, scarring, telangiectasia, and depigmentation (Fig. 30.1c). Hyperpigmentation is often seen at the active borders of lesions. The combination of peripheral hyperpigmentation and central depigmentation is especially prominent in African American DLE patients. Some lesions of DLE can present only as macular hyperpigmentation, especially in Asian Indians [20].

DLE lesions occur most often on the face, ears (especially the conchae), scalp, V-area of the neck, and extensor aspect of the arms. Any facial structure can be involved, including eyebrows, eyelids, nose and lips. Periocular lesions are often misdiagnosed and can present as blepharitis, conjunctivitis, or periorbital edema [2]. Lesions can occur in the malar distribution, but their chronicity, epidermal change and scarring should distinguish them from the classic malar rash of ACLE. An acneiform pattern (often in the perioral area or the chin) that resolves with pitted scarring is rarely seen [2, 21]. Compared with ACLE or SCLE, DLE is less commonly reported to be associated with ultraviolet (UV) exposure. Patients are often unaware of the time lag (up to 4 weeks) following sun exposure, and many lesions do not occur in sun-exposed areas (e.g., hair-bearing scalp, conchal bowl of ears) [22, 23].

Scalp involvement occurs in 60 % of patients with DLE, with persistent activity resulting in permanent scarring (Fig. 30.1d). However, alopecia that is associated with DLE can be reversible when it is secondary to early inflammation of DLE; the telogen effluvium that represents an increase in underlying SLE activity; and alopecia areata that has been shown to be commonly associated with DLE [24].

DLE lesions are termed "localized" if they occur only on the head and neck, while lesions above and below the neck are referred to as "generalized". Lesions can also occur on the palmar or plantar surfaces [25, 26], the nail unit [2, 27], in areas of trauma (the Koebner or isomorphic response) [28]. Follicular DLE lesions have been described, often around the elbow, and may be more common in African-American and Asian patients [28, 29].

Hypertrophic DLE is a rare variant in which hyperkeratotic lesions occur (often on the extensor extremities, upper back, and face). Histopathology can reveal features of squamous-cell carcinoma which can lead to confusion regarding diagnosis [115]. Even if patients have classic DLE lesions elsewhere, the clinician should still be aware that squamous-cell carcinoma can develop in long-standing, scarring DLE lesions [30, 31].

Well-developed lesions of DLE do not usually present a problem with differential diagnosis, although early lesions can be confused with PMLE, granuloma faciale, sarcoidosis, cutaneous lymphoid hyperplasia, lupus vulgaris, angiolymphoid hyperplasia with eosinophilia, and tertiary syphilis.

Mucosal DLE occurs in approximately 25 % of CCLE patients [16]. Oral lesions tend to occur on the buccal mucosa, and less commonly on the palate, gums, and tongue. Lesions have a sharply marginated, scalloped white border with central erythema. Central areas can erode, although lesions are typically painless. The surfaces of well-developed plaques on the palate can have a meshwork of raised hyperkeratotic strands giving a "honeycomb" appearance [16]. Fixed mucosal DLE lesions can be distinguished clinically

from the transient superficial mucosal ulcerations that are often seen in active SLE patients. The lips can be involved with well-defined plaques or a diffuse cheilitis [3]. Such lesions can degenerate into squamous cell carcinoma [32]. Involvement of the nasal, conjunctival, and genital mucosa can occur [33].

Chilblain LE is characterized by red-purple patches or papules on the toes, fingers, and/or face that are precipitated by cold or damp climates. At the onset these lesions are clinically indistinguishable from simple chilblains (or, pernio) lesions that occur in healthy individuals [34, 35]. However, chilblains LE lesions tend to evolve into more classic acral DLE lesions, and it is postulated that this may be the result of a Koebner phenomenon in otherwise typical lesions of perniosis [3]. Differential diagnosis includes other cold-induced vasculopathies, such as cold agglutinin disease or cryoglobulinemia.

LE profundus (syn. LE panniculitis) is a form of CCLE characterized by inflammation in the lower dermis or subcutis. This lesion occurs more commonly in women and is seen in 1–3 % of SLE patients [3]. Approximately 70 % of patients will have overlying DLE lesions [36, 37]. Some have used the term "LE profundus" to specify those lesions that have concurrent overlying DLE activity and the term "LE panniculitis" to refer to lesions displaying only subcutaneous inflammation. However, this is not a universally accepted convention.

LE profundus/panniculitis lesions are characterized by firm, deep nodules with initially normal appearing overlying skin. With time, the nodules resolve and draw the surface of the skin inward, leaving deep, saucerized depressions. Lesions tend to occur in the head, upper arms, buttocks and thighs. Rarely, this entity can present as periorbital edema. Dystrophic calcification can occur in older lesions. Breast lesions ("lupus mastitis") can be confused with carcinoma [2]. Persistent, extensive LE profundus/panniculitis lesions of the breast can necessitate mastectomy. Early lesions can be confused with morphea, while other forms of panniculitis (subcutaneous panniculitic T cell lymphoma, sarcoidosis. factitial or traumatic panniculitis, subcutaneous granuloma annulare) and lipoatrophy (partial lipodystrophy associated with autoimmune disease, drug-induced lipoatrophy, HIV-associated lipoatrophy) must be ruled out.

Typical lesions of lupus erythematosus tumidus (LET) are succulent, edematous papules and plaques that arise due to accumulation of dermal mucin. These lesions are found with decreasing frequency on the face, back, arms, and chest [38, 39]. In some individuals, large annular edematous plaques can be seen. The largest series reported resolution with no or mild topical treatment in nearly half of cases [39], although it has since been questioned that this series may have included many patients with PMLE [38]. It is possible that this might account for the extreme photosensitivity that was reported in these patients [39]. Other authors report these lesions to be chronic and difficult to treat and such patients are typically ANA-negative. Most affected patients do not have SLE [38–41].

Lesions are characterized by perivascular and periappendageal lymphocytic inflammation with dermal mucin deposition. Unlike other forms of LE-specific skin disease, there is absence of basal vacuolar changes in 80–100 % of cases, with positive cases showing only focal and sparse keratinocyte necrosis [38, 42]. This fact has led to discussions about how to best categorize LET. Some authors have characterized LET as a separate category of CLE called "intermittent CLE" due to histological differences and lack of scarring potential seen in other forms of CCLE [3]. LET lesions must be differentiated from PMLE, Jessner's lymphocytic infiltrate, atypical lymphoid infiltrates, myocosis fungoides, reticular erythematous mucinosis, DLE, SCLE, and figurate erythemas. Some have argued that LE tumidus and Jessner's lymphocytic infiltrate in reality cannot be clearly be distinguished [39].

Laboratory Abnormalities

Little data are available concerning laboratory assessment of patients with ACLE. It is assumed that this would closely parallel the data that are available for patients with SLE.

Approximately 60–80 % of SCLE patients have detectable antinuclear antibodies (ANAs) with a speckled/particulate ANA pattern being most common [43]. This disease is characterized by positive anti-Ro/SSA antibodies, present in 40–100 % of patients, depending on the assays used [44, 45]. Anticardiolipin antibodies are present in 10–16 % [46]. Rheumatoid factor is present in one third of SCLE patients [44], and some patients initially present with rheumatoid arthritis long before a diagnosis of SCLE is made. Sm, dsDNA, and U1RNP antibodies are present in 10 % of SCLE patients [44]. Anti-thyroid antibodies were reported in 18 % [47] and 44 % [48] of SCLE patients. Depending on the presence of SLE disease activity, cytopenias, hypergammaglobulinemia, proteinuria, hematuria, and depressed complement levels can also be seen.

In DLE, low ANA titers/levels (e.g., ≤1:40) are present 30–40 % of the time in assays that employ human tumor cells as substrates. However, higher titers that are typically seen in SLE (≥1:160) are rarely encountered in patients having isolated forms of DLE [2]. Anti-Ro/SSA antibodies are occasionally found, but the presence of anti-Sm, dsDNA, and La/SS-B antibodies is uncommon [49]. Fewer than 10 % of patients have IgG anticardiolipin antibodies [50]. A small percentage of DLE patients will have positive rheumatoid factor, slight depression in complement, and leucopenia (see below). Antinuclear antibodies are present in approximately

75 % of patients with lupus profundus/panniculitis [2]. The frequency of ANAs in patients with chilblains lupus was reported as 9 out of 14 patients, with anti-dsDNA antibodies in 4 of 14 patients—these numbers might be an overestimate [35]. Anti-Ro/SS-A antibodies have been variably found in these patients, and some authors have suggested that this is a marker for this disorder [35, 51].

Relationship to Systemic Disease

For ACLE, as it is generally presumed that this is a fundamental component of SLE, there are not many data regarding the relationship of ACLE and SLE disease activity. One study suggests that the course of rash severity parallels SLE activity [12]. Interestingly, authors have failed to support an association with renal or CNS disease, although this has not been studied adequately [2]. One small study indicates that SCLE and DLE patients with normal lymphocyte counts are unlikely to have SLE [52].

Approximately 50 % of patients with SCLE meet American College of Rheumatology (ACR) criteria for SLE [44, 53]. However, severe systemic disease (i.e., nephritis, CNS disease) develops in only 10 % of SCLE patients [44]. Some data support that the papulosquamous form of SCLE is more associated with renal involvement [2]. As stated above, rheumatoid arthritis has been reported to precede as well as follow a diagnosis of SCLE. In addition, 3–12 % of SCLE patients will later develop Sjögren's syndrome [2]. Finally, there are some reports that suggest that SCLE might be a paraneoplastic syndrome [2]—due to the paucity of cases, a causal relationship has not been proven.

Historically it has been felt that 5–10 % of patients presenting only with DLE lesions will eventually develop SLE [2]. Two more recent prospective studies suggest the risk may be in the 10–20 % range [1, 4] However, a minority of those that eventually develop SLE by criteria experience moderate or severe disease [4]. Risk factors for progression include lesions above and below the neck, unexplained anemia, leucopenia, persistently positive high-titer ANA, hypergammaglobulinemia, and positive lupus band test of nonlesional skin [54]. Patients with evidence of nephropathy or arthralgias are also at increased risk of having SLE [55]. Similar to SCLE, patients with lupus panniculitis have a 50 % chance of having SLE, although this is usually mild with only 10 % meeting strict ACR criteria for SLE [2].

In patients with known SLE, the presence of CCLE lesions (namely DLE, lupus panniculitis, chronic mucosal plaques), appears to be associated with less severe systemic disease [2]. A more recent study suggested SLE patients with DLE had a decreased risk of arthritis and pleuritis but no effect on risk of nephritis [5].

Histopathology

The histopathology of CLE will be mentioned only briefly as it has been described in detail elsewhere [2]. In general, ACLE, SCLE and DLE have similar features that do not allow for distinction between the subsets of CLE. Characteristic findings include liquefactive degeneration of the epidermal basal-cell layer, variable hyperkeratosis, dermal edema and mucin deposition, and mononuclear cell infiltration around the dermal-epidermal junction and dermis. This infiltrate consists mainly of CD3+ (both CD4+ and CD8+) cells, with other cell types including histiocytes and plasmacytoid dendritic cells (see below). In DLE, the dermal infiltrate is generally denser and can extend more deeply into the reticular dermis. In addition, DLE lesions can demonstrate follicular plugging and more pronounced basement membrane thickening.

Variable deposition of immunoglobulin (IgM, IgG, IgA in decreasing frequency) and complement components can also be detected at the basement membrane zone of lesional skin. The frequency and intensity with which this is detected varies between studies, anatomic location of skin biopsies, and type of CLE [2].

Hypertrophic forms of DLE are characterized by a greater degree of epidermal acanthosis and hyperkeratosis. Notably, some areas can have features of squamous cell carcinoma or keratoacanthoma. Lupus panniculitis/profundus generally spares the dermal-epidermal junction (if overlying DLE is not present), and is characterized by a lobular panniculitis and perivascular mononuclear cell infiltrate [2]. The infiltrate in the fat is composed of histiocytes and lymphocytes (sometimes forming nodules) and can show variable hyaline-fat necrosis or calcification. LE tumidus shows a perivascular and periadnexal lymphocytic infiltrate with dermal mucin deposition. Studies show focal spotty keratinocyte necrosis in 0–20 % of cases [38, 42]. Chilblain LE shows basal vacuolar degeneration, superficial dermal edema, and a perivascular lymphocytic infiltrate. Some authors conclude that these entities can be distinguished by histopathology, with idiopathic chilblains being characterized by perieccrine inflammation and spongiosis [56, 57].

Pathogenesis

Most of the work pertaining to pathogenesis of cutaneous lupus relates to those forms of CLE that are characterized by interface dermatitis (i.e., ACLE, SCLE, DLE). Thus, this section will focus on these manifestations of CLE. In addition, much of the discussion will not distinguish between the different types of CLE, except for when specifically noted in the text.

Before considering the etiology of LE-specific skin disease, it is interesting to consider its relationship with disease mechanisms that are associated with SLE. Evidence for a pathogenic relationship between cutaneous and systemic disease includes the association of LE-specific skin disease with SLE as well as the fact that, even in "skin-limited" disease, certain characteristic T and B lymphocyte abnormalities can be found systemically that mirror those seen in SLE [58, 59]. The general concept that genetic susceptibility (i.e., HLA haplotypes) and environmental triggers (infection, medication, ultraviolet light) result in a loss of immunologic self-tolerance which then is manifested by generation of autoantibodies and antigen-specific T lymphocytes that mediate tissue injury is likely operative in both cutaneous and systemic disease. However, it should be noted that there is no definitive evidence at present that demonstrates the cutaneous inflammation of CLE is due to an autoimmune response to antigen(s) in the skin. However, studies showing an oligoclonal expansion of T cells in the CCLE lesions are suggestive of an antigen driven reaction either in the skin or periphery [60, 61]. Interestingly, there is no evidence for this in infiltrates of lupus panniculitis [62].

Various genetic abnormalities are associated with different forms of LE-specific skin disease. Several HLA haplotypes have been associated with ACLE, SCLE, and DLE [3]. This implicates a role of T lymphocytes, and may relate specifically to their role in providing help for antigen-specific B cell responses, as a particular HLA B8 DR2 (DRB1*1501) DR3 (DRB1*0301) extended haplotype correlates with the anti-Ro/SS-A response [2]. A polymorphic variant in the TNF-α promoter that is associated with increased TNF-α production is highly associated with SCLE and neonatal LE [63, 64]. Genetic deficiencies in complement components, such as C2, C3, C4 and C5, have been associated with SCLE and/or DLE [2]. The role of C1q seems important, as complete congenital genetic deficiencies of this protein are a strong risk factor for photosensitive SLE [2]. In addition, a polymorphism in the C1QA gene is associated with SCLE [65].

Environmental factors play a role in the pathogenesis of CLE. The paramount role of UV irradiation is discussed below. Assuming that ACLE is triggered by the same mechanisms as for SLE, chemicals such as L-canavanine present in alfalfa sprouts (which induce SLE) may be important [2]. Infections, especially those caused by viruses, are also triggers for SLE. Multiple medications have been associated with the clinical induction of SCLE and less so with DLE [2, 116, 117].

It has been proposed that these may do so via inducing photosensitivity, which might result in disease activity via UV-specific mechanisms or simply via the Köebner phenomenon that results from photodamage. Although numerous drugs can induce SLE (e.g., procainamide, hydralazine, isoniazid), drug-induced SLE is typically not associated with cutaneous findings. Similarly, trauma appears to induce a Köebner phenomenon, especially in DLE patients. Smoking has been implicated as a risk factor for the development of SCLE and DLE [2]. It is unclear if this reflects a primary role for smoking in the disease process or simply results from its known association with antimalarial resistance.

Any consideration of the molecular pathogenesis of CLE must involve consideration of the role of ultraviolet (UV) light. Evidence for the role of UV light in CLE is strong: first, most CLE lesions are in photo-exposed regions of the body; second, 50 % of patients with lupus report photosensitivity; third, 54 % of patients with CLE demonstrate UV photoprovocation of their lesions in the lab [66]. Finally, an immune response against UV-altered DNA has been shown to occur in both mouse models of lupus and patients with SLE. However, the relative importance of UV light in the pathogenesis of likely multiple genetic and phenotypic forms of CLE is not currently known. It is likely that other environmental triggers (i.e., infection, cellular injury, medications) can lead to CLE as well, although the mechanisms for these are not well worked out. Thus, although most of the data presented related to how UV light induces CLE, other forms of keratinocyte damage and/or activation of the cutaneous immune system can be applied in the final model.

Although it is clear that UV light (UVA or UVB) can induce CLE lesions in susceptible patients, the mechanistic link between UV exposure and the cutaneous inflammation that is observed is still not clear—many of the proposed mechanisms may be operating simultaneously. Ultraviolet light can generate neoantigens, such as UV-modified DNA; when injected into mice, this altered DNA can cause lupus like disease [66]. Another mechanism might be the ability of UV light to induce apoptosis of keratinocytes by multiple mechanisms, including oxidative damage to mitochondrial membranes, damage to DNA, induction of p53, activation of membrane death receptors (Fas), and sensitization to TNF-α (and TNF-related apoptosis inducing ligand, TRAIL). Normally, the immunologic clearance of apoptotic cells is a non-inflammatory event. An increased rate of formation and/or decreased ability to "clear" these apoptotic cells, however, can lead to early necrosis of cells and result in their capacity to stimulate the immune system. This occurs via multiple mechanisms, including the ability of necrotic elements to induce maturation and activation of local antigen presenting cells [67]. Necrotic cells can release pro-inflammatory mediators such as high mobility group 1 (HMG1) protein, which is found in high levels in the skin of CLE patients [68]. The C1QA and other complement deficiencies that are associated with CLE suggest that these patients might have a defect in removal of apoptotic cells. Is there evidence of defective

clearance of apoptotic keratinocytes in CLE? Data are conflicting in this regard [69, 70]. Whether or not CLE patients have an increased number of apoptotic cells, it is still possible that these cells could somehow lead to inflammatory sequelae in CLE patients. Indeed, a recent observation suggests that detectable inflammation correlates with the presence of apoptotic cells in the near vicinity in CLE patients [70].

If one accepts that in CLE patients, UV-damages keratinocytes with an inflammatory response, then how might such a response be propagated? One theory is that the binding of circulating autoantibodies against cellular constituents of dying keratinocytes results in a local inflammatory response (via FcR-dependent or complement-dependent mechanisms) [66]. Since the seminal observation by Casciola-Rosen and colleagues that UV light induces translocation of intracellular keratinocyte antigens to the cell surface (in structures called blebs) [71], and that these antigens include the SSA/Ro and SSB/La antigens that are the targets of commonly found autoantibodies in CLE (especially SCLE), the ability to definitively link this process with the clinical findings of CLE has eluded investigators. In fact, the frequency and/or titers of SSA/Ro antibodies do not always correlate with skin activity in CLE patients [66]. However, it has recently been suggested that SSA/Ro autoantibodies are capable of interfering with the clearance of apoptotic cells [119]. Still, it might be that the critical antibodies are not being measured, and that apoptotic-modified forms of these antigens are the critical targets [66]. In general, LE patients have antibodies that appear to be directed against antigens involved in the cellular-stress response and heat shock response. Whatever the answer, it seems unlikely that such autoantibodies play a role in initiating CLE disease, as the deposition of antibodies in CLE tends to follow, not precede, the cellular inflammation [72].

UV light can also promote inflammation by inducing the secretion of cytokines and chemokines, as well as upregulating the expression of adhesion molecules [73]. UVB induces IL1-α and TNF-α in the epidermis. These cytokines induce release of IL-6, PGE2, IL-8 and granulocyte-monocyte colony-stimulating factor (GM-CSF) by keratinocytes [66]. The end result is activation of Langerhans cells, chemotaxis of lymphocytes, and up-regulation of adhesion molecules on keratinocytes (ICAM-1) and endothelial cells (ICAM-1, VCAM-1, E-selectin). UVB irradiation also induces expression of chemokines, such as CCL5, CCL27 and CXCL8 [74]; these have all been found at high levels in CLE skin, and function to recruit memory T cells into the vicinity. Via production of oxygen-free radicals, UVA upregulates ICAM-1 in keratinocytes, but, because it can penetrate deeper into the skin, is also able to upregulate vascular endothelial ICAM-1 and E selectin, which allows leukocyte extravasation into the skin [66]. In addition, UVA is able to induce secretion of IL-12, a potent immunostimulant [66].

T lymphocytes are likely to play a major pathological role in CLE. Skin infiltrates consist primarily of CD3+ T cells, both CD4+ and CD8+ [66]. CD4+ cells appear early in the skin, with CD8+ appearing later. Recent data suggest that skin homing (CLA+) CD8+ cytotoxic cells might be responsible for the scarring that is seen in CCLE [75]. These cells are seen predominantly in the skin of DLE patients (as opposed to other CLE subsets), and an expanded population of circulating, CCR4+, CLA+ CD8+ cells is associated exclusively with generalized DLE [76]. These cells secrete granzyme B, a serine protease that causes tissue death and could conceivably account for injury (and resulting scar) to adnexal and epidermal structures. IFN−α may also play a role in this process, as local IFN-α activity was found to be correlated with CD8+ cell infiltration. Further evidence for the role of activated T cells in CLE comes from the increased expression of HLA-DR and CD25 (both activation markers) on circulating CD4+ and CD8+ cells in patients with DLE and SCLE—furthermore, these levels correlated with cutaneous disease activity [58, 59].

The cytokine expression pattern found in DLE lesions is representative of a mixed Th1 and Th2 profile. Lesions are characterized by high levels of IL-1, IL-2, IFN-γ, TNF-α, IFN-α, IL-5 and IL-10 [66, 67]. TNF-α is found in increased levels in the skin of DLE and SCLE patients and serum levels correlate with disease [77, 78]. TNF-α can promote many of the findings seen in CLE: translocation of SSA/Ro to the cell surface of keratinocytes; apoptosis of keratinocytes; hyperkeratosis; and increased expression of adhesion molecules that favors cutaneous leukocyte infiltration [79]. In addition to the effects mentioned above, IFN-γ has been shown to cause keratinocyte apoptosis [80]; a mouse strain that overexpresses IFN- γ in keratinocytes results in clinical features of SLE and cutaneous inflammation [66]. IL-1 is generated by keratinocytes in response to UV light, and transgenic expression of IL-1 in mice results in hair loss, scaling, and focal inflammatory lesions [66]. Keratinocytes also express an antagonist of the IL-1 receptor, and null alleles of this protein have been reported in SLE patients with photosensitivity as well as in CCLE patients [66].

The role of the innate immune system in CLE is beginning to be explored. It has recently been discovered that IFN-α plays an important role in the pathogenesis of SLE [81]—evidence shows that the source of this IFN-α is the plasmacytoid dendritic cell (pDC). High numbers of pDC have been detected in the lesions of CLE [82], with accompanying high levels of local IFN-α activity [76, 82–84]. IFN-α is known to induce the chemokines CXCL9, CXCL10, and CXCL11, which are also at high levels in CLE skin [74]. The ligand for these chemokines, CXCR3, is found on infiltrating T cells in CLE. Thus, local emigration of activated pDC to the skin of CLE patients might represent the mechanism whereby T cells initially migrate into cutaneous lupus lesions. At present it is unclear what the signals are that cause

pDC migration to the skin; however, it is tempting to speculate that locally deposited immune complexes (i.e., the lupus band) might play a role in their ongoing local activation, since it is known that immune complexes containing nucleic acid (from apoptotic cells) activate pDC via toll-like receptors (TLRs), resulting in the production of IFN-α [85].

Treatment

Due to the critical role of UV light in CLE pathogenesis, the mainstay of any treatment regimen is sun protection. Protection against UVB and UVA are critical, as both can induce CLE in the laboratory [23, 86]. Patients should be counseled on the importance of avoiding direct sun exposure, as well as the benefits of protective clothing including hats, and tightly woven clothing. Broad-spectrum sunscreens are important, and there is evidence showing that the use of these agents inhibits experimentally-induced CLE lesions in patients [87] as well as potentially decreasing the burden of systemic disease in SLE patients [88].

Local therapy with corticosteroids and/or calcineurin inhibitors (tacrolimus or pimecrolimus) can be used in CLE [2]. The current strengths and formulations of calcineurin inhibitors available in the United States have limited efficacy for skin sites other than the face. However, higher concentrations of calcineurin inhibitors have been reported anecdotally to be of value in classical DLE [89]. Calcineurin inhibitors are presumed to act by inhibiting activation of infiltrating T cells that are known to be present in CLE.

Antimalarials (hydroxychloroquine, chloroquine, and quinacrine) are used as first-line systemic agents for SCLE or DLE lesions, with approximately 75 % of patients responding favorably [3]. Efficacy data is based mostly upon anecdotal reports, although one controlled trial with hydroxychloroquine suggested 50 % efficacy for DLE or SCLE [90] while another with chloroquine showed 82 % efficacy for ACLE, SCLE, or DLE [91]. More common side effects include gastrointestinal disturbance, and blue-black pigmentation of skin or mucosa. Rarer side effects include retina, muscle, nerve, and hepatic toxicity. Potential mechanisms of action include inhibition of antigen presentation (via their known ability to disrupt lysosomal acidification), inhibition of cytokine secretion, interference with activation of extracellular signal-regulated kinses (ERKs), inhibition of prostaglandins, stabilization of membranes, and photoprotection [92]. Recent evidence suggests that they might operate via interference with intracellular TLR signaling [93], which is tantalizing given the mounting evidence for a role of the innate immune system (i.e., pDCs) in LE and its dependence on TLR-signaling.

The value of systemic photo-protective agents in cutaneous lupus is not well studied. One case report suggested a benefit of adding the supplement polypodium leucotomos, which has photoprotective effects on human keratinocytes, to hydroxychloroquine in a patient with SCLE [6].

Diaminodiphenylsulfone (Dapsone) is also used for CLE, especially when treating the patient with LE-nonspecific vesiculobullous lesions related to SLE [2]. Others have reported efficacy in SCLE [94]. Hematologic, renal, and hepatic toxicity can occur with this drug. Dapsone is known to affect neutrophil function at many levels (chemotaxis, CD11b-mediated epidermal adherence, enzyme production, generation of reactive oxygen intermediates) [95] and this may be relevant in light of the variable cutaneous infiltrate of neutrophils that is seen in CLE.

Retinoids (acitretin and isotretinoin) are advocated for SCLE and hypertrophic DLE lesions [2], although disease usually returns following removal of the drug. The mechanism of action is unclear, although inhibition of cutaneous T lymphocyte infiltration has been demonstrated in humans and animal models [96, 97].

Thalidomide can be especially effective for SCLE and DLE [99, 118], with a response seen in 75 % of antimalarial-resistant patients [98]. Efficacy is seen as early as two weeks and peaks at three months, although relapses following cessation of therapy are common. The most common side effect is sedation. Besides its teratogenicity, it can produce a sensory neuropathy in 50–70 % of patients, with no correlation between cumulative dose and duration of treatment [98]. In some cases the neuropathy can be persistent despite withdrawl of the medication. Reports of thromboembolic events occurring in thalidomide-treated patients should prompt caution with its use in high-risk patients, including those with antiphospholipid antibodies. A thalidomide anolog, lenolidomide, has more recently been reported to be effective in refractory cutaneous lupus and may carry less risk of neuropathy and thrombosis [7, 8].

Traditional immunosuppressive agents are sometimes used for CLE. These include methotrexate, mycophenolate mofetil, azathioprine, and cyclophosphamide [2]. Methotrexate has perhaps the most data to support its use, with a retrospective study of 43 CLE patients (including ACLE, SCLE, and DLE) showing improvement in 98 % of patients [100]. Mycophenolate mofetil has been used effectively in CLE patients that have adequately responded to antimalarials. Doses of 2–3 g a day appear most effective.

Intravenous immunoglobulin (IVIG) has been used in some cases of CLE, the largest being an open label prospective study of 12 patients with SCLE or DLE in which 5/12 had virtual clearing of disease [101]. Some investigators, however, have not observed a beneficial effect [102]. Possible mechanisms of action have been reviewed elsewhere [103].

Belimumab is a human monoclonal antibody that in 2011 became the first drug to receive FDA approval for the treatment of active systemic lupus in over 50 years. The

drug's mechanism of action is to inhibit B-lymphocyte stimulator which affects B-cell survival and reduces the differentiation of B cells into immunoglobulin producing plasma cells [10]. Studies assessing the organ specific response of cutaneous lesions to belimumab in LE patients have not yet been performed. Rituximab is a chimeric monoclonal antibody that destroys B cells. While it is thought to be a promising treatment for LE, two randomized trials in SLE have failed to meet efficacy endpoints and experience in CLE is limited [11].

One intriguing and somewhat counterintuitive therapy for LE is that of UV light, namely low dose UVA1 (340–400 nm). This may not be so unexpected, as the wavelengths responsible for inducing SLE flares are thought to be within the UVB (280–320 nm) and UVA2 (320–340 nm) wavebands [23, 104], and "pure" (not contaminated with UVC or longer wavelengths) of UVA1 and UVB do not induce (and may improve) CLE [105]. Several small trials using low dose UVA1 (6–12 J/cm^2) have demonstrated benefit in systemic symptoms of SLE (including a decrease in autoantibodies). As for the skin, one of the trials noted "improvement of rash" [106], and this was also reported separately in two patients with DLE [107]. Caution should be noted, as exacerbation of skin disease has been noted in some patients [108, 109]. The mechanism of action is unclear, but might involve immunodeviation to Th1 patterns, apoptosis of resident T cells, inhibition of antigen presentation, or inhibition of TNF-α production [110].

Future Directions

An increased understanding of the immune dysregulation seen in CLE will lead to more effective therapies for this disease. Many of these therapies will parallel development of treatments for SLE [111]. Novel treatments might include agents targeted at T lymphocytes, such as anti-CD4 antibodies or CTLA4-Ig (which blocks T cell costimulation). Although clearly important in SLE, the role of B lymphocytes is unclear in CLE, and it will be interesting to evaluate the current application of B cell directed therapies (such as Rituximab) for efficacy in LE-related skin disease. There is anecdotal evidence for efficacy of TNF-α inhibitors such as etanercept in some forms of CLE [112–114]. However, the tendency for this class of biologics to induced lupus serological changes (ANA, double-stranded DNA antibodies) and, at times, clinical changes of cutaneous and SLE limits their value in this regard. The increasing role of innate immunity, pDCs, and TLR signaling suggests that agents specifically designed to inhibit TLR signaling or pDC infiltration/maturation might be very effective for CLE. The compelling role of IFN-α, along with studies showing interference with type-I interferon receptor signaling improves lupus-like disease in mice, make this an attractive target.

Questions

1. What is the association between different types of cutaneous lupus and systemic lupus erythematosus?
   A. All forms of cutaneous LE are strongly associated with SLE
   B. Certain forms of cutaneous LE such as acute cutaneous LE are strongly associated with SLE
   C. All patients with chronic cutaneous LE meet ARA criteria for SLE
   D. Subacute cutaneous LE is never associated with SLE

Correct Answer: (B) Some forms of cutaneous LE are strongly associated with SLE

2. What is the difference between lupus-specific and lupus non-specific skin disease?
   A. All skin manifestations of LE are lupus-specific
   B. The non-Lupus specific cutaneous manifestations of lupus are not relevant to the clinical course of the disease
   C. The non-lupus specific cutaneous manifestations can be observed in other disorders (for example, alopecia)
   D. Chronic cutaneous LE is one of the few lupus-specific manifestations
   E. A + B only
   F. C + D only

Correct answer: (F)

3. What genetic HLA types, polymorphisms and deficiencies have been associated with cutaneous lupus?
   A. Certain HLA types
   B. Cytokine promoter polymorphisms
   C. Polymorphisms of the C1qA genes
   D. Genetic deficiencies of complement
   E. All of the above
   F. None of the above

Correct answer: (E) All of these genetic factors have been associated with different presentations of cutaneous LE

4. How might ultraviolet light exposure induce cutaneous lupus in susceptible individuals?
   A. Increased immune response to altered DNA
   B. Increase in Th2 lymphocyte activity
   C. Loss of Tregulatory cells
   D. Acceleration of DNA repair

Correct answer: (A) Increased immune response to altered DNA

5. What are treatment options for patients with cutaneous lupus that cannot tolerate or do not respond to antimalarials?
   A. Dapsone
   B. Isotretinoin
   C. Cytotoxic drugs

D. Thalidomide
E. All of the above
F. None of the above

Correct answer: (E) All of these drugs represent treatment options for the patient who fails antimalarial therapy

Lichen Planus

31

Aaron R. Mangold and Mark R. Pittelkow

Abstract

Lichen planus (LP) is the prototypical lichenoid tissue reaction (LTR) that affects approximately 1 % of the population worldwide. Classic LP is characterized by violaceous, flat-topped, polygonal papules, which favor the flexor aspects of the body. LP can affect any ectodermally derived tissues (skin, hair, nail, mucous membranes, esophagus) and therefore a complete physical examination and multidisciplinary approach is often needed. Histologically, LP is characterized by basal keratinocyte damage with a brisk LTR. While there is a clear genetic association with LP, the pathogenesis remains unknown. Antigen presenting cells and T-lymphocytes play a key role in antigen recognition, lymphocyte activation, keratinocyte apoptosis, and disease resolution. Numerous therapeutic modalities have been utilitzed in LP. We recommend the usage of anti-inflammatory agents, which specifically target T-lymphocytes. Future, novel therapeutic targeting of cytotoxic T-lymphocytes make mechanistic sense; although, future studies are needed for both clinical efficacy and safety.

Key Points

- Prevalence: Approximately 1 % worldwide
- Morphology: Classic disease is characterized by violaceous, flat- topped, polygonal papules
- Distribution: Classic disease commonly affects the flexor aspects of the body. Any ectodermally derived tissues (skin, hair, nail, mucous membranes, esophagus) may be involved
- Histology: Basal keratinocyte damage with a lichenoid tissue reaction
- Pathogenesis: Idiopathic, T-cell mediated process without a clear auto antigen

Introduction

Lichen planus (LP) is derived from the Greek word, *leichen*, meaning "tree moss" and the Latin world, *planus*, meaning "flat." LP is a often a clinical diagnosis typified by: purple, polygonal, pruritic, papules and plaques. LP has pathognomonic histological findings and represents the prototype of a broader category of lichenoid tissue reactions (LTRs).

History

Dr, Erasmus Wilson was the first to describe lichen ruber in 1869 [1]. He delineated the inflammatory nature of the lesions and its focus upon the epidermis. In all likelihood, Wilson was referring to the same entity previously described by Hebra. Similarly, Weyl originally described the white striae overlying lichenoid papules in 1885 and Wickham later elaborated upon them [2, 3]. Gougerot and Burnier later described the multimucosal involvement of LP [4].

Epidemiology

The exact incidence and prevalence of LP is unknown. The largest studies on LP focus on oral disease or cutaneous disease but few include both the cutaneous and mucosal spectrum.

In adult oral lichen planus (OLP), the data is heterogeneous within different geographic regions with reported rates ranging from 0.1 to 4 %, the best estimate is approximately 1.3 % (1 % men and 1.6 % women) [5]. Because the most common form of OLP is asymptomatic, oral disease is under-represented and, additionally, most of the studies did not differentiate LP from LTRs. The incidence of OLP is even less well studied and is essentially indeterminate. The best population studies found a peak age of onset between 55 and 74 in OLP [6]. There is no clear sexual predilection of disease and women tend to have an earlier age of onset than men.

Initial estimates found that 1–5 % of LP occurs in children. However, it is now believed that childhood LP may be much more common than previously thought with the largest childhood cohort representing 19 % of the total LP population [7]. The largest series of childhood LP are from India. Therefore, the generalizability of data as well as the possibility of genetic predisposition has come into question. The largest US study showed childhood LP to be more common in African Americans [8]. There is no clear sex predilection and disease onset is between 8 and 12 years of age [7–10].

True familial LP is rare; however, a strong family history has been reported in 1.5 % in adults and 3.8 % of pediatric cases [7, 11]. Small studies in adults suggest that familial LP may make up 5–10 % of cases [12, 13]. Familial LP is characterized by: earlier onset, widespread disease, mucosal involvement, and frequent relapses [14, 15]. Familial cases of bullous LP have also been reported [16].

Clinical Features

LP may affect any ectodermally derived tissue including: skin, mucous membranes (most commonly oral), hair, nails, genitalia and, rarely, esophagus. We will emphasize the findings in adult disease. However, LP in children has classic cutaneous findings in 42–60 % of cases, oral involvement in 17–30 % of cases, hair involvement in 2–6 % of cases, and nail involvement in 0–19 % of cases [7–10].

Skin lesions develop over the course of weeks. LP has many clinical subtypes based upon the configuration of lesions, morphological appearance, and site of involvement. The nuances of these subtypes are beyond the scope of this chapter and emphasis will be placed upon the classic findings and a few special forms of disease. Table 31.1 shows the variants of cutaneous, oral, and special forms of LP.

Cutaneous Disease

LP is characterized by four to six descriptive, repetitive "P" terms (pruritic, purple, polygonal, planar, papules and plaques). The individual lesions vary in size from a few millimeters to large, coalescent plaques (Fig. 31.1). The violaceous color of longstanding LP plaques results from the combination of red blood in the capillaries, interface lymphocytes, and the bluish-gray hue of dermal melanin

Table 31.1 Clinical subtypes of lichen planus

Subtypes	Most common sites of involvement
Cutaneous lichen planus	
Actinic	Sun-exposed areas
Annular	Male genitalia, intertriginous
Atrophic	Predominately on lower extremities, may occur on other areas of the body
Erosive	Soles of the feet
Guttate	Trunk
Hypertrophic	Anterior legs, ankles, interphalangeal joints
Linear	Lower extremities
Follicular	Trunk and proximal extremities
Papular	Flexural surfaces
Bullous	Feet
Pigmentosus	Sun-exposed areas
Pigmentosus-inversus	Intertriginous and flexural areas
Nail	Fingernails > toenails
Palmoplantar	(1) Malleoli (2) Soles
Lichen Planopilaris	(1) Classic- vertex scalp (2) Frontal fibrosing alopecia (3) Graham-Little-Piccardi-Lasseur Syndrome
Mucosal lichen planus	
Oral	
Reticular	(1) Buccal mucosa and mucobuccal folds
Atrophic	Attached gingiva
Hypertrophic	Buccal mucosa
Erosive	(1) Lateral and ventral tongue (2) Buccal mucosa
Bullous	Posterior and inferior areas of the buccal mucosa
Plaque-like	Dorsum of tongue and buccal mucosa
Vulvovaginal	Vaginal introitus, clitoral hood, labia minora, labia majora, vagina
Esophageal	(1) Proximal esophagus (2) Proximal and distal esophagus (3) Distal esophagus (80 % have mucosal involvement)
Special forms	
Drug-induced	Sun-exposed areas
Lichen planus-lupus erythematosus overlap	Distal extremities, sun-exposed
Lichen planus pemphigoides	Extremities

Adapted from: Gorouhi et al. [32]

[17]. Fine white lines, which represent areas of focal epidermal thickening, are termed Wickham's Striae (Fig. 31.2). The lesions are more clearly visualized using contact dermoscopy. LP is often localized to the flexor aspects of the extremities as well as the oral and genital mucosa. The face and interfollicular scalp are typically spared. Isomorphic phenomenon (Koebnerization) (Fig. 31.3) and Wolf's isotopic response are both seen in LP. The former represents disease at the site of prior trauma and the later represents secondary disease occurring in previously diseased skin, most commonly varicella zoster virus (VZV) [18–20].

Nail Disease

Nail disease occurs in up to 10 % of patients with LP and the fingernails are more commonly affected than the toenails [21, 22]. LP can affect the nail folds, bed, and matrix. The most common findings are: thinning, ridging (trachyonychia), and distal splitting of the nail plate (onychoschizia) (Fig. 31.4) [22]. One study found that nail matrix involvement was associated with trachyonychia (40 %), pitting (34 %), and dorsal pteryigium (21 %) [23]. Nail bed involvement was associated with chromonychia (56 %) and nail fragmentation (51 %). Paronychia was seen in 32 % of cases and disease of all

three-nail components was associated with longitudinal streaks (82 %). Similar nail patterns may be seen in alopecia areata, psoriasis, eczema, and pemphigus vulgaris.

Mucosal Disease

LP commonly involves the oral mucosa but the penis, vulva, vagina, anus, nose, larynx, esophagus and conjunctiva can also be affected. OLP is more common in women than men (2:1). Oral involvement occurs in approximately 60–70 % of individuals with LP and may be the only site of involvement in 20–30 % [11, 24–27].

Multiple subtypes of OLP have been described: reticular, erosive, atrophic, papular, plaque, and bullous. Ulcerative OLP is the most common subtype reported in studies, likely

due to symptomatology and severity of disease [26, 28]. However, clinical experience indicates that the reticular subtype is more common but patients are less likely to seek medical care due to its indolent and often asymptomatic nature. The lesions are often symmetrical and the buccal mucosa is the most common site of involvement (80–90 %) (Fig. 31.5) [25, 29–32]. Gingival involvement is uncommon, being the sole presentation in 8 % of cases, but remains the most common cause of desquamative gingivitis (75 % of cases) [33]. The classic lacy streaks (Wickham striae) are most commonly seen on the buccal mucosa. Koebnerogenic factors: smoking, dental caries and amalgams may exacerbate disease.

Oral lichenoid contact stomatitis can be clinically and histologically indistinguishable from OLP. In patients with OLP, one study identified a contact hypersensitivity in 40 % of the cases [34]. The most common culprits are amalgams in fillings as well as food flavorings (cinnamon, cinnamaldehyde, and spearmint) [34–36]. Some individuals may benefit in removal of damaged and corroded fillings despite negative patch testing [37]. This may be due to false negative patch testing, which would have been picked up with other methods (repeat open application testing (ROAT)) or due to the removal of a mucosal irritant.

Genital lesions (Fig. 31.6), including vulvar, vaginal, and penile, have been reported in 19–57 % of individuals with OLP and 15–50 % of cutaneous LP [25, 38–40]. Of patients with vaginal involvement, 44–100 % have oral disease. Therefore, when examining a patient with vulvar or vaginal inflammation, an oral and cutaneous examination is essential. Vulvo-vaginal gingival (VVG) syndrome is a specific subtype of vulvar and vaginal LP with oral involvement. Genital lesions, specifically penile, often have an annular appearance.

Fig. 31.6 Genital lichen planus: Shiny white, reticulated plaque with a violet hue and a small superficial erosion on the corona

Ocular disease is likely under-reported and up to one-third of patients with LP report blepharitis [41]. There are varying degrees of ocular involvement from the minor symptoms of dryness to cicatricial conjunctivitis [42].

Hair Disease

Hair disease has been reported in up to 40 % of LP [43–45]. Follicular involvement on the body often occurs; however, the classic cicatrical scalp alopecias of LP are the focus. Three clinical subtypes are: classic lichen-planopilaris (LPP), frontal fibrosing alopecia(FFA), and Gram-Little-Piccardi-Lasseur Syndrome(GLPLS) [44, 46]. LP of the scalp occurs more frequently in women (5 to 31:1) with FFA dominating the most [44]. Classic LPP affects the vertex scalp and consists of diffuse erythema with perifollicular hyperkeratosis and livid erythema (Fig. 31.7) [44]. Dermoscopy can aid in the diagnosis of early scarring LPP. Dermoscopic features of LPP include: absence of follicular opening, cicatricial white patches, peripilar casts and perifollicular scale, blue-gray dots, perifollicular erythema, and polytrichia (2–3 hairs) [47]. Late stage disease and progressive disease often lead to nondescript scarring (Pseudopelade of Brocq).

FFA most commonly affects postmenopausal women and is characterized clinically by a band-like alopecia of the frontal hairline [48]. Up to 75 % of women with FFA report concomitant loss of the eyebrows, which tends to be non-inflammatory [49]. Thyroid dysfunction is more common in individuals with FFA versus LPP (31 % versus 10 %) [44]. The difference seen may be partially age related. However, a more recent study found an elevated rate of thyroid dysfunction in individuals with LPP versus controls (34 % versus 11 %) [50]. The role of thyroid hormone receptors on keratinocytes, follicular function, and hair organ homeostasis remains unknown. GLPLS is a rare subtype characterized by Cicatricial alopecia of the scalp, non-scarring alopecia of the axilla and groin, and follicular papules on the trunk and extremities [51].

Special Forms

Drug-Induced Lichen Planus

Lichenoid drug eruptions (LDE) can be virtually indistinguishable from LP. LDE have been described with: oral ingestion or subcutaneous injection (angiogtensin converting enzyme inhibitors (ACEi), antimalarials, calcium channel blockers (CCB), gold, non-steroidal anti-inflammatory drugs (NSAIDs), tumor necrosis factor-alpha (TNF-α) inhibitors and contact factors (mercury, copper, gold, phenylenediamine (PPD) derivatives) [52]. Classically, LDE involve a photodistributed area, lack prominent epidermal changes, and lack mucosal involvement (with oral ingestion). LDE are typically delayed a few months from initial exposure but onset can vary from days to years [52]. LDE typically clear within a few weeks to few months after drug discontinuation. However, reactions post-gold exposure can persist for years.

Overlap Syndromes

LP pemphigoides has distinct features of both LP and bullous pemphigoid (BP) and occurs secondary to BP antigen 2 (BPAG-2) antibodies to the Medical College of Wisconsin-4 (MCW-4) epitope on the non-collagenous 16A (NC16A) domain [53]. The bullous and lichenoid lesions tend to occur on the extremities [54]. LP/Lupus erythematosus (LE) overlap has clinical, histological, and immunofluorescent features which overlap between these

Fig. 31.7 Lichen planopilaris (**a**) *Left*- Early disease with widening of the hair line and erythema of the scalp (**b**) *Right*- Dermoscopy (10× magnification) provides much higher resolution and shows classic features of lichen planopilaris: loss of follicular ostia, perifollicular scale and erythema

two entities and can have a positive anti-nuclear antibody (ANA). The extremities are commonly involved and the clinical features are atypical for LP with atrophic plaques and minimal epidermal disruption [55].

Associations with Systemic Diseases and Infections

Systemic Diseases

Patients with LP are at a higher risk of metabolic syndrome and tend to have more cardiac risk factors than healthy individuals [56, 57]. Thyroid dysfunction is found in up to 34 % of patients with LPP [50]. Lichen sclerosus et atrophicus (LS et A) is seen in up to 16 % of patients with OLP [38, 58]. OLP is associated with chronic liver disease.

Psychological and Neurogenic Factors

Increased stress, anxiety, sleep disturbance, and depression are reported in LP [59–61]. Up to 60 % of patients had chronic nervous distress or a stressful event near the time of a flare [11]. Recent studies examined the role of neural pathways and neurogenic factors in LP and showed co-localization of mast cells and nerve fibers as well as increased peripheral nerve innervation in OLP [62, 63]. The pattern of innervation appears to be different between lichenoid reactions and OLP [64]. The differences in nociceptive features are partially explained by the nature of the lesions (reticular versus erosive) rather than the innervation. Neuro-modulating drugs have been reportedly successful in OLP although larger studies verifying these findings are needed [65].

Infections

Patients with OLP and liver disease have significantly higher rates of hepatitis C (Hep C) in selected populations (78 % versus 3 %) [66]. There may be specific unidentified genetic factors contributing to this co-occurrence, as large studies on Hep C have not found LP to be a common finding [67]. Hep C and LP are associated in certain endemic regions (East and Southeast Asia, South America, the Middle East, and Southern Europe) but not in others (North America, South Asia, and Africa) [68]. In general, patients with LP have a six-fold risk of having Hep C relative to the control population [32]. The heterogeneity of Hep C and OLP may be related to the human leukocyte antigen-DR6 (HLA-DR6) haplotype, which is found in endemic regions with Hep C and LP [69, 70]. There is no strong link between hepatitis B (Hep B) and LP [71].

Other infections have been implicated in LP. Human papilloma virus (HPV) is more common in OLP with overall odds ratio (OR) of 5.12 and HPV-16 of 5.61 [72]. In

addition, the higher rates of oncogenic subtypes may explain part of the increased malignancy risk. Individuals with OLP are more likely to be colonized with Candida species than controls [73]. Non-Candida albicans species were isolated in patients with OLP, particularly those with OLP and diabetes mellitus (DM) [73]. In zosteriform LP, the lesions have expressed VZV antigens. In addition to being a potential trigger of LP, VZV antigen expression may differentiate zosteriform LP from linear presentations of LP [74].

Malignant Transformation

The malignant potential of LP is dependent upon the site of involvement, clinical subtype, duration of disease, and patient population. The reported rates of squamous cell carcinoma (SCC) development have varied: 0.8 % of OLP in the United States, 1.9 % in the United Kingdom, 0.6 % in China, and 1 % in the Swedish population [75–78]. Longstanding erosive and atrophic disease appears to have the highest risk of malignant transformation. The tongue is the most common site of involvement. Other risk factors for oral SCC, including tobacco and alcohol, have not been observed at greater frequency in OLP. Candida as well as HPV have been observed in higher frequency in OLP and may be contributory [72, 73].

No overall increased risk of malignancy has been observed in cutaneous LP [78]. There are rare case reports of cutaneous SCC arising in LP. Risk factors include: hypertrophic or verrucous LP, location on the lower extremity, a history of arsenic or x-ray exposure, and longstanding disease (average of 12 years) [78].

Laboratory Tests

No specific laboratory test abnormalities are seen in LP. Hep C testing should be considered in those with risk factors as well as those in endemic areas having a prevalence of greater than 7 % [79]. Testing for dyslipemia and thyroid dysfunction (thyroid stimulating hormone (TSH) and thyroid peroxidase (TPO) antibody) is part of routine health maintenance and determining the psychosocial impact of disease is essential [50, 56, 57, 60, 61]. Individuals with a normal TSH and TPO antibodies will require follow up monitoring for the development of clinical hypothyroidism. In oral disease, allergic contact dermatitis (ACD) should be ruled out, as oral contact stomatitis can appear identical to LP [34–36, 80].

In most cases, LP is a clinical diagnosis and should be confirmed with a biopsy when atypical or overlap features are present. Dermoscopic driven biopsies showing the key features led to definitive diagnosis in 95 % of LPP cases [81]. In cases of vesiculobullous disease or erosive disease, direct immunofluorescence (DIF), indirect immunofluorescence (IIF), as well as enzyme linked immunosorbent assay (ELISA), may be needed to differentiate from other immunobullous diseases.

Pathology

Pinkus described the initial, modern understanding of the LTR which focused on the spectrum of epidermal damage to the basement membrane and its resulting cascade of events [82]. Two major pathologic findings were described, the lymphocytic LTR and consequent damage to basal, epidermal keratinocytes [82].

The earliest changes can be seen in uninvolved and non-inflamed skin and are characterized with colloid body formation and pigmented macrophages in the dermis [83]. Colloid bodies (also known as Civatte bodies) are degenerated keratinocytes and electron microscopy has shown fibrillar degeneration of basal keratinocytes specifically [84, 85].

Classic changes are seen in established lesions with: ortho-hyperkeratosis, wedge-shaped hypergranulosis, saw-toothed rete ridges, epidermal hyperplasia, lymphocytes at the dermal-epidermal junction, Max Joseph spaces (focal, sub-epidermal clefts seen in 20 % of cases), squamatization (loss of maturation and flattening of the basal layer), and colloid bodies [86] (Fig. 31.8). LP is characterized by a dense, continuous, and band-like lympho-histiocytic infiltrate at the dermal-epidermal junction (DEJ). The heavy infiltrate can result in effacement of the DEJ. Parakeratosis and eosinophils are absent.

Late disease is characterized by: atrophic epidermis, effacement of the rete ridges, occasional colloid bodies, dermal fibrosis, and melanophages. When few colloid bodies are present, distinguishing from poikiloderma may be very difficult.

Hypertrophic LP is characterized by: hyperkeratosis, acanthosis, papillomatosis, and thickened collagen bundles in the dermis. Hypertrophic LP can be mistaken for squamous cell carcinoma; therefore, good clinical pathological correlation is needed to avoid inappropriate treatment [87]. Eosinophils are more commonly seen in hypertrophic lesions [88]. Mucosal lesions tend to have less specific changes and genital disease can often be inconclusive. Parakeratosis and an absent granular layer are common at mucosal sites.

LPP is characterized by a perifollicular, lymphohistiocytic inflammatory reaction with perifollicular fibrosis, scarring, and follicular atrophy. Initial inflammation is at the level of the isthmus and infundibulum and spares the

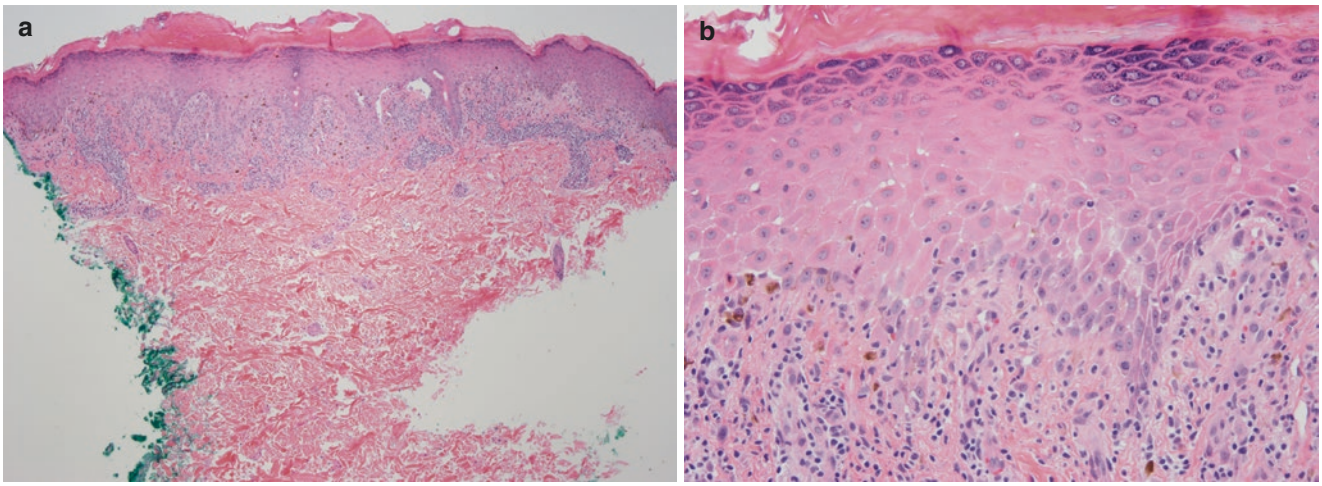

Fig. 31.8 Histology of classic cutaneous lichen planus (**a**) *Left*- Hematoxylin and Eosin (H&E) (40×) The characteristic findings of compact ortho-hyperkeratosis, wedge shaped hypergranulosis, saw-toothed rete ridges, and a lichenoid infiltrate. Small epidermal clefts (Max-Joseph space) can be seen centrally. (**b**) *Right*- (H&E 200×) Dense, lichenoid lymphocytic infiltrate with scattered apoptotic keratinocytes and pigment incontinence (Courtesy of David J DiCaudo MD)

lower segment [45]. Permanent hair loss likely results from damage to the stem cells in the bulge and subsequent fibrosis [89].

LDEs may be indistinguishable from LP. However, if present, atypical features like parakeratosis, eosinophils (seen in up to two-thirds of cases), plasma cells, large numbers of apoptotic keratinocytes, and perivascular lymphocytes extending into the reticular dermis may aid in the diagnosis [90, 91]. In one study, focal parakeratosis, focal clusters of colloid bodies in the granular layer and stratum corneum, and focal epidermal disruption were seen in 50 % of LDEs and no cases of LP [91]. Cluster of differentiation-8 (CD8) positive Granzyme B positive lymphocytes appear to predominate in LDE versus classic LP [90].

Immunofluorescence

In cases of LP with positive immunofluorescence, fibrin and IgM (bound to colloid bodies) are present in 100 % and 93–100 % of cases, respectively [83, 92] (Fig. 31.9). Shaggy fibrin is the most common finding and best predictor of LP and can be seen in early disease without a prominent inflammatory infiltrate. The criterion for LP requires basement membrane zone fibrinogen and colloid bodies with one or more conjugates (Mayo Clinic Criteria) [93]. Colloid bodies have a better predictive value in oral lesions. DIF of OLP (sensitivity of 61 % and specificity of 96 %) is inferior to both hematoxylin and eosin (H&E) (sensitivity of 84 % and specificity of 93 %) and clinical impression (sensitivity of

Morphology and age:
Classic: Psoriasis, Lichenoid drug, Lichen simplex chronicus, Chronic cutaneous lupus, Graft versus host disease, Secondary syphilis, Pityriasis rosea, Mycosis fungoides
Annular: Granuloma annulare, Tinea corporis
Linear: Lichen striatus, Linear epidermal nevus, Psoriasis, Darier's disease
Hypertrophic: Lichen simplex chronicus, Prurigo nodularis, Lichen amyloidosis, Kaposi sarcoma, Squamous cell carcinoma, Psoriasis
Atrophic: Lichen sclerosus, Cutaneous lupus erythematosus, Poikiloderma
Vesiculobullous: Lichen planus pemphigoides, Epidermolysis bullosa pruriginosa, Pemphigus vulgaris, Bullous pemphigoid, Bullous amyloidosis
Follicular: Lichen nitidus, Lichen spinulosa
Childhood: Lichen nitidus, Lichen striatus, Pityriasis lichenoides, Papular acrodermatitis of childhood
Special site:
Nail: Psoriasis, Onychomycosis, Alopecia areata
Genital: Psoriasis, Seborrheic dermatitis, Fixed drug eruption
Palms and soles: Secondary syphilis, Erythema multiforme
Scalp: Cicatricial alopecia, Lupus erythematosus, Inflammatory folliculitis, Alopecia areata, Cicatricial pemphigoid, Keratosis follicularis spinulosa decalvans
Mucosal: Paraneoplastic autoimmune multi-organ syndrome/Paraneoplastic pemphigus, Candidiasis, Lupus erythematosus, Leukokeratosis, Secondary syphilis, Traumatic patches, Chronic ulcerative stomatitis, Erythema multiforme
Histological:
Lichenoid keratosis, Poikiloderma, Chronic cutaneous lupus erythematosus, Fixed drug eruption, Lichen nitidus, Lichen striatus, Lichenoid drug, Graft versus host disease, Mycosis fungoides, Contact dermatitis, Keratosis lichenoides chronica, Erythema dyschromicum perstans, Lichenoid and granulomatous dermatitis

74 % and specificity of 87 %) [93]. These findings emphasize the importance of clinical examination and diagnosis in classic LP. DIF has a role in atypical disease as well as ulcerative and vesiculobullous variants.

Location of disease governs sensitivity of detection by DIF (in decreasing order): mouth floor, the ventral side of the tongue, superior labial mucosa, hard palate and buccal mucosa. The gingiva is the least sensitive location, although other studies refute this, and suggest the dorsal tongue [93, 94]. The optimal location for biopsy of cutaneous LP is on the proximal trunk with avoidance of the distal extremities [92]. A biopsy of lesional tissues for DIF can yield false negatives since immune deposits are degraded by intense inflammation or damage in the basal membrane zone.

Traditionally, biopsies have been taken from perilesional skin; however, more recent data, in OLP, suggests the same diagnostic yield of more distant biopsies (greater than 1 cm from the lesion) [94, 95]. Splitting of biopsy samples is common in oral disease; however, the sensitivity is significantly less on split samples (40 % versus 65 %) [94]. Subsequent studies of mucosal and glaborous skin showed no difference in sensitivity and specificity of DIF [92].

On DIF, there can be considerable overlap between LP and LE with the majority of cases of LE showing immune deposition on colloid bodies and fibrin at the DEJ. The clustering of colloid bodies is much more common in LP. Multiple immunoglobulin (IgG, A, and M) conjugates and granular, basilar deposition of Igs are more common in LE, and the diagnosis should be suspect when present in LP [96].

Differential Diagnosis

The differential diagnosis of LP is quite broad. A more practical approach is to look at the age of the individual, morphology of the primary lesion, and site of involvement (Table 31.2).

Prognosis

Most cutaneous LP resolves within 1–2 years. Disease duration, in ascending order, is: generalized cutaneous, non-generalized cutaneous, cutaneous and mucosal, mucosal, hypertrophic, and LPP [97]. Recurrence is seen in up to 20 % of cases but is more common in generalized cutaneous disease [11, 98]. In higher Fitzpatrick skin types, post-inflammatory changes manifest as significant, persistent pigmentary abnormalities.

Pathogenesis

The pathogenesis of LP is unknown. Many contributing factors are implicated and include, infectious, autoimmune, metabolic, psychosomatic, and genetic causes. The initial theories of LP, described by Sabouraud in 1910, emphasized a dermally based process with secondary involvement of the basal cells of the epidermis [99]. Thyresson and Moberger challenged this concept and proposed that LP was a process

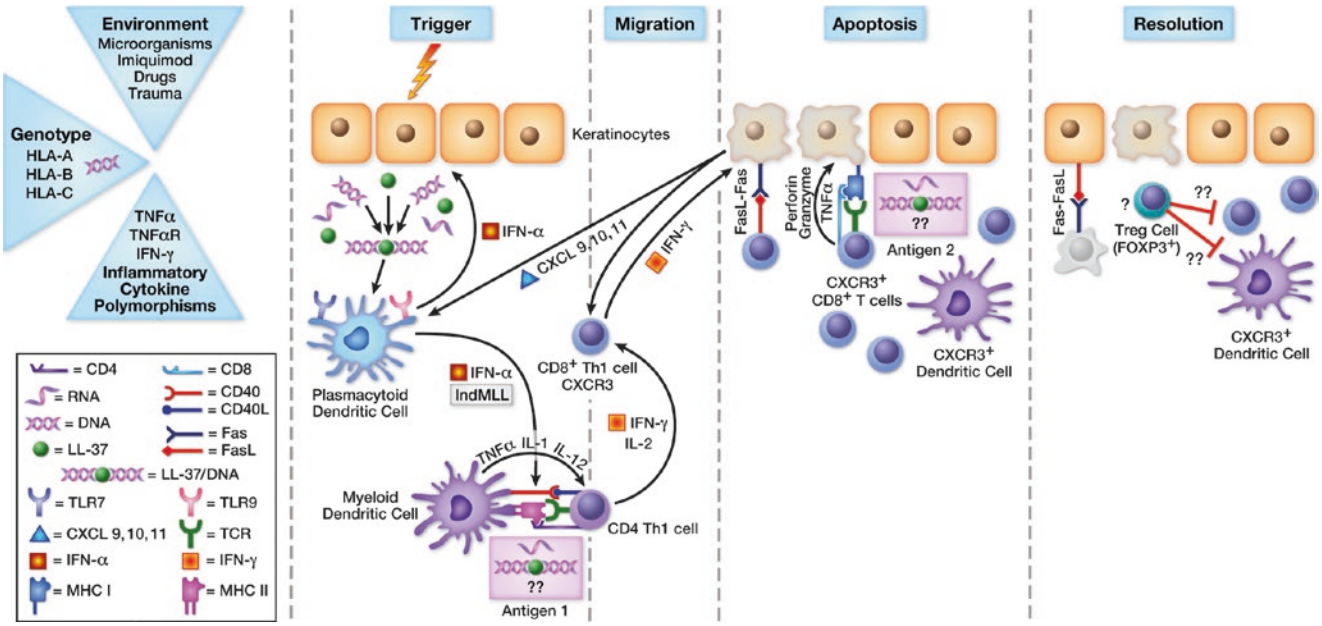

Fig. 31.10 Immunopathogenesis of lichen planus. The occurrence of triggering factors in a genetically predisposed individual carrying LP-associated genes, results in disease development. During the initiation phase, damage to keratinocytes results in the release of deoxyribonucleic acid (*DNA*), ribonucleic acid (*RNA*), and cathelcidin (*LL37*). These proteins stimulate plasmacytoid dendritic cells (*PDC*) via toll like receptors (*TLR*)-7,-9 which result in the release of interferon alpha (*IFN-α*). IFN-α can have both local and distant affects upon myeloid dendritic cells (*MDC*) as well as keratinocytes. Stimulated MDC will interact with CD4-Th cells with the correct antigen. The antigen remains unknown but may represent a viral derived peptide. MDC will stimulate CD4-Th cells via the release of TNF-α, Interleukin (IL) -1, and −12. In addition, CD40 and CD40 ligand (*CD40L*) will result in the co-stimulation of the CD4-Th/MDC interaction. Stimulated CD4-Th cells then release IFN-γ and IL-2. These cytokines stimulate CD8-Tc cells. The stimulated CD8-Tc cells expressing Chemokine receptor-3 (*CXCR-3*) will migrate to the DEJ following the release of chemokine ligands (*CXCL*) −9, −10,−11. These chemokines are released by stressed and stimulated keratinocytes. The stimulated CD8-Tc cells will interact with the stressed keratinocytes and can induce apoptosis with the proper signaling receptors. This antigen also remains unknown but may be a self-antigen released by local stress. The major kill signals are TNF-α, granzyme, and perforin. Fas and Fas ligand (*Fas-L*) are expressed on both keratinocytes and lymphocytes. Therefore, the Fas -Fas-L interaction is likely involved in both apoptosis as well as disease resolution. Local CXCR-3+ DC and T-regulatory (*T-reg*) cells may also modulate the LTR

focused at the DEJ [84]. Black provided evidence of decreased respiratory enzyme activity in the epidermal cells as a possible early driver of LP [100]. However, the changes seen may have been a secondary phenomenon to the basal damage. The basal keratinocyte damage was thought to be secondary to targeted cell mediated immune (CMI) mechanisms, but the exact pathogenesis remained largely illusive [101].

Shiohara et al. further described the T-cell mediated attack upon the epidermis and re-focused attention to CMI and away from secondary humoral mediated processes [102]. Immune complexes have been found to down regulate the ability of macrophages to present antigen as well as stimulate a cytotoxic response [103, 104]. CD4-positive T-helper (CD4-Th) cells persistent in the dermis despite disease chronicity, and CD8-positive T-cytotoxic (CD8-Tc) cells have been found in close proximity to damaged basal keratinocytes in conjunction with exocytosis [105].

Modern theories encompass three major stages: antigen recognition, lymphocyte activation, and keratinocyte apoptosis. A fourth stage, resolution, is a new and emerging topic and will be discussed briefly. Research on LP often separates oral and cutaneous disease. However, the major mechanisms underlying disease subtypes are likely the same, although mechanisms targeting specific epithelial sites are enigmatic. A unified theory of LP does not exist; however, we present the modern view of the topic (Fig. 31.10).

The Cellular Immune Response

Antigen Recognition

The predominate cell mediating LP is the CD8-Tc cell. The targeted antigen(s) and or trigger(s) for LP remain unknown. However, in other diseases like lichenoid graft versus host disease (GVHD), the target antigens are the alloantigens. In oral disease, a LP-specific antigen associated with major histocompatibility complex (MHC) class I on keratinocytes has been reported [106]. It remains to be established if this antigen is an auto-reactive peptide or an exogeneous antigen. Circulating antibodies have been identified in multiple

studies without a clear target antigen [83, 107]. The adaptive immune response is triggered by a "foreign" stimulus, and CD 56-positive CD 16-negative natural killer (NK) cells are recruited [108]. These cells are found in early lesions, express chemokine receptor-3 (CXCR-3), chemokine (c-c) motif ligand (CCL) -5, −6, and release IFN-γ and TNF-α [108]. NK cells may play a role in early propagation of LP.

The role of CD4-Th cells has come into focus in recent years. The CD4-Th population tends to be localized to the dermis with scattered cells in the epidermis. The level of CD4-Th cells correlates with the number of Langerhans cells (LC). LCs, one of the principal antigen-presenting cells of skin, upregulate MHC class II receptors in lichenoid disease [109]. In particular, the CD4-positive LC is seen in close approximation with the HLA-DR positive keratinocytes [110]. In addition, the CD4-Th cells have restricted V-beta gene expression, which suggests antigen specific oligoclonal T-cell expansion [111, 112]. Upon costimulation, these cells release large amounts of inflammatory cytokines including IFN-γ [113]. Taken together, these findings suggest an integral role of Langerhans cells, keratinocytes, and CD4 T helper cells in antigen presentation as well as propagation of the Th1 response via the production of IFN-γ.

The exact roles of exogenous and endogenous antigens in development of LP remain unknown. However, many drugs (see section "Drug-Induced Lichen Planus"), infections (see section "Infections"), contact allergens, and ultraviolet radiation (seen in LE) have been implicated [114–117]. With oral contactants, it has been debated if there is a bonafide hapten reaction or simply chronic inflammation, which manifests as a LTR. With the expanding use of biologics and inevitable adverse reactions, particularly TNF-α inhibitors, specifically LDE, imbalance and upregulation of type I IFN have been implicated in disease pathogenesis [118, 119]. This further substantiates previous reports of development of LP with therapeutic use of IFNs [120].

Lymphocyte Activation

Following antigen recognition, CD8-Tc cells are activated and undergo oligo-clonal expansion (outlined above). A cascade of both pro- and anti-inflammatory cytokines is released including: IL-2, −4, −10, IFN-γ, TNF-α, and transforming growth factor beta 1 (TGF-β1) [121, 122]. In LP, the balance between lymphocyte activation, down regulation, and the cytokine milieu may well determine the disease phenotype.

IFN-γ plays a central role in LP [123]. IFN-γ induces the expression of inflammatory chemokines such as chemokine ligand (CXCL)-9, −10, and −11 [123–125]. CXCR-3, their matching receptor, is predominantly expressed on the surface of IFN-γ-producing CD4-Th cells [124–127]. Peroxisome proliferated-activated receptor (PPAR) gamma inhibits CXCL-10 and −11 and its loss can result in scarring alopecia [128, 129]. IFN-γ increases peripheral blood mononuclear cell (PBMC) binding to HLA-DR positive keratinocytes [124]. However, blockade of the HLA-DR does not inhibit the interaction and lymphocyte function associated antigen-1 (LFA-1) is implicated in the interaction as it is reversed by neutralizing antibody [125]. LFA-1 is expressed on lymphocytes and interacts with intercellular adhesion molecule-1 (ICAM1) [130]. ICAM1 and vascular cell adhesion molecule (VCAM) expression is also enhanced by IFN-γ [126]. Mice pretreated with IFN-γ prior to transfer of T-helper cells exhibited a more brisk LTR but it was unchanged by pretreatment with TNF-α [127]. Therefore, IFN-γ is fundamentally involved in the upregulation of cellular adhesion molecules and the migration of lymphocytes to the DEJ [131, 132].

Keratinocyte Apoptosis

CD8-Tc cells are likely the terminal effector cells in LP. They have been found to co-localize with apoptotic keratinocytes and to have in-vitro cytotoxic activity against autologous keratinocytes [106, 133]. The cytotoxic effects of the CD8 positive cells can be inhibited by blockade of the MHC class I domain [106]. In addition to cytotoxic effects, lymphocytes in LP may be resistant to apoptosis suggested by increased levels of B-cell lymphoma-2 (Bcl-2) [134]. The markers of apoptosis include Caspase-3 and Bcl-associated X (BAX) expression. These proteins are elevated in LP in the basal and suprabasilar epidermis, respectively [134].

The exact mechanism of apoptosis in LP remains unknown. The possible mechanisms include: granzyme-B release, TNF-α-TNF-α R1 receptor interaction, and Fas-Fas-L interaction. Granzyme-B and granulysin are expressed at 100–200 fold higher levels in LP relative to normal skin [135]. Granzyme B, excreted by CD8-Tc cells, activates caspase-3 and likely promotes apoptosis in LP [136]. TNF-α upregulates the expression of matrix metalloproteinase-9 (MMP-9) in lesional T lymphocytes of OLP and has little effect upon the tissue inhibitor of metalloproteases (TIMPs) [137]. This likely leads to disruption of the basement membrane and damage to basilar keratinocytes. MMP-9 levels correlate with the phenotype, with higher lesional levels of messenger ribonucleic acid (mRNA) expression being associated with oral ulcerative disease [138]. MMP-9 is also involved in terminal differentiation and apoptosis of keratinocytes [139]. Taken together, MMP-9 likely disrupts the basement membrane homeostasis, blocking normal cell survival signaling and leads to apoptosis and cell death. Fas-Fas-L expression is elevated in OLP, correlates with disease progression, and likely contributes to apoptosis of keratinocytes [140–142].

Resolution

LP tends to be a self-resolving disease; however, there is a paucity of research into the resolution phase of disease. T-Regulatory (T-reg) cells are seen in OLP and correlates with disease subtype and activity [143, 144]. In vivo research in acute GVHD has shown the key role that T-reg cells play in the disruption of DC and allogeneic T-cell interactions [145]. DCs in LP have also been found to play a key role in T-cell migration [146]. However, DCs role is likely more complex as higher levels inversely correlate with the inflammatory infiltrate [147]. Fas-L, granzyme-B, and perforin can be expressed by keratinocytes allowing for apoptosis of lymphocytes [148, 149].

Genes and Gene Expression

Teleologically, immune system targeting of various naturally occurring but potentially deleterious antigens i.e., viruses and bacteria (see section "Toll-Like Receptors"), malignant cells, and exogenous contactants has potential benefit to the organism [150]. However, the generation of an immune response to exogenous antigens poses risk in the development of cross-reactivity to self-antigens or antigen mimicry and potential for cross-presentation [151, 152].

Genetic polymorphisms have been implicated in the risk of development of LP including: HLA, immune signaling molecules and receptors, and other polymorphisms, but their exact roles remain unknown. Copeman found HLA-B7 in 80% of individuals with familial LP; however, further studies found HLA-B7 to be in 0–50% of cases [15, 153–155]. Additional HLA types associated with familial and non-familial LP include: HLA-A3, −Aw19, −B18, −Cw8, −DR1, −DRB1*0101, −DQ1, −DQB1*0201 [32, 97]. The mode of inheritance appears to be autosomal dominant with variable penetrance. A study of OLP, in a Chinese family, found chromosome 3p14-3q13 as the candidate gene region for OLP [156].

Polymorphisms have been reported in immune related genes: IFN-γ, TNF-α, TNF-α R2, IL-4, −6, and −18 [32]. Polymorphisms in other genes include those involved in oxidative stress, prostaglandin-E2 (PGE2) synthesis, formation of transglutaminase, thyroid hormone synthesis, prothrombin, nuclear factor kappa-light-chain-enhancer of activated B cell (NFkB) as well as epigenetic regulation of genes by micro-RNA (miRNA)-146a and −155 [32] These polymorphisms may regulate increased activity of pro-inflammatory mediators as well as dysfunctional proteins and aberrant signaling. Gene expression profiling of LP, compared to atopic dermatitis and psoriasis, identified expression of the CXCR-3 ligand, CXCL-9, as the most specific marker for LP [157]. In addition, keratinocytes were confirmed as the source of type I IFNs (−α & -β) [157]. Future research using large, case-control genome-wide array studies, as was done with psoriasis, may clarify the current risk alleles and identify additional risk alleles for LP [158].

Cellular Immune Response

Dendritic Cells

Dendritic cells (DCs) play a key role in antigenic stimulation of naïve T-cells. Three major dendritic cell populations are involved in development of LP, including LCs (CD1a +, Langerin +), dendritic cell-specific intercellular adhesion molecule-3 grabbing non-integrin positive DCs (DC-SIGN DCs), and plasmacytoid DCs (PDC) (CD-123+, BDCA+) [159]. DCs are the primary antigen presenting cells and are involved in antigen processing as well as presentation to T-cells [160]. When DCs encounter an antigen, they undergo maturation, resulting in specific acquisition of phenotypic properties, including CCR7 expression, adhesion, and co-stimulatory marker expression, which induce nodal homing and T-cell stimulation [161, 162].

Langerhans Cells

LCs express: CD1a, Langerin, and E-cadherin, and are usually located in the suprabasal layer of the epidermis [163]. In LP, LCs are critical in the epidermal migration of T-cells. LCs present autoantigens or foreign antigens to T-cells, which can activate T-cells. Upon activation, LCs downregulate Langerin and E-cadherin as well as upregulate CD80 and 86, which enhances T-cell stimulation [164]. Over time, the LCs migrate towards the basal epidermis [165].

The exact role of LCs remains unknown, though they likely play integral roles in both promoting and regulating the inflammatory response. Mouse models show that the migration of T-cells can be impaired with tape-stripping of the skin (95% of LCs removed) [146]. In OLP the number of LCs inversely correlates with the number of inflammatory cells [147]. The paradoxical findings related to DCs may eventually be reconciled by the intricate balance of deletion of autoreactive populations versus potential propagation of autoimmunity, which may not be mutually exclusive [166].

DC-SIGN Dendritic Cells

The role of DC-SIGN DCs is unknown in LP. Interstitial DCs do not express langerin but do express DC-SIGN, which binds to ICAM2 and −3 and allows for extravasation as well as interaction of DCs and naïve T-cells [167–170]. DC-SIGN DCs have pluripotent differentiation in that one population

stimulates T-cells and another is macrophage-like, which lack T-cell stimulatory function and can stimulate B cells [171].

Plasmacytoid Dendritic Cells

PDCs express CD68, cutaneous lymphocyte-associated antigen (CLA), IL-3Rα (CD-123) and blood dendritic cell antigen-2 (BDCA2), but lack expression of CD11c [172]. PDCs are found in the dermis and are likely responsible for the maturation of DCs and play a central role in the amplification of cytotoxicity in lymphoid cells. Upon stimulation, PDCs upregulate CD40-L, express IL-12, and type I IFN, which stimulate a Th1 response [172]. With maturation, PDCs downregulate CXCR-3 and L-selectin, which allows for migration from the epidermis into the stroma, lymphatics, and eventually the lymph nodes [172, 173].

PDCs have the unique capacity to rapidly produce large amounts of interferon- α (IFN-α) upon recognition of viral RNA and deoxyribonucleic acid (DNA) through TLR7 and −9, respectively [174]. Type I IFN producing PDCs recruit CD8-Tc cells, carrying CXCR-3 ligands in their granules, via CXCR-3–CXCL-10 interaction, which represents an important amplification step in LP [150, 175]. In addition, PDCs express CXCR-3, which allows for migration, amplification, and modulation of the local LTR [175].

PDCs are normally unable to respond to self-nucleic acids; however, in cutaneous LE PDCs become activated to produce type I IFNs by self-nucleic acids in complex with antibodies to DNA or nucleoproteins [176–178]. Type I IFN results in the maturation of MDCs, DC-SIGN DCs and LCs, and increases MDCs' ability to stimulate T-cells, which can result in auto-reactive immune events [179]. It remains speculative whether these triggers exist in LP.

T-Cells

Both cytotoxic and helper T-lymphocytes play central roles in LP as described earlier (see section, "Antigen Recognition," "Lymphocyte Activation," "Keratinocyte Apoptosis," and "Resolution"). The role of T-Reg cells also remains speculative but their general mechanisms of activity are discussed below.

T-Regulatory Cells

Foxp3-positive CD4-positive CD25-positive regulatory T cells (T-Regs) are critical for the regulation of host tolerance and suppression of pathological immune responses. T-Reg cells can be readily identified in the skin; however, no significant differences were found between normal skin and many inflammatory dermatoses, including LP [180]. Recently, T-reg cells and the inducers and signaling molecules, TGF-β and IL-10, were found to be upregulated in OLP and were diminished after effective treatment [181]. This suggests a role for T-Regs, induced by IL-2 and TGFβ, as well as synthesis of IL-10 and TGF-β in the resolution of LP [182, 183]. Human anti-inflammatory macrophages (m2 type) induce T-Reg cells and may also play a role in disease resolution [184].

Polymorphisms in specific cytokines, and receptors, as well as pathways in the generation of suppressive immune cells may lead to a prolonged or inappropriate inflammatory response. Genetically altered mice with autoreactive CD8+ T cells do not develop toxic epidermal necrolysis, a severe, necrotic form of interface dermatitis, until they are depleted of T-Reg cells [185]. Taken together, T-Reg cells are involved in attenuating the immune response and are diminished in cutaneous LE and other LTR, but their role in propagation and clearance of LP has yet to be clearly defined [186].

Cytokines/Chemokines

Chemokines are a subset of cytokines that mediate migration and homing of leukocytes [122, 187]. Chemokines possess homeostatic as well as inflammatory properties.

CXCR-3 Ligands

CXCR-3 ligands, CXCL9, −10, −11, are required in the recruitment of CD8-Tc cells as well as PDCs in LTR [188]. CD8-Tc cells harbor CCL5 and CXCR10 in their granules, which suggest auto-inductive and propagating pathways of activation [188]. CXCL-12 is homeostatic in nature, has an unclear role in LP, but is upregulated in oral disease [189]. The upregulation of inflammatory and homeostatic chemokines results in the recruitment of memory T cells [114, 190]. IFN-γ and TNF-α stimulate keratinocytes to release CXCR-3 ligands [123, 191]. These ligands are upregulated in LP relative to other inflammatory skin diseases [157]. CXCR-3 positive CD8-Tc cells as well as PDCs have a high affinity for CXCR-3 ligands that facilitate migration and recruitment at the DEJ with subsequent basement membrane disruption [175, 190, 192]. Similar mechanisms, although mediated by different stimuli, have been described in cutaneous LE, and lichenoid GVHD [114, 192].

Interferon-α

IFN-α is produced primarily by PDCs and is a critical mediator in DC maturation (see section "Dendritic Cells"),

as well as the amplification and the recruitment of CD8-Tc cells [150] IFN-α is a potent mediator of the expression of CXCR-3 ligands. IFN-α rapidly induces CXCL-9, −10, −11, and −12 expression in primary keratinocytes, dermal fibroblasts, and dermal endothelial cells. The upregulation of CXCL-12 in conjuction with the CXCR-3 ligands suggests that IFN-α plays a key role in PDC recruitment as well as CD8-Tc cells and memory T cells. T-lymphocyte recruitment produces IFN-γ, which results in an amplification loop.

Interferon-γ

IFN-γ plays a central role in CMI and is over-expressed in lesional LP (see section "Lymphocyte Activation") [189, 193]. Upregulation of IFN-γ has been identified in keratinocytes as well as cytotoxic T cells of LP [113]. IFN-γ induces expression of Fas on keratinocytes contributing to apoptosis [194].

Toll-Like Receptors

TLRs are part of the innate immune response, which recognize specific molecular components conserved among microorganisms [195]. TLRs induce an innate inflammatory response and mediate antigen-specific adaptive immunity [195].

PDC are likely activated by TLR7 and −9 (see section "Dendritic Cells"). While specific triggers of LP are unknown, human herpes virus type 7 (HHV7) in LP has been found to co-localize with PDCs [115–117]. Though not conclusively confirmed, this suggests that viral DNA in conjunction with TLR9 may activate PDCs in early lesions of LP [115–117]. Increased expression of TLR9 has been demonstrated in both oral and cutaneous LP [196, 197]. Similarly, imiquimod, an inducer of TLR7, is reported to cause LP [198–200].

Koebnerization, disease triggered by local skin injury, may be induced by cathelcidin (LL37), an endogenous antimicrobial peptide, which can bind to self-DNA. While this has not been observed in LP, activation of PDCs by LL37 bound to self-DNA has been shown in psoriasis [201]. Meller has suggested that a similar mechanism may occur in an individual with a different genetic predisposition [122]. TLR2, which drives a humoral-mediated immune response, is downregulated in OLP while TLR4, which drives a CMI response, is upregulated in OLP [202]. TLR3 polymorphism has been associated with an increased risk in developing OLP as well as being a risk factor for poor survival in oral cancer [203, 204]. Taken together, there is an integral role between the host-microbial response in OLP and likely in cutaneous LP as well.

Treatment

The treatment of LP is challenging for both physicians as well as patients. Due to its ability to affect multiple ectodermally derived tissues, LP often requires a multidisciplinary approach with dermatologists, dentists, and gynecologists. The goal of therapy is to minimize morbidity and improve the patient's quality of life.

The basic concepts in the treatment of LP have remained largely unchanged over the last decade. The therapies are mainly divided into skin directed and systemic agents. The therapies for various ectodermal tissues are also similar. Nearly all of these agents act in a manner to depress the immune response. To date, there are not disease specific medications for LP. However, Janus Kinase (JAK) inhibitors target CD8-Tc cells and represent a potential, disease-specific treatment of lichenoid diseases, including LP [205]. This section will provide a brief overview of the general approach to therapy for LP; however, emphasis will be placed upon unique treatments for variants of LP and their potential pharmacological targets.

Cutaneous Lichen Planus

Topical Corticosteroids

Despite few clinical trials, high potency topical corticosteroids are considered first-line therapy for limited cutaneous LP. Occlusion may be necessary to increase penetration in cases of hypertrophic LP. The sole randomized controlled trial comparing calcipotriene to betamethasone valerate (twice daily for 12 weeks) found no difference between treatments [206]. If no response is observed to twice daily application for 2–4 weeks, changing to a higher potency corticosteroid or intralesional injections should be considered [207].

Topical Calcineurin Inhibitors

There are no trials using topical calcineurin inhibitors (TCIs) in cutaneous LP. However, clinical data in OLP suggests that topical TCIs are likely the most effective topical therapy for LP. Application of tacrolimus 0.1 % ointment is as effective as 0.05 % clobetasol [208].

Intralesional and Systemic Corticosteroids

Intralesional corticosteroids (5–10 mg/mL injected on a monthly basis) can be highly effective in resistant and hypertrophic LP. However, one should use caution to prevent

excessive trauma to avoid Koebnerization. Systemic corticosteroids for cutaneous LP have only been reported in one study with a 90 % response rate and 32 % relapse rate at 6 months [209]. In our clinical experience, systemic corticosteroids are highly effective but are associated with high rates of relapse upon discontinuation. Therefore, oral and intralesional therapy should always be combined with topical therapy.

Phototherapy

Phototherapy has been used successfully in many inflammatory diseases of the skin. Ultraviolet-B (UVB) exposure of DCs results in impaired DC-CD4-Th cell interaction that culminates with T-cell apoptosis [210]. In addition, phototherapy alters cytokine expression, which suppresses CD8-Tc cells [211]. UVB (three times weekly until remission with taper after remission over 3–6 weeks) has a 70 % remission rate and 85 % of those patients remained in remission at 34 months [212]. Narrowband UVB (311 nm) is as effective in LP and has largely supplanted Ultraviolet-A (UVA), psoralen plus UVA (PUVA), and UVB phototherapy [213].

Miscellaneous

The mechanism of action of metronidazole in LP is unknown but may be mediated by its antimicrobial activity as well as immunosuppressive effects on human blood lymphocytes [214]. An open labeled study of oral metronidazole (250 mg three times daily for 12 weeks) showed a 74 % response rate at 3 months of follow up [215]. Alternate dosing (500 mg twice daily for 20–60 days) has also been reported to be successful [216]. Due to its side effect profile, metronidazole is often considered first line; however, one should caution patients as well as monitor for possible sensory peripheral neuropathy [217].

Sulfasalazine (initial dose 1 g daily with an increase every 3 days by 0.5 g to a max of 2.5 g daily) has the highest level of evidence of efficacy for LP with an 83 % improvement in skin lesions and a 91 % improvement in itch at 6 weeks in the therapy group [218, 219]. Sulfasalazine likely downregulates the expression of ICAM1, decreases leukotriene synthesis, and decreases the number of lesional T lymphocytes [220].

A double blind, placebo control trial of acetretin (30 mg daily for 8 weeks) showed marked improvement in 64 % of individuals [221]. Mucocutaneous side effects and hyperlipidemia were common. Retinoids may have activity by downregulating VCAM1 on endothelial cells and modulation of cyclooxygenase-2 (COX2) and TNF-α preventing the homing of lymphocytes to the skin and stimulation of the inflammatory cascade [222, 223].

Methotrexate has been shown to be of benefit for more recalcitrant disease as well as in specific forms of disease, including hypertrophic LP and LPP. Methotrexate preferentially targets lymphocytes 1000-fold relative to keratinocytes and inhibits proliferation and has cytotoxic activity [224]. Recent, non-randomized, prospective data has shown methotrexate (15–20 mg weekly for 4–24 weeks) to be highly efficacious with complete responses in 58–91 % of cases [225–227].

Other therapies including: mycophenolate mofetil, cyclosporine, TNF-α inhibitors, trimethoprim-sulfamethoxazole, griseofulvin, itraconazole, terbinafine, antimalarials, tetracyclines, laser, IFN, allitretinoin, thalidomide, and low-dose heparin have also been reported.

Oral Lichen Planus

The cornerstone of treatment in OLP is good oral hygiene with regular professional dental cleanings [228]. Minimizing other exacerbating factors such as: contact allergens, drug reactions, reducing oral microbes, and minimizing trauma can reduce disease severity as well as frequency of flares. Replacement of dental amalgams and gold dental restorations can be beneficial, even in patients with negative patch testing [229, 230]. However, removal and restoration should be individualized based upon the severity of disease as well as the index of suspicion of the level of involvement of the metal or prosthesis.

Topical Corticosteroids

Topical steroids are first-line therapy in OLP with overall clinical responses on the order of 70–80 %. Although few direct comparisons between topical corticosteroids in LP exist, the most beneficial are likely: triamcinolone acetonide, clobetasol-17-propionate and fluocinonide [231]. However, only clobetasol and fluocinonide have clear benefit over placebo. In general, application of topical corticosteroids two to six times daily is indicated. The major complications of topical corticosteroids are fungal infections and, in general, higher rates of fungal infections are seen with more potent topical corticosteroids. Therefore, concomitant therapy with oral chlorohexidine gluconate mouthwash or other topical anti-candidal medications is recommended [232, 233].

Triamcinolone acetonide 0.1 % mouthwash and paste (four times daily for four weeks) are equally effective in the treatment of OLP [234]. Clobetasol 0.05 % in Orabase®

(twice times daily for 3 weeks, daily for 3 weeks, and every other day for 3 weeks) was found to be superior to triamcinolone 0.1 % in Orabase® at 3 weeks with equal efficacy at 6 and 9 weeks [235]. Another study found clobetasol to be superior to fluocinonide in OLP with faster resolution of lesions [232]. Studies comparing various preparations of clobetasol 0.05 % showed that there was faster clearing time in those using twice daily applications of clobetasol 0.05 % in adhesive denture paste [236]. There is no clinically significant difference in efficacy between clobetasol 0.05 % gel (twice daily for 2 months) versus clobetasol 0.025 % gel [237]. However, at 2-month follow up, the patients in the high concentration group had more stable disease. Fluocinonide 0.025 % (six times daily) in adhesive base was found to be superior to placebo [238]. Fluocinolone 0.1 % (four times daily for two to four weeks) in various preparations was found to be equally effective [239].

Topical Calcineurin Inhibitors

Pimecrolimus 1 % cream is effective in curing the erosive lesions of OLP but is ineffective at symptomatic control [231, 240]. Meta-analysis has found tacrolimus 0.1 % ointment (used one to four times daily) has been found to be more effective than clobetasol propionate ointment [231]. Unlike pimecrolimus, tacrolimus is effective at controlling the symptoms of OLP as well. However, the number of patients in the three RCTs is much lower than those using corticosteroids and; therefore, tacrolimus is reserved as a second-line topical therapy. Cyclosporine in various preparations has been found to be less effective than both clobetasol and triamcinolone [231, 241]. In lieu of alternative commercially available calcineurin inhibitors (CIs) and increasing restrictions on compounding, we would recommend this therapy third-line. Transient burning with usage of topical CIs is common and overlap therapy with topical corticosteroids may alleviate the burning sensation.

Intralesional and Oral Corticosteroids

Systemic steroids are the most effective treatment for OLP and can provide rapid improvement in acute exacerbations. However, there are no RCTs for systemic corticosteroids. Both clinical experience as well as prospective studies indicate that oral corticosteroids (1.5–2 mg/kg) are highly effective [242, 243]. Intralesional triamcinolone (0.5 mL of 40 mg/mL on a weekly basis for four weeks) is as effective as 0.1 % triamcinolone (three times daily for 6 weeks) mouthwash [244]. However, due to the discomfort of injection and few well-controlled studies, intralesional therapies are reserved after exhausting topical therapies. Additionally, studies examining pulsed betamethasone (5 mg on 2 consecutive days weekly for 3 months) versus topical 0.1 % triamcinolone paste (three times daily for 3 months) showed a more rapid response but no clear long-term advantage [245]. Intralesional and oral therapy should be done concomitantly with topical therapy, as patients will often flare upon discontinuation of oral therapy.

Miscellaneous

Many other therapies including: topical retinoids, mesalazine, antibiotics, hydroxychloroquine, griseofulvin, thalidomide, etretinate, acetretin, isotretinoin, cyclosporine, methotrexate, mycophenolate mofetil, azathioprine, as well as parenteral alefacept, extracorporeal photophoresis, laser therapy, and PUVA therapy. However, these therapies often have attendant side effects or do not show clear efficacy. They are reserved as third-line therapies, and the risks and benefits of therapy should be considered prior to institution.

Lichen Planopilaris-Frontal Fibrosing Alopecia

There are no randomized controlled trials in LPP and only one controlled study. Therefore, many of the therapies in LPP are based upon expert opinion [246]. LPP has three major subtypes; however, for therapeutic purposes, they will be divided into LPP and FFA. These clinically distinct entities also appear to be responsive to slightly different therapies [247]. When considering therapeutic modalities, the psychosocial effects of scarring alopecia should be taken into account. While the pathogenesis of LPP is unknown, there is destruction of the bulge region, which leads to scarring. Recent studies have indicated a deficiency of peroxisome proliferator-activated receptor PPARγ, which may lead to loss of immune privilege and scarring alopecia [129].

Lichen Planopilaris

First-line therapies for LPP are mid to high potency topical corticosteroids with an average 53 % response rate [43, 45, 247]. There is only limited data to determine the efficacy of topical CIs, but the side effect profile makes it common second-line topical therapy. Hydroxycholorquine (6.5 mg/kg for 6–12 months) is the second most commonly used drug

and showed a good response in 23 % of cases [247, 248]. There have been several negative studies using hydroxychloroquine, and there is good evidence that while clinical evidence of inflammation is decreased, progressive scarring of follicles continues [246]. Oral corticosteroids (1 mg/kg/day for 15 days with taper over 4 months) and cyclosporine (300 mg/day for 3–5 months) are the third most commonly used drugs with a good response in 60 % of cases [43, 45, 247, 249]. Relapse is common upon discontinuation of these medicines; therefore, topicals or intralesional therapy should be used concomitantly. Approximately one third of patients receiving oral tetracyclines (doxycycline 100 mg twice daily for 3–6 months), mycophenolate mofetil (2–3 g daily for 3–12 months), or intralesional steroids (10 mg/mL injected on a monthly basis) had marked improvement [43, 250–252].

One approach is superpotent topical corticosteroids, clobetasol, twice daily for 1 month, daily for 3 months, and every other day for 3 months [249]. Intralesional corticosteroids as well as oral hydroxychloroquine can be added if there is no effect at 3 months, recognizing that hydroxychloroquine alone is likely ineffective. Other systemic agents above should be reserved for severe cases.

Frontal Fibrosing Alopecia

High potency topical corticosteroids have not shown to be effective in FFA, for 93 % of cases, while intralesional corticosteroids (10–20 mg/mL injected every 3–6 months) led to partial improvement in 60 % of cases [247, 249, 253, 254]. Oral 5 alpha-reductase inhibitors, such as finasteride (2 or 5 mg daily dose for 12–18 months) or dutasteride (0.5 mg daily for 12 months), are the most commonly used and most effective drugs, and result in a good response in 45–47 % of cases [247, 253, 255–258]. The largest study of FFA to date found that androgenetic alopecia (AGA) was concurrently present in 40 % of the women and 67 % of the men [254]. Therefore, the benefit seen with anti-androgens may be due to the component of AGA. Hydroxychloroquine has been reported effective in approximately 30 % of cases; however, many of the studies had concomitant topical therapy with immunomodulators and minoxidil [49, 247]. Other reported therapies, e.g., systemic prednisone, hormone replacement, topical calcineurin inhibitors, topical minoxidil, cyclosporine, and mycophenolate mofetil have only been reported in small series and have highly variable response rates.

Based upon the above evidence, many hair experts will use as first-line therapy: oral 5-alpha reductase inhibitor, intralesional corticosteroids, and topical minoxidil.

Nail Lichen Planus

Nail LP can be extremely difficult to treat. The goal of therapy should be to reduce the number of inflammatory cells within the nail and to prevent irreversible pterygium. A therapeutic approach should be very similar to cutaneous LP. Ultra-potent topical and intralesional corticosteroids (5–10 mg/mL injected on a weekly basis) are first line therapies. Systemic therapies should be reserved for cases manifesting significant compromise of function and causing debilitating pain.

Conclusions

The exact mechanism of LP remains unknown. However, insight from other lichenoid diseases, specifically lichenoid GVHD and cutaneous LE, as well as psoriasis, have provided insight into the basic inflammatory cascade. Further insight into disease pathogenesis will likely come from better characterization of genetic, epigenetic, and microbiomic aberrations and their interactions [259–262].

Questions

1. What HLA type is common in the setting of hepatitis C and oral lichen planus (LP)?
   (A) HLA-B51
   (B) HLA-DR6
   (C) HLA-Cw6
   (D) HLA-DQ2
   (E) HLA-B*1502

Answer:

(A) HLA-B51- HLA-B51 is associated with Behçet' disease and is seen in approximately 80 % of Asian individuals but is much less common in Caucasians

(B) **HLA-DR6- HLA-DR6 is seen in patients with OLP and Hepatitis C (over 50 % of cases) and may explain geographic heterogeneity of the association of OLP and Hepatitis C** [1, 2]

(C) HLA-Cw6- HLA-Cw6 is associated with psoriasis (included in the PSORS1 locus) and is a risk factor for early onset of disease

(D) HLA-DQ2- HLA-DQ2 recognizes the gliadin peptide and is associated with dermatitis herpetiformis (DH). Nearly 90 % patients with DH have HLA-DQ2

(E) HLA-B*1502- HLA-B*1502 is associated with carbamazepine induced SJS/TEN in Asians in East India but not Europeans

2. What systemic disease is most strongly associated with lichen planopilaris (LPP)?
   (A) Hyperlipidemia
   (B) Diabetes
   (C) Hepatitis C
   (D) Hyperthyroidism
   (E) Hypothyroidism

Answer:

(A) Hyperlipidemia- Hyperlipidemia is not strongly associated with LPP and may even be less prevalent in LPP versus controls

(B) Diabetes- Diabetes is not strongly associated with LPP and may be less prevalent in LPP versus controls

(C) Hepatitis C- The association with Hepatitis C is strongest in OLP and may be related to HLA-DR6

(D) Hyperthyroidism- There is no clear association with hyperthyroidism

(E) **Hypothyroidism- There is a strong association with hypothyroidism and LPP with 29% of patients with LPP having hypothyroidism compared to 9% of controls** [3]

3. What is true in regards to the risk of malignant transformation in LP?
   (A) The risk of malignant transformation is highest in longstanding oral erosive disease
   (B) The risk of malignant transformation is highest in generalized cutaneous lichen planus
   (C) Smoking and alcohol consumption are clear risk factors for malignant degeneration
   (D) HPV16 is less common in those with oral lichen planus (OLP)
   (E) Hypertrophic LP and squamous cell carcinoma (SCC) can clearly be distinguished histologically

Answer:

(A) **The risk of malignant transformation is highest in longstanding oral erosive disease** [4, 5].

(B) The risk of malignant transformation is highest in generalized cutaneous lichen planus. Risk factors for malignant transformation in cutaneous LP include: hypertrophic or verrucous LP, location on the lower extremity, a history of arsenic or x-ray exposure, and longstanding disease (average of 12 years) [5]

(C) Smoking and alcohol consumption are clear risk factors for malignant degeneration- Interestingly, smoking and alcohol have not shown a clear association with malignant transformation of OLP

(D) HPV16 is less common in those with oral lichen planus (OLP)- HPV16 is nearly five times more common in OLP compared to controls and may account, in part, for the increased risk of malignancy [6]

(E) Hypertrophic LP and squamous cell carcinoma (SCC) can clearly be distinguished histologically.- Hypertrophic LP is often confused histologically with SCC; therefore, good clinical pathological correlation is require [7]

4. What is the key effector cell in LP?
   (A) T-cytotoxic cell
   (B) T-helper cell
   (C) NK cell
   (D) Langerhans cell
   (E) Plasmacytoid dendritic cell

Answer:

(A) **T-cytotoxic cell- The T-cytotoxic cells are likely the terminal effector cell in LP. These cells localize to the dermal-epidermal junction and in close proximity to damaged basal keratinocytes** [8]

(B) T-helper cell- T-helper cells tend to localize to the dermis and are involved in antigen recognition and are often found in close proximity to Langerhans cells [9]

(C) NK cell- NK cells may be involved in the early propagation of LP [10]

(D) Langerhans cell- Langerhans cells are involved in antigen presentation and T-cell stimulation [11]

(E) Plasmacytoid dendritic cell- Plasmacytoid dendritic cells produce large amounts of type I interferon and likely act as an early amplifying loop in LP [12]

Cutaneous Fibrosis and Normal Wound Healing

32

Emily Hamburg-Shields, Peggy Myung, and Shawn E. Cowper

Abstract

Normal cutaneous wound healing is a highly orchestrated process requiring the participation of numerous cell types, each performing highly individualized functions at specific times under the guidance of dozens of circulating proteins that are themselves tightly controlled by transcriptional and translational mechanisms. It should come as no surprise that genetic and environmental perturbations could lead to the disruption of the successful completion of this process, or that the mechanisms themselves could be hijacked and diverted into the production of unnecessary scar.

The first portion of this chapter introduces the cellular players in this drama, their normal roles in the maintenance of the extracellular matrix, and the overarching and coordinated production that is known as "normal" wound healing. The chapter culminates with the detailed examination of several cutaneous fibrosing processes that result when genetic and/or environmental influences steer the mechanisms of wound healing and injury repair into "pathological" fibrosing disorders that can be notoriously challenging to correct.

Keywords

Cutaneous • Fibrosis • Scar • Pathology • Mechanism • Pathway • TGF-β • Wound healing • Fibroblast • Myofibroblast • Scleroderma • Systemic sclerosis • Lichen sclerosus • Keloid • Nephrogenic systemic fibrosis

Important Cellular Contributors to Cutaneous Fibrosis

The cells that promote cutaneous fibrosis include fibroblasts, fibroblast progenitors, T lymphocytes, and macrophages. Additionally, in autoimmune fibrosing disorders such as systemic sclerosis (SSc), B lymphocytes play an important role, reflecting the diverse and unique pathogenesis of different fibrotic disorders. Each of these cell types, with additional focus on particular subsets of fibroblast progenitors, will be discussed in detail in this section.

Activated Fibroblasts and Myofibroblasts

Fibroblasts are a heterogeneous group of cells that are responsible for the production of the extracellular matrix (ECM)—composed broadly of collagen, elastin, and myxoid ground substance. Cutaneous fibrosis occurs when abnormal fibroblast activity leads to ECM with excess collagen. The dermis contains resident fibroblasts which produce type I collagen (the predominant type of collagen in adult skin) and other matrix proteins including type III collagen, fibronectin, fibrillin, and elastin [1]. Many different stimuli, both signaling factors and mechanical forces, can regulate the activity

of fibroblasts. These stimuli vary among the different fibrosing conditions.

Some conditions have a characteristically elevated fibroblast proliferation rate. These include normal healing wounds, keloidal and hypertrophic scars, and radiation-induced skin fibrosis [2–4]. In other fibrotic conditions, increased fibroblast proliferation is not a typical feature (i.e. SSc, morphea, and stiff skin syndrome).

Myofibroblasts, a fibroblast subtype, are present in many fibrosing conditions and in normal dermal wound healing [5, 6]. These contractile cells are defined by the presence of stress fibers and prominent endoplasmic reticulum and are critical for tissue contraction during wound healing. Expression of α-smooth muscle actin is widely accepted as a marker for myofibroblasts, although it is not specific; it is also expressed in endothelial cells, pericytes, and smooth muscle cells [7]. In addition, α-smooth muscle actin identifiable by confocal microscopy may not be readily seen in typical immunohistochemical preparations [8, 9]. Myofibroblasts are typically present in healing or fibrosing conditions, although fibrosis can occur in their absence. For example, early stage SSc skin does not always have myofibroblasts [10].

Potential Activated Fibroblast/Myofibroblast Sources

Determining the cellular sources of the fibroblasts that contribute to fibrosis is an active area of research and debate (Fig. 32.1). This question is relatively understudied in skin fibrosing processes as compared to renal, pulmonary, and hepatic fibrosis. Resident dermal fibroblasts are ideally situated to respond to injury and profibrotic stimuli, allowing for their local activation and contribution to fibrogenesis. However, several other cell types have been hypothesized to contribute to the population of ECM-producing fibroblasts in fibrosis [11]. For example, pericytes are perivascular mesenchymal progenitor cells that have been shown to contribute to murine fibrosis in multiple organs including skin [12–14] and to human fibrosis in lesional SSc skin, where they express markers common to myofibroblasts [8]. Circulating fibrocytes (CFs) are a population of monocyte-lineage, bone marrow-derived mesenchymal progenitor cells [15] that home to injured tissues and contribute to fibrosis in wounds, scars (including keloidal scars), and nephrogenic systemic fibrosis (Section Nephrogenic Systemic Fibrosis) [16, 17]. They have also been demonstrated in a bleomycin-induced murine model of skin fibrosis [18].

Furthermore, growing evidence suggests that subcutaneous adipocyte progenitors may also contribute to fibrosis, especially in SSc, in which adipose tissue is replaced by fibrotic tissue [19, 20]. Finally, both epithelial cells and endothelial cells have been postulated to trans-differentiate into fibroblasts in fibrosing skin and other tissues. Until further studies dissect the relative contributions of these diverse lineages to different fibrotic conditions, each of these cell types can be considered a potential source of matrix-producing fibroblasts in addition to the resident dermal fibroblasts.

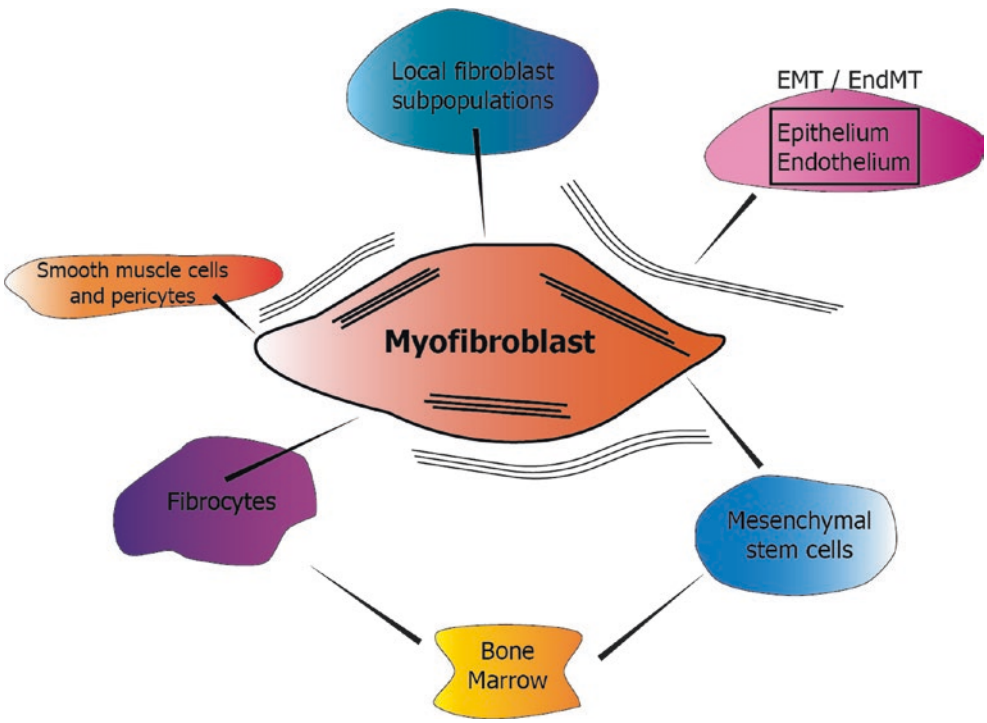

Fig. 32.1 Potential sources of myofibroblasts. Myofibroblasts, besides resulting from the differentiation of normal cutaneous resident fibroblasts, may also derive from several cellular sources, including pericytes, epithelial cells, endothelial cells, circulating fibrocytes, and mesenchymal stem cells. *EMT* epithelial to mesenchymal transition, *EndMT* endothelial to mesenchymal transition (Figure adapted per Creative Commons license from Micallef et al. [253])

Endothelial Cells

Endothelial cells are crucial mediators of the wound healing process (see Section Cutaneous Wound Healing). In fibrotic skin disorders, endothelial or microvascular dysfunction may play an important role in early stages of injury response leading to fibrogenesis [21].

The role of endothelial cells in fibrosis is of particular interest in SSc (see Section Scleroderma/Systemic Sclerosis), which is accompanied by skin microvessel vasculopathy and endothelial apoptosis and is often preceded by the appearance of Raynaud's phenomenon [22]. Tight-skin mice, which have an in-frame duplication of one allele of the gene encoding fibrillin-1, recapitulate several features of SSc, including excess collagen, thickened skin, and endothelial dysfunction [23]. In addition to contributing to tissue hypoxia, endothelial cell dysregulation may also directly contribute to fibrosis via endothelial-to-mesenchymal transition (EndMT), a phenomenon that produces activated fibroblasts in injured tissue [24, 25].

How endothelial cells might contribute to fibrotic scar formation is unclear. In contrast to SSc, keloidal and hypertrophic scars do not exhibit endothelial cell apoptosis [26]. Instead, dermal microvessels are more abundant in these scar tissues than in normal skin and tend to exhibit occlusion that may contribute to local tissue hypoxia [27, 28].

Epithelial Cells

Epithelial cells, including basal keratinocytes and hair follicle-associated stem cells, contribute to re-epithelialization during wound healing [2]. Therefore, in wound healing and scar formation, epithelial proliferation and migration are key steps that regulate fibrotic processes (see Section Cutaneous Wound Healing). As discussed in Section Activated Fibroblasts and Myofibroblasts, epithelial-to-mesenchymal transition (EMT) may serve as a source of matrix producing cells. EMT, a phenomenon in which epithelial cells transdifferentiate into mesenchymal cells, has important roles in embryonic development and tumorigenesis. It has been suggested that EMT contributes to the activated fibroblast population in fibrosis of the kidney, lung, and liver [29]. In contrast, the role of EMT in skin fibrosis has not been carefully studied [30]. In a transgenic mouse model of fibrosis, overexpression of profibrotic CTGF in mouse fibroblasts *in vivo* was sufficient for an EMT gene expression signature to become detectable in skin and lung epithelium [31]. However, dedicated lineage-tracing studies are still required in order to demonstrate a role for EMT in the bleomycin-induced and tight-skin murine models of skin fibrosis.

T Lymphocytes

T cells are present in the inflammatory phase of normal wound healing as well as in keloidal scars and lesional tissue affected by SSc and acute graft versus host disease (GVHD) [2, 32–34]. T lymphocytes have several potential roles in fibrosis. First, they can stimulate fibroblasts to produce excess collagen [35]. Second, they can induce local macrophages to produce profibrotic cytokines [21]. Finally, they can promote vascular dysfunction by inducing apoptosis of vascular endothelial cells, as observed in SSc [36].

Studies in animal models have not demonstrated a consistent role for T cells in skin fibrosis. CD4-deficient tight-skin mice (Tsk/+) have diminished skin fibrosis suggesting that CD4+ T lymphocytes are important for the development of skin fibrosis in this model [37]. Similarly, donor T cells appear to contribute to fibrosis in the murine model of sclerodermoid GVHD [38]. Conversely, subcutaneous injection of bleomycin in severe combined immunodeficiency mice, which lack functional T cells and B cells, does not appear to affect the fibrotic response [39]. These results indicate that the role for T cells in fibrogenesis may vary between animal models and human diseases. The balance between distinct regulatory and other CD4-lineage T cells is likely important and deserves further investigation [40].

B Lymphocytes

B cell activation is of mechanistic and therapeutic interest in SSc and morphea. B lymphocytes are a component of the inflammatory infiltrate in lesional SSc skin. They are detectable upon immunohistochemical staining using CD20 surface marker, and SSc skin has elevated expression of signature genes that are consistent with the presence of B cells [41–43]. Peripheral blood B cells from SSc patients have an activated phenotype, with elevated expression of surface marker CD19 and B cell activating factor receptor (BAFFR) [44, 45]. This observation suggests that B cells in SSc may be activated by B cell activating factor (BAFF). Similar to SSc, patients with morphea also have elevated serum levels of BAFF that correlate with disease severity [45–47].

The profibrotic effects of B cell activation are likely mediated by their production of specific autoantibodies and cytokines. In SSc, B cells produce multiple autoantibodies including anti-DNA topoisomerase I, anti-centromere, anti-fibrillin-1, anti-PDGFR, anti-fibroblast, anti-endothelial cell, anti-nuclear antibodies, and others [43]. Some of these autoantibodies may have direct pathogenic roles by inducing an inflammatory response against their antigenic targets [48] (Section Scleroderma/Systemic Sclerosis). In addition, B lymphocytes produce IL-6, a cytokine that stimulates fibroblast growth and collagen production [49, 50].

Two mouse models of skin fibrosis that possess B cell abnormalities have illuminated the precise pathogenic roles of B cells in autoimmune fibrosis. Both the tight-skin mouse (Tsk/+), a genetic model of skin fibrosis, and mice subcutaneously injected with bleomycin, an injury-induced model of skin fibrosis, have activated B cell phenotypes and autoantibody production [51, 52]. Depletion of CD19+ B cells in these mouse models, as well as inhibition of BAFF in tight-skin mice, inhibit the development of skin fibrosis [52–54]. These studies suggest that inhibition of B cell activation may have therapeutic benefit for fibrotic skin diseases.

Ongoing studies in SSc patients are investigating the therapeutic benefit of B cell depletion using rituximab, a chimeric anti-CD20 antibody. Recent studies have shown a significant reduction in clinical indicators of SSc severity, including the modified Rodnan skin score, with rituximab treatment [55–57]. In addition to being potential therapeutic targets, B cell-related factors such as BAFF may also serve as biomarkers of disease progression in SSc [58].

Macrophages

Macrophages are involved in wound healing and in skin fibrosis. They are present during the inflammatory phase of wound repair [2] and in skin lesions of SSc [59, 60], acute GVHD [61], and keloidal scars [32]. Although resident macrophages are present in normal dermis, recruited monocyte-derived macrophages also contribute to wound healing [62] and SSc [63].

Macrophages are activated by profibrotic signaling factors including TGF-β, IL-13, and platelet-derived growth factor (PDGF). Functional studies in mouse models have suggested that macrophage activation is a response to factors secreted by Th2 cells, a subset of T helper cells [21]. In turn, macrophages contribute to fibrosis by secreting profibrotic cytokines including angiotensin II, CCL3, and TGF-β1 [21, 64, 65].

In mice, macrophages are present in the dermis of the bleomycin and cutaneous GVHD mouse models of fibrosis [38, 39] and are required for bleomycin-induced skin fibrosis [66] as well as for normal wound healing [62, 67]. Specifically, CCL3 produced by macrophages is critical for fibrosis in the bleomycin-induced pulmonary fibrosis mouse model [64], suggesting that this cytokine may be a key mediator of fibrogenesis in these conditions.

Signaling

Fibrosis involves altered signaling activity between all of the cellular players. In particular, inflammatory cells and fibroblasts actively secrete signaling molecules that promote the development and maintenance of pathologic fibrosis, while many of these molecules are also important in physiologic wound healing.

Signaling molecules discussed here include interleukins, chemokines, and growth factors. Recipient cells detect these secreted molecules via specific membrane-bound receptors. Generally, these signals serve to alter the target cell's behavior (inducing migration, cell division, or another activity), identity (for example, differentiation of a mesenchymal stem cell to a fibroblast), or secretory profile (of additional signaling factors, extracellular matrix proteins, etc.). Often these changes are executed by downstream regulation of nuclear gene expression by the recipient cell. Dissecting the specific signaling pathways that result in fibrosis will provide important insight into potential targets for therapeutic intervention. As effective therapies for fibrotic diseases are sorely limited, identifying novel fibrotic signaling mediators and testing their importance in animal models is an active area of research [68].

The goal of this section is to focus on some of the prominent profibrotic signaling molecules that have been directly tested in murine models of fibrosis and wound healing. Their relevance to specific fibrosing disorders will be discussed in Section Cutaneous Fibrosing Disorders. The influence of mechanical stresses and the extracellular matrix on the signaling environment will also be discussed.

Inflammatory and Immunomodulatory Cytokines

IL-4/IL-13

IL-4 and IL-13 are cytokines produced by Th2 cells (a subset of T lymphocytes). They bind to a common receptor, IL-13Rα1 [69, 70] and both have profibrotic activity in skin.

The profibrotic effects of IL-4 include stimulating collagen production by fibroblasts, inducing expression of TGF-β, and enhancing mononuclear cell infiltration [43]. Similarly, IL-13 stimulates activation of TGF-β by cleavage from its latent binding complex, induces expression of TGF-β by macrophages, and induces expression of collagen and fibronectin by human dermal fibroblasts [21, 43, 71]. IL-13 can also induce expression of profibrotic CC-chemokines including CCL3 and CCL2 [21, 72].

Both IL-4 and IL-13 show elevated expression in lesional skin of SSc patients [71, 73], and IL-4 is expressed during normal wound healing [74]. In addition, a genetic signature consistent with IL-13 activation has been identified in the murine sclerodermatous GVHD model and in a subset of SSc patients with inflammatory disease. In these patients, IL-13 activation correlates with the severity of skin fibrosis [72]. Inhibition of IL-4 prevents dermal fibrosis in the

tight-skin mouse model of SSc, and results in delayed wound healing in mice [35, 74]. Similarly, deficiency of IL-13 or its receptor IL-4Rα1 is protective against fibrosis in the sclerodermatous GVHD murine model [72].

IL-17

IL-17 is an inflammatory cytokine characteristically produced by Th17 cells, a subset of T lymphocytes. The profibrotic effects of IL-17 in skin are largely indirect. IL-17 stimulates expression of inflammatory cytokines and adhesion factors by other cell types [70]. Specifically relevant to fibrosis, IL-17 stimulates fibroblast proliferation and endothelial cell production of IL-1 and adhesion molecules. Expression of IL-17 is increased in T cells in SSc peripheral blood and skin lesions [75]. Conversely, mice lacking IL-17A have a delayed wound closure phenotype [76]. In mouse models of bleomycin-induced skin and lung fibrosis, IL-17 and other Th17 cytokines showed elevated expression, suggesting a role for Th17 mediation of the early fibrotic response [77].

IL-1

IL-1 comprises a family of inflammatory cytokines with an established profibrotic role in fibrosis of the kidney and other organs. In renal fibrosis, IL-1β, via TGF-β1, regulates epithelial-mesenchymal transition and myofibroblast conversion from fibroblasts [78]. Its role in skin fibrosis and wound healing has not been as extensively studied as in fibrosis of other organs. Both IL-1α and IL-1β are upregulated during the inflammatory phase of wound healing [79], predominantly by polymorphonuclear leukocytes and macrophages [80]. IL-1β, possibly secreted by fibroblasts, is increased in SSc. It is thought to mediate inflammation in SSc and may drive myofibroblast conversion and collagen production [81]. There is also a potential role for IL-1α from keratinocytes in stimulating fibroblast activation and contractility in fibrosis and wound healing [82]. Functional studies in animal models are needed in order to more precisely determine the sources and roles of IL-1α and IL-1β in fibrosis *in vivo*.

Chemokines

Chemokines (chemotactic cytokines) include CXC- and CC-molecules. These are secreted factors that bind to specific cell surface G-protein coupled receptors (GPCRs). Their potential roles in fibrosis and wound healing include inflammatory cell recruitment to the wound site, re-epithelialization, tissue remodeling, and angiogenesis [83]. Here, we will focus on two CC-type chemokines, CCL2 and CCL3. Both CCL2 and CCL3 have established profibrotic effects in murine studies of pulmonary fibrosis, possibly mediated by induction of IL-13 [21].

CCL2

CCL2 (formerly known as MCP1) acts upon monocytes/macrophages, T cells, and mast cells [83]. It is a monocyte chemoattractant and may mediate profibrotic behaviors of T cells. During wound healing, CCL2 is expressed in monocytes, macrophages, and keratinocytes [83–85]. It is also elevated in the serum in early-stage SSc, perhaps corresponding with the inflammatory phase of the disease, and is elevated in an inflammatory subset of SSc patients [72, 86]. CCL2 stimulates fibroblast expression of genes encoding TGF-β1 and type I collagen, which may be an indirect effect mediated by IL-4 produced by T cells [87, 88].

CCL2 knockout mice have delayed wound re-epithelialization and reduced angiogenesis and collagen production, without altered macrophage recruitment to the wound bed [89]. Therefore, the role of CCL2 during wound healing may be predominated by its direct or indirect effects on fibroblasts, endothelial cells, and keratinocytes, rather than by monocyte chemoattraction. CCL2 knockout mice are also resistant to bleomycin-induced skin fibrosis [66]. Furthermore, treatment with an anti-CCL2 antibody prevents the development of fibrosis in the sclerodermatous GVHD mouse [72].

CCL3

CCL3 (formerly known as MIP1α) is expressed early during wound healing in mice, corresponding with macrophage infiltration [83]. CCL3 is present at elevated levels in SSc patient serum; however, unlike CCL2, the amount of CCL3 does not correspond to the degree of skin fibrosis [90]. CCL3 knockout mice have normal wound healing [89], and CCL3 mRNA is not detected in acute adult human wounds [85]. Although this chemokine may not have a compelling role in wound healing in mice or humans, its elevated expression in SSc tissues and the possible profibrotic role of its receptor CCR5 [91] warrants its further investigation as a profibrotic mediator in human disease.

Growth Factors/Morphogens

TGF-β (Transforming Growth Factor-β)

TGF-β is the prototypic profibrotic signaling factor, and has been extensively studied in human disease conditions and animal models (Fig. 32.2). The TGF-β ligand family comprises three isoforms; TGF-β1 is the most abundant isoform in tissues. The ligand is secreted in a complex with a latent binding protein, which must be proteolytically cleaved to yield active extracellular ligand [92]. The active ligand binds to cell surface receptors, which are heterotrimers of TGF-β receptor I and TGF-β receptor II (TGFBRI and TGFBRII), stimulating their serine-threonine kinase activity [83]. Downstream intracellular transducers of TGF-β signaling

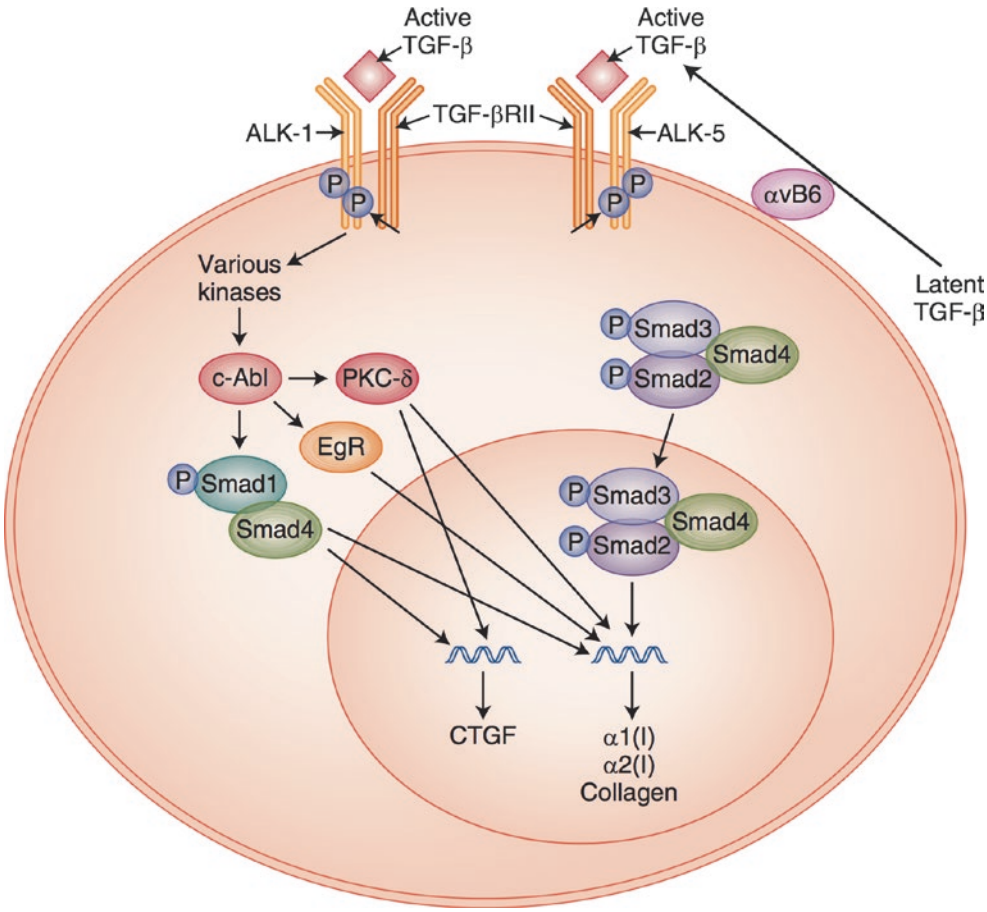

Fig. 32.2 TGF-β signaling in fibroblasts. Extracellular latent TGF-β is activated by αvβ6 integrin to its active form. Active TGF-β can signal through the classical pathway utilizing ALK-5 to phosphorylate Smad2 and -3, which then complex with Smad4. The complex is transported to the nucleus where, through additional factor interactions, critical genes can be transcribed. Non-classical signaling through ALK-1 can effect similar results through alternate pathways

activity include the canonical Smad2/Smad3-mediated response as well as non-canonical pathways [93].

The TGF-β ligand is expressed and secreted by platelets [83], activated T lymphocytes [94], monocytes and macrophages, fibroblasts, neutrophils, and epithelial cells [92]. Cells that respond to TGF-β ligand include neutrophils, macrophages, and fibroblasts [83]. The functions of TGF-β are pleiotropic and sometimes even contradictory. Depending on the cellular context, its effects may be both pro- and anti-fibrotic [21] and pro- and anti-inflammatory [92]. In the settings of fibrosis and wound healing, the prominent functions of TGF-β include promotion of monocyte activation, chemotaxis, cytokine production [92], fibroblast proliferation, expression of ECM proteins and integrins, and myofibroblast conversion [83, 95].

Elevated expression of TGF-β ligand and/or its receptors is broadly evident in fibrotic tissues including SSc lesional skin, hypertrophic scars, and keloidal scar fibroblasts [96–98]. In SSc primary fibroblasts, a TGF-β-responsive gene signature is correlated with more severe disease, providing a rationale for this signaling pathway as a therapeutic target [99]. In a transgenic mouse model, expression of constitutively active TGF-β type I receptor in fibroblasts is sufficient to cause dermal fibrosis [100]. Conversely, inhibition of TGF-β signaling results in reduced matrix deposition and scar formation in a rat model of wound healing [101] and prevents skin and lung fibrosis in the mouse model of sclerodermatous GVHD [102]. Deletion of *TGFBR2* expression in fibroblasts of transgenic mice results in altered wound healing, including reduced collagen deposition with increased macrophage infiltration, and accelerated re-epithelialization and wound closure [103]. This complex phenotype highlights the importance of TGF-β signaling in regulating a variety of cellular behaviors *in vivo*.

Due to its many profibrotic effects on both fibroblasts and macrophages, TGF-β signaling has been under intense investigation for the treatment of fibrosis in skin and other organs. Nevertheless, neutralizing antibodies against TGF-β have not been successful in clinical trials [93]. Alternative strategies for inhibiting the profibrotic effects of TGF-β include precisely manipulating other mediators of this pathway in order to avoid off-target effects of ligand inhibition [104] and combination therapies involving inhibition of both TGF-β and other profibrotic signaling pathways [105]. A currently promising strategy involves blockade of αV integrin-mediated activation of TGF-β. This membrane-associated integrin liberates the TGF-β ligand from its inactive complex with latent binding protein (Fig. 32.2). The

newly activated TGF-β then mediates myofibroblast conversion and *COL1A2* expression in SSc fibroblasts [106]. Integrin blockade is anti-fibrotic in pulmonary fibrosis [107], and genetic deletion of the αV subunit in mice is protective against lung, liver, and renal fibrosis [108]. Therefore, integrin blockade and other novel manipulations of TGF-β ligand activity are of continued interest for the treatment of skin fibrosis.

Embryonic Developmental Pathways: Wnt, Notch, and Hedgehog Signaling

Classic embryonic developmental pathways are often less utilized in healthy adult tissues, but are re-activated in the contexts of tissue regeneration, wound healing, and fibrosis [19, 109]. Notch, Hedgehog, and canonical Wnt signaling are three pathways that have important gene-regulatory roles in skin development, wound healing, and fibrosis [105, 110].

The canonical Wnt/β-catenin signaling pathway is active in the presence of extracellular Wnt ligands. Activation of cell surface receptors by ligand binding results in signal transduction by intracellular β-catenin and regulates target gene expression by the Tcf/Lef family transcription factors. Wnt signaling is important for dermal reconstitution during wound healing and contributing to fibroblast proliferation, migration, motility, and matrix production [111]. Wnt signaling is activated in hypertrophic scar and keloidal scar fibroblasts and the lesional dermis of SSc and morphea patients [112–114], perhaps due to elevated expression of Wnt ligands in the skin [115, 116]. Importantly, inhibition of Wnt signaling is therapeutic in mouse models of skin fibrosis [117].

Notch signaling depends upon the interaction between transmembrane Delta-like/Jagged ligand on one cell and transmembrane Notch receptor on an adjacent cell. Mediation of this interaction by the intracellular domain of the Notch receptor results in regulation of target gene expression by the recipient cell [110]. The Notch-1 receptor is required for normal wound healing in mice, and appears to promote macrophage recruitment as well as migration of fibroblasts and vascular endothelial cells [118, 119]. This signaling pathway has elevated activity in SSc skin, and inhibition of Notch signaling is therapeutic in mouse models of skin fibrosis [120].

Hedgehog signaling involves binding of an extracellular ligand such as Sonic hedgehog (Shh) to its transmembrane receptor Patched (PTCH). This signal is transduced intracellularly to regulate target gene expression [110]. In wound healing, Shh signaling is required for normal wound closure, granulation tissue formation, and vasculogenesis [121]. This signaling pathway has elevated activity in SSc skin, and inhibition of its transducer Smoothened (Smo) is therapeutic in mouse models of skin fibrosis [122].

CTGF

Connective tissue growth factor (CTGF/CCN2) is a matricellular protein that is typically secreted by mesenchymal cells, including fibroblasts and endothelial cells [123]. Its expression is induced by TGF-β signaling (Fig. 32.2) as well as other profibrotic signaling pathways [123]. In the extracellular space, CTGF can bind to integrins as well as other secreted proteins, including TGF-β1 [124]. Based upon these properties, it follows that CTGF can mediate fibroblast and endothelial cell adhesion and potentially TGF-β1 ligand bioavailability [124, 125]. Consistent with this, CTGF is sufficient to cause increased collagen and fibronectin synthesis in human fibroblasts *in vitro* [126].

CTGF expression is elevated in lesional fibroblasts and plasma from SSc patients. CTGF levels correlate with the severity of fibrosis, suggesting its possible utility as a biomarker of fibrotic disease [123, 124, 126]. The role of CTGF in fibrosis and wound healing has been tested using multiple animal models. In murine models of skin fibrosis, *CTGF* over-expression in fibroblasts is sufficient to cause dermal, renal, and pulmonary fibrosis; and deletion of *CTGF* in fibroblasts protects against bleomycin-induced dermal fibrosis [127, 128]. CTGF expression is also elevated in healing wounds in rats during granulation and vasculogenesis [129]. Finally, inhibition of CTGF mRNA in a rabbit model of scar formation resulted in reduced hypertrophic scarring with lower numbers of myofibroblasts, but with maintenance of normal wound healing with respect to inflammation and angiogenesis [130].

PDGF

Platelet-derived growth factors (PDGFs) are secreted growth factors that bind to cell surface receptors that are homo- or heterodimers of PDGFRα and PDGFRβ. The PDGFRs are receptor tyrosine kinases that, when activated, trigger downstream signaling cascades including the Ras/MAP kinase (ERK) pathway. PDGF ligands are produced by fibroblasts, endothelial cells, macrophages, and platelets [131]. Fibroblasts express the PDGF receptor and respond to this signal with increased proliferation, migration, expression of extracellular matrix genes (including collagen-encoding genes), and conversion to a myofibroblast phenotype [132, 133]. Murine dermal fibrosis is associated with activation of PDGF receptors, presumably due to increased production or availability of PDGF ligands [134]. In SSc, activation of PDGF receptors can occur in response to stimulatory autoantibodies against the receptor. These autoantibodies are able to stimulate tyrosine kinase activity, type I collagen gene expression, and myofibroblast conversion in human fibroblasts in vitro [135] and therefore may be an important factor in the pathogenesis of SSc (see Section Scleroderma/Systemic Sclerosis).

A study in mice found that transgenic expression of activated PDGFRA is sufficient to cause fibrosis in skin

and other organs [136]. Many more studies have evaluated readily available tyrosine kinase inhibitors (TKIs), which block PDGF signaling and other related pathways, to test for a possible therapeutic benefit of PDGF inhibition [137]. Imatinib mesylate, a TKI, inhibits PDGF signaling and reduces fibroblast proliferation, migration, collagen gene expression, and myofibroblast conversion in mouse wound healing and fibrosis models [132, 138]. One caveat is that some of the *in vivo* effects of imatinib and other TKIs may be due to inhibition of c-Abl (Fig. 32.2) or other protein tyrosine kinases [139, 140]. The therapeutic effects of imatinib against pre-existing dermal fibrosis in mouse models [141] provided a strong rationale for studies of its efficacy in SSc skin fibrosis. However, a phase II clinical trial did not demonstrate clinical efficacy over 6 months of treatment [142]. Additional studies addressing the profibrotic functions of specific tyrosine kinase receptors and the specificities of particular TKIs against these receptors will yield additional therapeutic options in the future.

Extracellular Matrix, Adhesion, and Mechanical Stresses

Recently, there has been a growing appreciation of the importance of tissue stiffness on cell behavior and gene expression, especially in the context of fibrosis and wound healing [143]. The fibrotic extracellular matrix has different mechanical properties from normal tissue, and this results in altered forces on fibroblasts and other cells. Elevated matrix stiffness *in vitro* results in increased conversion of dermal fibroblasts to a myofibroblast phenotype, and elevated expression of fibrosis-related genes such as *COL1A1* and *CTGF* [144]. The mechanoresponsiveness of fibroblasts may be via signaling pathways that have already been established to be profibrotic, such as TGF-β/Smad2/3 (Fig. 32.2) and Wnt/β-catenin pathways [145].

Adhesion molecules, namely integrins, also mediate effects of the extracellular environment on fibroblast biology. Focal adhesion kinase (FAK), the downstream signaling transducer of integrins, is required in dermal fibroblasts for mechanosensation during scar formation; mice lacking FAK in dermal fibroblasts have reduced CCL2-mediated recruitment of inflammatory cells after wounding. This results in reduced fibrosis in a hypertrophic scar model [146]. In addition, FAK is required for dermal fibroblast expression of fibrosis-related genes including *ACTA2*, *CTGF*, and *COL1A1* [147]. These findings suggest that modulating the extracellular matrix and mechanical environment during scar formation may be of therapeutic benefit. They also illustrate how physical factors can be integrated with molecular and cellular events during wound healing.

Genetic Mutations and Epigenetic Factors

Many of the classic profibrotic signaling factors exert their effects by altering expression of particular target genes. Consequently, cells and tissues in fibrosing diseases and related animal models have characteristic gene signatures that have been defined by microarray-based studies. These gene signatures are useful for identifying up- or downregulated genes that encode novel mediators of fibrosis, both in human disease [99, 148] and animal models of fibrosis [149]. In SSc, these genetic profiles can be used to divide patients into stable subtypes that predict the clinical response to treatment [150–152]. Gene expression studies can also yield insight into the pathogenesis of fibrotic disease, for example by the discovery of a B lymphocyte expression signature in SSc patient skin [42]. Next-generation sequencing technology has recently enabled the discovery of elevated fungal (*Rhodotorula*) gene transcripts in SSc patient skin, suggesting that this pathogen may play a provocative role in susceptibility to or in the pathogenesis of SSc [153].

In addition to altered regulation of protein-coding genes, fibrotic conditions can be associated with genetic mutations. Namely, a mutation in the protein-coding region of *FBN1*, which encodes fibrillin-1, causes stiff-skin syndrome [154]. This mutation is an in-frame duplication, in contrast to the single point mutation in *FBN1* that causes Marfan syndrome. In addition, several single-nucleotide polymorphisms (SNPs) were found to be associated with fibrotic disease, including a SNP in the promoter region of *IL1A* in SSc patients [155, 156].

The presence of broad changes in gene expression, as well as the stability of the fibrosis phenotype in lesional fibroblasts cultured *in vitro*, has provided strong evidence for the role of epigenetic changes in fibrosis [157]. Epigenetic regulation of gene expression is often repressive in nature and can be mediated by micro-RNAs (miRNAs), methylation of DNA, and chemical modifications of DNA-associated histone complexes [158]. Down-regulation of micro-RNA (miR)-29 has been found in the skin of SSc patients and the bleomycin-induced mouse model of skin fibrosis, and miR-196a is downregulated in keloidal fibroblasts. Both of these miRs appear to inhibit expression of type I and type III collagen genes in dermal fibroblasts; therefore, decreased expression of each miR could enable elevated expression of collagen in the dermis [159, 160].

A role for DNA methylation in fibrosis has been found in dermal fibroblasts from SSc patients, where the promoter region of *FLI1*, which encodes a repressor of *COL1A1*, is heavily methylated. This methylation results in repressed expression of *FLI1*, which enables increased expression of type I collagen [161]. A role for decreased histone modifications in fibrosis has been identified in mice, where inhibition of methylation of lysine 27 on histone H3 (H3K27me3) is sufficient to cause dermal fibrosis, possibly by enabling expression of the profibrotic transcription factor Fra2 [162].

The increasing feasibility of genomic studies in human patients and mouse models will certainly yield additional novel pro-fibrotic mediators that may serve as therapeutic targets or biomarkers of disease progression, in addition to providing insight into how epigenetic factors might contribute to the pathogenesis of fibrosis.

Cutaneous Wound Healing

Wound healing is a physiologic process that involves many of the same cellular players and molecular pathways that promote pathologic fibrosis. Cutaneous wound healing serves to prevent infection and to repair the wound, thus preventing dehydration and restoring the protective characteristics of intact skin. In adult human skin, this process is not completely restorative, since the resulting scar tissue is mechanically weaker than native dermis and lacks functional structures, such as hair follicles and sweat glands [163]. Consequently, several studies of wound healing in humans and animal models have focused on elucidating the factors that drive fibrotic repair as opposed to faithful regeneration of skin to its original form and function.

Principles of Wound Healing

In adult mammalian tissue, partial- and full-thickness cutaneous wounds are resolved in a series of phases. Each phase involves particular cellular constituents and signaling pathways. The initial injury results in vascular disruption at the wound site, with activation of the clotting cascade producing a fibrin clot (Fig. 32.3). In the inflammatory phase of wound healing, which begins within hours of the injury, platelets in

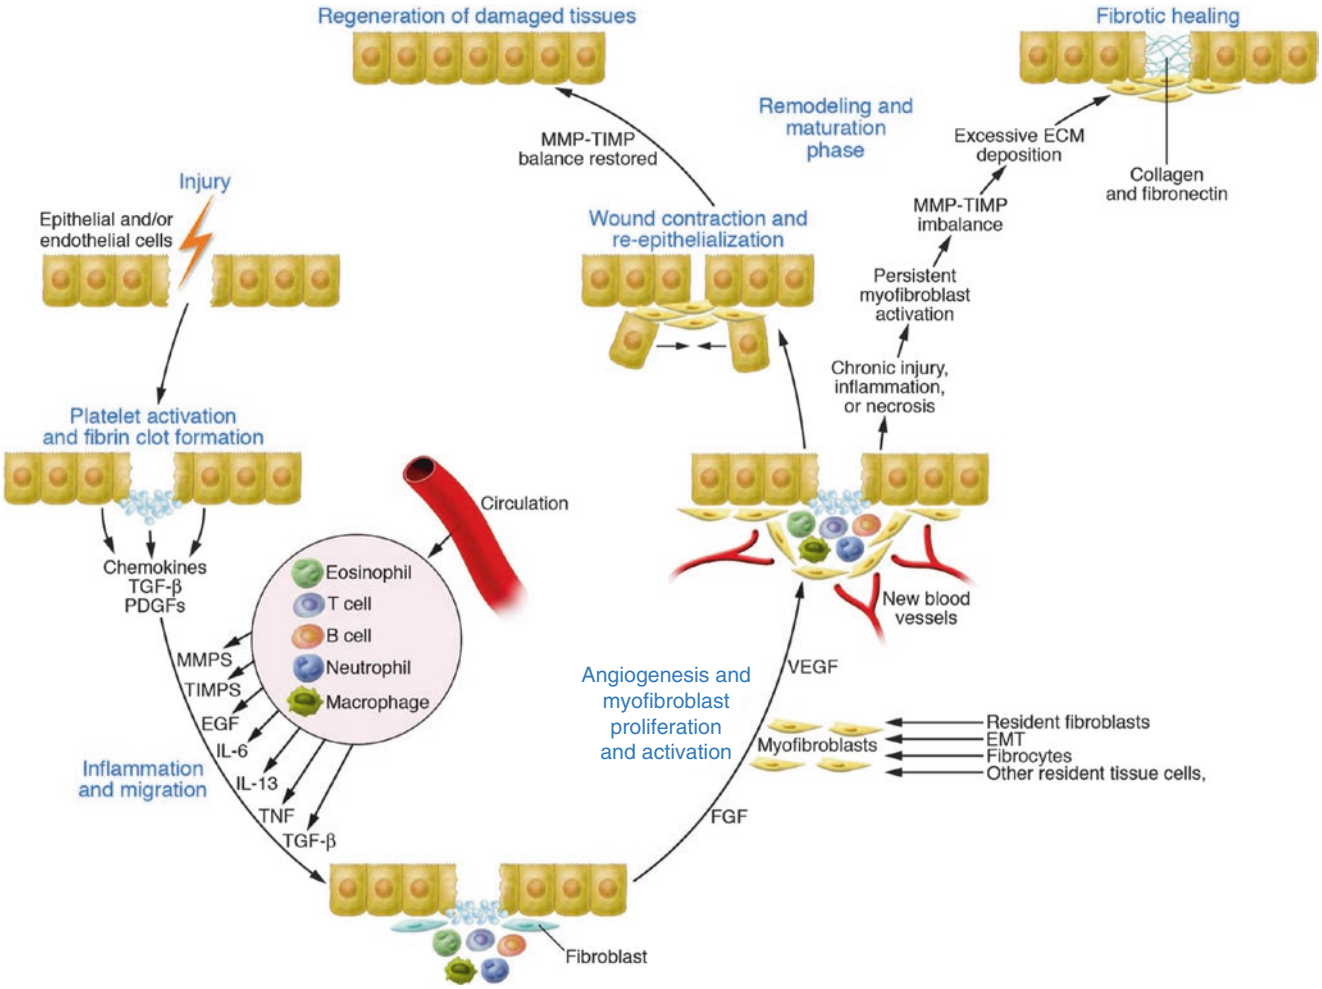

Fig. 32.3 Wound healing: regeneration and fibrosis. Following injury, signaling molecules influence the migration of fibroblasts, macrophages, and other inflammatory cells to the wound. Myofibroblasts, derived from a variety of potential sources, initiate the deposition of extracellular matrix elements and contract the wound. Provided re-injury and/or chronic inflammation do not ensue, tissue regeneration should occur. Persistent inflammation and injury signals may result in excessive matrix deposition, leading to a fibrotic scar. Many fibrosing conditions, in lieu of an actual wounding event, can elaborate similar inflammatory signals that also result in fibrosis and potential organ dysfunction (Figure utilized with permission from Wynn [68])

the clot release chemotactic factors that recruit neutrophils and monocytes to the site [2]. Neutrophils predominate during the early inflammatory phase to protect against infection [164]. Monocyte-derived tissue macrophages predominate later in the inflammatory phase (within days following the wound) and release growth factors that are important for new tissue formation [62].

The new tissue that forms at the wound site during the days and weeks following the initial injury is called granulation tissue. Cells in the local inflammatory infiltrate produce growth factors that promote fibroproliferation and migration of fibroblasts, including myofibroblasts, into the wound bed [5, 6]. Angiogenesis and vasculogenesis, which involve proliferation and migration of endothelial cells, also occur during this phase. Wound repair also requires re-epithelialization over the granulation tissue and is dependent upon growth and chemotactic factors released by activated keratinocytes and underlying fibroblasts [2]. Particular populations of epidermal stem cells, which have been carefully defined in murine studies (see Section Principles of Wound Healing), contribute to the newly forming epidermis.

In the weeks to months following injury, the granulation tissue is replaced by mature scar tissue. Inflammation resolves and myofibroblasts undergo apoptosis [6]. Mature scar tissue is more collagenous than granulation tissue, better approximating the dermal extracellular matrix [2]. However, mechanical and functional properties of the skin are not wholly restored to their original state [165].

Repair and Regeneration in Animal Models of Wound Healing

Studies of wound healing in transgenic mice have defined specific populations of cells that contribute to tissue repair and regeneration. Extensive lineage-tracing experiments have labeled epidermal stem cell and progenitor populations and followed their contribution to re-epithelialization following wounding [166]. This work has shown that the healed epithelium is derived from epidermal stem/progenitor populations peripheral to the wound [167, 168].

Similar lineage-tracing studies have recently defined the mesenchymal populations that contribute to the dermal component of wound healing. PDGFRα-expressing fibroblasts residing in the upper (papillary) and lower (reticular) dermis adjacent to the wound bed contribute substantially to the healing dermis, with earlier and more robust invasion by the deeper dermal fibroblasts [169]. These fibroblasts may be recruited or supported by intradermal (subcutaneous) adipocytes, which are required for normal wound healing [170].

Mammalian fetal skin and lower vertebrates, such as zebrafish and amphibians, are champions of scarless wound healing and perfect tissue regeneration in the absence of fibrotic repair [110, 163]. One of the key differences between scarring and scar-free wound healing in these studies is that animals that can heal wounds without scars are relatively immunodeficient, suggesting that inflammation is directly related to fibrotic wound healing. Determining the specific cell types and molecular pathways engaged in tissue regeneration may point toward therapeutic strategies to help regenerate functional skin (or other organs) after injury without scarring and loss of organ function. Other than fetal wound healing, there are few examples of true regeneration in mammalian tissues. However, one such example is adult murine wound-induced hair neogenesis, in which a subpopulation of γδ T cells has been shown to be important for the formation of neogenic hair follicles in healing full-thickness wounds by regulating dermal fibroblasts to acquire more inductive characteristics [171, 172]. Continued studies of this and similar regenerative phenomena may provide provocative keys to promoting regeneration instead of scar formation during cutaneous wound healing and fibrosing skin disorders.

Cutaneous Fibrosing Disorders

Cutaneous fibrosis is a final common pathway for many disorders characterized by chronic inflammation and/or tissue injury. As noted in the preceding sections, a complex interplay of cells, growth factors, chemokines, cytokines and signaling pathways are involved in the processes of wound healing, injury recovery, and matrix homeostasis. Imbalance of any of these factors has the potential to create self-sustaining feedback loops of signaling that eventuate in fibroblast/myofibroblast activation and excess tissue matrix deposition. While a detailed mechanistic discussion of all such conditions (Table 32.1) is beyond the scope of this chapter, an in depth discussion of several common and/or well-characterized conditions is provided in the following sections to illustrate how pathological fibrosis can be triggered and sustained.

Scleroderma/Systemic Sclerosis

Clinical

Scleroderma (also known as systemic sclerosis, SSc) is a chronic progressive systemic disease of unknown etiology, characterized by autoimmunity, inflammation and multi-organ tissue fibrosis [173, 174]. Various lines of evidence suggest SSc is caused by interactions between the host genetic background and certain environmental factors [175]. The pathophysiology of SSc is characterized by (1) immune system activation/autoimmunity, (2) proliferative and obliterative

Table 32.1 Disorders commonly associated with cutaneous fibrosis

Dermatofibroma
Diabetic digital sclerosis
Eosinophilic fasciitis (Shulman syndrome)
Hypertrophic scar
Keloidal scar
Lichen sclerosus
Lipodermatosclerosis
Morphea
Nephrogenic systemic fibrosis
Porphyria cutanea tarda (sclerodermoid)
Radiation induced fibrosis
Scleredema diabeticorum
Sclerodermoid GVHD
Scleromyxedema
Stiff skin syndrome/congenital fascial dystrophy
Systemic sclerosis (scleroderma)
Toxin-associated (Spanish toxic oil syndrome, vinyl chloride)

vasculopathy, and (3) tissue fibrosis [176]. The clinical presentation of SSc is heterogeneous and can be subdivided into two entities based upon the level of skin involvement: limited (with fibrosis distal to the elbow and knee including the face), and diffuse (including proximal fibrosis) [177]. A subset of patients with limited cutaneous SSc present with "CREST" syndrome (calcinosis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia). While both limited and diffuse SSc can exhibit internal organ involvement, life-threatening damage to the lungs, heart, gut, and kidneys is more common in diffuse SSc. Localized scleroderma (morphea, linear scleroderma) does not have internal organ involvement [176].

Histopathology

Skin biopsies from patients with SSc are essentially indistinguishable from those with localized scleroderma (morphea). In both entities there is thickening of collagen with loss of the clefts between the bundles. Over time, a relatively acellular hyalinized matrix replaces the fibrillar collagen. There is a variably dense superficial and mostly deep perivascular and interstitial lymphoplasmacytic infiltrate with occasional eosinophils that typically extends into the underlying subcutis by widening of the fatty septa. Loss of peri-eccrine fat is typical [178].

Autoimmunity

Oligoclonal expansion of T cells, induced by presumed environmental antigens, have been observed in SSc [179]. A variety of autoantibodies may be found in SSc [180, 181], although there is disagreement regarding their roles. Some investigators believe the autoantibodies are directly pathogenic while others suggest they may be epiphenomena, arising only after tissue damage has already occurred [182]. It is surmised that some, including antinuclear antibodies (ANA) and anti-endothelial cell antibodies, lead to the microvascular endothelial apoptosis that has been identified as the initiating pathogenic event in SSc [26, 183]. Damage to the microvascular endothelium leads to the release of proinflammatory mediators, growth factors, and chemokines.

Vasculopathy

Raynaud's phenomenon, usually the earliest clinical sign of the disease [184], signals the presence of vasomotor dysregulation and vasculopathy. Endothelial damage triggers the activation of the coagulation and fibrinolytic cascades and ultimately the vascular occlusion, capillary necrosis, and capillary dropout seen in SSc [175, 185]. Loss of capillaries leads to tissue hypoxia, which, in turn, induces pro-angiogenic signals [186]. Other investigators have shown that exposure of endothelial cells to IFN-γ stimulates the profibrotic mediators ET-1, CTGF and TGF-β2, and that these induce the transition of endothelial cells to myofibroblasts [187].

Fibrosis and Matrix Alterations

The inappropriate leukocyte accumulation triggered by antibody-driven vascular damage leads to the elaboration of TNF (tumor necrosis factor), the release of degradative

matrix metalloproteinases (MMPs), and the production of reactive oxygen species (ROS), which perpetuate additional tissue injury. With tissue hypoxia as a driving force, multiple genes for chemokines, cytokines, growth factors and their receptors are upregulated [175]. Fibroblasts respond to hypoxia by producing proteins involved in the remodeling of the ECM, such as TGF-β, thrombospondin, and CTGF [188] (see Section Growth Factors/Morphogens). In SSc, serum levels of tissue inhibitors of metalloproteinases (TIMPs) are significantly elevated, leading to an imbalance in the turnover of the ECM that favors matrix deposition [182]. In skin biopsies from SSc patients, TIMP-1 is markedly elevated while MMP-1 is not detectable [189].

The net result of these processes is the production of "damage-associated membrane proteins" (DAMPs). DAMPs, which result from cell damage, oxidative stress, and ECM remodeling, and are recognized by Toll-like receptors (TL4) on the surface of fibroblasts. One particular DAMP, a variant of fibronectin (FnEDA), seems to fulfill the functions of both structural ECM scaffold and signaling molecule [173]. FnEDA is present in significantly elevated quantities in the serum and tissue of patients with SSc. Increased FnEDA increases collagen cross-linking, promotes myofibroblast differentiation, and increases collagen gene expression. FnEDA expression, normally absent in adult tissue except during tissue injury, can also be expressed by normal fibroblasts when stimulated by TGF-β. In turn, activated fibroblasts can produce additional FnEDA, which then perpetuates a self-sustaining feedback loop that promotes the ongoing profibrotic milieu and the differentiation of a steady supply of matrix producing myofibroblasts [173].

Myofibroblasts are the primary effector cells in SSc [174], although their precise origin is debated (see Section Activated Fibroblasts and Myofibroblasts). Myofibroblasts may potentially derive from several sources (Fig. 32.1) including circulating fibrocytes (CFs), resident fibroblasts, pericytes, and epithelial or endothelial cells (via epithelial- and/or endothelial- to mesenchymal transition) [182].

The expression of genes in SSc has offered a few clues. In one gene microarray study comparing cultured fibroblasts from patients with diffuse SSc to those from normal control patients, only down-regulation of the gene MMP9 was significant after quantitative PCR analysis [190]. Another study comparing lesional and non-lesional fibroblasts in patients with diffuse SSc by gene microarray analysis showed that 26 markers performed well as predictors of fibrosis [191]. The findings of several such studies suggest that SSc is characterized by a proinflammatory gene profile that includes TGF-β and Wnt expression [192]. Activation of the Wnt pathway also stimulated an increase in fibroblast migration and proliferation, activities known to be critical in SSc [113] (Section Growth Factors/Morphogens).

Patients with SSc have also been shown to have elevation of sonic hedgehog protein (Shh) in skin fibroblasts, endothelial cells, and keratinocytes. Shh can induce myofibroblast differentiation, and its inhibition has resulted in anti-fibrotic effects in a model of SSc [122] (Section Growth Factors/Morphogens).

In human SSc, cutaneous CFs (CD45+/Collagen+) are present at high levels in the dermis, and are attracted along a chemical gradient of CCR5 (which is overexpressed by SSc monocytes). CSD (Caveolin-1 scaffolding domain peptide) has been shown in a mouse model of SSc to inhibit the accumulation of CFs, CCR5, and the CCR5 ligands CCL3 and CCL4 in the dermis. These results parallel the findings in a similar study examining lung fibrosis triggered by bleomycin injury, suggesting blockade of this CCR5 axis may have general applicability in many fibrotic conditions [91].

Nephrogenic Systemic Fibrosis

Clinical

Nephrogenic systemic fibrosis (NSF), first described in 2000, is an acquired fibrotic dermatosis associated with the use of gadolinium-containing magnetic resonance contrast agents in the setting of renal insufficiency [193]. While there is lingering controversy over the precise triggering events, evidence supports the hypothesis that certain chemical formulations of these agents are capable of promoting fibrosis in patients with transient or chronic renal disease [194, 195].

The clinical lesions of NSF typically present on the extremities (legs more commonly than arms), and occasionally involve the trunk, buttocks, and in very rare instances, the face. They consist of papules, plaques and nodules that coalesce into erythematous to brawny skin thickening, often with a peau d'orange appearance. Encompassing dermal fibrosis near joints often leads to restriction of range of motion and contractures. Pruritus and burning pain are common clinical complaints, and sometimes there is palpable warmth. It is not uncommon to observe an evolution of lesions that appears first as dependent edema, gradually becoming more erythematous, and then evolving into woody induration [193, 194].

Microscopic

Biopsies of early NSF are remarkably bland, with splaying of dermal collagen by edema and increasing numbers of banal, spindle cells in the dermis, that frequently extend into the subcutaneous tissue along fibroconnective septa [193]. There is no inflammation, although small collections of

mononuclear cells may be noted adjacent to blood vessels. Fully involved biopsies show markedly thickened dermal collagen bundles associated with a complex network of CD34+ dermal spindle cells. Besides the membranous staining observed with CD34, the cytoplasm of these cells stains with procollagen I [16, 194]. Procollagen I can also be found in the dermis between these fibrocytes, along with increased amounts of dermal elastin and mucin. Collagen bundles are typically separated by clefts from one another, and a mix of thick and thin bundles is typical. These findings extend into the subcutaneous tissue along septa, and will frequently infiltrate the fascia and underlying skeletal muscle. CD68+ histiocytes are also present in variable numbers, sometimes forming multinucleated giant cells. In a small number of cases pale pink osteoid forms around protruding elastin fibers creating the so-called "lollipop" body, which is considered virtually pathognomonic for NSF. On occasion these bodies will mineralize [194]. Rarely, widespread mineralization of dermal collagen can occur. Initial tissue staining studies showed markedly increased TGF-β1 mRNA by in situ hybridization throughout the dermis of all patients examined [196].

Triggers

Epidemiological evidence has convincingly established that NSF is a disease of the renally impaired. Patients at risk for NSF have acute kidney injury (AKI) or an estimated glomerular filtration rate (eGFR) of less 30 ml/min/1.73 m^2. Investigators have concluded that NSF is triggered by the administration of gadolinium based contrast agents (GBCAs) to patients with the requisite degree of renal impairment. Gadolinium (Gd) is a paramagnetic element of the lanthanide series, making it an ideal contrast agent in magnetic resonance imaging (MRI) studies. As ionized Gd^{3+} is considered toxic because of its potent calcium channel blocking abilities, the ion is chelated with a proprietary organic ligand that may be linear or macrocyclic in structure. This reduces the toxicity of Gd while simultaneously facilitating the excretion of the chelated complex, which in a patient with normal renal function has a half-life of about 90 min. Over the years since the discovery of NSF, there have been several brands of GBCA available on the market in the United States and abroad. Epidemiological evidence has associated the vast majority of cases of NSF with three brands of GBCA, these being agents with a linear organic ligand. The use of these agents in the renally-impaired has been specifically contraindicated by regulatory agencies, leading to a very rapid decline in new cases of NSF since 2010 [195].

While these agents were still being used in the at-risk population, it became clear that only 2–6 % of those at risk actually contracted NSF upon exposure to one or more doses of the agent. The reasons for this variability in the at-risk population are unknown, although some have surmised there might be a genetic propensity or some other as yet unrecognized risk factor for NSF [197].

Cell Culture Studies

Epidemiological and clinical aspects of NSF have implicated excess extravasated GBCA as the initial triggering event in NSF. Electron microscopy with energy dispersive spectroscopy has identified Gd within the macrophages seen in abundance in early lesions of NSF [198]. The dominant cells in the histopathological specimens from NSF, macrophages and fibrocytes, have been extensively studied by cell culture techniques.

Fibroblasts/Fibrocytes

In 2003, a compelling case was made for the involvement of bone marrow-derived circulating fibrocytes in NSF [16]. Circulating fibrocytes, defined by their dual marker positivity for CD34 and procollagen I, participate in normal wound healing and have been shown to be active in several fibrotic processes. In their fully mature form they histologically resemble and likely supplement the activities of resident dermal fibroblasts.

When added to the serum of normal cultured fibroblasts, Omniscan™, the GBCA associated with the majority of NSF cases, increases the fibroblast proliferation by more than two-fold. It also increases MMP-1 (1.5-fold) and TIMP-1 (12-fold). While individual cell procollagen production was not directly stimulated, the cumulative effects of increased fibroblast proliferation and altered collagen turnover were judged to contribute to the fibrosis of NSF [199]. While both MMP-1 and TIMP-1 are increased, the vast excess production of TIMP-1 effectively outweighs the collagenolytic activity provided by MMP-1 [200]. The increased TIMP-1 and absent MMP-1 pattern has been directly visualized in immunohistochemical studies from NSF biopsy specimens, corroborating the culture observations [189].

Dermal fibroblasts obtained from patients with NSF display a marked increase in the production of type I (2 to 3-fold) and type III (3.5 to 6-fold) collagen, fibronectin (3 to 7-fold), and hyaluronic acid (4 to 5-fold). This effect was maintained after 11 culture passages, suggesting the effect might be a stable epigenetic change. Collagen I production was increased at both the translational and transcriptional levels. The increased transcriptional activity of the COL1A1 promoter was due to increased cREL, NF1, and CBF transcription factor binding [201]. In NSF, cREL and NF1 appeared to show the most binding

activity, in contrast to CBF and Sp1, which are the most active transcription factors in SSc [202]. The elevation of TGF-β combined with the markedly increased cREL component of the NF-kB family of transcription factors suggests that there may be an important interaction between these pathways in NSF [201].

A culture study conducted on normal human fibroblasts concluded that Gd^{3+} directly or indirectly modulates signaling through the PDGF receptor. The investigators postulated that Gd^{3+} attaches to an available protein or some other "carrier molecule" that allows it to remain soluble long enough to interact with the PDGF receptor. They also noted that fibrotic changes similar to those seen in NSF have been produced in rats exposed to other chelated lanthanides, suggesting that the observed effects are not Gd specific. This observation offers the intriguing possibility that metallic elements other than Gd, in the correct clinical setting, may be capable of interacting with the PDGF receptor to produce similar fibrotic outcomes [203].

Another study examining normal human fibroblasts concluded that the PDGF stimulatory effects of Omniscan™ could be abrogated by exogenously administered CCN3 (also known as nephroblastoma overexpressed gene). CCN3 is a matricellular protein that is able to suppress CTGF/CCN2, a molecule critical to the initiation and progression of renal fibrosis [204]. The authors noted that Omniscan™ suppressed the endogenous production of CTGF/CCN2, leading to a permissive environment for both PDGF and TGF-β driven fibrogenic processes [205].

Monocyte/Macrophages

In human peripheral blood monocyte studies, Gd compounds caused significant upregulation of multiple cytokines and growth factors, including VEGF (253-fold), IL-13 (68-fold), IL-4 (28-fold) and IL-6. TGF-β was increased two to three fold (depending on the agent used) and IFN-γ was elevated up to 50-fold. The timing and magnitude of the effects varied with the agents used and the subjects, although intrasubject response was stable [206]. Normal fibroblasts cultured with media conditioned by peripheral blood monocytes that had been exposed to Omniscan™ displayed a dose-dependent increase in production of type I procollagen [206].

In a gene microarray evaluation of normal human macrophages incubated with 50 mM Omniscan™, 551 differentially expressed genes were noted. There was potent stimulation of CCL8 (669 ± 108-fold), CXCL10 (401 ± 72-fold), CCL2 (245 ± 36-fold) and CXCL11 (551 ± 48-fold). Pathway analysis proved that exposure to Omniscan™ elicits chemokine gene expression in macrophages that is dependent on NFkB activation [207]. As it is widely accepted that circulating fibrocytes home to the skin following a specific chemokine gradient, the investigators concluded that macrophages stimulated by this mechanism produce the chemokines needed for fibrocyte chemotaxis to skin.

In addition, the effects of Omniscan™ and gadodiamide in macrophages are dependent on TLR4 and TLR7. It is hypothesized that these agents possess a unique, specific molecular shape or pattern that renders them capable of this interaction. Initial engagement of TLR4 by Omniscan™ at the macrophage surface could induce and increase the rates of phagocytosis, which could amplify its TLR signaling capacity through the engagement of TLR7 within the endosome [208]. As fibroblasts also express surface TLR4, it is possible that some of the direct effects of Gd compounds on fibroblasts could be due to engagement of these receptors (Fig. 32.4) [208].

These investigators conclude that all Gd compounds examined were capable of inducing expression of genes associated with TLR signaling and that the shape of individual GBCAs, in combination with direct effects of free Gd^{3+} likely both contribute to NSF pathogenesis [209].

Animal Modeling

Utilizing a rat model of NSF exposed to gadodiamide (the active ingredient in Omniscan™) investigators have induced high levels of serum cytokines, the most significantly elevated being CCL2 (6.5-fold) and CCL7 (6.8-fold), macrophage inflammatory proteins CCL4 (2.8-fold) and CXCL2 (2.5-fold), TIMP-1 (3.6-fold), TNF-α (3.4-fold), osteopontin (6.1-fold), and VEGF (1.6-fold) [210]. The role of osteopontin is particularly intriguing to these investigators as it is known as a mediator in lung disease, interacting with receptors (CXCR4, CCR7) of circulating fibrocytes [211].

These same investigators also noted a drop in serum albumin that correlated with marked vascular permeability within 6 h of gadodiamide exposure [212], a finding that parallels the early edema and erythema seen in NSF patients clinically. This tissue vascular leakage facilitates the extravasation of GBCA into the extravascular space, where it is subsequently phagocytosed by macrophages.

Fascinating work completed using mouse modeling has shown that Gd^{3+} and GBCA activate the NLRP3 inflammasome, primarily in undifferentiated and LPS-primed M2 macrophages [213]. The NLRP3 inflammasome is involved in the rapid recruitment of inflammatory monocytes and granulocytes to the site of Gd deposition in vivo, and can be stimulated by extracellular calcium and Gd^{3+} through a calcium-sensing receptor (CASR) [214]. GBCAs also induce the production of mature IL-1β by macrophages in vitro through NLRP3-dependent mechanisms. IL-1β can promote fibrosis by stimulating fibroblasts and by inducing TGF-β1 [213].

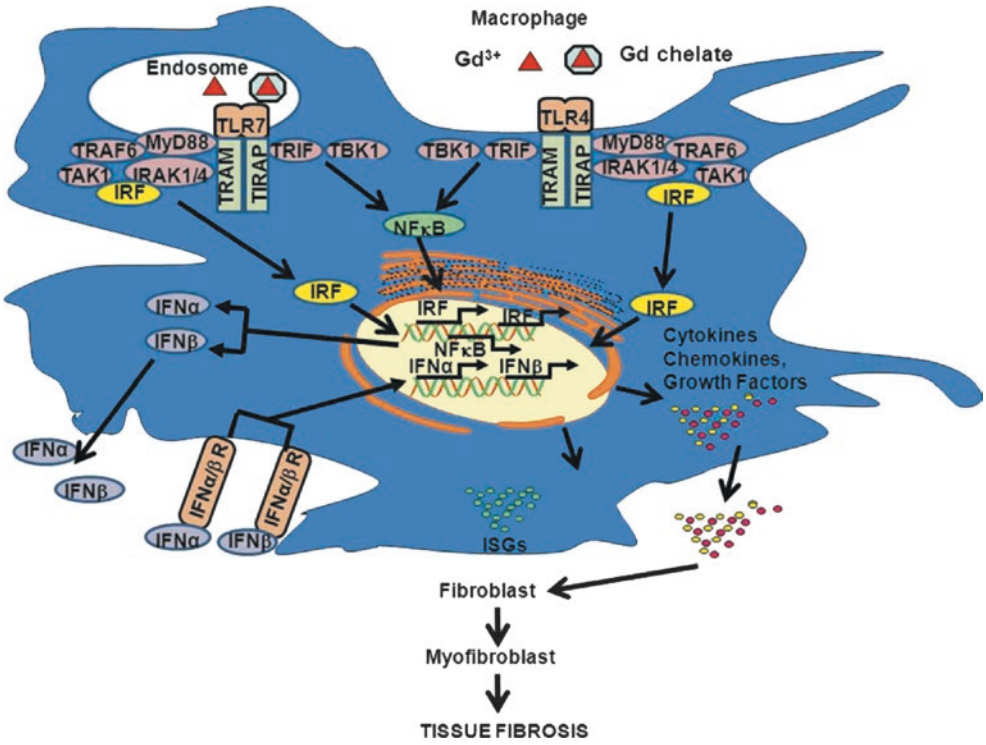

Fig. 32.4 Gadolinium based contrast agent (GBCA) induction of a proinflammatory/profibrotic phenotype in normal human macrophages. Gd^{3+} or GBCA is phagocytosed. Within the acidic environment of the endosome, dechelation is facilitated. Either Gd^{3+} or GBCA interact through TLR 4 and 7 to upregulate the NFkB protein complex, leading to the production of proinflammatory and profibrotic factors that are subsequently secreted by these "activated" macrophages. These secreted factors facilitate the development and migration of myofibroblasts from a variety of tissue sources, which then result in sustained and dysregulated matrix production (Figure utilized with permission from Wermuth and Jimenez [209])

Keloids

Clinical

Keloids are defined as exuberant scar tissue formation extending beyond the area of original tissue injury [215]. Clinically, keloids are firm broad nodules with a shiny surface that often have a claw-like appearance beyond the original site of injury [215]. Keloids may show a delayed onset, sometimes forming months after the original injury. They can be painful or pruritic [215]. Persons of African or Asian heritage are reportedly ten times more susceptible to keloids than are whites [216].

Microscopic

Histologically, keloids show thickened, hyalinized collagen fibers that frequently form whorls and nodules. The collagen fibers can be large and irregular, and tend to be organized somewhat randomly. Blood vessels and ground substance are more abundant than in typical scars, and the epidermis can be effaced [217]. Partial occlusion of blood vessels by exuberant endothelial cell growth has led some investigators to hypothesize that keloids arise in a hypoxic milieu [218]. Some believe that keloidal fibroblasts may derive from pericytes that accompany the attendant hypoxia-driven proliferation of capillary endothelial cells [28].

Culture Studies

Cultured keloid derived fibroblasts (KDFs) have been shown to have several unusual growth characteristics. KDFs overproduce type I procollagen while keeping type III procollagen levels unaltered. This results in a markedly increased type I/III procollagen mRNA ratio [219]. The rate of collagen synthesis in KDFs is twice that of normal scars at six months, and continues to be higher for two to three years after wounding [217]. Collagenase activity is also increased in KDFs, although the abundance of chondroitin-4-sulfate may make collagen fibers resistant to degradation. Keloidal collagen has a low proportion of cross-linking despite having normal lysyl-oxidase activity [217].

KDFs have a reduced growth factor requirement for proliferation and have been reported to grow to higher cell densities in low-serum medium than normal dermal fibroblasts [220]. In a three-dimensional culture system of KDFs, type I and III procollagen levels remain high, despite the tendency for both procollagen types to gradually diminish over time in cultures of normal fibroblasts [221]. KDFs overproduce fibronectin and maintain its high expression over time as well [222].

Three dimensionally cultured KDFs have a high level of plasminogen activator inhibitor-1 (PAI-1) expression and a low level of urokinase plasminogen activator expression [223]. The elevated PAI-1 expression seems to be induced by hypoxia, and is supported by the observations of increased levels of the hypoxia marker HIF-1a (hypoxia induced

factor-1a) [224] and increased vascular endothelial growth factor (VEGF) expression, also triggered by hypoxia [225].

TGF-β1 induced collagen synthesis is more marked in KDFs than in those from the normal dermis [226]. This effect can be further increased after co-stimulation with insulin-like growth factor 1 (IGF-1), an effect correlated with increased phosphorylation of p38 MAP kinase and ATF-2 [227]. KDFs exposed to TGF-β1 showed increased production of reactive oxygen species (ROS) via the action of NAPDH oxidase 2 (NOX2). NOX2 has been shown to be essential for the transformation of KDFs to myofibroblasts in response to TGF-β1. NADPH oxidase-derived ROS also stimulate MAPK phosphorylation and Smad2/3 activation [228].

Ladin et al. [229] demonstrated that the apoptosis rate of KDFs was relatively low, an observation corroborated by others [230, 231]. KDFs are significantly more resistant than normal fibroblasts to Fas-mediated apoptosis [232]. In addition, their over-expression of IGF-1 receptor protects KDFs from ceramide-induced apoptosis [233]. Co-culture of KDFs with keloidal keratinocytes induced the expression of anti-apoptotic bcl-2 and the phosphorylation of ERK and JNK in KDFs, also known to be anti-apoptotic [215].

Normal keratinocytes have been shown to express IL-1, which is known to stimulate the expression of keratinocyte growth factor (KGF) in dermal fibroblasts. Co-culture experiments using keloidal and normal keratinocytes and fibroblasts have yielded interesting results. In these studies, keloid-derived keratinocytes promoted the proliferation of KDFs to a greater extent than keratinocytes derived from normal skin, lending credibility to the hypothesis that keloid pathogenesis involves interactions between abnormal fibroblasts and abnormal keratinocytes [215].

An enhanced response of KDFs to PDGF has also been reported [234].

Gene Studies

To date, no single gene mutation sufficient for keloids has been reported. The multiple growth and behavior anomalies noted in cultured KDFs suggest that a single gene could not account for all of the findings [215].

In DNA microarray studies, KDFs show an upregulation of approximately 15% of genes. Among the most pertinent of these are interleukin (IL)-1α, IL-1β, IL-6 and TNF-α [235, 236].

The NF-kB signaling pathway is activated in KDFs. NF-kB is involved in signal transduction pathways essential for the transcription of a variety of pro-inflammatory genes, and it is presumed that its activation contributes to the persistence of inflammation in keloids and also the inhibition of apoptosis in keloidal fibroblasts [236]. The observed clinical inhibition of keloid formation by glucocorticoids may be mediated through inhibition of this signaling pathway [237].

Proteomic analysis of normal and keloidal tissue has revealed 11 key proteins with altered expression in keloids. Of these, annexin A2 was prominently downregulated in keloidal tissue [238]. Annexin A2 is a profibrinolytic receptor that assists in localizing fibrinolytic activity to endothelial and monocyte cell surfaces [239]. In annexin A2 deficient animals, the primary histological feature is the accumulation of fibrin within microvessels in all tissues examined [240]. Additionally, keloid derived fibroblast proliferation, ordinarily inducible by recombinant human epidermal growth factor, is blocked by blocking the action of annexin A2. These findings suggest that the observed annexin A2 downregulation would result in fibrin accumulation within vessels and diminished fibroblast proliferation. In scars, a decrease in annexin A2 inhibits wound healing at the remodeling phase. It may be that keloids result from an inability to properly remodel collagen laid down following injury [238].

Lichen Sclerosus

Clinical

Lichen sclerosus (LS) is an acquired, chronic, inflammatory dermatosis with a predilection for genital skin. Symptoms include pruritus and scarring of skin and squamous mucosa. LS can lead to physical morbidity and serious sexual dysfunction [241]. Longstanding cases may be complicated by squamous cell carcinoma [241, 242]. Women are reportedly affected up to ten times more frequently than men, and several studies have identified an increased rate of coincident autoimmunity [242].

The underlying cause of LS is unknown although genetic, infectious and environmental triggers have been proposed [241, 242]. Some investigators offer strong circumstantial evidence that genital LS is due to chronic, intermittent exposure to urine, and that in certain individuals this may unmask site-specific skin epitopes that promote the development of autoantibodies [241].

The clinical lesions of LS consist of indurated papules and plaques with ivory-white, scar-like atrophy. The lesions commonly involve the vulva and perianal areas in women and the distal penis in men. Extragenital involvement of the scalp, neck, palms and soles, oral cavity, and peristomal sites has also been reported [242].

Microscopic

Early biopsies of LS reveal a band-like infiltrate of lymphocytes at the dermal-epidermal junction. As the process continues, this infiltrate retreats into the deeper dermis, leaving a homogenized and hyalinized (sclerotic) matrix in its wake [242]. Within the

hyalinized zone elastic fibers are typically lost [243]. The inflammatory component consists chiefly of T lymphocytes, and these are joined in later stages by macrophages and mast cells. Over time, initially normal or thickened epidermis becomes markedly atrophic.

Lipoid proteinosis, a rare genodermatosis associated with pathogenic mutations in the extracellular matrix protein 1 (ECM1) [244], shares some histopathological features with LS. This observation prompted investigation of the potential role of ECM1 in the pathogenesis of LS. In 2003, investigators found circulating IgG class antibodies to ECM1 in 74 % of female patients with LS [242] and subsequent work has confirmed similar results in male patients with LS [241]. There are mixed opinions regarding whether the circulating autoantibodies are responsible for triggering LS or are a consequence of the unmasking of antigens after inflammatory damage has already occurred. The finding of a variety of other autoantibody populations in LS has led many investigators to favor the latter interpretation [245, 246].

Matrix Analysis

The profound histopathological changes seen in the zone of dermal sclerosis in LS has focused attention on the constituents of the ECM. Investigators have determined that the distribution of collagens I and III, elastin, and fibrillin are abnormal in LS. Type I and III collagens provide tensile strength to the dermis. Type I collagen (80 % of dermal collagen) is normally distributed throughout the dermis, whereas type III collagen tends to localize to the papillary dermis. In the dermis of patients with LS, the proportions of these collagen types are variably and unpredictably increased or reduced relative to normal controls. In addition, the fibrillar nature of the proteins becomes indistinct and homogeneous [243].

Elastic fibers, which provide elasticity to dermal tissues, are reduced throughout the sclerotic zone of most patients with LS [243]. Fibrillin staining is also reduced throughout the sclerotic zone [243]. The mechanisms contributing to the reduction of elastin and fibrillin are unknown.

Compared to normal controls, tenascin staining is increased within the areas of sclerosis in LS [247, 248]. The normal role of tensacin in the dermis is not fully understood, although some lines of evidence indicate it is involved in cell adhesion and/or mobility. Tenascin is also increased in morphea and SSc, two other fibrosing disorders with histopathological features that overlap with LS [247]. Tenascin has also been reported to upregulate the synthesis of MMPs. Tenascin production by human fibroblasts is stimulated by IL-4 [249]. Investigators have reported variable responses to tenascin production by TGF-β [248, 249]. Tenascin mRNA signals in LS have been identified in fibroblasts, endothelial cells and basal keratinocytes [248].

Fibrinogen and fibronectin are ECM components that appear early in the process of wound repair and scar formation. Because of their many attachment points for extracellular macromolecules and cell surface proteins, they are ideally suited to creating a provisional matrix optimized for cell migration. In LS, fibronectin is reduced in areas of dermal sclerosis but increased in the zone of active inflammation immediately subjacent to the sclerotic areas [247]. Like tenascin, fibronectin has been reported to upregulate the synthesis of MMPs. Compared to normal controls, fibrinogen shows increased staining in both the zones of sclerosis and the underlying inflammatory zone.

Since tenascin and fibronectin both increase the levels of dermal MMPs, it is important to understand the role of MMPs in the normal dermis. MMPs are endopeptidases that are capable of degrading several different macromolecules in the ECM. As such, they are critical in tissue remodeling, wound healing, and cancer invasion. MMP activity is modulated by specific inhibitors known as tissue inhibitors of metalloproteinases (TIMPs). The balance between MMP and TIMP activity determines whether ECM components are being actively synthesized or degraded [250]. MMPs and TIMPs are activated in the extracellular environment and are found predominantly in the active form in the ECM [251].

In the dermis of patients with LS, MMP-2 and MMP-9 density is increased over that of normal skin if stromal cells, inflammatory cells, and vessels are all included in the analysis. It is hypothesized that the increased MMP-2 in the sclerotic zone of LS leads to MMP-2 driven degradation of decorin [250]. Decorin is a peri-cellular matrix proteoglycan that binds to type I collagen and modulates the effects of TGF-β during matrix assembly. Since MMP-2 and MMP-9 are also increased in the keratinocytes of LS, investigators have speculated that the basement membrane changes seen in LS are the result of MMP-driven degradation of laminin and type IV collagen, important components of the basement membrane zone at the dermal-epidermal junction [250]. Unsurprisingly, TIMP-1 and TIMP-2 activity is also greater in LS than in normal skin, a pattern verified through cell culture studies.

Growth Factors

In LS fibroblasts, similar to the pattern seen in scleroderma fibroblasts, maintenance of the profibrotic phenotype can be independent of Smad-dependent TGF-β signaling [252]. While there is significant upregulation of CTGF/CCN2 with concurrent elevations of mRNA levels of several ECM components (biglycan, versican, fibronectin), observations indicate that TGF-β1 and Smad-3 expression is not significantly altered in chronic lesions of LS [252].

Clonal T-Lymphocytes

Approximately 30–50 % of biopsies of genital LS contain T cells with monoclonally rearranged T-cell receptor γ-chain genes. These cases show predominantly CD4-positive T-cells that form an irregular meshwork with B lymphocytes and antigen presenting dendritic cells. The target antigen triggering this clonal growth is not known; however, the persistence of this clonal population may be further evidence of the systemic immune dysfunction inferred by epidemiological associations between LS and other autoimmune disorders [246].

Conclusion

In many ways, the study and understanding of cutaneous fibrosis is in its earliest stages. Conceptually, fibrosis represents a perturbation of a normal process, namely, coordinated wound healing. In an extended analogy, it is fair to say that a successfully healed and remodeled wound is analogous to a classical Shakespearian drama—the actors (cells) are clearly defined, the script is historically (evolutionarily) refined and unchanging, and the storyline and plot (pathways) lead to established and expected consequences and a satisfying resolution. The addition or subtraction of actors and plot elements from Hamlet will almost certainly create confusion—and so, too, will the addition of unexpected elements to the orderly repair of tissue damage (i.e. continuing infectious insult, re-injury, environmental factors, autoimmunity). It is this perturbation of a complex and harmonious process that leads to undesired fibrosis, and it will be the re-establishment of the natural storyline that will eventually result in its eradication.

Questions

1. Cellular origins of fibrosis: which of the following cell types is NOT considered to be a potential source (cellular progenitor) of extracellular matrix-producing fibroblasts in fibrosis?
   A. Pericyte
   B. Fibrocyte
   C. Epithelial cell
   D. Lymphocyte
   E. Adipocyte progenitor cell

(Answer = D)

2. Name three specific effects of elevated TGF-beta signaling activity on fibroblasts or other cell types.

   (Potential answers include fibroblast proliferation; fibroblast expression of extracellular matrix genes and deposition of ECM; conversion of fibroblasts to myofibroblasts; monocyte activation; cytokine production.)

3. True or false: Microarray-based gene expression profiles of fibrotic tissue versus healthy tissue are essentially identical.

   (False; many studies have identified differential expression of specific genes in fibrotic tissue.)

4. Identify and elaborate on the phases of cutaneous wound healing.

   (Hemostasis (formation of fibrin clot), inflammatory phase, proliferative phase (formation of granulation tissue), resolution (remodeling to mature scar tissue).)

Pemphigus Family of Disease

33

Jun Yamagami and Masayuki Amagai

Abstract

Pemphigus is a group of autoimmune blistering diseases of the skin and mucous membranes, which are mediated by IgG autoantibodies against desmogleins (Dsgs), cadherin type cell-cell adhesion molecules in desmosomes. Oral and cutaneous blisters and erosions with acantholysis, which is defined as intraepidermal blisters due to the loss of cell-cell adhesion of keratinocytes, are typically observed. For the diagnosis of pemphigus, immunopathological findings of *in vivo*-bound and circulating IgG autoantibodies directed against the cell surface of keratinocytes are essential. Pemphigus has three major forms: pemphigus vulgaris (PV), pemphigus foliaceus (PF), and paraneoplastic pemphigus (PNP). Patients with PV and PF have IgG autoantibodies against Dsg3 and Dsg1, respectively, while patients with PNP are characterized by autoantibodies against plakin molecules in addition to Dsgs and interface dermatitis suggesting the involvement of cell-mediated cytotoxicity. The relationship between clinical features and antibody profiles in pemphigus are logically explained by the Dsg compensation theory: The intraepithelial expression pattern of Dsg1 and Dsg3 is different between the skin and mucous membranes, and Dsg1 and Dsg3 compensate for each other when they are coexpressed in the same cell. Systemic corticosteroids are the mainstay of therapy for pemphigus, and adjuvant therapies, including immunosuppressive agents, plasmapheresis, high-dose intravenous immunoglobulin, and anti-CD20 monoclonal antibody are used for severe cases.

Keywords

Pemphigus • Skin disease • Desmosomes • Desmogleins • Mucous membrane • Acantholysis • Pemphigus vulgaris • Pemphigus foliaceus • Paraneoplastic pemphigus • Blisters • Autoimmune • Intraepithelial blister • Autoimmunity • Autoantibody

Key Features

- Pemphigus is a group of autoimmune blistering diseases of the skin and mucous membranes, which are mediated by IgG autoantibodies against cadherin type cell-cell adhesion molecules in desmosomes, desmogleins.
- Pemphigus is histologically characterized by acantholysis, i.e. intraepidermal blisters due to the loss of cell–cell adhesion of keratinocytes, and immunopathologically by the finding of *in vivo*-bound and circulating IgG autoantibodies directed against the cell surface of keratinocytes.
- Pemphigus has three major forms: pemphigus vulgaris, pemphigus foliaceus, and paraneoplastic pemphigus. Pemphigus vegetans is a variant of pemphigus vulgaris. Pemphigus erythematosus is a localized variant of pemphigus foliaceus and fogo

selvagem is an endemic variant of pemphigus foliaceus.
- Patients with pemphigus vulgaris and pemphigus foliaceus have IgG autoantibodies against desmoglein 3 and desmoglein 1, respectively, while patients with paraneoplastic pemphigus have IgG autoantibodies against plakin molecules in addition to desmogleins.
- Systemic corticosteroids are the mainstay of therapy for pemphigus, and adjuvant therapies, including immunosuppressive agents, plasmapheresis, high-dose intravenous immunoglobulin, and anti-CD20 monoclonal antibody are used for severe cases.

Historical Background

The term pemphigus stems from the Greek *pemphix* meaning blister or bubble and it describes a group of chronic blistering skin diseases in which autoantibodies are directed against the cell surface of keratinocytes, resulting in the loss of cell–cell adhesion of keratinocytes through a process called acantholysis (Table 33.1). The modern history of pemphigus began with the discovery by Beutner and Jordon in 1964 of circulating antibodies directed against the cell surface of keratinocytes in the sera of pemphigus vulgaris patients [1]. In the late 1970s to early 1980s, pemphigus autoantibodies were shown to have a pathogenic activity in induction of blister formation in skin organ-culture systems as well as by passive transfer of patients' IgG to neonatal mice [2, 3]. In the mid and late 1980s, the target antigens of pemphigus were characterized by immunochemical methods, such as immunoprecipitation and immunoblotting [4, 5]. In the early 1990s, the isolation of cDNA for pemphigus antigens demonstrated that the target antigens in pemphigus are desmogleins [6, 7].

Table 33.1 Classification of pemphigus

Pemphigus vulgaris
Pemphigus vegetans
Pemphigus foliaceus
Pemphigus erythematosus: localized
Fogo selvagem: endemic
Paraneoplastic pemphigus
Drug-induced pemphigus
IgA pemphigus

Pathogenesis

Pemphigus Target Antigens are Desmogleins

The hallmark of pemphigus is the finding of IgG autoantibodies against the cell surface of keratinocytes. The pemphigus autoantibodies found in patients' sera play a primary pathogenic role in inducing blisters. When IgG fraction from patients is passively transferred to neonatal mice, the mice develop blisters with typical histologic findings [3]. Even monovalent Fab' fragments of IgG or single chain fragment variables (monoclonal antibodies isolated using phage display technique, consisting of the variable regions of light chain and heavy chain of immunoglobulin) from patients are sufficient to cause blisters in neonatal mice, indicating complement activation and surface cross-linking may not be relevant in keratinocyte detachment [8–10].

Immunoelectron microscopy localized both pemphigus vulgaris and pemphigus foliaceus antigens to the desmosomes, the most prominent cell–cell adhesion junctions in stratified squamous epithelia [11]. Immunochemical characterization of pemphigus antigens by immunoprecipitation or immunoblotting with extracts from cultured keratinocytes or epidermis demonstrated that the pemphigus vulgaris and foliaceus antigens were 130 kD and 160 kD transmembrane glycoproteins, respectively [4, 5, 12]. The 160 kD protein recognized by pemphigus foliaceus sera was subsequently shown to be identical with desmoglein 1 (Dsg1) by comparative immunochemical studies [13].

Molecular cloning of cDNA encoding Dsg1 and pemphigus vulgaris antigens indicated that both molecules were desmogleins, which are the members of the cadherin supergene family [6, 7] (Fig. 33.1). Thus, pemphigus was discovered to be an anti-desmoglein autoimmune disease. The pemphigus vulgaris antigen was termed desmoglein 3 (Dsg3).

Desmosomes are intercellular adhesive junctions in the epidermis and mucous membranes and contain two major transmembrane components, desmogleins and desmocollins, both of which are cadherin type cell adhesion molecules. Desmogleins have four isoforms (Dsg1 to Dsg4). Expression of Dsg1 and Dsg3 is basically restricted to stratified squamous epithelia, where blisters are formed in pemphigus, while Dsg2 is expressed in all desmosome-possessing tissues, including simple epithelia and myocardium [14]. Dsg4 plays an important adhesive role mainly in hair follicles because mutations in *DSG4* gene cause abnormal hair development [15]. The molecular structure of desmogleins is unique and they have four cadherin repeats in their extracellular domain as do classic cadherins and have an extra carboxyl-terminal domain containing repeats of a 29 ± 1 residues (Fig. 33.1).

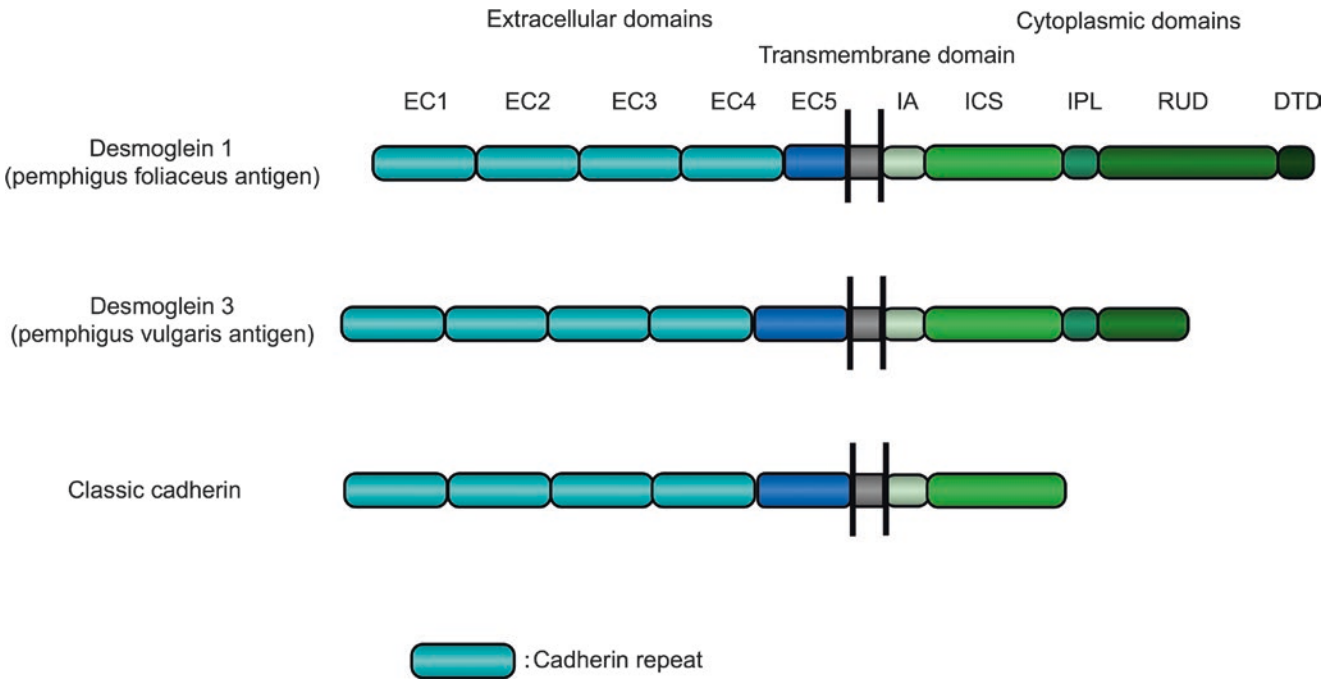

Fig. 33.1 Molecular structure of the pemphigus antigens. Cadherin is a single span transmembrane protein with a unique structure. The extracellular (EC) region of each cadherin member has four cadherin repeats of about 110 amino acid residues with calcium-binding motifs. *Boxes* with the *same color* have similarities in their amino acid sequences. Desmogleins have their own unique sequences of 29 ± 1 residues (repeating unit domain or RUD). *ICS* intracellular cadherin-specific domain, *IA* intracellular anchor domain, *IPL* intracellular proline-rich linker, *DTD* desmoglein-specific terminal domain

Compelling evidence has accumulated that IgG autoantibodies against Dsg1 and Dsg3 are pathogenic and play a primary role in inducing the blister formation in pemphigus. Essentially, all patients with pemphigus have IgG autoantibodies against Dsg1 and/or Dsg3, depending on the subtype of pemphigus [16, 17]. When anti-desmoglein IgG autoantibodies are removed from patients' sera of pemphigus vulgaris, pemphigus foliaceus or paraneoplastic pemphigus by immunoadsorption with recombinant desmoglein proteins, the sera are no longer pathogenic in blister formation [18, 19]. Furthermore, anti-desmoglein IgG autoantibodies that were affinity-purified from pemphigus sera on the desmoglein recombinant proteins can cause blisters when injected in neonatal mice [19, 20]. Some pemphigus sera react with Dsg4 due to cross-reactivity of a subset of anti-Dsg1 IgG, although Dsg4/Dsg1-cross-reacting IgG has no demonstrable pathogenic effect [21]. IgG autoantibodies against acetylcholine receptors or annexin-like molecules are reported, but their pathogenic relevance in pemphigus remains to be determined [22–24].

Thus, the basic pathophysiology of pemphigus is that IgG autoantibodies raised against Dsg1 and/or Dsg3 inhibit their adhesive function and lead to the loss of the cell–cell adhesion of keratinocytes, resulting in blister formation. Recent studies, in which pathogenic and non-pathogenic monoclonal antibodies were isolated from pemphigus patients, suggest that patients would have polyclonal IgG with diverse pathogenic activities [10, 25, 26]. Although the mechanism of blister formation in pemphigus is not fully understood, it is considered that the loss of cell-cell adhesion is triggered by the combination of direct inhibition of Dsg interactions (steric hindrance), the activation of cellular signal pathways, and endocytosis of cell surface Dsg [27–29].

Desmoglein Compensation Theory as Explanation for Localization of Blisters

Although the disruption of desmoglein-dependent cell adhesion by autoantibodies is the basic pathophysiology underlying blister formation in pemphigus, the clinical spectrum is more complex. The complex clinical features of pemphigus are explained logically by the desmoglein compensation theory: Dsg1 and Dsg3 compensate for each other when they are coexpressed in the same cell [30–32] (Fig. 33.2).

The intraepithelial expression pattern of Dsg1 and Dsg3 is different between the skin and mucous membranes. In the skin, Dsg1 is expressed throughout the epidermis, but more

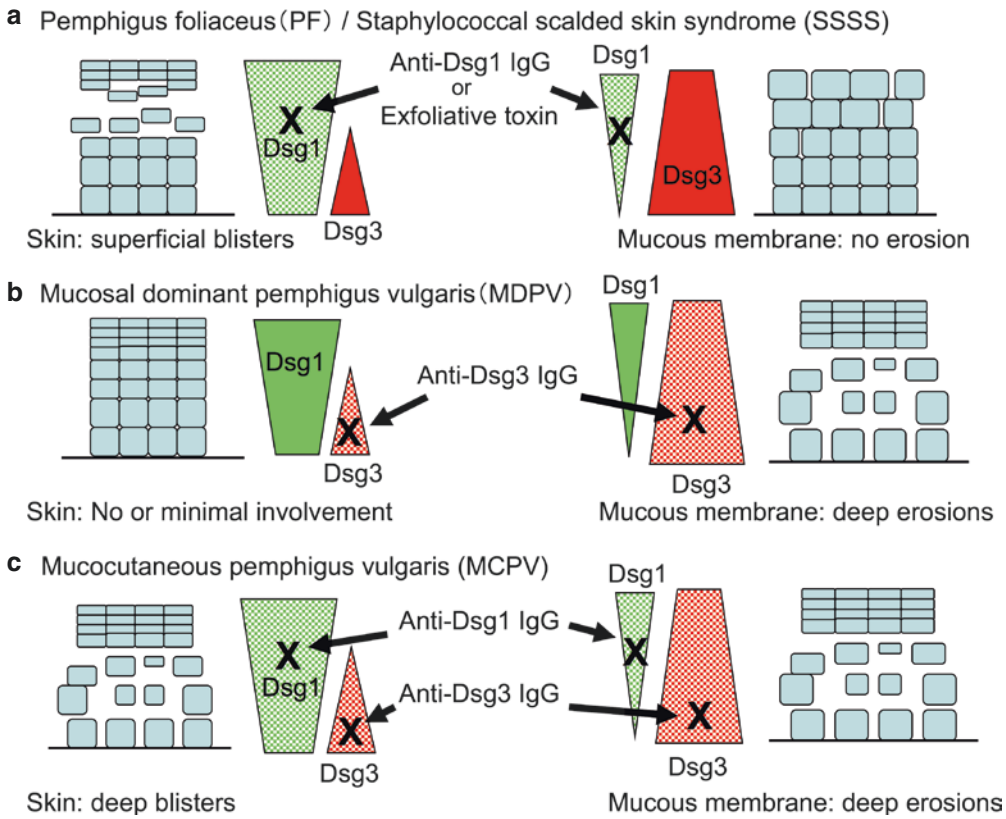

Fig. 33.2 Desmoglein compensation theory. Anti-Dsg1 IgG autoantibodies in serum from patients with pemphigus foliaceus or exfoliative toxin in staphylococcal scalded-skin syndrome (SSSS) cause superficial blisters in the skin; no blisters form in the lower epidermis or mucous membrane, because Dsg3 maintains cell-cell adhesion in those areas (**a**). Serum from patients with mucosal-dominant pemphigus vulgaris contains only anti-Dsg3 IgG, which causes mucosal blisters and erosions where there is no significant compensation by Dsg1, but no or minimal involvement in the skin where Dsg1 maintains cell-cell adhesion (**b**). Serum from patients with mucocutaneous pemphigus vulgaris containing anti-Dsg1 and Dsg3 causes blisters and erosions in the epidermis as well as in the mucous membranes because of no compensation (**c**)

intensely in the superficial layers, while Dsg3 is expressed in the lower portion of the epidermis, primarily in the basal and parabasal layers. In contrast, Dsg1 and Dsg3 are expressed throughout the squamous layer of mucosa, but Dsg1 is expressed at a much lower level than Dsg3.

Patients with pemphigus foliaceus have only anti-Dsg1 IgG autoantibodies (Table 33.2). Patients with the mucosal dominant type of pemphigus vulgaris have only anti-Dsg3 IgG autoantibodies, whereas those with the mucocutaneous type of pemphigus vulgaris have both anti-Dsg3 and anti-Dsg1 IgG autoantibodies [33, 34].

For example, when sera contain only anti-Dsg1 IgG, which interferes with the function of Dsg1, the presence of Dsg3 compensates for the loss of function of Dsg1 in the lower epidermis. In contrast, in upper epidermis, there is no compensation by Dsg3. Therefore, blisters only appear in the superficial epidermis of the skin because that is the only area in which Dsg1 is present without coexpression of Dsg3. Although the anti-Dsg1 IgG binds to mucosa, no blisters are formed because of the coexpression of Dsg 3. Thus, sera containing only anti-Dsg1 IgG cause superficial blisters in the skin without mucosal involvement, as is seen in patients with pemphigus foliaceus.

The desmoglein compensation theory also explains the clinical and histological phenotype of bullous impetigo and staphylococcal scalded skin syndrome (SSSS) [32]. The blisters of bullous impetigo and SSSS are caused by exfoliative toxin (ET), which is produced by *Staphylococcus aureus*. ET was recently discovered to bind specifically to Dsg1 and cleave only the site after glutamic acid residue 381 between extracellular domains 3 and 4 [35–37]. When ET reaches the skin and digests Dsg1 in the lower layers of the epidermis, Dsg3 compensates for the loss of function of Dsg1 and manages to maintain cell–cell adhesion, while no compensation by Dsg3 occurs in the superficial layers of the epidermis. Therefore, ET induces superficial blisters on the skin. In mucous membranes, the Dsg3 expressed throughout the squamous layers of the mucosa compensates for the impaired Dsg1 and maintains cell–cell adhesion with no mucosal involvement.

Table 33.2 Target antigens in pemphigus

Diseases	Autoantibodies	Antigens
Pemphigus vulgaris		
Mucosal dominant type	IgG	Desmoglein 3
Mucocutaneous type	IgG	Desmoglein 3
		Desmoglein 1
Pemphigus foliaceus	IgG	Desmoglein 1
Paraneoplastic pemphigus	IgG	Desmoglein 3
		Desmoglein 1
		Plectin/HD1 (500 kD)
		Desmoplakin I (250 kD)
		Desmoplakin II (210 kD)
		BPAG1 (230 kD)
		Envoplakin (210 kD)
		Periplakin (190 kD)
		alpha-2-macroglobulin-like-1 (170 kD)
Drug-induced pemphigus	IgG	Desmoglein 3
		Desmoglein 1
IgA pemphigus		
SPD type	IgA	Desmocollin 1
IEN type	IgA	?

Paraneoplastic Pemphigus Has a More Complex Autoimmune Reaction Than Classic Pemphigus

In addition to IgG autoantibodies against Dsg3 and/or Dsg1, patients with paraneoplastic pemphigus (PNP) develop characteristic IgG autoantibodies against multiple antigens with molecular weights of 500, 250, 230, 210, 190 and 170 kDa [19, 38] (Table 33.2). By immunochemical studies and cDNA cloning, most of these antigens were identified. The 500 kD antigen is plectin. The 250 kD and 210 kD antigens are desmoplakins I and II, respectively. The 230 kDa antigen is bullous pemphigoid antigen 1, the major plaque protein of the epidermal hemidesmosome and also a target antigen in bullous pemphigoid. The 210 kDa band also contains envoplakin. The 190 kDa antigen is periplakin, and 170 kDa antigen was recently identified as alpha-2-macroglobulin-like-1, a broad-range protease inhibitor [39, 40].

Anti-desmoglein antibodies play a role in inducing the loss of cellular adhesion of keratinocytes and initiate blister formation, while the pathophysiological relevance of the anti-plakin autoantibodies is unclear. The intracellular location of plakin proteins makes it unlikely that anti-plakin autoantibodies initiate pathology in paraneoplastic pemphigus because IgG cannot penetrate cell membranes. It is also important to bear in mind that not only humoral immunity but also cell-mediated cytotoxicity is involved in the pathogenesis of paraneoplastic pemphigus in a form of interface dermatitis. Patients with PNP show more severe and refractory oral erosions and stomatitis as well as more polymorphic skin eruptions when compared with classic forms of pemphigus. Recent studies using the pemphigus mouse model indicated that $CD4^+$ T cells recognizing Dsg3 are able to directly infiltrate to dermal-epidermal junctions and induce interface dermatitis, suggesting the involvement of the cellular autoimmune reaction to epidermal antigens in PNP [41].

Clinical Features

Pemphigus Vulgaris

Pemphigus vulgaris has two clinical subtypes: mucosal dominant type and mucocutaneous type. Patients with mucosal dominant type show mucosal erosions mainly in the oral cavity with minimal or limited skin involvement. Patients with mucocutaneous type show extensive flaccid blisters and erosions on the skin in addition to the mucosal erosions. Any stratified squamous epithelia where Dsg1 and/or Dsg3 are expressed can be involved in pemphigus vulgaris.

Mucous membrane lesions are usually seen as painful erosions (Fig. 33.3). Intact blisters are rare, probably because they are fragile and break easily. Scattered and often extensive erosions may be seen on any part of the oral cavity. Extensive erosions and painful lesions in the mouth may

Fig. 33.3 Pemphigus vulgaris. Essentially all patients develop painful oral mucous membrane erosions

result in decreased food and drink intake. Involvement of throat may produce hoarseness and difficulty in swallowing. The esophagus, conjunctiva, nasal mucosa, vagina, penis, anus and labia may also be involved. The diagnosis of pemphigus vulgaris tends to be delayed in patients presenting with only oral involvement, as compared to patients with skin lesions.

The primary skin lesions of pemphigus vulgaris are flaccid, thin-walled, easily ruptured blisters that appear anywhere on the skin surface (Fig. 33.4). The blisters arise on normal-appearing skin or erythematous bases. The blisters are fragile and soon rupture to form painful erosions that ooze and bleed easily. The erosions soon become partially covered with crusts that have little or no tendency to heal. Without appropriate treatment, pemphigus vulgaris can be fatal because large area of the skin lose epidermal barrier function, leading to loss of body fluids or secondary bacterial infection. Because of absence of cohesion in the epidermis, the upper layers are easily made to slip laterally by slight pressure or rubbing in active patients with pemphigus (Nikolsky sign).

Fig. 33.4 Pemphigus vulgaris. Skin lesions are flaccid blisters which are fragile and soon rupture to form painful erosions that ooze and bleed easily

Pemphigus Foliaceus

Patients with pemphigus foliaceus develop scaly, crusted erosions, often on an erythematous base in the skin, but do not have apparent mucous membrane involvement even with widespread disease (Fig. 33.5). The absence of oral involvement may be a clue to clinically differentiate pemphigus foliaceus from pemphigus vulgaris.

The onset of disease is often subtle with a few scattered crusted lesions which come and go, and are frequently mistaken for impetigo. These lesions are usually well demarcated and scattered in a seborrheic distribution, including face, scalp, and upper trunk. Because the vesicle is so superficial and fragile, often only the crust and scale that result from a ruptured vesicle are seen. Disease may stay localized for years or may rapidly progress, in some cases, to generalized involvement resulting in an erythrodermic exfoliative dermatitis. Nikolsky sign is present. Generally patients with pemphigus foliaceus are not severely ill.

Paraneoplastic Pemphigus

Paraneoplastic pemphigus is a recently described form of pemphigus that occurs in association with underlying neoplasms [38, 39]. PNP is unique and distinct from the classic forms of pemphigus vulgaris and foliaceus by clinical, histologic, and immunopathologic criteria. The associated neoplasms are non-Hodgkin's lymphoma (42 %), chronic lymphocytic leukemia (29 %), Castleman's tumor (10 %), malignant and benign thymoma (6 %), spindle cell neoplasms (reticulum cell sarcoma) (6 %), and Waldenstrom's macroglobulinemia (6 %). The combination of non-Hodgkin's lymphoma and chronic lymphocytic leukemia represents almost two thirds of cases. Castleman's disease,

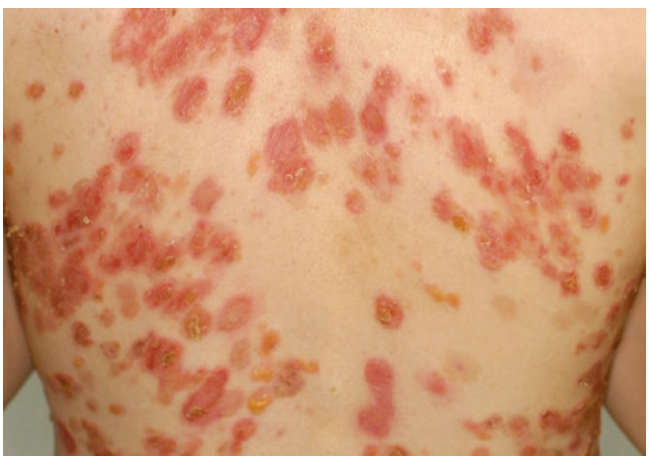

Fig. 33.5 Pemphigus foliaceus. Skin lesions are scaly crusted erosions and vesicles that are fragile and easily ruptured

which is a very rare lymphoproliferative lesion, is the third most commonly associated neoplasm. The absence of common tumors, such as adenocarcinoma of breast or bowel and squamous cell carcinomas, is notable.

The most constant clinical feature of paraneoplastic pemphigus is the presence of intractable stomatitis (Fig. 33.6). The severe stomatitis is usually the earliest presenting sign and after treatment it is the one that persists and is extremely resistant to therapy. This stomatitis consists of erosions and ulcerations that affect all surfaces of the oropharynx and characteristically extend onto the vermillion of the lip. Most patients also have a severe pseudomembranous conjunctivitis with scarring. Esophageal, nasopharyngeal, vaginal, labial, and penile mucosal lesions may also be affected.

The cutaneous lesions are quite polymorphic and may appear as erythematous macules, flaccid blisters and erosions resembling pemphigus vulgaris, tense blisters resembling bullous pemphigoid, erythema multiforme-like lesions, and lichenoid eruptions. Extensive cases show clinical resemblance with toxic epidermal necrolysis (TEN). The occurrence of blisters and erythema multiforme-like lesions on the palms and soles can be used to clinically differentiate paraneoplastic pemphigus from pemphigus vulgaris. Cutaneous lichenoid eruptions are very common together with severe stomatitis. In the chronic form of the disease lichenoid eruption may predominate over blistering lesions.

Paraneoplastic pemphigus is the only form of pemphigus that has involvement of non-stratified squamous epithelia. Approximately, 30–40 % of patients develop pulmonary symptoms [42, 43]. The earliest symptoms are progressive dyspnea, and pulmonary function studies show airflow obstruction, involving large and small airways, as seen in bronchiolitis obliterans, which can be fatal through respiratory failure. Recently, it has been demonstrated that the ectopic expression of Dsg3 or other epidermal antigens in the lung in the form of squamous metaplasia, which is often found in the lungs of PNP patients, is able to render the lung a target organ in PNP [44].

Fig. 33.6 Paraneoplastic pemphigus. The characteristic clinical feature is severe intractable stomatitis that extends onto the vermillion of the lip

Other Forms of Pemphigus

Pemphigus Vegetans

Pemphigus vegetans is a rare vegetative variant of pemphigus vulgaris and considered to be one reactive pattern of the skin to autoimmune insult of pemphigus vulgaris. Pemphigus vegetans is characterized by flaccid blisters that become erosions and form fungoid vegetations or papillomatous proliferations, especially in intertriginous area and in the scalp or on the face. Pustules rather than vesicles characterize early lesions but these soon progress to vegetative plaques.

Pemphigus Erythematosus (Senear-Usher Syndrome)

Pemphigus erythematosus is simply a localized variant of pemphigus foliaceus. Typical scaly and crusted lesions of pemphigus foliaceus occur across the malar area of the face and in other seborrheic areas. Originally, pemphigus erythematosus was introduced for patients with immunological features of both lupus erythematosus and pemphigus, i.e. *in vivo* IgG and C3 deposition on keratinocyte cell surfaces as well as basement membrane zone and circulating antinuclear antibodies [45]. However, only few patients have been reported to actually have the two diseases concurrently [46].

Drug-Induced Pemphigus

There are sporadic cases of pemphigus in association with the use of drugs, such as penicillamine and captopril [47]. Pemphigus foliaceus is more common than pemphigus vulgaris in penicillamine-treated patients. Although most of patients with drug-induced pemphigus are shown to have autoantibodies against Dsg1 or Dsg3 [48], evidence suggests that some drugs may induce acantholysis without production of antibodies. Both penicillamine and captopril contain sulfhydryl groups that are speculated to interact with the sulfhydryl groups in desmoglein 1 and 3. Most, but not all, patients with drug-induced pemphigus go into remission after the offending drug is stopped.

IgA Pemphigus

IgA pemphigus is a newly characterized group of autoimmune intraepidermal blistering diseases presenting with a vesiculopustular eruption, neutrophilic infiltration, and in vivo-bound and circulating IgA autoantibodies against the keratinocyte cell surface, but no IgG autoantibodies [49–51]. IgA deposition

on cell surfaces of the epidermis is present in all cases by direct immunofluorescence, and many patients have detectable circulating IgA autoantibodies by indirect immunofluorescence. There have been two distinct types of IgA pemphigus, subcorneal pustular dermatosis (SPD) type and intraepidermal neutrophilic (IEN) type. IgA autoantibodies in the SPD type react with desmocollin 1, which is expressed on COS7 cells [50], while autoimmune targets of the IEN type remain to be identified (Table 33.2). Subsets of IgA pemphigus patients have IgA autoantibodies against Dsg1 or Dsg3, making the autoimmune target of IgA pemphigus more heterogeneous. The exact pathogenic role of IgA autoantibodies in pustular formation in IgA pemphigus remains to be elucidated.

The patients with both types of IgA pemphigus clinically present with flaccid vesicles or pustules both on erythematous or normal skin. In both types the pustules tend to coalesce to form an annular or circinate pattern with crusts in the central area, although sunflower-like configuration of pustules is a characteristic sign of the IEN type. The predilection sites are the axillary and groin areas, but the trunk, proximal extremities, and lower aspect of the abdomen are commonly involved. Mucous membrane involvement is rare. Pruritus is often a significant symptom. Because the SPD type of IgA pemphigus is clinically and histologically indistinguishable from classic subcorneal pustular dermatosis (Sneddon-Wilkinson disease), immunological characterization is essential to differentiate the two diseases.

Histology

Pemphigus Vulgaris

The characteristic histological finding of the classic form of pemphigus is intraepidermal blister formation due to loss of cell-to-cell adhesion (acantholysis) of keratinocytes without keratinocyte necrosis. In pemphigus vulgaris, acantholysis usually occurs just above the basal cell layer (suprabasilar acantholysis) (Fig. 33.7). A few rounded up (acantholytic) keratinocytes as well as clusters of epidermal cells are often seen in the blister cavity. Although the basal cells lose contact with their neighbors, they maintain their attachment to the basement membrane, thus giving the appearance of a "row of tombstones". Eosinophilic spongiosis can be also seen in very early lesions of pemphigus.

Pemphigus Foliaceus

In pemphigus foliaceus, acantholysis is found in the upper epidermis, within or adjacent to the granular layer (Fig. 33.8). As the blisters are superficial, it is often very difficult to obtain an intact lesion for diagnosis. These histologic findings of superficial blisters are indistinguishable from those seen in staphylococcal scalded skin syndrome or bullous impetigo, because desmoglein 1 is targeted in both diseases. Sometimes the blisters contain numerous acute inflammatory cells, particularly neutrophils.

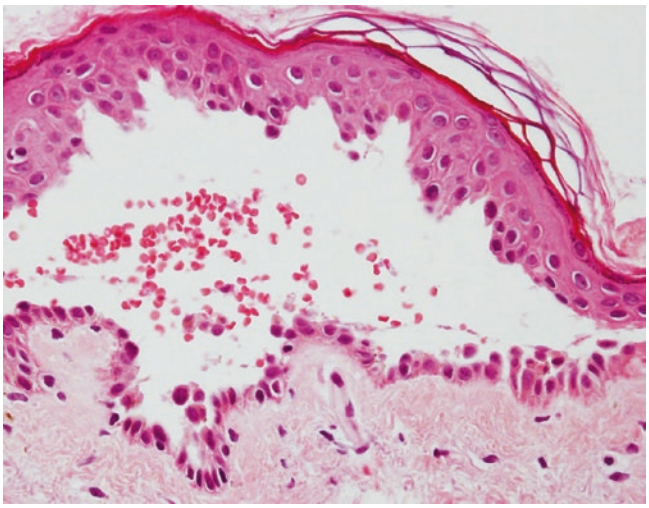

Fig. 33.7 Histology of pemphigus vulgaris. The characteristic histological finding of pemphigus is intraepidermal blister formation due to loss of cell-to-cell adhesion of keratinocytes without keratinocyte necrosis. In pemphigus vulgaris, blisters usually occur just above the basal cell layer (suprabasilar acantholysis)

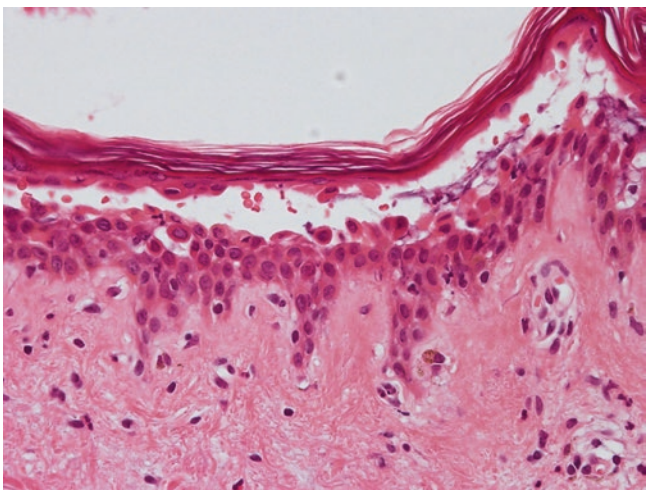

Fig. 33.8 Histology of pemphigus foliaceus. In pemphigus foliaceus, blisters usually occur around the granular layer of the epidermis (subcorneal acantholysis)

Paraneoplastic Pemphigus

In paraneoplastic pemphigus, the histologic findings of lesions show considerable variability, reflecting the polymorphism of the clinical lesions. The lesions show a unique

combination of pemphigus vulgaris-like histology and erythema multiforme-like or lichen planus-like histology. Intact cutaneous blisters may show suprabasilar acantholysis and individual keratinocyte necrosis with lymphocytic infiltration in the epidermis. In addition, basal cell liquefactive degeneration or band-like dense lymphocytic infiltration in the upper dermis can be seen.

Diagnosis

Once the diagnosis of pemphigus is suspected from clinical findings, it is important to take a biopsy for histology and direct immunofluorescence as well as perform serum tests to look for IgG autoantibodies against cell surfaces of keratinocytes or desmogleins. The definitive diagnosis of pemphigus requires the demonstration of the IgG autoantibodies. Methods to demonstrate pemphigus autoantibodies include direct immunofluorescence, indirect immunofluorescence, immunoprecipitation, immunoblot, and enzyme-linked immunosorbent assay (ELISA).

Direct immunofluorescence examines patients' skin or mucous membranes to demonstrate *in vivo* bound IgG deposition on the keratinocyte cell surfaces (Fig. 33.9). Direct immunofluorescence is the most reliable and sensitive diagnostic test for all forms of pemphigus. If the direct immunofluorescence is negative, the diagnosis of pemphigus should be seriously questioned. The biopsy specimen should be taken from perilesional normal skin or mucous membrane, because blister sites may give a false negative. IgM deposition is not seen, but occasionally IgA deposition may be seen in addition. Complement (C3) deposition is not necessarily demonstrated, probably because the dominant subclass of IgG is IgG4, which does not fix complement. In IgA pemphigus IgA deposition, but not IgG deposition, is detected on keratinocyte cell surfaces.

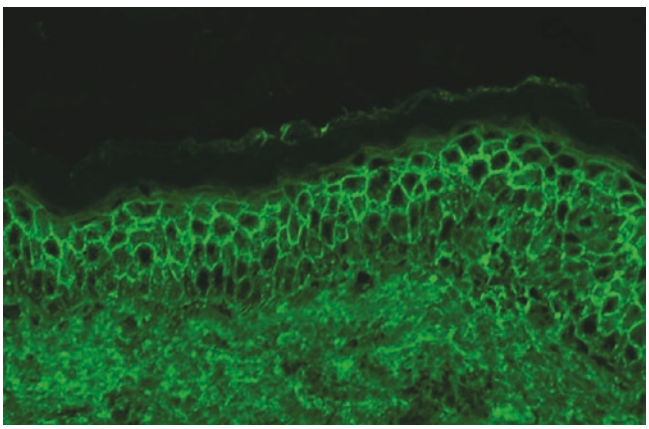

Fig. 33.9 Direct immunofluorescence of pemphigus foliaceus. Direct immunofluorescence using patients' skin as a substrate shows *in vivo* bound IgG deposition on the keratinocyte cell surfaces, indicating IgG autoantibodies bind to the native target antigen, desmoglein1 and/or desmoglein3, as an initial step of blister formation in pemphigus

Indirect immunofluorescence examines patients' sera to demonstrate circulating IgG autoantibodies that react with epithelial cell surfaces. Expression level of Dsg1 and Dsg3 varies among different epithelial cells. As a substrate of indirect immunofluorescence staining, monkey esophagus is more suitable for detecting anti-Dsg3 IgG autoantibodies, and normal human skin or guinea pig esophagus is better for anti-Dsg1 IgG autoantibodies. Rat bladder is used for paraneoplastic pemphigus or anti-plakin autoantibodies. Despite the different antigens involved in pemphigus vulgaris and foliaceus, the staining pattern using direct or indirect immunofluorescence is similar, which makes it difficult to serologically distinguish the two diseases.

ELISA provides a specific, sensitive, and quantitative assay to detect and measure circulating IgG autoantibodies in the diagnosis of pemphigus [16, 17]. The patient's serum is tested on ELISA plates pre-coated with recombinant proteins of Dsg1 or Dsg3. ELISA enables us to serologically distinguish subtypes of pemphigus vulgaris and foliaceus. In general, if a serum is positive against desmoglein 1 but negative against desmoglein 3, it suggests a diagnosis of pemphigus foliaceus. If negative against desmoglein 1 but positive against desmoglein 3, it suggests a diagnosis of mucosal dominant type of pemphigus vulgaris. If positive against both desmoglein 1 and desmoglein 3, it suggests a diagnosis of mucocutaneous type of pemphigus vulgaris. Furthermore, ELISA scores show parallel fluctuation with the disease activity. Thus ELISA is also useful to monitor the disease activity to plan tapering schedules of corticosteroids and to predict flares or relapses before clinical evidence of disease flares are noticed.

Treatment

The introduction of systemic glucocorticoids and immunosuppressive agents has greatly improved the prognosis of pemphigus, however, the morbidity and mortality is still significant because death sometimes occurs from complications of therapy. Systemic glucocorticoids are the mainstay of therapy for pemphigus and immunosuppressive agents are often used for a steroid-sparing effect to reduce the side effects of steroids. The goal of therapy is to control the disease at the lowest possible dose of glucocorticoids. Complete remission on therapy is defined as the absence of new or established lesions while the patient is receiving minimal therapy (less than or equal to 10 mg/day of prednisone or the equivalent and /or minimal adjuvant therapy) [52].

Prednisone at 1.0 mg/kg/day (usually 60 mg/day) is a typical initial treatment. During initial treatment, disease activity is assessed primarily through clinical symptoms,

typically based on PDAI (pemphigus disease area index), a recently established scoring system that can reliably capture all ranges of cutaneous and mucosal disease extent, and prednisone is planned to be gradually tapered [53]. However, once clinical remission is obtained, changes in the titers of circulating autoantibodies are helpful in gauging the dose of prednisone [17, 54–56].

Immunosuppressive agents, such as azathioprine (2–4 mg/kg/day) and cyclophosphamide (1–3 mg/kg/day), when combined with corticosteroids, are beneficial to gain early control of the disease and increase numbers of remissions [57–59]. If complete clinical remission is achieved with the combined therapy, the dosage of the immunosuppressive drug is maintained while the prednisone is gradually tapered to 5 mg/day. In young patients the potential increase in malignancies that might be associated with the use of these drugs must be taken into account. Mycophenolate mofetil (2–3 g/day) is another choice for an effective immunosuppressive agent of the combination therapy with glucocorticoids [60].

Plasmapheresis is useful to quickly reduce the titers of circulating autoantibodies and should be considered for severe pemphigus if the disease is unresponsive to a combination of prednisone and immunosuppressives [61]. Concomitant immunosuppression with glucocorticoids and cyclophosphamide prevents a rebound increase in the production of autoantibody.

High dose intravenous immunoglobulin is another option for resistant disease [62]. Intravenous immunoglobulin has immunomodulatory effects when used in a high dose although their exact mechanisms remain to be elucidated. The efficacy of IVIG (400 mg/kg/day for 5 consecutive days) has been verified by a multicenter, randomized, placebo-controlled, double-blind clinical trial [63]. Recently, anti-CD20 monoclonal antibody (rituximab) was reported to be effective in patients with refractory pemphigus by a single cycle or multiple cycles of the treatment [64–66].

Conclusion

Pemphigus is a group of autoimmune blistering diseases caused by IgG autoantibodies against desmogleins. Understanding the pathomechanism leads to the correct diagnosis and appropriate treatment in pemphigus.

Questions

1. How do you explain the sites of blisters in pemphigus with anti-desmoglein antibody profiles in a logical way?
2. What are essential findings to confirm the diagnosis of pemphigus vulgaris or foliaceus?
3. What is the key difference between paraneoplastic pemphigus and pemphigus vulgaris?
4. How do you set the goal of therapy for patients with pemphigus?

Answers

1. The relationship between phenotypes of pemphigus and anti-desmoglein antibody profile is explained by desmoglein compensation theory. Dsg1 and Dsg3 compensate for each other when they are coexpressed in the same cell. The intraepithelial expression pattern of Dsg1 and Dsg3 is different between the skin and the mucous membranes
2. Clinical findings, histological findings (intraepidermal blister formation with acantholysis), and detection of in vivo bound IgG deposition on the keratinocyte cell surface in direct immunofluorescence of patient's skin or mucous membranes
3. Not only humoral immunity but also cell-mediated cytotoxicity is involved in the pathogeniesis of paraneoplastic pemphigus
4. The goal of therapy is to control the disease at the lowest possible dose of glucocorticoids

Immunoglobulin A Dermatoses

34

Julia A. Curtis and John J. Zone

Abstract

Immunoglobulin A (IgA) dermatoses represent a distinct but diverse category of immunologic skin diseases, including linear IgA bullous dermatosis, dermatitis herpetiformis, IgA subcorneal pemphigus, IgA intraepidermal pemphigus and IgA vasculitis (Henoch-Schönlein purpura).

The common findings that tie all of these disorders together are the cutaneous deposition of IgA at the histopathologic site of inflammation on direct immunofluorescence microscopy and a neutrophilic inflammatory infiltrate on hematoxylin and eosin staining of involved skin.

IgA is found in respiratory, gastrointestinal and genitourinary mucosal secretions, as well as human serum. The IgA dermatoses share activation of the IgA receptor, FcαR1, on neutrophils, which is also present on eosinophils and monocytes. This receptor activation starts an inflammatory cascade believed to be essential in these disorders that include: a neutrophilic response, endocytosis, antibody-dependent cell-mediated cytotoxicity, the respiratory burst, degranulation in the skin and subsequent tissue damage.

The main therapy for these disorders remains dapsone, a sulfone antibiotic, and its related medications, which are effective agents against neutrophil activity that include inhibition of adhesion, chemotaxis and myeloperoxidase production for the respiratory burst. Topical therapy consists mainly of high potency corticosteroids.

Keywords

Immunoglobulin A • Bullous dermatoses • Vesiculobullous • Bullae • Linear IgA • LABD • Mucosal involvement • Subcorneal pemphigus • Intraepidermal pemphigus • Pustules • Drug-induced • Dermatitis herpetiformis • Vesicles • Papules • Papulovesicular • Duhring's • IgA vasculitis • Henoch-Schönlein purpura • Neutrophilic dermatoses • IgA FcαR1 • Dapsone

Key Points

- Immunoglobulin A (IgA) dermatoses encompass a number of diseases, including linear IgA bullous dermatosis, dermatitis herpetiformis, IgA subcorneal pemphigus, IgA intraepidermal pemphigus and Henoch-Schonlein purpura. The common finding is that all of the disorders are characterized by deposition of IgA on direct immunofluorescence at the histopathologic site of inflammation in the skin.

A.A. Gaspari et al. (eds.), *Clinical and Basic Immunodermatology*, DOI 10.1007/978-3-319-29785-9_34

- Additional shared findings include a neutrophilic inflammatory infiltrate and a response to dapsone therapy.
- Neutrophils have an IgA receptor, FcaR1, which is not present on all immune response cells. Activation of this receptor starts the cellular cascade that is believed to be operative in these disorders: neutrophilic response, degranulation, respiratory burst, endocytosis and subsequent tissue damage.

The Immunoglobulin A (IgA) dermatoses represent a classification of immune cutaneous disorders sharing the finding of IgA deposition on direct immunofluorescence at the site of histopathologic inflammation. Neutrophils are the predominant inflammatory infiltrate in the skin in this group of diseases and dapsone is generally an effective pharmacologic agent.

Immunoglobulin A

IgA is abundantly found in the mucosal secretions of the respiratory, gastrointestinal and genitourinary tracts where it neutralizes pathogens; however, it is also present in human serum at a concentration second to that of IgG. This presence implies an immunologic function in the serum; however, this has yet to be elucidated [1].

There are two subclasses of IgA: IgA1 and IgA2. IgA1 is produced by the bone marrow and is found in higher quantities than IgA2 in the serum. IgA2 is found in high quantities in the secretions of the lungs, gastrointestinal and genitourinary tracts and accounts for 60–70 % of the total output of antibodies in the body [2]. Secretory IgA (S-IgA) is a dimer held together by a J chain with a polypeptide that is produced in mucosal lymphoid tissue by antigen-stimulated B cells and is transported to the apical epithelial border by a polymeric immunoglobulin receptor (pIgR). Once at the border of the mucosal cell, S-IgA is proteolytically cleaved and IgA is secreted into the lumen. This pIgR also transports secretory IgM into intestinal secretions [2]. Secretory IgA is the key defense mechanism preventing microbes from gaining access to the mucosae by coating them and preventing adherence. Additionally, the FcaR1 receptor, uniquely present on neutrophils, eosinophils, and monocytes activates antigen presentation, endocytosis, antibody-dependent cell-mediated cytotoxicity (ADCC), the respiratory burst and degranulation in the skin leading to the clinical findings of these diseases [2].

General Features of Immunoglobulin A Dermatoses

Microscopic examination of cutaneous histology reveals a neutrophil-predominant inflammatory infiltrate consistent with the IgA immune response. Because eosinophils and macrophages also have FcaR1, these immune cells can also be found scattered throughout the tissue. The main therapeutic agent for these dermatoses remains dapsone, an effective weapon against neutrophil activity, including inhibiting adhesion, chemotaxis and production of myeloperoxidase for the respiratory burst [3].

Dermatitis Herpetiformis

Dermatitis herpetiformis (DH) is unique among autoimmune diseases because there is a known human antigen – epidermal transglutaminase or transglutaminase 3 (TG3), a known human antibody – IgA and a known cause dietary gluten and celiac disease.

Dr. Louis Duhring first described DH in 1884. Patients develop an eruption of intensely pruritic, symmetrical inflammatory papules and papulo-vesicles on the extensor surfaces of the bilateral upper and lower extremities, as well as the scalp and buttocks and in areas of pressure or trauma such as the belt line. The vast majority of patients have associated celiac disease (CD), also referred to as gluten-sensitive enteropathy. Only 15–20 % of cases have gastrointestinal symptoms, but virtually all patients respond over time to dietary gluten restriction with healing of both the cutaneous and intestinal pathology. DH responds well to dapsone alone; however, symptoms recur in 48–72 h if dapsone is discontinued. Dietary gluten restriction produces a long-term remission but DH usually recurs in weeks to months if a gluten containing diet is resumed.

Epidemiology

DH occurs more frequently in patients of northern European descent. Incidence rates in northern Europe are between 0.4 and 3.5 per 100,000 people per year. Prevalence rates are between 1.2 and 75.3 per 100,000 people. One Finnish study found that the incidence of DH decreased over three successive decades beginning in 1970 possibly due to citizens having increased awareness of the association between gluten consumption and subclinical celiac disease [4].

A population-based study in Utah found incidence and prevalence rates similar to those reported in Europe, likely related to the high proportion of residents of northern European descent. In 1987 the incidence of DH was 0.98 per 100,000 people per year and the prevalence was 11.2 per 100,000 people [5].

Most epidemiologic studies report an increased frequency in males compared to females, ranging from 1.1:1 to 1.9:1. The cause of this male predominance has not been further illuminated [4].

Individuals of all ages may be affected; however, DH is uncommon in children and most patients develop it in the fourth or fifth decade of life [4].

Like CD, DH is associated with specific human leukocyte antigen (HLA) genes, HLA-DQ2 or HLA-DQ8 haplotypes [6]. One comparative study of 50 subjects with DH and 290 healthy controls found that 86 % of the patients with DH carried the HLA-DQ2 gene compared with 35 % of the healthy controls. Additionally, six of the seven DH patients without the HLA-DQ2 gene were positive for the HLA-DQ8 gene [7]. These HLA genes allow antigen presenting cells to recognize the alpha-gliadin antigen in wheat and other prolamins in rye and barley with the subsequent T cell response.

Additional support for the genetic contribution to DH is revealed in familial studies demonstrating that first-degree relatives of patients with DH have an increased risk for DH and celiac disease [8]. In a Finnish population of over 1000 patients with DH and celiac disease, 4–6 % of patients had a first-degree relative with DH and celiac, respectively [9].

Pathogenesis

Granular IgA deposition in dermal papillae is the hallmark of DH. DH has a complex pathogenesis, stemming from both intrinsic and extrinsic factors. DH virtually always occurs in genetically susceptible individuals as described above, and usually remits with a gluten-free diet.

Greater than 90 % of DH patients have small bowel biopsy findings consistent with a gluten-sensitive enteropathy, including varying degrees of atrophy of the jejunal villi, crypt hyperplasia and a lymphocytic and plasma cell infiltrate in the lamina propria and within the mucosal epithelium. These findings are indistinguishable from the findings in CD and span the entire gamut of CD histopathologic severity (Marsh grades 0–3). DH is best regarded as a cutaneous manifestation of CD. Up to 80 % of CD and DH patients have the histopathologic abnormality of gluten sensitive enteropathy but do not have classical gastrointestinal complaints of abdominal cramping, gas, bloating and diarrhea.

Gluten is a group of proteins in wheat, rye and barley that is not water-soluble. Prolamins are the alcohol-soluble portion of gluten and include gliadin in wheat, secalin in rye and hordein in barley. These peptides fit in the HLA determined antigen groove of antigen presenting cells. The protein is then deamidated by tissue transglutaminase (tTG or TG2), a calcium-dependent enzyme that also catalyzes crosslinking between glutamine and lysine protein residues and forms covalent bonds with gliadin. This deamidated gliadin and the bound tTG are key antigens in the pathogenesis of the disease and are used in diagnostic testing [10]. The deamidated peptide is then recognized by T helper (Th) cells. These activated Th cells produce proinflammatory cytokines and matrix metalloproteinases (MMP) that damage the intestinal mucosa and produce antibodies from B cells against tTG. Cutaneous manifestations of this inflammatory state are possibly mediated through epitope spreading. Epitope spreading occurs when the immune response from an endogenous antigen or multiple antigens spreads to self-antigens through the release of self peptides from tissue damage, mediated by self-reactive T helper 1 cells reacting against a chronic inflammatory state from endogenous antigens [11]. The antibodies that are produced from this process may bind and form an antigenic complex to epidermal transglutaminase (TG3). The IgA TG3 antibodies reach the dermis through the bloodstream and bind to TG3 produced by overlying epidermal cells. The TG3 enzyme continues to be enzymatically active and crosslinks IgA to surrounding dermal connective tissue. This deposition of immune complexes then stimulates an inflammatory state leading to cutaneous blistering from the recruitment of neutrophils, neutrophil chemotaxis and proteolytic cleavage in the lamina lucida of the basement membrane zone [12–14].

Clinical Features

The hallmark feature is the development of multiple intensely pruritic vesicles and papules, grouped in herpetiform arrangement, on the elbows, dorsal forearms, knees, scalp, back and buttocks; however, erosions, papulo-vesicles and excoriations are more readily found on exam and urticarial plaques may occur (Fig. 34.1a, b). Fully developed vesicles are rare and bullae are extremely uncommon.

Patients with mild disease usually have involvement of the knees, elbows and dorsal forearms. Those patients with severe disease usually present with additional involvement of the trunk and extremities. Lesions also frequently occur in areas of pressure such as the belt line. Although the skin generally heals without scarring after resolution of the symptoms, post-inflammatory hyperpigmentation may occur [10].

Other uncommon cutaneous findings are petechiae on the fingers or palms, mainly occurring in children, but also found in adults [15, 16]. Occasionally, these palmar lesions are the primary manifestation of the disease [17].

DH may also occur in the oral mucosa; however, this has not been confirmed through direct immunofluorescence microscopy, and in some cases may have been aphthous stomatitis that is known to be an oral manifestation of CD [10]. Mucosal and tongue involvement may occur as vesicles, erosions or erythematous macules with or without discomfort.

Fig. 34.1 Dermatitis herpetiformis. (**a**) Excoriated papules and papulo-vesicles on elbows and knees of a DH patient. (**b**) Urticarial plaques of DH

An additional association with celiac disease reveals itself in tooth enamel defects, such as horizontal grooves, pits or discoloration [18]. One study supporting this reported that in 30 adults with DH, 53 % had enamel defects compared with 2 % of 66 healthy controls [19]. One small study of ten children compared to healthy children controls showed eight had enamel defects while only 13 % of healthy children had similar defects [20].

Associated Diseases

The most common associated condition is autoimmune thyroid disease, with hypothyroidism being more likely [21–23]. One retrospective study of 264 adults with DH revealed that 11 % had thyroid disease [22].

Type 1 diabetes mellitus is also associated with DH with estimates between 2 and 5 % [10]. Pernicious anemia has a slightly higher frequency in patients with DH, ranging between 1 and 3 % [21].

An increased risk for non-Hodgkin lymphoma has reportedly been associated with celiac disease and this may also occur in DH [24]. One Swedish population-based study with 1354 patients with DH revealed a slight increased overall risk for malignancy (standard incidence ratio [SIR] 1.2, 95 % CI 1.0–1.4), due to increased cases of lymphoma and leukemia [25]. The effect of adherence to a gluten-free diet on the reduced risk for lymphoma was reported in one retrospective study in the United Kingdom; however, more studies are necessary to demonstrate the link between gluten-free diets and reduced risk of malignancy in DH. There is an increased risk of malignancy in CD, so it is likely that with a big enough sample size, a similar risk would be documented in CD's cutaneous manifestation, DH [25].

Additional autoimmune diseases with a possible increased frequency are alopecia areata, Addison's disease and vitiligo [21, 26].

Diagnosis

Confirming the diagnosis of DH through laboratory studies is essential, through histopathology of lesional skin, direct immunofluorescence microscopy (DIF) of perilesional skin and serologic studies. DIF is the gold standard test for diagnosis.

A 4 mm punch biopsy of a small intact vesicle is best for hematoxylin and eosin (H&E) staining. If there are no intact vesicles, involved erythematous skin is better than excoriated lesions, as these lesions may yield nonspecific results.

Findings on H&E staining vary with the age of the sampled lesion. Early lesions may show only a neutrophilic

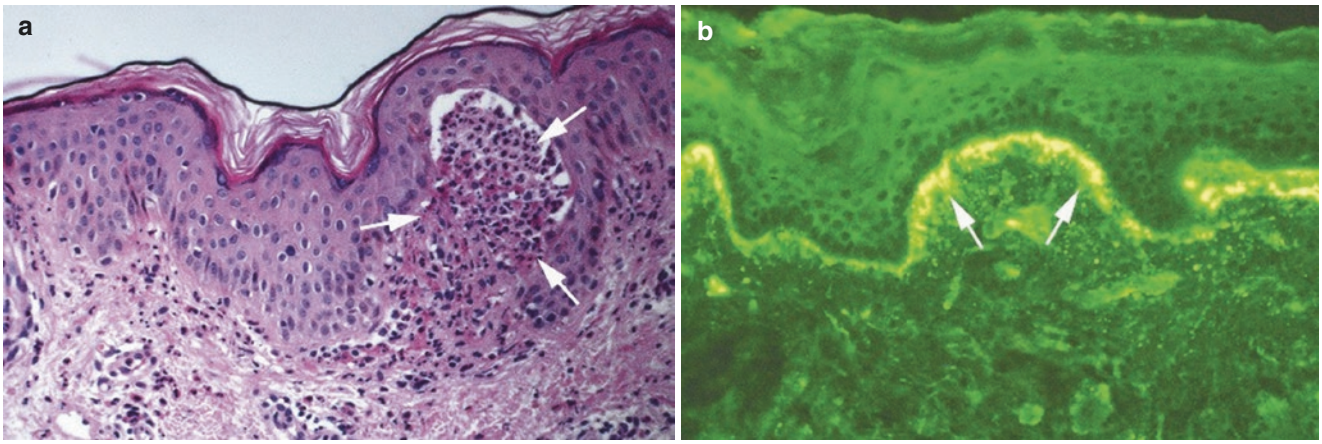

Fig. 34.2 Dermatitis herpetiformis. (**a**) Neutrophils in dermal papillary tips (*arrows*) on hematoxylin and eosin staining of biopsy from involved skin. (**b**) Granular IgA in the papillary dermis (*arrows*) with focusing of grains in dermal papillae from perilesional, clinically normal-appearing skin

infiltrate, with or without eosinophils, and papillary microabscesses, which are neutrophils in the tips of the dermal papillae (Fig. 34.2a) [27]. After 48 h, lesions on H&E show subepidermal vesiculation at the dermal tips which over time bridge to form larger subepidermal vesicles, containing neutrophils, eosinophils and fibrin. Additionally, the dermis shows a perivascular lymphocytic infiltrate with neutrophils and eosinophils [27].

The characteristics of DH on H&E histopathology are similar to other subepidermal bullous disorders. DH can be particularly difficult to distinguish from linear IgA bullous dermatosis, bullous systemic lupus erythematosus, and even bullous pemphigoid; however, numerous eosinophils are usually present in pemphigoid [27].

A punch biopsy for DIF must come from perilesional, clinically normal-appearing skin immediately adjacent to a lesion as biopsies taken from lesional skin are more likely to yield false negative findings [28]. The characteristic finding is granular deposits of IgA in the dermal papillae (Fig. 34.2b). DH may also show deposits of IgM, fibrinogen and C3 in a similar pattern [27]. A fibrillar pattern of IgA deposition is found occasionally rather than a granular one [29]. A retrospective study of 264 patients with DH found the DIF was positive in 92 % of patients (244) [21]. Of note, the DIF may be negative in patients on a strict gluten-free diet as this reduces IgA deposits in the skin. One retrospective series found that 10 of 41 patients with DH on a strict gluten-free diet after 13 years did not have detectable IgA deposition in the skin [30]. Treatment of DH with dapsone alone does not alter the findings of IgA deposition on DIF [10].

At times, granular deposits of IgA along the basement membrane appear on DIF, which may confound the diagnosis with linear IgA bullous dermatosis; however, the sharp linear IgA deposition usually separates the two disorders [6, 31]. In these instances, indirect immunofluorescence testing for basement membrane antibodies of linear IgA disease and serologic testing for IgA antibodies to TG2 and TG3 in DH may aid in clarification of the diagnosis. The same testing is useful in the extremely rare occasions when the DIF findings are equivocal or negative [32]. Additionally, these levels fall when a strict gluten-free diet is followed serving as a useful tool for monitoring response and adherence to this diet. Lastly, another useful serology in the evaluation of patients with DH is a serum total IgA level for detecting partial IgA deficiency, which occurs at an increased frequency in celiac disease. Such patients may not show IgA autoantibodies; therefore, IgG tissue transglutaminase and endomysium are better markers for this occasion [10].

Treatment

A strict gluten-free diet is the most effective therapy for patients with DH; however, remission can take months to years [33]. The most effective pharmacologic agent is dapsone, which can resolve skin lesions and pruritus within 48–72 h [33].

Dapsone therapy in adults is started at 25–50 mg daily and slowly increased to 2 mg/kg daily based on response and tolerance to therapy, in association with adherence to a gluten-free diet. Adults on unrestricted diets may need between 50 and 150 mg daily for complete response [34]. Even at optimal dosing, mild eruptions of one to two new lesions per week are possible. These events do not warrant an increase in dose, rather a potent topical corticosteroid may be applied to the new lesions.

As dapsone is a sulfone antibiotic, mild asymptomatic side effects of this medication are expected in nearly all patients. Dapsone competitively inhibits dihydropteroate synthase, an enzyme involved in folic acid reduction; therefore, most patients will have some red blood cell (RBC) hemolysis. Patients with glucose-6-phosphate deficiency

(G6PD) should not take dapsone, as they are at increased risk for severe hemolytic anemia from oxidative stress. Testing for this deficiency is recommended before starting therapy.

Methemoglobinemia is another dose-related side effect of dapsone therapy. Methemoglobin, an oxidized form of hemoglobin, has a reduced ability to carry oxygen, leading to symptoms of hypoxia and anemia. Cardiovascularly-compromised patients may have symptoms even at low doses. Supplementation of these patients with antioxidants such as Vitamin E may theoretically help mitigate these effects.

Additional potential side effects include agranulocytosis and a hypersensitivity reaction. Agranulocytosis generally appears 2–12 weeks after commencement of dapsone. Surveillance through lab monitoring will detect early signs of this potentially lethal side effect, allowing discontinuation of the drug. Dapsone-associated hypersensitivity symptoms are a morbilliform cutaneous eruption with flu-like symptoms, including fever, lymphadenopathy, hepatitis and eosinophilia.

Because dapsone is associated with potential serious side effects, careful laboratory monitoring is crucial. Initial lab screening should include a complete blood count (CBC), liver and renal function panels, and G6PD screening. After initiation of dapsone, interval lab screening is recommended: CBC every 1–2 weeks for 1 month then every 1–3 months for 6 months; thereafter CBC and liver function should be checked every 3–6 months if dapsone is not increased during this time frame.

After 2–3 months of dapsone therapy and a gluten-free diet, dapsone can be tapered slowly. Reduction of 12.5 mg every 2–4 weeks is recommended.

For patients who are intolerant of dapsone, there are other sulfa-based drugs available, sulfasalazine and sulfapyridine. Sulfapyridine is not available commercially in the United States, but can be obtained through compounding pharmacies. Sulfasalazine is metabolized to sulfapyridine in the intestine; however, the level of active metabolite is more predictable when sulfapyridine itself is given [35]. Sulfapyridine dosing should be started at 0.5 g three times per day and increased up to 6 g daily for control of symptoms. Sulfasalazine should be dosed between 1 and 2 g daily [35]. Both medications have the potential adverse effects of agranulocytosis and hypersensitivity reactions, but not hemolysis. Adequate fluid intake and possible alkalinization of the urine with oral bicarbonate is also recommended to reduce the risk of drug-induced nephrolithiasis. As with dapsone, lab monitoring (CBC, LFTs and urinalysis) is recommended periodically.

Although adherence to a strict gluten-free diet is challenging, as gluten is hidden in many common foods, patients will benefit from this and will be able to decrease or discontinue medications. A 36-month study of 81 patients with DH on a gluten-free diet for 6–36 months and 49 patients with DH on a normal diet reported that 93 % of patients on a gluten-free diet achieved reductions in dapsone dosing versus 16 % of patients on a normal diet [36]. There are many resources for patients about gluten-free diets, including the Celiac Disease Foundation (www.celiac.org) and the Gluten Intolerance Group (www.gluten.net).

An additional adjunctive treatment for the pruritic skin lesions of DH is potent topical corticosteroids. These topicals are not effective monotherapy, and systemic glucocorticoids are generally ineffective.

Treatment of Children

Management of children is the same as for adults. They should follow a gluten-free diet and if necessary take dapsone 0.5–2 mg/kg/day [35]. As with adults, dapsone may be tapered as the gluten-free diet controls the disease.

Prognosis

Dermatitis herpetiformis is a chronic condition that requires life-long adherence to a gluten-free diet or treatment with dapsone. When gluten is re-introduced into the diet, symptoms may recur within weeks to months and when dapsone is discontinued, symptoms may appear within 2 days [37]. A small percentage of patients (10–15 %) may maintain remission despite the discontinuation of both dietary and pharmacological therapy [38].

Linear Immunoglobulin A Bullous Dermatosis

Linear IgA bullous dermatosis (LABD) or linear IgA disease is a rare, acquired idiopathic or drug-induced autoimmune subepidermal blistering disease. The main feature of this disease is the linear deposition of IgA at the dermo-epidermal junction. Distinguishing this from DH can be difficult, since similar clinical and histopathologic findings may occur; however, LABD is rarely associated with gluten-sensitive enteropathy and its sharp linear IgA deposition is easily distinguished from the granular IgA of DH by the experienced immunopathologist [39].

LABD occurs in both adults and children. In children, the disorder once known as chronic bullous disease of childhood is now recognized as the childhood form of LABD [40]. Adults may present with tense vesicles and bullae within erythematous annular plaques (Fig. 34.1b) or like DH as excoriated papules on the extremities, buttocks and face. Different from adults, children present clinically with

Table 34.1 Medications implicated in precipitating linear IgA bullous dermatosis

Drugs associated with linear IgA bullous dermatosis	
Common	Vancomycin
Multiple reports	Captopril
	B-lactams
	Cephalosporins
	NSAIDs
	Phenytoin
Isolated reports	Acetaminophen
	Amiodarone
	Atorvastatin
	Benazepril
	Candesartan/eprosartan
	Carbamazepine
	Furosemide
	Gemcitabine
	Interleukin-2
	Lithium
	Somatostatin
	Trimethoprim/sulfamethoxazole

widespread annular lesions with peripheral vesiculation on the lower abdomen, thighs and groin area [41]. The oral mucosa can be involved in both adults and children.

Epidemiology

Reported incidence rates range from less than 0.5–2.3 cases per million individuals yearly [42]. No predilection based on ethnicity or gender for LABD has been established [42]. LABD rarely occurs in neonates [43]. It can develop in children between the ages of 6 months and 10 years. The average age of onset in 25 affected children was 4.5 years [40]. Adults present with LABD later in life, with many cases occurring after age 60 [40, 42]. Drug-induced cases may occur at any age.

Risk Factors

There is no known inciting factor for most cases of LABD. Medications are suspected in multiple cases. The most common drug implicated is vancomycin [42]. Other reported associations are listed in Table 34.1.

Pathogenesis

A search for target autoantigens in LABD has been complicated, as studies of patient sera have shown varied results. LABD can be initially divided into subtypes based on ultrastructural location of IgA (sublamina densa type and lamina lucida type); however, overlap between the two types may occur. These can be established using basement membrane zone human salt-split skin and indirect immunofluorescence in cases where there is circulating IgA basement membrane antibody, since such separation occurs in the lower lamina lucida. Lamina lucida antigens will adhere to the epidermal side of the basement membrane separation and sub-lamina densa reactive antibodies will bind to the dermal side. In cases without circulating IgA basement membrane antibody, immunoelectron microscopy or basement membrane separation of the DIF-positive biopsy can be used to identify the type. In most cases this is unnecessary since treatment for both variants of LABD is the same.

The lamina lucida type predominantly targets a 97-kDa antigen and a 120-kDa antigen that are the proteolytic fragments of the extracellular portion of the bullous pemphigoid antigen 2 (BP180), a key epidermal-dermal adhesion transmembrane protein [44, 45]. Less frequently, LABD is associated with the NC16a epitope of BP180 [46–48]. The sub-lamina densa type of LABD has been reported to be predominantly type VII collagen, although a number of other antigens have been proposed [49]. Lastly, there is a subset of patients with features consistent with LABD who have both IgA and IgG antibodies against the basement membrane zone. A Japanese review of 213 patients with LABD found both antibodies in approximately 20 % of the cases [50].

Both humoral and cellular immunity may contribute to the pathogenesis of the lesions. Skin and mucosal findings may be the result of an antibody-induced local inflammatory response from the release of proteolytic enzymes by neutrophils and other inflammatory cells [42].

Clinical Manifestations

Patients generally present with lesions on the skin, or on the mucous membranes, or on both locations. Blister formation is sub-epidermal; therefore, the vesicles and bullae are typically tense, rather than flaccid as is found in pemphigus. Similar to DH, pruritus and scratching may leave only excoriations and erosions.

Adults and Children Manifest the Disease Differently (Fig. 34.3a–d)

Children often present with acute development of vesicles or bullae on sites of erythematous or normal skin. The distribution of these lesions is generally widespread, involving the face (usually the perioral area), trunk, genitalia, hands and feet. The lower abdomen, perineum and inner thighs may be the most intensely involved areas [40, 51, 52]. At the periphery of resolving lesions, new blisters often form, resulting in an arciform or annular configuration. These lesions are classically known as "string of pearls", "crown of jewels" or "rosettes" [53]. Children usually have pruritus, which can be severe, while other affected children may be asymptomatic. For some children, intense pruritus heralds relapse of their condition [54, 55].

Adults with LABD present typically with acute onset of skin lesions, rather than a gradual onset [41]. The lesions arise on uninvolved skin or within erythematous plaques. Adults generally do not develop the string of pearls lesions with peripheral vesiculation, but this may occur [41]. The general distribution of lesions in adults involves the face (also the perioral area, like children), trunk, extensor extremities and buttocks [42]. With the distribution including the

Fig. 34.3 Linear IgA bullous dermatosis. (**a**) Papulo-vesicles on the extensor forearms resembling DH. (**b**) Scattered tense vesicles with associated urticarial lesions. (**c**) Diffuse erythema and superficial vesicles in a case of vancomycin-induced LABD. (**d**) Scrotal and inguinal vesicles in childhood LABD

extensor extremities, this disease can be difficult to distinguish from DH. Additionally, localized variants of LABD presenting as limited eruptions of bullae or annular erythematous plaques have been reported in several different case reports [20, 56–62]. As with children, adults can also experience intense pruritus resulting in the development of excoriated papules or prurigo nodularis-like lesions [63, 64].

Mucosal Involvement

Adults and children can develop mucous membrane involvement. One study reported that up to 80 % of adults have mucosal lesions [40]; however, in children, estimates of mucosal involvement are varied. One study with 25 children from the United Kingdom reported 64 % had mucosal lesions [65]. Alternatively, two retrospective studies of similar sample size from Tunisia and Japan reported only 8–3 % involvement, respectively [66].

Infrequently the mucosa is the sole manifestation of LABD [67–70]. In these cases, mucosal-predominant LABD is considered a form of cicatricial mucous membrane pemphigoid [48].

Erosions or ulcers are the primary mucosal lesions as it is rare to find intact vesicles or bullae. Affected sites include any mucosal surface of the body, including the ocular conjunctivae, oro- and nasopharynx, larynx, esophagus, vagina and anus, with the ocular and oral mucosae being the most common sites [40–43]. Within the oral mucosa, the lesions are frequently found on the palate, palatine arches and buccal mucosae [42]. Additionally, erosive gingivitis and cheilitis may occur as manifestations of mucosal LABD [40, 70]. Ocular symptoms manifest as erythematous conjunctivae, discharge, pain or a foreign body-like sensation [65]. Occasionally, patients develop symblepharon and ectropion, thus the disease is essentially an IgA variant of ocular pemphigoid [71]. Mucosal scarring can lead to serious adverse sequelae, including corneal damage leading to blindness, airway obstruction and esophageal strictures [71–73].

Drug-induced and Idiopathic LABD

Medications are often causes of LABD. Vancomycin is the most common offending medication; however, over 20 other medications have also been linked to it. Other antibiotic classes in this list are beta-lactams and cephalosporins. Nonsteroidal anti-inflammatory medications and acetylcholinesterase inhibitors, such as captopril, have been cited in case reports (Table 34.1). The idiopathic form of LABD does not differ significantly from the drug-induced form [42]. Presentations of both of these forms of LABD can be with localized involvement rather than widespread. They may or may not involve the mucosa [42]. They can be morbilliform eruptions. They can even resemble erythema multiforme or toxic epidermal necrolysis [29, 74–79]. Therefore, one should consider drug-induced LABD in the differential diagnosis when evaluating a patient with possible toxic epidermal necrolysis.

The similarities between drug-induced LABD and idiopathic LABD were evaluated in a retrospective study of 16 patients presumed to have spontaneous LABD and 12 patients presumed to have drug-induced LABD. This study found closely associated frequencies in both groups of erythematous plaques, string of pearls-like configurations, target lesions and mucosal involvement [29]. The drug-induced group contained a higher frequency of patients with atypical presentations of large erosions and positive Nikolsky signs.

Adults are more frequently afflicted with drug-induced LABD; however, it has also been reported in children [20, 40, 42]. The onset of lesions generally begins within the first month of drug administration and then they resolve gradually over the ensuing several weeks [20, 80, 81]. Some patients may have the lesions persist beyond this timeframe. Furthermore, if the patient is re-exposed to the inciting medication, rapid reappearance of the lesions can occur [82].

Associated Disorders

The most common non-malignant disorder associated with LABD is ulcerative colitis (UC) [50, 83–87]. Two retrospective studies reported this possible association, one from the United Kingdom and one from Japan. The study from the UK found that of 70 patients, 5 patients (7 %) had LABD, and UC preceded the diagnosis of LABD by an average of 6 years [85]. The review from Japan of 213 cases of LABD found four patients with UC [50]. This association is not well elucidated. Some authors suggest that abnormal IgA1 production by the inflamed bowel may contribute to the development of LABD; however, even after removal of the colon, some patients continue to have recurrences of LABD, while others have the disease completely resolve [83, 85, 87].

Malignant disorders, lymphoproliferative and solid organ types have also been associated with LABD in multiple case reports [31, 58, 88–104]. Despite these reports, no retrospective analyses have been performed to confirm this association. Further studies may confirm this suspected link between LABD and certain malignancies.

Other conditions with reported associations to LABD include systemic lupus erythematosus [50, 105] and psoriasis [106, 107]. Lastly, there are reports of LABD following exposure to ultraviolet light [108].

Diagnosis

The histopathologic findings with hematoxylin and eosin staining of involved skin are identical to those of dermatitis herpetiformis, showing lymphocytes, eosinophils and papillary microabscesses [42, 55] (Fig. 34.4a). Other characteristic findings are a subepidermal blister with a diffuse underlying neutrophilic infiltrate in the dermis.

A biopsy of perilesional skin demonstrating linear deposits of IgA along the basement membrane zone on direct immunofluorescence (DIF) testing is the gold standard test for diagnosis (Fig. 34.4b) [55]. Indirect immunofluorescence

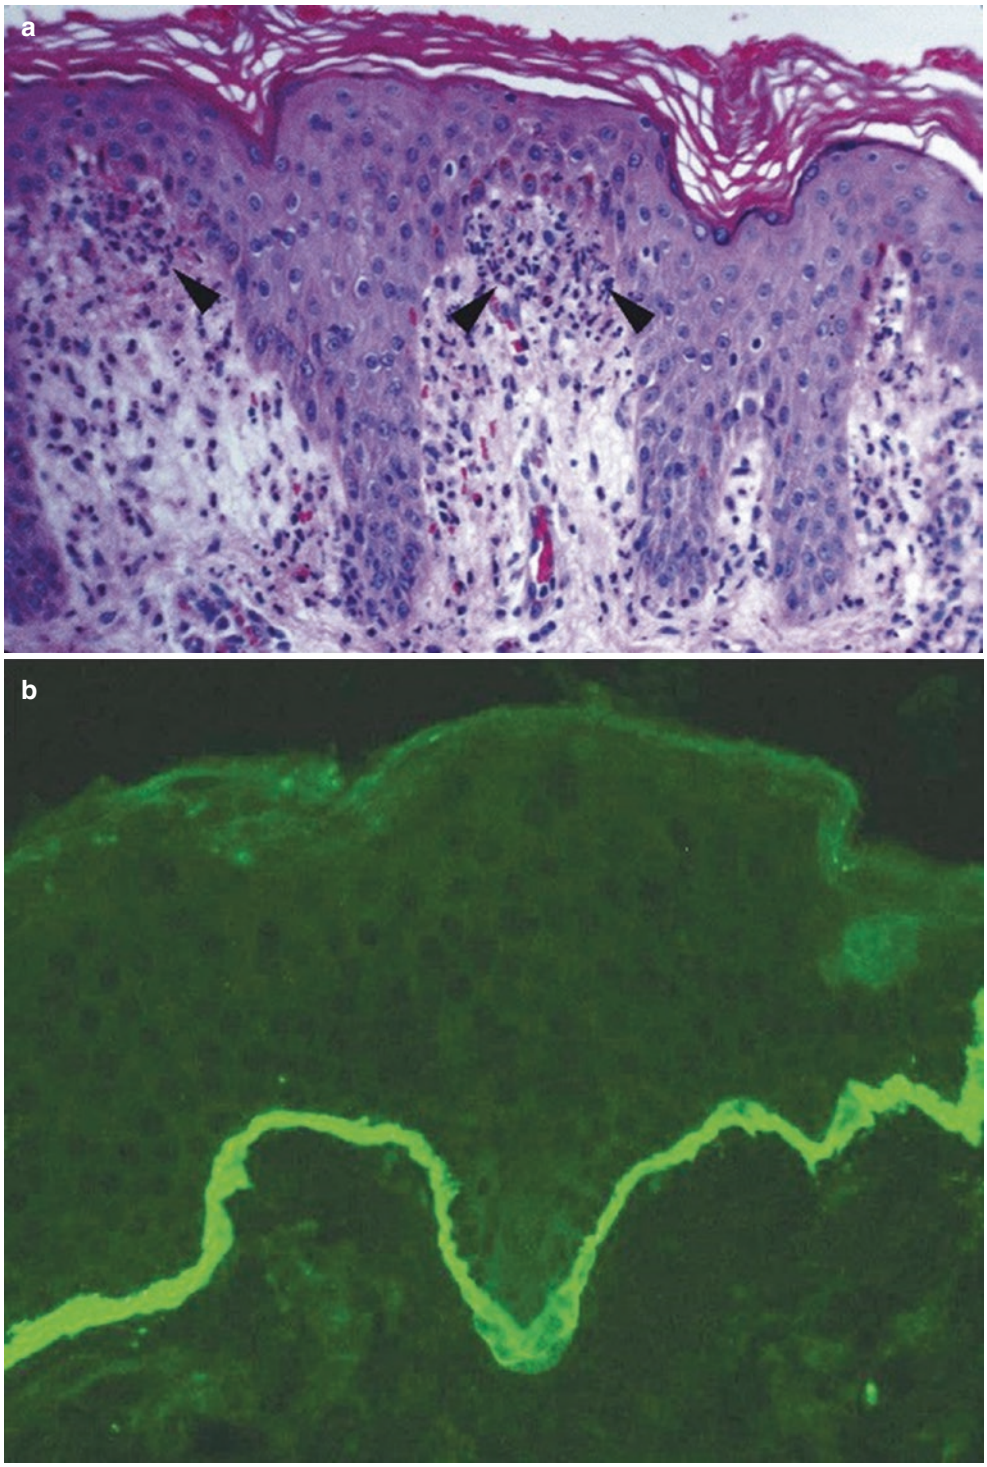

Fig. 34.4 Linear IgA bullous dermatoses. (**a**) Dermal papillary edema with a neutrophilic infiltrate (*arrowheads*) similar to DH. (**b**) Characteristic sharp linear IgA antibody deposition along the basement membrane zone

may be positive. Antibody binding on indirect immunofluorescence with basement membrane zone human salt-split substrate to the epidermal side of the induced cleavage zone is the most common location, while binding to the dermal side may occur in older patients or those who have both IgA and IgG deposits on the epidermal side of the basement membrane zone [50].

Treatment

The first-line medication therapy for LABD, as with DH, is dapsone [42, 52, 54, 55, 109]. Dapsone is started at a low dose, less than 0.5 mg/kg daily for children and 25–50 mg in adults. Gradually this dose is titrated upward over several weeks, depending on tolerance and treatment response [110]. This response can be immediate, resolving lesions within a few days of initiating therapy; however, some patients with more extensive disease and incomplete response to dapsone may need oral corticosteroids to accelerate improvement and effectively suppress the lesions [41, 54, 66, 111]. When patients need longer periods of immunosuppressive therapy or patients with predominantly mucosal involvement need more aggressive therapy, steroid-sparing agents can be effective, such as mycophenolate mofetil, azathioprine, intravenous immunoglobulin (IVIG), cyclophosphamide and rituximab [57, 111–122].

For patients who cannot tolerate dapsone, sulfapyridine or sulfamethoxypryridazine may be effective second-line therapies. Evidence for this is limited to reports from specialists in the field, as prospective therapeutic trials have not been performed to confirm this [42, 54, 55, 110, 123]. Sulfamethoxypyridazine is not available in the United States and sulfapyridine is only available through compounding pharmacies. The adult dosing range is 1000–1500 mg daily of either agent [54]. The sulfapyridine dosing range for children is 15–60 mg/kg daily [42, 55]. There is not an established dosing range for sulfamethoxypyridazine in children [42]. Both of these medications have been used in combination therapy with dapsone [55, 123, 124].

Colchicine can be effective in children with LABD. Some case reports and case series have shown it to be a reasonable substitute therapy for dapsone [111, 125–127]. In a series of eight children with systemic glucocorticoid-refractory LABD, the addition of colchicine led to dramatic improvement in five patients within 4–6 weeks. Furthermore, these children were able to taper off steroid therapy. The typical dosage in children is 0.6 mg twice daily.

Adults have also responded to colchicine according to some reports [56, 128]; however, other authors have not seen such reported results [54]. The adult dose range for colchicine is 0.6–1 mg two to three times daily [42, 52, 111, 127].

Additional therapies that have been used for LABD include tetracycline in combination with nicotinamide and topical tacrolimus ointment. This therapeutic combination has been effective for the treatment of bullous pemphigoid and has been applied to LABD. Three adult patients with LABD reported disease resolution within a few weeks of starting therapy [129–131]. The dosing range for tetracycline and nicotinamide are 1000–1500 mg daily and 900–2000 mg daily, respectively. Children under age nine cannot take tetracycline due to the adverse effect on developing teeth. Additional studies will help to confirm the efficacy of this treatment.

Children with LABD may respond to systemic antibiotic therapy. The mechanism for efficacy is not known, whether it is due to anti-inflammatory or antibacterial properties, or another unknown action remains to be clarified. One case series reports that in seven children treated with flucloxacillin, all had complete resolution, but only four children stayed in remission off of therapy [132]. Additional antibiotics reported to effectively treat LABD in children are oxacillin, dicloxacillin, erythromycin, micocamycin and trimethoprim-sulfamethoxazole [48, 66, 133–139].

Potent topical corticosteroids may be used adjunctively to accelerate resolution of lesions on the trunk or extremities, while low potency topical steroid creams can be used on the face, genitals or intertriginous areas.

Lastly, drug-induced LABD typically resolves when the inciting agent is stopped; however, in severe or persistent cases, dapsone and/or prednisone may be used to achieve faster resolution. Therapy should be tapered off early in the treatment course, within 4–6 weeks, to ascertain whether the disease is still active, warranting continuation of systemic therapy. A prolonged treatment course rarely occurs in this disease.

Prognosis

Idiopathic LABD can persist from months to several years in adults, whereas in children, it typically resolves before puberty [40, 52, 54]. This disease can also prevail for a decade or even longer. It can also recur after long periods of remission [54]. This is in contrast to drug-induced LABD, which usually improves within a few days of cessation of offending drug and resolves within several weeks [80].

The treatment duration for idiopathic LABD is variable. Therapy is generally continued for several weeks after complete resolution of lesions and then gradually tapered off. If at any point lesions recur, the treatment medication should be restarted [54].

Cutaneous lesions typically heal without scarring; however, mucosal lesions may lead to stricture formation or conjunctival and corneal scarring. These sequelae can have a significant impact on patients' oral hygiene and nutritional status.

Immunoglobulin A Pemphigus

IgA pemphigus, with subtypes subcorneal pustular dermatosis-type IgA pemphigus and intraepidermal neutrophilic IgA dermatosis, is a blistering disorder characterized by autoantibodies against the desmosomal components of keratinocytes. Subcorneal pustular dermatosis (SPD) appears clinically to resemble Sneddon-Wilkinson disease and IgA cell surface staining locates to the upper epidermis on DIF. The intraepidermal neutrophilic IgA dermatosis (IEN), as the name implies, exhibits IgA cell surface staining throughout the entire epidermis [140].

Epidemiology

Because of the rarity of these disorders, not many cases have been reported and epidemiologic information is scant. Reports suggest that they can occur at any age and that females might be slightly more predisposed [140]. Most cases have appeared in the United States, Europe and Japan [141].

Pathogenesis

In contrast to IgG-mediated pemphigus vulgaris, IgA pemphigus is an IgA-mediated anti-keratinocyte cell surface autoantibody disorder [142]. As stated above the target antigen in the SPD type is desmocollin 1, a calcium-dependent transmembrane glycoprotein of the cadherin family within the desmosomes [142, 143]. The target antigen in IEN has not been completely elucidated and studies have shown varying targets. Several patients have shown autoantibodies against desmoglein 1 and 3; however, when viewed through immunoelectron microscopy, the targets have been unidentified non-desmosomal transmembrane proteins [142, 144–147].

Clinical Features

Both types of IgA pemphigus are characterized by the subacute development of vesicles that evolve into pustules on erythematous plaques, usually distributed across the trunk and proximal extremities [140]. Other sites of involvement are the scalp, postauricular skin and intertriginous areas, while the mucous membranes are generally spared [48]. Pruritus may or may not be present, but can be pronounced if it is. Patterns of configurations may be herpetiform, annular or circinate [140]. Because the SPD type of IgA pemphigus so closely resembles Sneddon-Wilkinson disease, DIF must be performed to distinguish the two disorders.

Diagnosis

The diagnosis of IgA pemphigus is made through all tools available to the clinician, including clinical, histological, immunopathological and serological findings. Histological features are intraepidermal pustules and clefts with microabscesses in the subcorneal region for SPD and throughout the epidermis for IEN. There is a neutrophilic infiltrate in the epidermis and dermis with sparse or no acantholysis, especially in IEN [27].

DIF studies of perilesional skin reflect H&E findings in that intercellular IgA staining is located in the upper epidermal layers in SPD and throughout the epidermis in IEN. Weak intercellular IgG and/or C3 deposits may also be present [140]. IIF studies on monkey esophagus show expected intercellular IgA deposits, with testing positive about 50% of the time [140].

Additional tests used to identify circulating IgA autoantibodies to desmocollin 1 are immunoblotting, ELISA using recombinant desmocollin, and immunofluorescence molecular assay using desmocollin-transfected COS-7 cells (monkey fibroblast-like kidney cells), which are performed only in research laboratories at this time [48, 143, 148]. In one series of 22 patients, ELISA tests showed positive autoantibodies to desmoglein 1 in three patients and desmoglein 3 in one patient [142]. All four patients had either the IEN subtype of IgA pemphigus or even clinical and histological features of pemphigus foliaceus. Ten of the 22 patients had the SPD subtype, and they did not have autoantibodies to the desmogleins, rather they had autoantibodies to desmocollin 1 in COS-7 cells [142].

Treatment

As with all other IgA dermatoses, dapsone is the first-line therapy in both subtypes of IgA pemphigus; however, it is not always effective and response to treatment is varied, with the SPD type being more resistant to therapy [149]. Dapsone doses range between 75–100 mg for initial disease control and may be tapered down for maintenance therapy. Colchicine may also be used if dapsone is not well tolerated [150]. The SPD subtype is generally more recalcitrant to treatment. In these cases, isotretinoin or acitretin may be used alone or with dapsone as combination therapy [151]. For patients with the IEN subtype who fail dapsone monotherapy, oral steroids may be added in concert with dapsone. Occasionally, patients may need more aggressive immunosuppressive therapy with a monoclonal antibody, adalimumab, or mycophenolate mofetil [140, 152]. High potency topical corticosteroids may be used adjunctively with oral therapy.

Immunoglobulin A Vasculitis (Henoch-Schönlein Purpura)

Henoch-Schönlein Purpura (HSP), now also defined as IgA vasculitis (IgAV), is a leukocytoclastic small vessel vasculitis of the dermis that occurs most commonly in children after a precipitating infection or drug reaction [153]. The hallmark manifestations of the disease are the tetrad of palpable purpura, arthralgias, abdominal pain and glomerulonephritis. Although IgA deposition can occur in other isolated cases of small vessel vasculitis and secondarily in other associated diseases with small and large vessel vasculitis involvement, such as systemic lupus erythematosus, Sjögren's syndrome, rheumatoid arthritis and polyarteritis nodosa, HSP is the only disease that occurs because of the primary deposition of IgA complexes in the vessel walls [154–156]. Its manifestations are caused by this IgA deposition. The disease is generally self-limiting; however, protracted cases do occur and recurrences can happen. Adults can also manifest the disease after an inciting infection or drug reaction or for no identifiable reason.

Epidemiology

Children develop HSP most frequently between the ages of 3 and 12 years [157]. The annual incidence rates range from 3 to 26.7 per 100,000 for children and infants and from 0.8 to 1.8 per 100,000 for adults [157]. A population-based study from the United Kingdom showed a peak incidence for children between the ages of 4 and 7 years old. Adults appear to contract the illness between 45 and 50 years old; however, it has occurred in patients up to the age of 86 years [158–160].

HSP shows a slight predilection for males, with male-to-female ratios of 0.9–1.8 in children and 1.7–2.4 in adults [157–160]. Ethnic population studies reveal an increased frequency in white and Asian children and decreased frequency in blacks [157, 161]. Additionally, patients with familial Mediterranean fever have a significantly higher incidence rate for HSP [157, 162, 163].

Many epidemiological studies have shown a seasonality to the disease in children, with a prevalence for the fall and winter seasons and abatement in the summer [157]. This trend may be due to the association of HSP with increased winter-triggered upper respiratory infections in children [159]. Studies show that 30–65 % of IgA vasculitis cases develop after an upper respiratory infection [157, 164–168]. This seasonal association is not borne out in studies of adult cases; furthermore, no clear variations to the disease incidence have been illuminated [157]. Some epidemiologic studies have shown a possible association with preceding or concurrent malignancies; however, further studies are necessary to elucidate this possibility [157, 169–173].

Genetic factors have been investigated for predisposing and protective susceptibilities in the human leukocyte antigen (HLA) region. Two independent patient cohorts found an increased risk of HSP in patients with HLA-DRB1*01, HLA-DRB1*11, HLA-B35 and HLA-A11 alleles, while patients with HLA-DRB1*07 alleles in Spanish and Italian populations were found to be protected from HSP [6, 47, 157, 174–176].

Pathogenesis

IgAV is classified as a leukocytoclastic vasculitis due to the involvement of small vessels within the papillary dermis, generally the postcapillary venules. Neutrophils and monocytes are the main inflammatory infiltrate. Although the definitive role of IgA in the pathogenesis of HSP remains undefined, IgA deposition occurs within the small vessels of the affected organs, as evidenced on histological examination. Immunofluorescence staining reveals IgA, C3 and fibrin in these vessels. Additionally, infections and medications are the purported triggers for HSP; however, this has also not been completely clarified. Many studies have shown that immunologic, genetic and environmental components are involved [177–179].

IgA1, predominant in serum, is the main IgA antibody present in HSP. One theory regarding why this is found posits that abnormal glycosylation of the IgA1 hinge region would allow aggregation and large complexes to form [180]. Additional theories from research regarding the pathogenesis of IgAV include a role for IgA anticardiolipin antibodies, IgA rheumatoid factor antibodies and beta-2 glycoprotein 1 antibodies; however, more studies are needed to validate these potential contributors [181–185].

Clinical Features

The classic tetrad of HSP is palpable purpura, abdominal pain, arthralgias and glomerulonephritis. The palpable purpura generally occurs on the dependent areas of the body, starting on the bilateral lower extremities and extending up to the buttocks and back. Development of all the features is usually a subacute onset over days to weeks, with purpura and arthralgias presenting initially.

Skin manifestations are present in nearly 100 % of the presentation; however, the purpura may not always be the first sign. The rash generally appears with petechial, macular or even urticarial lesions that evolve shortly into palpable purpura, some with necrotic centers. Retiform plaques of purpura are common and characteristic (Fig. 34.5a, b). Sometimes, acral, scalp and facial edema accompany the rash.

Fig. 34.5 IgA vasculitis (Henoch-Schonlein Purpura). (**a**) Confluent purpura on the foot. (**b**) Characteristic irregular plaques of retiform purpura

Some children have presented initially with abdominal pain and arthralgias, making the diagnosis of HSP more difficult. One review of the literature over a 5 year period reported this presentation occurring 15 % of the time [186]. The arthralgias typically involve the joints of the lower extremities and rarely the upper extremities [164, 186, 187]. Edema and pain accompany the joint pain. Chronic sequelae of the arthralgias are rare.

Gastrointestinal complications can range from mild pain, nausea and vomiting to extreme cases of gastrointestinal hemorrhage, ischemia and necrosis, as well as intussusception and perforation. If symptoms are not initially present, they manifest generally within a week of onset of the purpura. Rarely, abdominal symptoms are the sole manifestations of HSP without rash [188–190]. Although intestinal symptoms can be mild, testing confirms that mucosal injury is generally

present with heme-positive stools and other findings to suggest involvement [191]. In cases when intussusception is suspected, an ultrasound rather than a contrast enema is the initial screening test. Intussusception related to HSP involves the small bowel in about 60 % of cases, where as idiopathic intussusception usually involves the ileocolic region [192]. Contrast enemas can reliably detect idiopathic intussusceptions but not those involving the small bowel as well. Adults rarely develop intussusception.

Hematuria with or without proteinuria heralds renal involvement in HSP cases, which is seen in about 20–54 % of children and adults, with adults and older children manifesting it more frequently [187]. When renal involvement occurs it is a potential sign of long-term morbidity associated with HSP. One French study showed that of 250 patients with HSP, one-third had renal insufficiency within 4 months and that almost 15 years later, 80 patients (32 %) continued to have renal impairment, 27 (11 %) of whom had end-stage renal failure [160].

Diagnosis

Diagnosis of HSP or IgAV is usually a clinical one, owing to the classic tetrad of symptoms described above; however, confirmatory diagnostic tests with skin biopsies for H&E and DIF are recommended, especially with unusual presentations.

Histology of skin with H&E staining reveals classic leukocytoclastic vasculitic findings of fibrin deposition and a predominant neutrophilic inflammatory infiltrate in vessel walls. Direct immunofluorescence of lesional skin shows IgA and C3 deposition in the vessel walls. It is essential that early lesions be biopsied (less than 48 h old and pink in color rather than black or necrotic lesions), since severe inflammation in a lesion will destroy the diagnostic IgA epitopes [193].

When renal biopsies are performed, H&E staining demonstrates a range of isolated mesangial proliferation to crescentic glomerulonephritis. DIF reveals IgA deposition in the mesangial cells.

Laboratory testing should include a CBC with differential, renal function tests and a urinalysis to evaluate for hematuria and proteinuria. Abdominal imaging should be based on severity of symptoms. Because HSP is typically self-limiting, supportive or symptomatic care is usually all that is needed. Children and adults with renal involvement should be referred to a nephrologist for monitoring of resolution.

Treatment

There is much debate regarding the use of glucocorticoids in HSP; however, patients with severe enough symptoms that they cannot manage their oral intake, ambulate without difficulty or perform their activities of daily living may benefit. Dosing regimens should be between 1 and 2 mg/kg, with a maximum daily dose of 60–80 mg daily. Many studies, both retrospective reports and randomized trials, examined whether steroids were beneficial and the only benefits found were reduction of the duration of abdominal pain and development of chronic renal disease [194, 195]. Many authors do not recommend routine glucocorticoid therapy for all patients [196–198].

There are case reports demonstrating efficacy of dapsone in adults with chronic cutaneous involvement. Lesions disappeared with initiation of dapsone; however, they recurred once it was stopped [199–203].

Conclusion

Immunoglobulin A dermatoses represent a distinct but diverse category of immunologic skin diseases. They all have IgA deposition in the skin as their unifying characteristic, which leads to unique clinical presentations based on the pathophysiologic process within the skin. Because neutrophils are able to express the unique IgA receptor (FcaR1), they are the predominant infiltrate in the epidermis and dermis, which also leads to tissue damage mediated through their proteolytic actions. Lastly, owing to the effectiveness of sulfone therapy, dapsone and its related medications are the first-line treatment for this group of dermatoses.

Questions

1. What are the common findings in the skin for all of the IgA dermatoses?
   A. Cutaneous deposition of IgA at the histopathologic site of inflammation on direct immunofluorescence microscopy and a neutrophilic inflammatory infiltrate on hematoxylin and eosin staining of involved skin

2. Where is IgA found in the body?
   A. IgA is found in respiratory, gastrointestinal and genitourinary mucosal secretions, as well as human serum

3. What is the name of the IgA receptor common to these disorders?
   A. FcαR1

4. What are some of the cutaneous findings in these conditions?
   A. Bullae, vesicles, papules and pustules

5. What is the main therapy for the IgA dermatoses?
   A. Dapsone

The Pemphigoid Spectrum

35

Donna A. Culton, Zhi Liu, and Luis A. Diaz

Abstract

The pemphigoid spectrum represents a group of blistering diseases of the skin defined by autoantibody formation against components of the hemidesmosome that collectively comprise the basement membrane zone. These autoantibodies along with complement are detected in perilesional tissue of affected individuals by direct immunofluorescence. Autoantibodies can also be detected in the sera in some individuals by indirect immunofluorescence and ELISA studies. Histology shows a subepidermal split with variable inflammatory infiltrate in the upper dermis. There are several variants of pemphigoid with unique clinical manifestations. Treatment is aimed at suppressing the misguided immune response through the use of topical and/or systemic steroids and immunosuppressive agents.

Keywords

Bullous pemphigoid • Cicatricial pemphigoid • Mucous membrane pemphigoid • Herpes gestationis • Pemphigoid gestationis

Key Points

- Bullous pemphigoid is a subepidermal autoimmune blistering disease of the skin, and is predominantly a disease of the elderly in its classical presentation.
- There are distinct clinical variants of this disease (bullous pemphigoid, cicatricial pemphigoid, and pemphigoid gestationis).
- The autoimmune response in BP is directed against two hemidesmosomal antigens, BP180 (collagen XVII or BPAg2) and BP230 (BPAg1).
- The diagnosis is based upon clinical findings, histology and immunofluorescence (direct and/or indirect immunofluorescence).
- Therapy includes topical and/or systemic corticosteroids along with immunosuppressive agents depending on the extent of disease.

Bullous Pemphigoid

Overview

Bullous Pemphigoid (BP) is a subepidermal autoimmune bullous disorder and is the most common adult bullous disorder. BP typically occurs in elderly patients and presents with generalized pruritic tense bullae, with rare involvement of the mucous membranes. The pathogenesis of BP has been clarified by advances in the field of immunodermatology, which have also aided in diagnosis of atypical cases. Therapy focuses on immunosuppression to attenuate the autoimmune response.

Historical Background

BP was first described by Lever in 1953 as a subepidermal bullous dermatosis seen in elderly individuals [1]. Based on histologic evaluation, BP was characterized by detachment of the epidermis and an intense inflammatory cell infiltrate in the upper dermis. Jordon and Beutner discovered anti-skin

A.A. Gaspari et al. (eds.), *Clinical and Basic Immunodermatology*, DOI 10.1007/978-3-319-29785-9_35

autoantibodies in BP patients, present in the serum and bound to the dermal-epidermal junction in a linear fashion [2]. Further specification of the anti-skin autoantibodies was provided by Stanley et al., with the characterization of antibodies against a 230-kD epidermal protein within the sera of BP patients [3]. Subsequently, Mutasim et al. described that BP autoantibodies localize to hemidesmosomes, and Labib et al. described the binding of BP autoantibodies to an 180-kD epidermal protein [4, 5].

Further molecular characterization of the BP180 antigen was performed by Diaz et al. [6], demonstrating that BP180 is a transmembrane hemidesmosomal glycoprotein with both an extracellular C-terminus projecting into the lamina lucida, and an intracellular N-terminus. Development of a passive transfer murine model, and progress towards an active immunization murine model by Liu et al. have provided further clarification of the pathogenesis of BP [7].

Epidemiology

With onset typically occurring after the sixth decade, BP is classically considered a disease of the elderly. Indeed, the relative risk of developing BP in patients older than 90 years of age compared to those less than 60 years of age is approximately 300 [8]. Recent studies have suggested that even when age is controlled for, individuals with neurological diseases including dementia, stroke, and Parkinson's disease show an increased risk of developing BP [9–13]. In one of the most robust studies, the association of BP and neurological disease was only observed when the diagnosis of neurological disease was present prior to the development of BP, suggesting a possible causal association [10]. Though there have been numerous case reports of bullous pemphigoid developing in patients with malignancy, case–control studies have shown no increase in the frequency of malignancy in BP patients compared to age-matched controls [12, 14, 15]. There are no ethnic or gender predilections for developing BP.

Previous estimates of the incidence of BP range from 7 per million per year to 14 per million per year in France, Germany, and Scotland [16–18]. However, recent studies from the United Kingdom and France suggest that the incidence of BP has increased over the last several decades and may be as high as 22 per million per year to 43 per million per year [19, 20].

Given the advanced age of most patients with BP, assessing survival in this patient population has provided variable figures, with one year mortality ranging from 23 to 62 % [20–29]. Increased patient age, poor general health, extent of bullous lesions, presence of anti-BP180 autoantibodies, and dosing of oral steroids have all been associated with increased mortality in BP to varying degrees [23, 25, 26, 30].

Various human leukocyte antigen (HLA) classes have been associated with BP, specifically in regards to patient race. In Caucasians, HLA-DQB1*0301, has been associated with not only classic BP, but also ocular and mucous membrane involvement [31, 32]. Among patients of Japanese descent, increased incidence of the HLA-DRB1*04, DRB1*1101, and DQB1*0302 alleles have been noted [33]. Focusing on the geographic region of northern China, comparison of patients with BP to controls revealed decreased frequency of HLA-DRB1*08 and HLA-DQB1*06 in patients with BP [34].

Pathogenesis

The autoimmune response in BP is directed against two hemidesmosomal antigens, BP180 (BP Antigen 2, BPAg2 or collagen XVII), and BP230 (BP Antigen 1 or BPAg1). BP180 has been characterized as a member of the collagen family, possessing both an intracellular N-terminus domain and an extracellular C-terminus domain, which projects into the lamina lucida [6]. In contrast, BP230 is a cytoplasmic protein with structural similarity to plectin and desmoplakins I and II [35, 36]. As components of the hemidesmosome, BP180 and BP230 promote adhesion of the basement membrane to the basal layer of keratinocytes (Fig. 35.1).

Characterization of autoantibodies reveals a polyclonal response, with the majority of antibodies recognizing a cluster of epitopes about the largest noncollagen domain (referred to as NC16A) of the BP180 antigen [37, 38]. The BP180NC16A specific autoantibodies are predominantly IgE, IgG1, and IgG4 [39–41]. Titers of IgG and IgE BP180NC16A autoantibodies correlate to the degree of clinical severity [40–42]. Furthermore, autoantibodies against the BP180NC16A domain are sufficient to induce subepidermal blisters in the neonatal passive transfer model [43].

B cell production of pathogenic autoantibodies likely begins with development of autoreactive T cells. Most patients with BP demonstrate circulating autoreactive BP180-specific CD4 T cells as well as T-helper 2 (Th2) and Th1 responses against the BP180 ectodomain [44, 45]. Furthermore, BP180-reactive Th cells and IgG autoantibodies recognize similar or identical epitopes clustered in distinct regions of the BP180 ectodomain; the majority of autoreactive Th2 and Th1 cells and B cells recognize epitopes within the NC16A, followed by reactivity against the COOH-terminal and central regions [45–48]. Interestingly, T and B cell reactivity against the BP180 NC16A ectodomain is associated with severe BP, with widespread blisters and erosions, while responses against the central portion is more common in limited BP, with few blisters and erosions [47]. Less than 50 % of BP patients also show a combined T and B cell response against the COOH- and NH_2-terminal globular domains of BP230 [48].

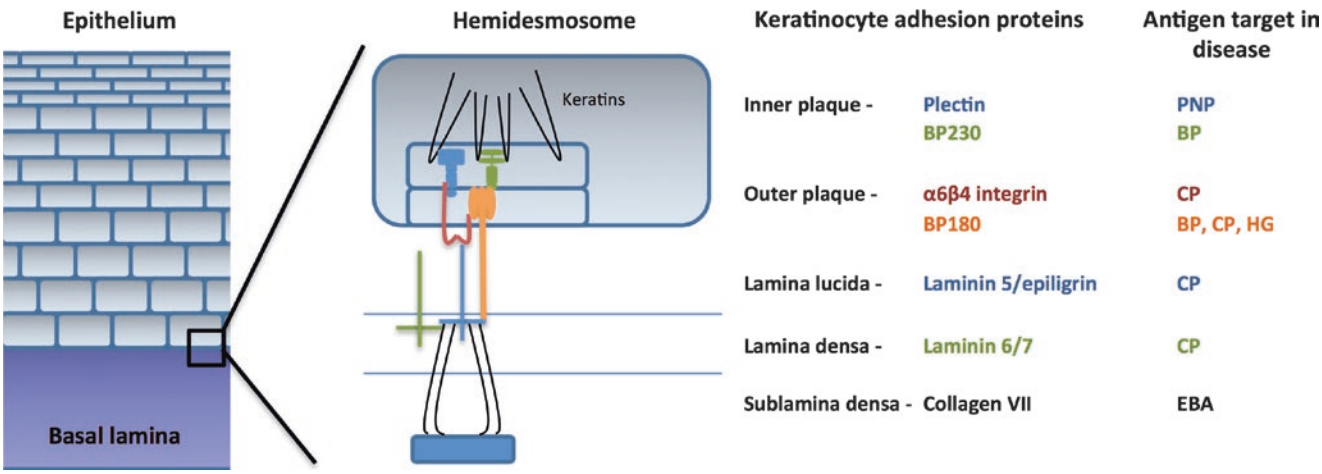

Fig. 35.1 Diagram of the hemidesmosome. Individual proteins comprise the hemidesmosome and many of these proteins serve as antigenic targets in clinical variants along the pemphigoid spectrum

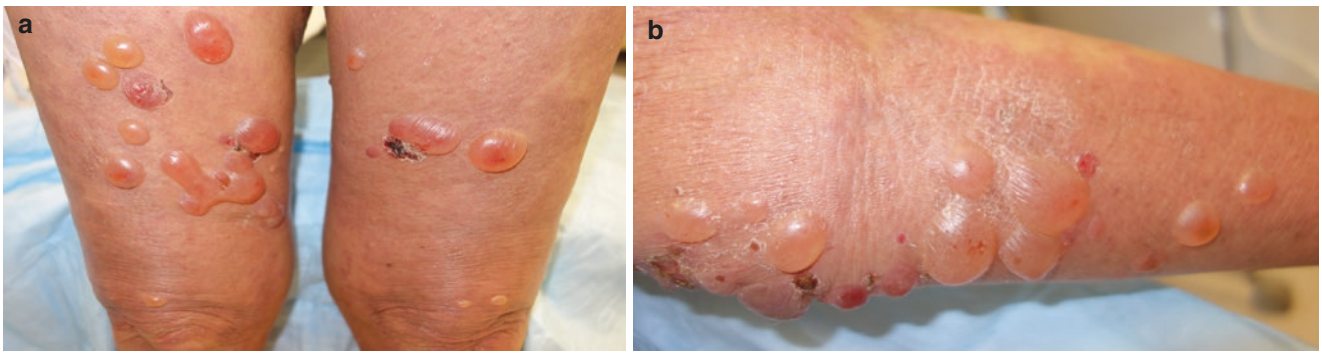

Fig. 35.2 BP classically presents with tense bullae overlying urticarial plaques on the trunk and extremities lower extremities (**a**) upper extremity (**b**) of elderly patients

The characteristic histologic and clinical features of BP are a result of the inflammatory cascade triggered by the binding of pathogenic autoantibodies to the antigen targets within the hemidesmosome structure. In vitro and in vivo studies show that antibodies against BP180 are pathogenic [7, 49]. In the in vivo model, neonatal mice injected intraperitoneally or intradermally with anti-murine BP180 antibodies develop BP-like skin lesions, including in situ deposition of IgG and complement C3 at the BMZ and an inflammatory cell infiltrate. Subepidermal blistering in this IgG passive transfer model of BP requires complement activation, mast cells and neutrophils [50–53]. Inflammatory cell products, such as neutrophil elastase, gelatinase and plasmin, result in tissue destruction at the dermal-epidermal junction, which manifests histologically as a sub-epidermal split [54–58].

Although the IgG autoantibodies in BP have been most studied to date, there is increasing evidence that IgE autoantibodies may also play a role in the pathogenesis of BP. As previously mentioned, over 90 % of BP patients have detectable circulating IgE anti-BP180 autoantibodies, and titers of IgE anti-BP180NC16A autoantibodies correlate with disease activity [40, 59]. IgE anti-BP180 autoantibodies likely play a role in the pathogenesis of BP by activation of mast cells and recruitment of eosinophils, as shown in murine models [60, 61]. Additional evidence comes from the dramatic improvement of several recalcitrant BP patients treated with the omalizumab, a monoclonal antibody that inhibits IgE binding to the high affinity IgE receptor [62, 63].

Clinical Features

Clinical manifestations of BP include pruritic, large, tense bullae overlying urticarial plaques (Fig. 35.2) [1]. However, over half of BP patients present with nonbullous lesions, as the prodromal phase is typically non-specific [64]. Intense pruritus, with or without an eczematous or urticarial eruption, are typically the first signs of the disease. In most patients, the prodromal phase is followed by the development of symmetric tense bullae, distributed primarily on the flexural aspects of the extremities and lower trunk. The

bullae are symptomatically pruritic, and may be filled with clear or hemorrhagic fluid. Rupture of the bullae results in shallow crusted erosions. Lesions heal without scarring, though milia formation may occur and postinflammatory pigmentation is quite common. Involvement of intertriginous areas may produce vegetative moist plaques. The mucous membranes are involved in a minority of patients (less than 10 %) and lesions are typically limited to the oral mucosa [1, 65, 66].

Diagnosis

Once the suspicion of BP is raised on the basis of clinical and historical patient information, definitive diagnosis is based not only on histologic evaluation, but also on further characterization of the autoantibody response through immunological techniques including direct and indirect immunofluorescence (IF) microscopy and enzyme linked immunosorbant assay (ELISA). Standard histologic evaluation via light microscopy reveals a subepidermal split with inflammatory infiltrate composed mainly of eosinophils and neutrophils in the upper dermis [1]. Occasionally, cell poor BP is observed where the inflammatory infiltrate is minimal or absent. Eosinophilic spongiosis has also been described in BP [67].

Direct IF (from perilesional, uninvolved skin) demonstrates a fine linear band at the dermal-epidermal junction of IgG and/or C3 with a sensitivity of 91 % [68] (Fig. 35.3a). Indirect IF (from patient's serum) demonstrates autoantibodies that bind the dermal-epidermal junction in a linear fashion with a sensitivity of roughly 70 %. The use of salt split skin as the substrate increases the sensitivity of indirect IF and also allows for distinction between BP (with localization of the autoantibodies to the epidermal side of salt split skin) and epidermolysis bullosa acquisita (with localization of autoantibodies to the dermal side of salt split skin) (Fig. 35.3b) [69, 70]. The BP180 NC16A domain ELISA is emerging as a more readily available test to evaluate for circulating autoantibodies in the serum and is being utilized in both the clinical and research setting. ELISA index values tend to correlate with disease activity with a sensitivity ranging from 72 to 89 % [68, 71]. However, approximately 7 % of the normal population has detectable anti-BP180 autoantibodies by ELISA without regard to age [68, 72]. The relevance of a positive BP180 ELISA in the absence of clinical findings is unclear, but the 7 % false positive rate suggests that ELISA should be used in the appropriate clinical context and with supporting direct and indirect IF studies rather than as the sole immunological criteria for diagnosis.

Therapy

Topical high potency corticosteroids are useful for limited areas of involvement in motivated patients. More generalized or severe manifestations typically require systemic corticosteroids, in initial dosing ranging from 0.5 to 1 mg/kg/day. After gaining control of development of new bullae, the dose may be tapered over 6–8 months, with dosing adjusted to account for the recurrence of disease. A recent study suggests that high potency topical steroids (clobetasol) may be an excellent approach to induce clinical remission in BP [24, 73].

In cases refractory to systemic corticosteroids, additional immunosuppressive medications may be employed. Methotrexate, azathioprine (dose adjusted for variability in thiopurine methyltransferase levels) and mycophenolate mofetil are all options, with selection based upon each medication's side effect profile [74–79]. Dapsone may be useful in some cases where systemic steroids or immunosuppressive drugs are contraindicated [80–82]. Plasmapheresis and intravenous immunoglobulin have been used successfully to induce remission in BP [83–85]. Rituximab, a monoclonal anti-CD20 antibody that targets B lymphocytes, has also shown efficacy in treating bullous pemphigoid [86]. In a small cohort of patients, low serum B cell activating factor (BAFF) levels and a higher proportion of memory B lymphocytes during B cell recovery post treatment were seen in those patients that flared post treatment [87]. While other

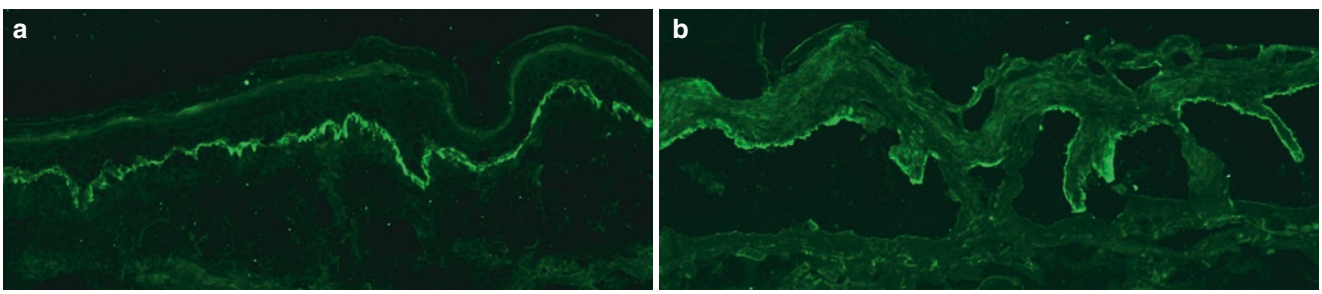

Fig. 35.3 Direct and indirect immunofluorescence (IF) findings of BP. (**a**) Direct IF shows C3 and IgG deposition in a linear pattern along the basement membrane zone. (**b**) Indirect IF shows IgG localization to the epidermal side of salt split skin

dermatologists have found tetracycline family members and nicotinamide useful in the control of BP, in our hands it has had a limited effect in some rare patients.

Cicatricial Pemphigoid

Overview

Cicatricial Pemphigoid (CP), also known as mucous membrane pemphigoid, is a rare chronic autoimmune blistering disorder, characterized by mucosal involvement and a high risk of scarring within the affected areas. Any or all mucous membranes may be involved in any individual patient. Direct IF demonstrates linear deposition of autoantibodies against various basement membrane zone components. The clinical course tends to be chronic and best managed with a multi-disciplinary approach to avoid major sequelae secondary to scarring [88].

Historical Background

Chronic blistering conditions with both skin and eye involvement were described throughout the 1800s [89, 90]. Up to the mid-1900s, CP was considered a variant of pemphigus, until Civatte and Lever separated the disorder based on histopathologic criteria [91, 92]. Lever suggested changing the name from "benign mucous membrane pemphigoid" to "cicatricial pemphigoid" based upon the tendency for scar formation [1, 93]. Tissue-bound immunoglobulins and complement components along the basement membrane zone were identified in the 1970s [94, 95] and circulating antoantibodies were demonstrated by Dantzig and Bean shortly thereafter [96, 97].

Epidemiology

CP has been documented to occur at any age, and is one of the most rare subepidermal bullous diseases, with an estimated annual incidence of approximately 1 per million per year [16, 18, 98]. There is a female predilection with females being affected twice as frequently as males with onset typically in the 60s [16, 18, 99]. In a recent review of patients with circulating antibodies recognizing laminin-5, over 30% of patients demonstrated internal malignancy, suggesting an increased relative risk of developing malignancy in this type of CP [100–102].

Pathogenesis

While CP is clinically characterized by the unifying clinical feature of mucosal involvement and scar formation and immunofluorescence finding of autoantibody deposition at the basement membrane zone, the antigenic targets can be quite heterogeneous. Commonly recognized target antigens in CP include BP180, BP230, laminin-332 (also known as laminin-5, or epiligrin), laminin-6, integrin $ß_4$ subunit, and integrin α subunit [103–106]. While autoantibodies are typically of the IgG class, IgA autoantibodies are also detected in some patients as well. The collective contribution of how the autoantibodies, the specific antigenic targets, and the microenvironment lead to mucosal-predominant inflammation and scar formation is still not understood.

Clinical Features

While any mucosal surface may be affected in CP, the oral site is most commonly involved, followed by, in decreasing order of involvement, the ocular, nasal, nasopharyngeal, anogenital, laryngeal, and esophageal sites [107–109]. Oral disease may present as erosive or desquamative gingivitis; intact blisters are rarely observed (Fig. 35.4a). Chronic erosions on the palate and lateral tongue are commonly seen, as well. Once healed, the areas may resemble lesions of lichen planus, with white reticulated striations.

Conjunctival involvement is also commonly seen, and, if not appropriately addressed, may result in blindness. Conjunctival inflammation, erosions, symblepharon, entropion and trichiasis may be present (Fig. 35.4b). Symptoms include dryness, burning and foreign body sensation of the eyes. Similar to the appearance of lesions in the oral mucosa, intact bullae are very rarely observed [107]. CP may be limited to the ocular mucosa in some patients without other sites of involvement. Examination by an ophthalmologist is critical for detection of early disease by slit-lamp evaluation.

Nasopharyngeal involvement may be associated with lesions of the upper aerodigestive tract [108]. Symptoms suggestive of nasopharyngeal involvement include nasal crusting, recurrent epistaxis, and nasal airway obstruction. A history of persistent pharyngalgia, dysphagia, odynophagia, dysphonia, or dyspepsia may suggest pharyngeal and laryngeal involvement [110]. Development of strictures or stenosis of the pharynx or larynx may prove life threatening, if not identified at an early stage.

Genital and anal involvement is relatively rare. Progressive disease may lead to narrowing of the introitus in women, or to phimosis in men. Anal involvement may lead to scarring, and potentially to stricture. The skin is involved in approximately a quarter of patients with CP with lesions most frequently appearing on the head, neck, and upper trunk. Erythematous plaques develop recurrent blisters, and heal with atrophic scarring.

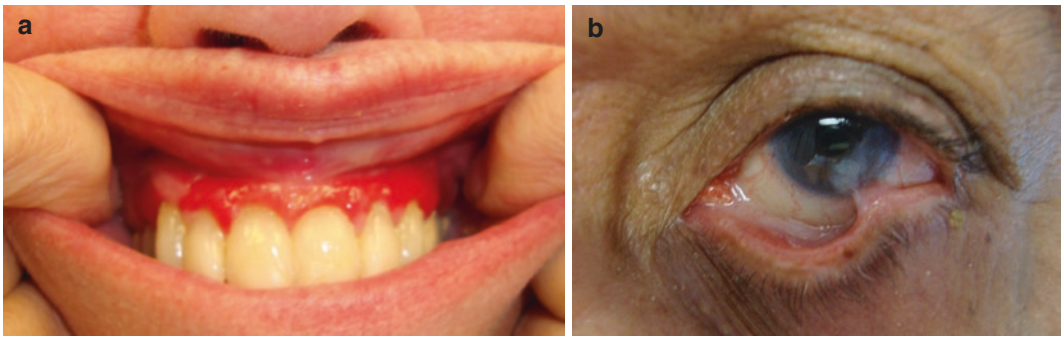

Fig. 35.4 Clinical manifestations of cicatricial pemphigoid (CP). (**a**) Oral manifestations of CP often include desquamative gingivitis. (**b**) Ocular manifestations of CP can include symblepharon formation

Diagnosis

Diagnosis of CP relies on immuofluorescent evaluation. Direct IF performed on perilesional mucosa or skin reveals IgG, IgA, and/or C3 in a continuous fine linear pattern along the basement membrane zone [88, 111–114]. Direct IF is most likely to provide conclusive information when performed on an area of mucosa adjacent to an area of inflammation [88]. In order to minimize the risk of conjunctival scarring, other anatomic areas of involvement should be biopsied preferentially, as injury to the conjunctiva may increase disease activity [88]. Indirect IF reveals autoantibodies at the basement membrane zone in 20–30 % of patients with clinical disease. Localization of autoantibodies, when performed on human salt-split skin substrate, is variable, depending upon the diversity of each patient's autoantibody milleu and the location of the autoantigens targeted [70, 115–119].

Therapy

In patients with mild, low-risk disease (defined as oral mucosa involvement, with or without skin involvement), potent topical corticosteroids may be sufficient. However, in patients with high-risk disease (defined as involvement of ocular, genital, laryngeal, nasopharyngeal, esophageal sites), initial therapy should involve systemic corticosteroids, with consideration of addition of cyclophosphamide or azathioprine [88]. Dapsone is also a consideration for stable or mild disease. Case reports document the use of various other modalities, including intravenous immunoglobulin, mycophenolate mofetil, and most recently, rituximab [120–125].

Herpes Gestationis (Pemphigoid Gestationis)

Overview

Herpes Gestationis (HG) is a rare dermatosis of pregnancy and the immediate post-partum period characterized by intensely pruritic urticarial lesions and eventually tense bullae. Most patients demonstrate autoantibodies to the BP180 antigen, with generation of a subepidermal separation on histologic evaluation. In pregnancies affected with HG, there is increased risk of prematurity and small for gestational age birth. The clinical course tends to be quite variable, and most cases resolve following delivery.

Historical Background

The term *herpes gestationis* was first cited by Milton in 1872, with demonstration of complement deposition along the basement membrane zone first documented by Provost in 1973 [126]. In 1976, Jordon et al and Katz et al characterized the "HG" factor as an IgG antibody that activates the complement pathway [127, 128]. Guidice et al identified the structural antigen for the "HG factor" as BP180, and provided further structural analysis of the antigen [37, 129].

Epidemiology

HG is a rare disorder exclusively seen during late pregnancy and the immediate post-partum period. Even more rare is its association with trophoblastic malignancy or molar pregnancy [130, 131]. Estimates of incidence for HG range from 1 in 10,000 to 1 in 50,000 pregnancies [132, 133]. HG often recurs in subsequent pregnancies, and may occur earlier and in a more severe form [134]. Also, with subsequent pregnancies, the time to resolution in the post-partum period may become progressively prolonged [135].

Pathogenesis

Generation of autoreactive T cells stimulate production of autoantibodies against the NC16A region of the BP180 antigen, prompting histopathologic and clinical manifestations of HG. Characterization of the autoreactive T cells has revealed

expression of a Th1 cytokine profile, supporting the production of IgG1 autoantibodies against BP180 [136, 137].

Deposition of the autoantibodies prompts complement activation, primarily through the classical pathway, followed by mast cell recruitment, degranulation, recruitment of inflammatory cells (primarily eosinophils), and production of destructive proteases [138–140]. The resultant damage at the dermal-epidermal junction manifests as a subepidermal separation on histologic examination.

HG has been associated with HLA-DR3, HLA-DR4, or both alleles [138–144]. Correspondingly, patients with HG are at increased risk for the development of other autoimmune disorders, such as Grave's disease [142].

Clinical Features

Typically, abdominal urticarial lesions appear abruptly during the second or third trimester, followed by the appearance of a generalized bullous reaction sparing the face, mucous membranes, palms and soles [133, 134, 145, 146]. However, initial onset in the immediate postpartum period has been described in 20 % of cases [147]. Most patients experience a flare with delivery, which spontaneously resolves over weeks to months following delivery. Flares with subsequent pregnancies, menstruation, or initiation of oral contraceptive use are common [145, 148].

Neonatal vesicles are present in approximately 10 % of cases, presumably secondary to passive transfer of pathogenic antibodies [145, 149, 150]. While the lesions are transient and typically mild, they are at increased risk of superinfection secondary to the infant's relatively immunocompromised status. Although associations have been reported in regards to preterm delivery and small for gestational age infants, there have been no reports of increased fetal morbidity or mortality [151, 152].

Diagnosis

Standard light microscopy of involved skin reveals a subepidermal vesicle with a lymphocytic and eosinophilic perivascular infiltrate. Direct IF of perilesional skin demonstrates linear C3 along the basement membrane zone; occasionally, IgG is also present, but to a lesser degree than C3 [140, 153]. While standard indirect IF is rarely positive, complement-added indirect IF is almost universally positive for pathogenic IgG antibodies [153].

Therapy

For limited disease, high potency topical corticosteroids along with oral antihistamines may provide sufficient control. However, more severe eruptions may require oral corticosteroids for adequate response. Intravenous immunoglobulin has also been effective for some patients [154]. More therapeutic options are feasible during the postpartum period, such as cyclophosphamide and methotrexate, although only sporadic reports of variable efficacy are available [155, 156].

Summary

The pemphigoid spectrum of diseases shares histological and immunofluorescence features of subepidermal blister formation with detection of autoantibodies and complement along the basement membrane zone. While BP180 is the antigenic target in the most classic form of the disease, clinical variants exist with more heterogeneous target autoantigens. The diagnosis of these diseases relies upon the triad of supporting clinical, histological, and immunological features. Treatment is aimed at suppressing the misguided immune response with topical and/or systemic corticosteroids in addition to other immunosuppressive agents. Progress continues to be made in understanding disease initiation, pathogenesis and more targeted treatment strategies.

Questions and Answers

1. What diseases are associated with bullous pemphigoid?
   Patients with neurological diseases including dementia, stroke, and Parkinson's disease show an increased risk of developing BP

2. Describe the stepwise events involved in the pathogenesis of bullous pemphigoid.
   The pathogenesis of bullous pemphigoid starts with autoantibody formation against BP180 and BP230. Bound autoantibodies fix complement at the basement membrane zone and elicit an inflammatory cell infiltrate of neutrophils, mast cells, and eosinophils. Inflammatory cell products, such as neutrophil elastase, gelatinase and plasmin, result in tissue destruction at the dermal-epidermal junction, which manifests histologically as a sub-epidermal split

3. What are the most common sites of involvement in cicatricial pemphigoid?
   While any mucosal surface may be affected in CP, the oral site is most commonly involved, followed by, in decreasing order of involvement, the ocular, nasal, nasopharyngeal, anogenital, laryngeal, and esophageal sites. The skin is involved in a minority of patients

Epidermolysis Bullosa Acquisita

36

Brittney De Clerck, Mei Chen, and David T. Woodley

Abstract

In 1895, two cases of a blistering disease with adult onset and features highly reminiscent of hereditary dystrophic epidermolysis bullosa (EB) were reported by Elliott. These clinical features included skin fragility, erosions, blisters, and a healing response characterized by scarring and the formation of milial cysts.

Keywords

Epidermolysis bullosa acquisita • EBA • Autoimmune disease • Blisters • Skin disease • Porphyria cutanea tarda • PCT • Bullous pemphigoid • BP • Cicatricial pemphigoid • CP • Immunoelectron Microscopy • IM • Anti–tumor necrosis factor-a • TNF-a • Pathogenesis

Key Points

- Epidermolysis bullosa acquisita (EBA) is an autoimmune, blistering skin condition, in which there is an autoantibody to type VII collagen, a component of the anchoring fibril complex of the basement membrane zone.
- There are a number of clinical presentations of this disease: the classic porphyria cutanea tarda (PCT)-like, noninflammatory mechanobullous disease; the bullous pemphigoid (BP) presentation of widespread inflammatory blisters; the cicatricial pemphigoid (CP)–like presentation with mucous membrane involvement; the Brunsting- Perry–like presentation (disease localized to the head and neck area); and the immunoglobulin A (IgA) bullous dermatosis–like presentation (inflammatory presentation with a neutrophil- rich infiltrate).
- Complications of EBA include: esophageal strictures, loss of nails, scarring, and contractures of the hands.
- Epidermolysis bullosa acquisita may be associated with underlying diseases such as inflammatory bowel disease, systemic lupus erythematosus, amyloidosis, and other inflammatory and autoimmune conditions.
- Clinical presentation and histological findings are used to confirm this diagnosis. Indirect and direct immunofluorescence mapping studies on NaCl split skin can facilitate distinguishing EBA from bullous pemphigoid. Western blotting confirms that the sera from EBA patients bind to a 290-kd autoantigen (type VII collagen).
- Epidermolysis bullosa acquisita can be challenging to treat. Colchicine and systemic glucocorticosteroids alone or in combination with cytotoxic drugs or cyclosporine have been used to treat severe disease. Recently, rituximab has shown promising results as a treatment option for EBA.

In 1895, two cases of a blistering disease with adult onset and features highly reminiscent of hereditary dystrophic epidermolysis bullosa (EB) were reported by Elliott [1]. These clinical features included skin fragility, erosions, blisters, and a healing response characterized by scarring and the formation of milial cysts.

In the early 1970s, Roenigk et al. [2] summarized the epidermolysis bullosa acquisita (EBA) world literature, reported three new cases, and suggested the first diagnostic criteria: (1) a negative family and personal history for a previous blistering disorder, (2) an adult onset of the eruption, (3) spontaneous or trauma-induced blisters that resemble those of hereditary dystrophic epidermolysis bullosa, and (4) the exclusion of all other bullous diseases.

Kushniruk [3], Gibbs and Minus [4], and Nieboer et al. [5] showed that patients with EBA had immunoglobulin G (IgG) deposits at the dermal– epidermal junction identical to patients with bullous pemphigoid (BP). However, Nieboer et al. and Yaoita et al.[6] showed that the IgG deposits in EBA were within and below the lamina densa area of the basement membrane zone (BMZ), whereas BP immune deposits are within hemidesmosomes and high in the lamina lucida. Distinguishing EBA from the BP group is important because the clinical, pathologic, and immunologic presentations of EBA may be identical to BP and cicatricial pemphigoid (CP) but treatments may vary (see below) [7–12].

Clinical Findings

As noted above, the cutaneous lesions of EBA can be quite varied and can mimic other types of acquired autoimmune bullous diseases. The common denominator for patients with EBA is autoimmunity to type VII (anchoring fibril) collagen. Although the clinical spectrum of EBA is still being defined, there are at least five clinical presentations: (1) a classic presentation, (2) a BP-like presentation, (3) a CP-like presentation, (4) a presentation reminiscent of Brunsting- Perry pemphigoid with scarring lesions and a predominant head and neck distribution, and (5) a presentation reminiscent of linear IgA bullous dermatosis or chronic bullous disease of childhood [11–14].

Classic Presentation

This disease classically presents with non-inflammatory bullous lesions with an acral distribution that heals with scars and milia formation. When clinically mild, this form of EBA is reminiscent of porphyria cutanea tarda (PCT). However, when clinically severe, EBA will resemble the hereditary form of recessive dystrophic EB. The classic form of EBA is thus a mechanobullous disease marked by skin fragility. These patients have erosions, tense blisters within non-inflamed skin, and scars over trauma-prone surfaces such as the backs of the hands, knuckles, elbows, knees, sacral area, and toes. Some blisters may be hemorrhagic or develop scales, crusts, or erosions. The lesions heal with scarring and frequently form pearl-like milia cysts within the scarred areas. Additionally, a scarring alopecia and some degree of nail dystrophy may be seen. Although this presentation may be reminiscent of PCT, these patients do not have other hallmarks of PCT such as hirsutism, a photodistribution of the eruption, or scleroderma-like changes. Additional, their urinary porphyrins are within normal limits.

Although the disease is usually not as severe as that of patients with hereditary forms of recessive dystrophic EB, EBA patients with the classic form of the disease may have many of the same sequelae such as scarring, loss of scalp hair, loss of nails, fibrosis of the hands and fingers, and esophageal stenosis [15–28].

Bullous Pemphigoid-Like Presentation

A second clinical presentation of EBA is of a wide- spread, inflammatory vesiculobullous eruption involving the trunk, central body, skin folds, and extremities [7]. These tense bullous lesions are surrounded by inflamed or even urticarial skin. Large areas of skin may be without any blisters but with erythematous and urticarial plaques. These patients often complain of pruritus and do not demonstrate prominent skin fragility, scarring, or milia formation. This clinical constellation is more reminiscent of BP than of a mechanobullous disorder. Like BP, the distribution of the lesions may show an accentuation within flexural areas and skin folds. About 25 % of patients with EBA may present with a BP-like clinical appearance.

Cicatricial Pemphigoid-Like Presentation

Both the classic and BP-like forms of EBA may have involvement of mucosal surfaces. However, EBA also may present with such predominant mucosal involvement that the clinical appearance is reminiscent of CP [8]. These patients usually have erosions and scars on the mucosal membrane of the mouth, upper esophagus, conjunctiva, anus, or vagina with or without similar lesions on the glabrous skin. The clinical phenotype of EBA that is reminiscent of pure CP occurs in fewer than 10 % of all EBA cases.

Brunsting-Perry Pemphigoid-Like Presentation

Brunsting-Perry pemphigoid is a chronic recurrent vesiculobullous eruption localized to the head and neck and characterized by residual scars, subepidermal bullae, IgG deposits at the dermal–epidermal junction, and minimal or no mucosal involvement. The antigentic target for the IgG autoantibodies has yet to be defined; however, a patient reported with these findings had IgG autoantibodies directed against anchoring fibrils below the lamina densa [12]. It appears that EBA patients may present with a clinical phenotype similar to Brunsting-Perry pemphigoid.

Linear Immunoglobulin A Bullous Dermatosis-Like Presentation

This form of EBA manifests as a subepidermal bullous eruption with a neutrophilic infiltrate and linear IgA deposits at the BMZ when viewed by direct immunofluorescence (DIF). Clinically, it may resemble linear IgA bullous dermatosis (LABD), dermatitis herpetiformis, or chronic bullous disease of childhood (CBDC), and may feature tense vesicles arranged in an annular fashion with or without involvement of mucous membranes [29–34]. The autoantibodies are usually IgA, IgG, or both. Some clinicians regard these patients as having purely LABD [31], whereas others regard them as having a subset of EBA [32].

Childhood EBA

Childhood EBA is a rare disease with a variable presentation. Out of 14 patients reviewed, 5 presented with an LABD-like disease, another 5 presented with BP-like disease, and 4 presented with the classical manifestations [34]. Mucosal involvement is frequent in childhood EBA. The overall prognosis is more favorable than for adults with EBA [30, 34].

Additional Clinical Findings

In addition to the protean clinical manifestations of EBA, patients may suffer from a number of associated clinical problems that add to the morbidity of the disease. These include oral erosions, esophageal strictures, nail loss, milia formation, scarring, and a degree fibrosis of the hands. These are all associated clinical conditions that are shared (albeit usually milder) with hereditary dystropic EB.

Associated Systemic Diseases

Epidermolysis bullosa acquisita has been linked to several systemic diseases. Most commonly, inflammatory bowel disease (IBD) occurs in 20–30 % of all EBA patients. Patients with IBD, particularly Crohn's disease, have circulating antibodies to collagen 7 (C7) in approximately 70 % of cases [35, 37]. Recently, Ishii et al. have shown that injection of rabbit anti-murine C7 IgG (passive acquisition of EBA) or immunization with a fragment of murine C7 (active acquisition of EBA) not only produced cutaneous symptoms of EBA but also resulted in autoantibody deposition in the gastrointestinal tract with resultant blister formation [36, 38]. These findings in a mice model suggest that the correlation between IBD and EBA is more direct than previous thought. In addition to its relationship with IBD, anecdotal reports suggest that EBA may have other associated systemic diseases including systemic lupus erythematosus (SLE), amyloidosis, thyroiditis, multiple endocrinopathy syndrome, rheumatoid arthritis, pulmonary fibrosis, chronic lymphocytic leukemia, thymoma, diabetes, and other diseases in which an autoimmune pathogenesis has been implicated [37, 38].

Clinical Evaluation

Histopathology

Histopathology of an EBA lesion shows a subepidermal blister. In the classic mechanobullous presentation of EBA, there is fibrin in the blister cavity and an overall paucity of associated inflammatory cells within the blister cavity and dermis. Fibrosis and scaring may also be present in the underlying dermis. In the BP-like EBA presentation, the histopathology shows a more significant dermal inflammatory infiltrate of lymphocytes, macrophages, neutrophils, and eosinophils. In the IgA pemphigoid-like EBA form, there is often a predominance of neutrophils.

Direct Immunofluorescence

Krushnick et al. [3], Gibbs and Minor [4], Nieboer et al. [5], and Yaoita et al. [6] have shown that a positive direct immunofluorescence (DIF) is necessary for the diagnosis of EBA. Immunoglobulin G (IgG) and, to a lesser extent C3, deposits are present at the dermal–epidermal junction by DIF from a perilesional biopsy. However, the immunodeposits are almost identical in pattern to those seen in bullous pemphigoid. EBA may have stronger IgG deposition, while BP may have strong C3 deposition. Therefore, performing salt-split skin (SSS) DIF and SSS indirect immunofluorescence

(IIF) are necessary to distinguish EBA from the pemphigoid group of disorders. To perform the SSS technique, perilesional skin showing immunodeposits during routine DIF is incubated in 1 mol/L cold NaCl for 72 h. The procedure fractures the dermal–epidermal junction through the lamina lucida of the basement membrane zone. This places the bullous pemphigoid autoantigens associated with the hemidesmosome (i.e., BPAg 1 and BPAg 2, also known as type XVII collagen) on the epidermal roof of the separation [36–45]. The EBA antigen, type VII collagen, remains with the dermal floor [47]. The immunoreactants (usually IgG and C3) are again incubated with the tissue. If the patient has EBA, the immune deposits are detected on the dermal side of the separation.

Indirect Immunofluorescence

Many, but not all, EBA patients have an anti–BMZ IgG autoantibody circulating in their blood that can be detected by IIF. The EBA serum autoantibodies label frozen sections of human skin or monkey esophagus, producing a crisp linear fluorescent staining at the dermal–epidermal junction of the frozen sections after incubation with anti-IgG fluorescent-labeled antibodies. As with the routine DIF procedure, one cannot distinguish EBA from the pemphigoid group of diseases without doing salt-split IIF, which is always done on human skin substrate. Human skin is incubated in 1 mol/L NaCl, and the dermal–epidermal junction fractures cleanly through the lamina lucida zone, placing the BP antigens on the epidermal roof and the EBA antigen (type VII anchoring fibril collagen) on the dermal floor [41]. Salt-split skin substrate can be used to distinguish EBA and BP sera [42]. If the serum antibody is IgG and labels the epidermal roof, the patient does not have EBA, and BP should be considered. If, on the other hand, the antibody labels the dermal side of the separation, the patient usually has either EBA or bullous SLE. The latter can be ruled out by other serology and clinical criteria.

Rare Diseases that Give Dermal Staining by Salt-Split Immunofluorescence

It was thought that only EBA and bullous SLE show dermal staining of the salt-split skin on IIF or DIF. In recent years, other very rare autoimmune diseases have been shown to have IgG deposits in the lower lamina lucida space that map to the dermal side when the skin substrate is fractured by SSS technique. These diseases include anti-laminin 5 cicatricial pemphigoid [43], a BP-like disease in which the patients have autoantibodies to a 105- kd lamina lucida glycoprotein that is unrelated to laminin-5 [44], a newly discovered disease reported by Ghohestani and colleagues [46], with IgG autoantibodies directed against the α5 chain of type IV (lamina densa) collagen in association with renal failure, and another BP-like disease called protein 200 pemphigoid in which the autoantigen is a 200-kd glycoprotein in the lower part of the lamina lucida.

Electron Microscopy

Electron microscopy (EM) shows that the dermal–epidermal separation in an EBA lesion is associated with a paucity of normal anchoring fibrils and an amorphous, electron dense band beneath the lamina densa due to the IgG deposits over the anchoring fibrils [9]. Despite the sublamina densa deposits, EBA blisters frequently separate above the immune deposits within the lamina lucida [39].

Immunoelectron Microscopy

Immunoelectron microscopy (IEM) localizes the EBA IgG autoantibody deposits in the BMZ to within and below the lamina densa, the location of the anchoring fibrils. Immunoelectron microscopy showing these sublamina densa IgG deposits is the gold standard for the diagnosis, as first demonstrated by Nieboer et al. [13] and Yaoita et al. [6] This localization is distinct from BP IgG deposits which are localized to the hemidesmosomes of the basal keratinocytes and the IgG autoantibody deposits in CP and are confined to the lower lamina lucida.

Western Immunoblotting

Antibodies in EBA sera bind to a 290-kd band in Western blots of human skin basement membrane proteins containing type VII collagen, whereas sera from other primary blistering diseases do not [13].

This band corresponds to the alpha-chain of type VII collagen. Often a second band of 145 kd will be labeled with EBA antibodies. This band is the amino-terminal globular NC1 domain of the type VII collagen alpha-chain that is rich in carbohydrate and contains the antigenic epitopes of EBA autoantibodies, bullous SLE autoantibodies, and monoclonal antibodies against type VII collagen [13, 48].

Enzyme-Linked Immunosorbent Assay

Now that purified, recombinant, human, type VII collagen is readily available, an enzyme-linked immunosorbent assay (ELISA) for the diagnosis of EBA has been developed by Chen et al. [24, 49]. It has proven to be more sensitive for detecting anti-COL7 EBA autoantibodies in the sera of

patients than either IIF or Western blotting analysis. ELISA is performed quickly and easily with a very high sensitivity in determining which circulating autoantibodies are present.

Pathogenesis

Although EBA does not have a mendelian pattern of inheritance, African-American EBA patients in the Southeastern part of the United States have a high incidence of the human leukocyte antigen (HLA)-DR2 phenotype. The calculated relative risk for EBA in HLA-DR2+ individuals is 13.1 in these patients [27]. It is thought that, although it is not the primary cause, these patients have an immune profile that makes them susceptible to the disease.

While the etiology of EBA is unknown, it appears that when IgG autoantibodies bind to the patient's anchoring fibrils, a paucity of normal anchoring fibrils at the BMZ develops, and this is associated with poor dermal–epidermal adherence. This is exactly the same problem as hereditary dystrophic forms of EB due to a defect in the gene that encodes for type VII collagen.

Epidermolysis bullosa acquisita likely has an autoimmune etiology. Direct immunofluorescence of perilesional skin biopsies from EBA patients reveals IgG deposits at the dermal–epidermal junction [3–6]. The EBA antibodies bind to type VII collagen within anchoring fibrils [13, 14], structures that emanate perpendicularly from the BMZ and attach to the papillary dermis. This process results in decreased anchoring fibrils, but the pathway leading to this reduction is unknown. Type VII collagen has an affinity for fibronectin, a large glycoprotein in the papillary dermis and this interaction between the two may play a role in anchoring the basement membrane [22]. It is conceivable that EBA autoantibodies binding to type VII collagen interrupt the interaction between type VII collagen and fibronectin and a separation ensues.

Diagnosis

The diagnostic criteria for EBA developed by Yaoita et al. [6] still stand. These criteria, with slightly updated modifications, are as follows:

- A bullous disorder within the clinical spectrum outlined earlier
- No family history of a bullous disorder
- Histology showing a subepidermal blister
- Deposition of IgG deposits within the dermal–epidermal junction with a positive DIF on perilesional skin
- IgG deposits localized to the lower lamina densa or sublamina densa zone of the dermal epidermal junction when perilesional skin is examined by IEM. Alternatives also include indirect or direct salt split skin immunofluorescence, Western blotting, and ELISA.

Treatment

Epidermolysis bullosa acquisita is difficult to treat and can be refractory to many therapies. The therapy with the least associated risk known is colchicine at high doses. Colchicine is a well known microtubule inhibitor that also inhibits antigen presentation to T-cells and downregulates autoimmunity. The side effects of colchicine are relatively benign compared with other agents. Diarrhea is a common side effect, particularly at high doses. We do not use colchicine in EBA patients who also have inflammatory bowel disease [50, 51].

The noninflammatory, mechanobullous type of EBA is notoriously resistant to systemic steroids.

Immunosuppressants such as mycophenolic acid, azathioprine, methotrexate, cyclosporin A, and cyclophosphamide may be somewhat helpful in controlling EBA when it appears as an inflammatory BP-like disease. When using cyclosporin A high doses are needed, typically in the range of 6 mg/kg, and the nephrotoxicity of this drug sometimes limits its use [52, 53]. Some EBA patients improve on dapsone, especially when neutrophils are present in their dermal infiltrate.

Supportive therapy is warranted in all patients with EBA. This includes instruction on wound care and strategies for avoiding trauma. Patients should be warned not to over wash and overuse hot water or harsh soaps, and to avoid prolonged or vigorous rubbing of their skin with a washcloth or towel. In some, it appears that prolonged sun exposure may aggravate or promote new lesions on the dorsal hands and knuckles. Avoidance of prolonged sun exposure and the use of sunscreens may be beneficial. Patients should be educated to recognize localized skin infections and to seek medical care and antibiotic therapy promptly when they occur.

Rituximab, a monoclonal anti-CD20 antibody, has been used successfully to treat patients with EBA [54–60]. Many of the patients who have responded to rituximab have been refractory to numerous other intensive treatment regimens. Of interest, rituximab has resulted in complete or partial sustained remission of disease after cessation of the course of therapy. In many of the case reports, patients were maintained on other immunosuppressive therapies as well. One of these case reports was in a pediatric patient [54].

Photophoresis has been used anecdotally with success in various autoimmune bullous diseases. One reported case of life-threatening EBA had a remarkable recovery with photophoresis [61]. In a small trial of three EBA patients,

photophoresis lowered the circulating anti–type VII collagen antibodies in the patients' sera, increased the suctioning blistering times of the patients, and improved the disease [62]. Plasmaphoresis has been shown to reduce the burden of circulating anti-C7 antibodies in a patient with EBA [63].

Intravenous immunoglobulin (IVIG) has been reported to be effective in some patients with EBA [64]. The mechanism by which IVIG may invoke a positive response in EBA is unknown.

The anti–tumor necrosis factor-a (TNF-a) biologics have been tried in EBA with some success in limited open trials.

Conclusion

Epidermolysis bullosa acquisita is an autoimmune disorder characterized by autoantibodies to type VII collagen leading to blistering of the skin. There are a number of clinical variants that can be diagnosed with clinical findings, histopathology, direct immunofluorescence, and indirect immunofluorescence. When this disease is diagnosed, it is imperative to consider complications of the disease, as well as the associated autoimmune and inflammatory conditions that are frequently associated with EBA. Immunosuppressive therapy is usually required.

Questions

1. **Which of the following tests support the diagnosis of EBA:**
   A. Salt-split skin direct immunofluorescence (DIF) with the IgG deposits going to the epidermal roof
   B. Immuno-electron microscopy with the IgG immune deposits localized within and below the lamina densa
   C. Serum indirect immunofluorescence (IIF) showing an antibody that labels the roof of the epidermal- dermal separation
   D. Anti-endomysial IgA autoantibodies

2. **Autoantibodies in EBA patient sera are usually IgG and most commonly bind to which of the following structures in the skin?**
   A. Anchoring plaques
   B. Integrin a6b4 emanating from the hemidesmosome into the lamina lucida
   C. Anchoring filaments
   D. Anchoring fibrils

3. **Of the possible underlying systemic diseases associated with EBA, which one is the most common?**
   A. Amyloidosis
   B. Bullous amyloidosis
   C. Inflammatory bowel disease
   D. Lymphoma

4. **Regarding EBA treatment, which of the following is true?**
   A. The mechanobullous form of EBA usually responds nicely to high doses of systemic corticosteroids
   B. Colchicine is a good first line drug in EBA patients with underlying inflammatory bowel disease
   C. Cyclosporine A can be used to treat EBA at doses similar to those used in psoriasis patients
   D. Rituximab infusions are a useful therapy for EBA

5. **Patients with Brunsting-Perry Pemphigoid usually have:**
   A. Serum autoantibodies to the BP 180 antigen
   B. Serum autoantibodies to type XVII collagen
   C. Serum autoantibodies that label the floor of salt-split human skin substrate
   D. Serum antibodies that only bind to proteins within mucous membranes

Granulomatosus

37

Sridhar M. Dronavalli

Abstract

The disease entities in the group of granulomatous disorders share some histological commonalities, however the etiology of most remain largely unknown. In previous editions, the authors offered a schematic by which to classify granulomatous inflammation based on appearance, precipitating factors, and degree of lymphocytic infiltration ('non-immunologic vs. immunologic') but warned us that the distinctions are more apparent than real. More than a decade later, this caveat holds true. Granulomatosus represents a distinctive reactive process in the spectrum of inflammation where the histiocyte is the key involved cell. A granuloma is a focal collection of activated and modified histiocytes, sometimes 'epithelioid' in appearance, usually surrounded by a rim of leukocytes. While histiocytes are now firmly established as monocyte/macrophage-derived cells based on surface immunohistochemical markers, past reliance solely on cell morphology has led to confusion as numerous diverse, reactive, and neoplastic cell populations can aggregate in the cutaneous microenvironment resembling histiocytes, commonly referred as 'histiocytoid'.

Keywords

Granulomatous • Monocytes • Macrophages • MGC • Multinucleated giant cells • Sarcoidosis • Non-infectious epithelioid granulomas • Inflamed blood vessels • Granulomatosis Disease

Introduction

Conceptually, the etiology of granulomatosus is thought of as an immune defense and reactive process. This is exemplified by various prototypic diseases such as tuberculosis and leprosy, representing infectious granulomas, and common conditions such as ruptured keratin cysts and suture granulomas, respectively representing endogenous and exogenous foreign-body reactions. Either undiscovered or undetectable by current investigative modalities several granulomatous entities, such as sarcoidosis and the group of necrobiotic granulomas, do not consistently demonstrate the presence of either infectious or foreign-body material.

Another classification distinguishes granulomas as immunologic vs. non-immunologic [1]. While both classifications involve macrophage activation admixed with leukocytes at the initiation of granuloma formation, the persistence of lymphocytes within the lesion are features of immunologic granulomas. In general, non-immunologic granulomas involve the introduction of large amounts of insoluble material while immunologic granulomas may result from introduction of a small amount of substances. These substances range from pathogenic stimuli such as bacteria, fungi, mycobacteria, or certain viruses and molds to chemical initiators. Still, even within the immunologic scheme, sarcoidosis and the necrobiotic granulomas cannot be neatly classified.

Role of Monocytes and Macrophages

Some insight into the clinical spectrum of granulomatous diseases may be gained by examining the characteristics and function of the histiocyte or monocytes/macrophages (Mo/Mac). Mo/Mac are often regarded as the primary phagocytic population of the innate immune system with some antigen presenting capabilities. They express several classes of receptors and are able to produce a cadre of enzymatic and metabolic mediators, suggesting a broader role than microbial surveillance [3].

In its innate immunity role, the Mo/Mac bear multiple cell surface molecules that mediate diverse pathogen recognition and processing as well as those that mediate recruitment and trafficking of inflammatory cells to the site of infection, such as toll-like receptors (TLRs) and chemokine receptors [4, 5]. A cornerstone feature of the Mo/Mac is their dynamic modification in response to acute inflammation or infection. They display high cellular plasticity and are driven by local microanatomic and systemic factors [6, 7]. Resting monocytes comprise 2–10 % of peripheral blood leukocytes and can be marginated in response to chemotactic factors released as a result of systemic events. The cells can infiltrate most tissue where they transform into activated macrophages. Additionally, various organs have resident tissue-specific differentiated Mo/Mac, mostly myeloid in origin, comprising a network called the mononuclear phagocyte system [8].

Mo/Mac also occupy a unique niche in the inflammatory response. One bystander effect of inflammation is apoptosis, requiring swift and efficient engulfment without inciting further inflammation or allowing leakage of potentially immunogenic material [9]. It has recently been shown that macrophages use distinct processes to clear apoptotic cells vs. necrotic cells by a "zipper-like" phagocytosis vs. macropinocytosis, respectively [10]. Mo/Mac express and utilize various receptors including scavenger receptors, complement receptors, and integrins to recognize apoptotic bodies and mediate removal to control potential inflammatory responses [11]. Hence, Mo/Mac are slowly being appreciated to have a more sophisticated role in inflammation.

Multinucleated Giant Cells

In the face of infection, the presence of Mo/Mac may signal both a reactive, protective process and also a homeostatic, restorative process. As fusion and aggregation ensue, they form histologically striking structures such as multinucleated giant cells (MGC) and granulomas, respectively (Fig. 37.1) [12]. The process resulting in formation of these structures remains poorly understood. Mo/Mac can be stimulated to generate MGC in vitro by addition of various cytokine and conditioned media [13]. Interferon γ has been identified as a critical cytokine in MGC formation [14]. In specialized multinucleated giant cells, such as osteoclasts and foreign body giant cells, macrophage fusion receptor (MFR) and its ligand CD47 have been implicated to facilitate cell fusion and cell-to-cell recognition [15]. The latter is important for cell-cell reciprocity, allowing multinucleation rather than activation of intracellular degradative processes in the newly fused cell. Recently, a molecule called DC specific transmembrane protein (DC-STAMP) was shown to be required for fusion of Mo/Mac into giant cells [16]. The ligand for DC-STAMP is currently unknown; however, it is structural similar to chemokine receptors, suggesting the possibility that the ligand may be a soluble chemokine. Chemokines such as CCL2 have already been shown to play a role in foreign body giant cell formation [17].

Recently, it was demonstrated that during cell differentiation into MGC, high amounts of chemokines were induced in Mo/Mac [18]. However, once the MGC become fully differentiated, the expression of the chemokines such as CCL2 and CXCL10 become constitutive and can not be further upregulated by exposure to *Mycobacterium tuberculosis*. This suggests two distinct phases in MGC formation. First, in acute infection, the development of MGC induces rapid recruitment of Mo/Mac via chemokine release. In the second phase, the differentiated MGC stimulates a steady influx of Mo/Mac, presumably towards the development of granulomas, via a steady state of chemokines. The connection between granulomatous infections and chemokines is supported by reports demonstrating high amounts of chemokines in lung specimens of patients with tuberculosis [19, 20].

Granuloma Formation

Presence of granulomas may represent an intact immune protective process, an exaggerated reactive process, and/or an attempt at restoring homeostasis. The experimental model of granuloma formation traditionally relies on a murine model of persistent infection, usually with *Mycobacterium* species, to examine the interaction of pathogen with Mo/Mac. Research aimed at unraveling the inciting signals has implicated a role for TLRs, the pro-inflammatory cytokine TNF-α, and T-helper 1 (Th1) cytokines IL-2 and IFN-γ [21, 22].

The elicitation of the host's Mo/Mac TLRs response in the *M. tuberculosis* model is complex because both pro-inflammatory and anti-inflammatory cytokines have been reported following *M. tuberculosis* exposure [23]. It is unclear if this dichotomy represents an immune evasion strategy employed by the pathogen or a balancing act by the host in an attempt to control inflammatory responses. Surprisingly, the susceptibility to *M. tuberculosis* was low in numerous TLRs

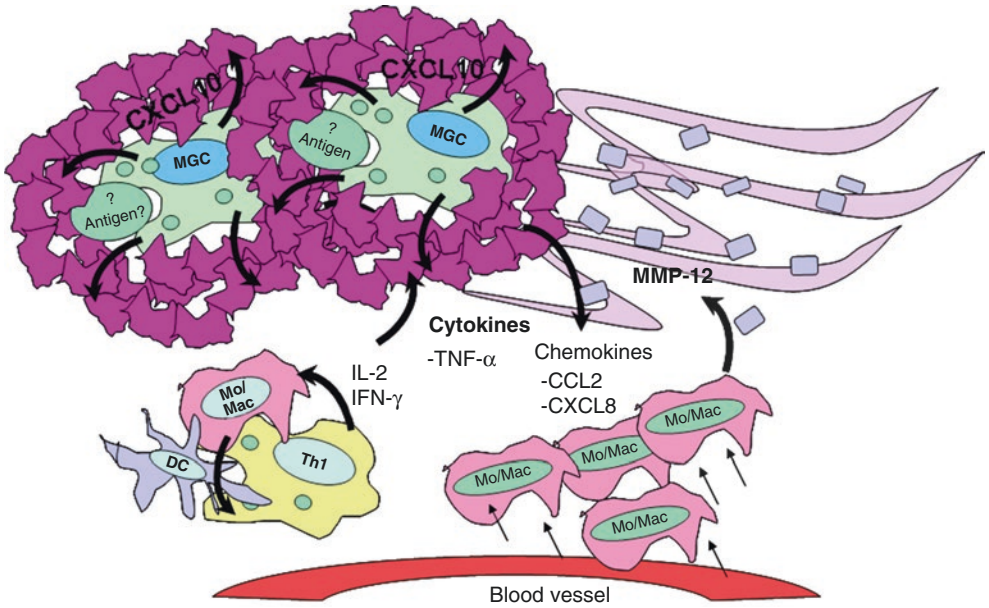

Fig. 37.1 Schematic for granuloma formation. Monocyte/macrophage (*Mo/Mac*) interaction with an antigen provokes an inflammatory response. Under influence of various cytokines and chemokines, some Mo/Macs undergo cell fusion to form multinucleated giant cells (*MGCs*). Once formed, MGCs secrete steady-state chemokines, attracting more Mo/Macs. Other activated Mo/Macs enlarge and differentiate into epithelioid histiocytes. Aggregation results in granulomas. Activation by tumor necrosis factor-a (*TNF-α*) and interferon-g (IFN-γ) is important in granuloma formation and maintenance

knockout (TLR2, TLR4, and TLR6) mouse models. However, the myeloid differentiation factor 88 (MyD88) knockout mice displayed high susceptibility to disease thus demonstrating the importance of TLRs in host defense against mycobacteria since MyD88 functions an adaptor molecule used by many TLRs following ligand activation. Studies using mycobacteria and other pathogens have demonstrated the importance of MyD88 in granuloma formation via IFN-γ induction [24–27].

More than a decade earlier, Flynn and colleagues reported that IFN-γ knockout mice infected with *M. tuberculosis* develop disseminated tuberculosis. They demonstrated that disease susceptibility followed granuloma necrosis due to the lack of macrophages activating signals needed for granuloma maintenance [28, 29]. Th1 cells play a role in both the formation and maintenance of granulomas by inducing and sustaining Mo/Mac recruitment. Similarly, mice deficient in TNF-α succumb to disseminated tuberculosis infection. In the absence of TNF-α, the granulomas formed are structurally disorganized leading to eventual necrosis [30, 31].

Matrix metalloproteinase (MMP), specifically MMP-12, also known as macrophage metalloelastase, has recently been reported to be abundantly expressed in granulomas [32]. Although not directly related to granuloma formation via macrophage activation but rather macrophage migration, MMP-12 has been shown in vivo to be important in macrophage penetration of basement membrane by digesting a variety of stromal substrates [33, 34]. Furthermore, surveys of several different human granulomatous skin disorders, including sarcoidosis, necrobiosis lipoidica diabeticorum, and granuloma annulare demonstrate that MMP-12 is abundantly expressed in co-localization with $CD68^+$ macrophages [35].

While the murine model provides a useful mammalian in vivo experimental tool, there are limitations. For example, cross strain murine infection with *Mycobacterium tuberculosis* produces multi-bacillary non-caseating granulomas, contrasting the usual course in human disease [36]. Furthermore, study of early events in granuloma formation, namely Mo/Mac recruitment, modification, and aggregation is limited by static ex vivo histological examination of tissue in this model.

Recent development of non-mammalian granuloma models have helped broadened our understanding of granuloma formation. This is possible through examination of host interaction with *Mycobacterium marinum* in species phylogenetically distinct from humans such as *Dictyostelium*, *Drosophila*, and zebrafish [37]. While extrapolation into human disease pathogenesis may not be immediately apparent, the observations suggest that pathogen recognition via pathogen associated molecule patterns (PAMPs) and macrophage aggregation may be evolutionary conserved processes. The *Dictyostelium* is a single cell amoeba that has similarities to the human phagocytic histiocyte. *Drosophila* is a known model of innate immunity. By utilizing the transparent zebrafish embryos, researchers have directly visualized migration and aggregation of macrophages, the hallmark of granuloma

formation, following infection with *M. marinum* [38]. Furthermore, at the embryonic stage, zebrafish lack circulating lymphocytes, suggesting that granuloma formation can be initiated in the absence of an adaptive immune contribution.

Granulomatous Disease

Except for infectious and foreign body granulomatosus, the factors determining the non-infectious granulomatous diseases are largely unknown. It likely results from the interplay between genetic susceptibility and environmental factors. Understanding the reaction patterns as well as the cellular and soluble mediators involved will be informative for understanding the etiopathogenesis of granulomatous diseases (Fig. 37.2). While this group of diseases involves infiltration and aggregation of immune cells, this does not necessitate that these disorders are immunologically mediated. Histiocytic aggregation may be seen in reactive processes.

Sarcoidosis is the most studied non-tuberculid granulomatous disease because of its affect on multiple organ systems and associated mortality and morbidity. Understanding the underlying molecular and cellular processes of this prototypic granulomatous disease may help elucidate the pathogenesis of other non-infectious granulomatous disorders.

Other diseases include cutaneous Crohn's disease, which is a spectrum of cutaneous manifestations associated with the inflammatory gastrointestinal disease, not all of which are granulomatous. The group of necrobiotic granulomas including granuloma annulare, necrobiosis lipoidica, and rheumatoid nodule share some common histological features but no consistent correlations with a single underlying systemic disease. Except for vasculitis and potential ulceration in the latter entity, the cutaneous conditions are largely benign. Annular elastolytic giant cell granuloma is a rare disease that is considered by some to be a variant of granuloma annulare, but with histologically distinct features. Similarly, it has a fairly benign course and may be self-limiting. Interstitial granulomatous dermatitis and palisaded neutrophilic and granulomatous dermatitis are two more recently classified granulomatous diseases that shares histologic features with granuloma annulare and necrobiosis lipoidica, though not much is known about their etiopathogenesis.

Non-infectious Epithelioid Granulomas

Sarcoidosis

Clinical Manifestations

Sarcoidosis is a multisystem disease characterized by non-caseating granulomas of unknown etiology [39]. The most commonly affected organ is the lung. Involvement of the skin is seen in up to one-third of patients, and may be the

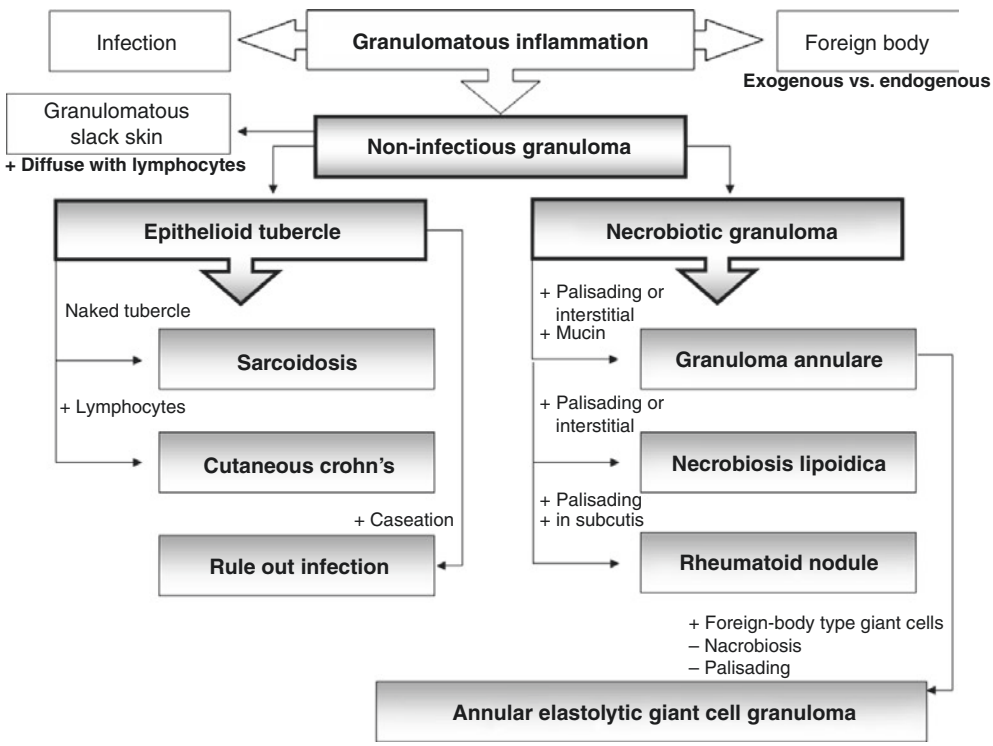

Fig. 37.2 An approach to the histologic diagnosis of granulomas

only clinical sign of the disease. Although the cutaneous lesions usually appear at onset of disease, it can occur at any time. Other organs affected include the liver, spleen, eyes, kidneys, glands, and less commonly, the central nervous system, heart, and musculoskeletal system. Several syndromes have been described in sarcoidosis depending on the constellation of symptoms and involved organs that include: Heerfordt-Waldenstrom syndrome (fever, parotid gland enlargement, anterior uveitis, and facial nerve palsy); Mikulicz's syndrome (infiltration of the parotid, submandibular, lacrimal, and sublingual glands) [40]; and Lofgren syndrome (fever, erythema nodosum, polyarthralgias, and bilateral hilar adenopathy). The latter is associated with a benign self-remitting course [41]. In general, while the mortality rate associated with severe pulmonary disease is low in sarcoidosis, 10–30 % of patients develop chronic debilitating disease.

Sarcoidosis affects all races worldwide with varying incidence. In the United States, African Americans have a 3.8-fold increased risk compared to whites, affecting women more than men [42]. The disease tends to be more chronic and fatal in African Americans [119].

Several studies have established that the skin disease does not correlate with prognosis or the extent of visceral involvement [42, 43]. However, there is correlation with erythema nodosum, usually a self-limiting condition seen most frequently in young women on initial presentation, with acute disease and large plaques with chronic disease [42, 44, 45]. Recent retrospective analysis of a small cohort of patients with the subcutaneous form of sarcoidosis suggests that this variant may be a subset associated with systemic disease [46].

The most common skin manifestations include non-painful reddish-brown papules and plaques often symmetrically involving the face, lips, neck, trunk, or upper extremities [47, 131]. Typically lesions lack scale or ulceration, though some lesions may develop these features. Cutaneous sarcoid is a great mimic and can have diverse clinical presentations. A variety of uncommon manifestions include an ichthyosiform, annular, angiolupoid (large telangiectatic), psoriasiform, or subcutaneous (Darier-Roussy) appearance. Atrophy can be seen in plaques. Scalp lesions have varying amounts of scales and may result in alopecia. Various non-specific nail and mucosal changes can also be seen.

Another manifestation of sarcoidosis is lupus pernio, indurated and violaceous papules and plaques on the nose, cheeks, and ears [48]. Ulceration can be seen in these lesions and can lead to scarring. Nasal alar lesions can extend into the nasal vestibule and nasal floor and is associated with granulomas in the upper respiratory tract and lungs in the majority of patients [49, 50]. The digits and toes may have sausage-shaped swelling due to underlying cystic lesions of the phalanges [51].

Histopathology

Langerhans, granulomas seen in sarcoidosis have the characteristic appearance of focal collections of epithelioid histiocytes associated with absent or sparse ring of lymphocytes composed of T and B lymphocytes. The term "naked tubercle" refers to a common observation of a granuloma devoid of lymphocytes and plasma cells. Multinucleated giant cells may be present, usually of the Langhans type, and these giant cells may contain asteroid and Schaumann bodies. There is typically no central caseation; however, there may be fibrinoid changes secondary to deposition of immunoglobulins, complement, and fibrinogen in up to 10 % of cases. The presence of caseation should prompt a search for infectious causes.

Both TNF-α and IFN-γ have been associated with granuloma formation [52, 53]. It is known that prolonged activation by these cytokines usually leads to apoptosis but the characteristic granulomas in sarcoidosis patients are non-caseating. It is unclear why there is the absence of apoptosis in the sarcoid granulomas. Recent studies have associated upregulated expression of an IFN-γ induced anti-apoptotic molecule p21Waf1, a cdk inhibitor, in sarcoidosis patients [54].

Pathogenesis

Numerous hypotheses have been put forth on the etiology of sarcoidosis, including infectious, autoimmune, and environmental. The identity of a causative antigen responsible for granuloma formation remains uncertain. The etiology and pathogenesis of sarcoidosis is complicated by highly varied disease presentation ranging from single organ to multisystem involvement, the lack of specific symptomology, and the waxing and waning nature of the disease. Both the clinical and tissue diagnosis of the disease require exclusion of other conditions such as mycobacterial or deep fungal infections, Wegener's granulomatosus, and malignancy.

A historic test for the diagnosis of sarcoidosis is the Kveim-Siltzbach skin test [55–57]. This was performed by injecting a patient with a suspension of sarcoid spleen material intradermally into the skin of a suspected patient. The formation of a non-caseating granuloma observed histologically 4 weeks later at the site of injection indicates a positive test. Studies of T cells at the Kveim-Siltzbach reaction sites have demonstrated an oligoclonal population of $CD4^+$ T cells which argues for sarcoidosis as an antigen driven disease [58]. This is supported by findings of similar oligoclonality, with a dominant V beta bias, in sarcoid lung T cells [59].

Infectious Etiology

Despite investigations for viral and mycobacterial causes of sarcoidosis, no consistency has been found. Human herpesvirus-8 (HHV-8) was postulated to be associated with sarcoidosis but has been met with many reports of negative

findings in sarcoidosis patients worldwide [60–63]. Mycobacterial DNA sequences have been found in various tissues in some sarcoidosis patients, while others report negative findings [64–67]. To date, no mycobacteria have been successfully cultured [68].

Recent reports have identified various mycobacterial components as potential pathogenic antigens in sarcoidosis. Serum from patients with sarcoidosis were found to have antibodies to Mycobacterium tuberculosis katG, M. tuberculosis heat shock protein 70, and Mycobacterium tuberculosis mycolyl transferase antigen 85A [58, 126, 127].

Environmental Exposure

Evidence for the role of environmental exposure in the pathogenesis of sarcoidosis comes from reports of higher incidence of disease in certain occupations, such as firefighters and aircraft carrier personnel [69, 70]. A recent study by Izbicki et al. noted an increased incidence among New York City Fire Department workers involved in the 2001 World Trade Center emergency [125]. Such disease clusters indirectly implicate an environmental etiology [71]. In a recent multi-center case control study, researchers did not find a single proximate cause. This group did report positive associations with insecticides, an agricultural environment, and microbial bioaerosols such as mold and mildew [72]. Interestingly, a negative association with cigarette smoking was found in the study, consistent with previous reports [73, 74].

Genetic Susceptibility

Familial predisposition of sarcoidosis is well-known: having a first-degree relative with the disease confers a five-times increased likelihood of having the disease. There are also reports of sibling discordance [84]. Several studies have reported disease susceptibility with HLA-1, HLA-B8, HLA-DRB1, HLA-DRB3, and HLA-DQB1 alleles [75, 118]. No definitive HLA genes have been uniquely established in African American sarcoidosis patients, a group identified to have 3.8-times increased annual incidence in the United States. Recent linkage studies suggest that more than one gene may be involved in disease susceptibility in African Americans [86]. A recent study by Valentonyte et al. reported an association of the butyrophilin-like 2 (BTNL2) gene on chromosome 6p with sarcoidosis but its precise function in sarcoidosis is still unknown [121].

CARD15/NOD2 has been linked to Blau syndrome, a granulomatous disease affecting the eyes, joints, and skin [76]. CARD15, expressed by mononuclear phagocytes, encodes NOD2 which recognizes a component of bacterial peptidoglycan [77]. The gene has also been associated with inflammatory bowel disease [78]. One report found an association of mutations in CARD15/NOD2 with early-onset childhood sarcoidosis, a distinct type of sarcoidosis in children younger than 4 years of age characterized by eye, joint, and skin involvement [79]. Attempts to find an association of CARD15/NOD2 in adult sarcoidosis have demonstrated no relationship [75].

Despite several proposals of correlative serum markers, including serum amyloid A and C-reactive protein, no consistent correlations have been demonstrated. Even serum angiotensin converting enzyme (ACE), initially promising, has not been a consistent marker of disease activity [80, 81]. Other markers currently being examined include macrophage inflammatory protein 1 (MIP-1) and vascular endothelial growth factor (VEGF) [82, 83].

Immune Regulation

There are numerous lines of research indicating that the involved lymphocytes are of the Th1 phenotype, producing cytokines such as IL-2, IFN-γ, and enhanced TNF-α [87, 88]. Findings of hypergammaglobulinemia in sarcoidosis patients leads to the question of B cell involvement in disease pathogenesis. It is now believed that the hypergammaglobulinemia is secondary to IL-2 and IFN-γ stimulation of B cells [89, 90]. Adding to the puzzle of sarcoidosis is that despite activation of networks of pro-inflammatory cytokines and robust recruitment of cells, there is often an associated state of either complete or partial anergy [91, 92]. This has been demonstrated by a lack of response to the tuberculin skin test or decreased sensitization to agents like the contact sensitizer dinitrochlorobenzene (DNCB) seen in up to two-thirds of sarcoidosis patients. Explanations offered for the observation of decreased delayed-type hypersensitivity was due to peripheral lymphopenia from sequestering and compartmentalization of T cells into granulomas. Recent data suggests that sarcoidosis patients have an unusually high number of innate T regulatory cells (T_{regs}), with constitutive $CD25^{bright}$/$CD4^{+}$ cells, both in the peripheral circulation and at the periphery of granulomas [93]. T_{regs} from sarcoidosis patients demonstrated similar capabilities of suppressing responder cell proliferation as compared to controls. The T_{regs} from sarcoidosis patients inhibit IL-2 but not TNF-α or IFN-γ production by responder cells compared to normal controls in which all three cytokines were completely inhibited. Since TNF-α is associated with sarcoidosis and granuloma formation, these findings may explain the concurrence of cell activation with a global state of anergy.

Th17, a CD4+ effector T cell population, has been linked to chronic inflammatory diseases involving Th1 cells including psoriasis, rheumatoid arthritis, and inflammatory bowel disease [117]. Recent studies have shown the presence of Th17 in the lung and peripheral blood of patients with active sarcoidosis [116]. Presence of these cells likely play a role in the chronic inflammatory state found in sarcoidosis [117].

It is known that 8–21 % of patients with common variable immunodeficiency (CVID) develop a granulomatous disease resembling sarcoidosis [94]. Since CVID is not a

single entity but rather a heterogeneous syndrome, a retrospective study correlating patients with granulomatous disease and specific immunologic derangement may provide some clues in the pathogenesis of sarcoidosis. Some CVID patients develop hyperproliferation of $CD4^+$ cells, yet some have increased apoptosis of $CD4^+$ cells. Sixty percent of patients have a diminished response to T cell receptor stimulation and expression of CD25, the receptors for IL-2.

Treatment

Many individuals require no treatment, though the decision to treat depends on the site and severity of organ involvement [122]. There are numerous anecdotal and case series that discuss the treatment of sarcoidosis but few clinical trials. The mainstay therapy includes corticosteroids. Other commonly used agents include minocycline (particularly for cutaneous sarcoidosis), anti-malarials, methotrexate, and TNF-alpha agents [95, 122]. Paradoxically, several reports have noted the appearance of cutaneous sarcoid lesions while on TNF-alpha therapy for other diseases [123, 124].

Cutaneous Crohn's Disease

Crohn's Disease (CD) is characterized by segmental granulomatous inflammation of the intestinal tract. Cutaneous manifestations of the disease occur in 14–44 % of patients, and include CD-specific, reactive, and associated conditions. CD-specific lesions involve the skin by the same mechanism as the GI tract and include fissures and fistulae, oral Crohn's disease, and metastatic Crohn's disease. The latter is a rare entity that denotes a cutaneous lesion distant from extension or fistulae formation from oral, anal, or ostomy sites. Reactive lesions involve the skin by distinct pathogenic mechanisms and include erythema nodosum, pyoderma gangrenosum, Sweet syndrome, and polyarteritis nodosa [96, 128].

The cutaneous manifestations of Crohn's Disease, including metastatic Crohn's disease, have inconsistent correlation with internal disease activity. Classically, extra-genital metastatic Crohn's disease presents with dusky erythematous plaques that may develop into ulcers. Histopathologic examination reveals a sarcoid-like epithelial granuloma, usually with a notable lymphocytic infiltrate and occasionally with necrobiosis [97, 98]. The inflammatory infiltrate can often surround dermal blood vessels, termed granulomatous perivasculitis [98].

A recent study attempted to elucidate the etiology of cutaneous Crohn's by examining the gastrointestinal and corresponding skin specimens in patients with Crohn's and cutaneous Crohn's disease for bacterial 16s rRNA. They report no bacterial 16S rRNA, examined by in situ real time vs reverse transcriptase polymerase chain reaction (RT-PCR), in skin lesions whilst being present in gastrointestinal biopsies, suggesting that bacterial dissemination may not be involved in cutaneous lesions. Reactivity to bacterial products may play a role in the cutaneous manifestation of Crohn's [99].

As discussed earlier, polymorphisms in CARD15/NOD2 have been associated with Crohn's disease but, the mechanism leading to predisposition of disease is unclear [100]. One hypothesis is that mutations in CARD15 leads to a defect in the acute inflammatory response to intestinal bacteria, leading to allowance of materials to breach the gut barrier. The subsequent response to the bacterial products leads to a granulomatous reaction [101].

Necrobiotic Granuloma

The group of necrobiotic granulomas consists of granuloma annulare (GA), necrobiosis lipoidica, and rheumatoid nodules. The etiology of these diseases is unknown. The common histological reaction pattern is palisading granulomas with areas of altered or degenerated connective tissue. Variations such as interstitial granulomatous inflammation can be see in GA and necrobiosis lipoidica, as well as interstitial granulomatous dermatitis and palisaded neutrophilic and granulomatous dermatitis, two recently categorized granulomatous diseases.

Granuloma Annulare

GA is a benign disorder limited to the skin. There have been many proposed inciting factors such as trauma, insect bites, and viral infection. A delayed-type hypersensitivity reaction to an unknown antigen may be the formative event; this hypothesis is supported by a study showing T-cell subpopulations in histologic specimens of GA lesions [129]. The association with systemic disease such as diabetes mellitus has been inconsistent. Atypical variants of GA have been described in patients with HIV/AIDS and lymphoma [102, 103]. The localized variant is most commonly seen, occurring as annular or arcuate plaques on the hands and arms [104]. It can also involve the extremities and trunk. Other variants include papular, generalized, perforating, subcutaneous, and patch forms of the disease. On histology, the recognizable pattern is of palisaded epithelioid histiocytes with a central acellular area of pallor, increased mucin, and altered collagen and elastic fibers. The most common pattern is the infiltrative or interstitial pattern where histiocytes are interspersed between collagen with subtle alteration of the fibers.

The entity annular elastolytic giant cell granuloma is regarded by some as a variant of GA. Lesions are also asymptomatic. On histology there are foreign body type giant cells without a palisading granulomatous inflammation. There is usually no altered collagen. An elastin stain shows loss of elastic fibers in granulomatous areas.

Rheumatoid Nodules

Rheumatoid nodules can be seen in the clinical setting of adult-type polyarticular rheumatoid arthritis and is a rare feature of rheumatic fever [105]. History and context of presentation will aid in the diagnosis. The etiology of rheumatoid arthritis (RA) remains unknown. Disease susceptibility is strongly associated with class II region genes, HLA-DRB1 [106–108].

Clinically, rheumatoid nodules present as firm papules or nodules along extensor surfaces of joints. Histology reveals a palisading layer of histiocytes and granulation tissue surrounding a central zone of fibrin [130].

There is high suspicion that RA is mediated by autoantibodies, specifically by a group that recognizes citrullinated proteins, including the antiperinuclear factor, antikeratin antibodies, and antifilaggrin antibodies [109]. These antibodies are commonly found in the sera and synovial fluid of RA patients [110]. In a small study of 26 patients, citrullinated proteins were observed in 70 % of the rheumatoid nodules [111].

Citrullination, a post-translation modification process, has been demonstrated to increase peptide and MHC affinity, suggesting that it can modulate immune responses [112]. The enzyme mediating citrullination is peptidylarginine deaminase, found in inflammatory cells including neutrophils, monocytes, and macrophages [113]. Hence, it is tempting to speculate a relation of the Mo/Mac and granulomatous reaction in the skin with citrullination as a potential source of "autoantigens". Recently, T cells recognizing the specific modification of antigens by citrullination was described [114]. It remains to be determined if they are the pathogenic mediators of RA.

Necrobiosis Lipoidica

Necrobiosis lipoidica "diabeticorum" (NLD) was originally described in patients with diabetes but demonstration of non-diabetic patients with the condition have lead to reconsideration of its name. The disease has a characteristic presentation of asymptomatic yellow-brown plaques involving the pretibial areas. The lesions over time become atrophic with development of telangiectasias. Ulceration can develop but the disease is generally benign. On histology the "cake layers" of granulomatous inflammation and parallel degenerated collagen is typically seen. The pattern can be palisaded or interstitial.

The etiology of NLD is unknown. Twenty years ago Ullman and Dahl suggested that the disease may be secondary to vasculitis based on findings of IgM and complement C3 deposition in blood vessels of affected skin [115]. Recently, NLD skin sections were shown to stain for GLI-1, a transcription factor in the hedgehog signaling pathway. The significance remains to be seen.

Closing Remarks

Traditionally the Mo/Mac is simply thought of as phagocytes. That frame of reference prompted investigations with the goal to identify causal pathogens in granulomatous diseases. Macrophages are very plastic cells found in most tissues and are responsive to their microenvironment. New understanding of the diverse homeostatic and regulatory functions of Mo/Mac should broaden our understanding of this inflammatory response.

Furthermore, diseases with overactive and chronic persistence of Mo/Mac and granulomatous inflammation can be the potential target of liposomes, specific uptake by Mo/Mac, or via targeting their unique receptors such as anti-Fc©RII receptor (CD 32). However, the degree to which macrophages play a role in promoting lesions and their persistence is not fully understood in some of these diseases. Agents that limit Mo/Mac response may play an important role in understanding the pathophysiology of these dermatoses.

Questions

1. Which of the following are involved in the mechanisms of macrophages forming multinucleated giant cells?
   A. Antigen recognition
   B. Inflammatory response
   C. Cell fusion
   D. Production of chemokines
   E. All of the above
   F. None of the above

Correct answer: (E) All of the above steps are involved in giant cell formation

2. What relevant immune factors are *not* involved in granuloma formation?
   A. Persistence of antigen
   B. Innate Recognition by TLR
   C. Th2 lymphocyte reactivity and associate cytokines
   D. Formation and maintenance of granulomas by reactive lymphocytes

Correct answer: (C) Th2 lymphocytes are not involved in granduloma formation (it is actually Th1 lymphocytes)

3. What role does immune regulation play in sarcoidosis?
   A. Sarcoidosis is an antigen-driven disease that is dependent on T-lynphocytes
   B. Autoantibodies are critical in the pathogenesis
   C. Infections are the commonest cause of sarcoidosis.
   D. The diagnosis is dependent on a positive skin test (Kveim-Siltzbach skin test)
   E. Mycobacterial infections are central to the pathogenesis.

Correct answer: (A) Sarcoidosis is an antigen driven disease that is T lymphocyte dependent

Cutaneous Graft-Versus-Host Disease

38

Edward W. Cowen

Abstract

Allogeneic hematopoietic stem cell transplantation (HSCT) is a potentially life-saving treatment modality. However, many patients who undergo allogeneic HSCT develop graft-versus-host disease (GVHD) of the skin, potentially resulting in significant long-term morbidity. Chronic GVHD may manifest on the skin in many different clinical presentations, including skin fibrosis, and represents a significant treatment challenge that is often compounded by co-morbidities due to GVHD involvement of other organ systems.

Keywords

Graft-versus-host disease • Hematopoietic stem cell transplantation • Morphea • Scleroderma • Fasciitis

Hematopoietic Stem Cell Transplantation

Allogeneic hematopoietic stem cell transplantation (HSCT) is a potentially curative intervention for more than 15,000 patients each year suffering from cancer, primary immunodeficiency, and other serious heritable and acquired disorders (Table 38.1). However, allogeneic HSCT may lead to graft-versus-host disease (GVHD), a complex multi-organ disease that is a major cause of post-transplant non-relapse morbidity and mortality. Although it occurs most frequently in association with allogeneic HSCT, GVHD may also result from autologous HSCT, allogeneic liver transplantation, or blood transfusion. Practically every organ system may be affected by GVHD, but the skin is the most common site of involvement, and chronic cutaneous GVHD is perhaps most remarkable for its variable cutaneous manifestations.

The first step in allogeneic HSCT is the identification of a suitable stem cell donor. The donor is selected based on the similarity of his/her histocompatibility antigen (HLA) profile to that of the recipient. There are three major Class I HLA antigens, HLA-A, –B, and –C, and three major Class II HLA antigens: HLA-DP, –DQ, and –DR. Because the alleles in each HLA class tend to be inherited together, there is approximately a 25 % chance that a sibling donor will be a 6/6 HLA-identical match. If no related donor is available, then a bone marrow registry will be utilized to search for an unrelated donor. International registries now contain over 9 million potential donors and identify an unrelated donor for approximately 50 % of patients [1]. The risk of GVHD is directly proportional to the degree of mismatch in major HLA alleles between donor and recipient. In addition, mismatch of minor HLA antigens is more likely to occur in the setting of unrelated donor HSCT, also contributing to the development of GVHD. Once a suitable donor is identified, the stem cells are collected from the donor's bone marrow, or colony-stimulating factor (CSF) is administered to the donor in order to mobilize stem cells from the marrow prior to pheresis from the peripheral blood. Umbilical cord blood is a third source for stem cell transplantation but currently accounts for a small percentage of transplants performed worldwide. The source of the stem cell graft is an important factor in the development of GVHD as peripheral blood grafts may be associated with a higher risk of GVHD than bone marrow-derived grafts [2]. After harvesting, donor stem cells are selected by physical and immunologic sorting methods. Specific T-cell depletion of the graft may be utilized in order to decrease the risk of GVHD prior to transfusion.

Histiocytoses
Idiopathic hypereosinophilic syndrome
Myelofibrosis
Polycythemia vera
Paroxysmal nocturnal hemoglobinuria
Sickle cell disease
Thalassemia
Waldenstrom macroglobulinemia

Pre-treatment of the recipient's marrow before transplantation is necessary in order to allow engraftment of the donor stem cells. Traditional myeloablative regimens utilize a combination of total-body irradiation and chemotherapeutic agents such as cyclophosphamide to permit engraftment. These regimens create an immunosuppressed state, preventing the host from rejecting the foreign stem cells. Myeloablative preparative regimens may also reduce tumor burden through a direct effect on the cancer; however, they are associated with a high rate of toxicity [3]. Over the last several years, reduced-intensity (nonmyeloablative) preparative regimens have resulted in less acute toxicity and have expanded the use of allogeneic transplantation to higher risk groups including older patients or those with significant organ dysfunction. Reduced-intensity regimens rely primarily on the transplanted graft for anti-cancer activity rather than the direct cytotoxicity of the preparative regimen [1].

Autologous stem cell transplantation, which utilizes the patient's own stem cells following ablation of the hematopoietic system, is an important treatment for certain malignancies such as non-Hodgkin's lymphoma and multiple myeloma. More than 30,000 autologous procedures are performed worldwide each year. Although the risk of GVHD and overall non-relapse mortality are greatly reduced following autologous transplantation when compared with allogeneic transplantation, autologous procedures are associated with an increased rate of malignancy relapse [4].

Acute Versus Chronic GVHD

Traditionally, the onset of GVHD symptoms before or after the 100 day mark following transplantation has been used to designate acute versus chronic GVHD, respectively. However, this temporal distinction is somewhat arbitrary, as patients may manifest classic signs of acute GVHD after day 100, and chronic manifestations may occur before 100 days post-transplantation. Whereas acute cutaneous GVHD typically presents as an exanthematous skin eruption with gastrointestinal and hepatic involvement, chronic cutaneous GVHD is remarkable for its protean skin presentation and is associated with variable but potentially widespread organ dysfunction and immunodsyregulation. Changes in transplant protocols have also impacted the onset of acute and chronic symptoms. Nonmyeloablative conditioning regimens may delay the onset of manifestations of acute GVHD until after 100 days following transplantation [5]. Similarly, the use of donor lymphocyte infusions (DLI), wherein additional stem cells are administered weeks or months following transplantation to augment the graft-versus-tumor response, may induce symptoms of acute GVHD after the 100 day period [18].

Clinical Manifestations of GVHD

Acute GVHD

Acute GVHD is a potentially life-threatening complication of allogeneic transplantation. The risk of developing acute GVHD depends on a number of factors, including HLA-compatibility, the age and sex of the donor and recipient, the GVHD prophylaxis regimen used, and the T cell composition of the graft. Without prophylactic immunosuppression, acute GVHD will develop in most allogeneic HSCT recipients. Therefore a calcineurin inhibitor (cyclosporine or tacrolimus) or other immunosuppressant regimen is commonly used in the first several weeks to months following transplantation during which time the risk of acute GVHD is greatest.

Despite prophylactic immunosuppressive therapy, nearly 30 % of HLA-identical related transplant procedures result in significant acute GVHD [6]. This risk is significantly higher in HLA-matched unrelated and mismatched transplants. The skin is often the earliest clinical sign of acute GVHD. Long-term survival from acute GVHD is directly related to the severity of skin, liver, and gut involvement. The 1994 Consensus Conference grading for acute GVHD is demonstrated in Table 38.2 [7].

Acute GVHD primarily involves the skin, liver, and gastrointestinal tract, although other organ systems may be affected less frequently. Skin involvement most often occurs within 2–4 weeks after transplantation. Cutaneous involvement may range in severity from an asymptomatic maculopapular erythematous eruption to widespread necrolysis, but most commonly presents with an exanthem-like eruption that preferentially involves the head, ears, palms, and soles (Fig. 38.1). In early GVHD, there may be involvement of the hair follicles creating a folliculocentric-appearance [8]. When severe, diffuse erythroderma or bullae with epidermal necrolysis may occur (Fig. 38.2).

Histologically, acute GVHD is characterized by widespread keratinocyte necrosis with a dermal lymphocytic infiltrate and basal cell hydropic degeneration (Fig. 38.3). Histologic changes mimicking GVHD may be found following high-dose chemotherapy or radiation therapy, in the setting of drug hypersensitivity, and with the eruption of lymphocyte recovery; therefore clinicopathologic correlation is often helpful [9]. In cases in which the clinical and histologic diagnosis of acute skin GVHD is non-diagnostic, the presence of hyperbilirubinemia or symptoms of nausea, vomiting, diarrhea, or abdominal pain are important indicators of hepatic and gastrointestinal involvement. Even in the setting of equivocal cutaneous and histological findings, the mortality associated with severe acute GVHD necessitates a low threshold for initiating empiric corticosteroid therapy.

Table 38.2 Staging and grading of acute GVHD

Stage	Skin	Liver	Gut
1	Rash <25 % BSA	Bilirubin 2 mg/dL to <3 mg/dL	Diarrhea 500–1000 mL/day or persistent nausea
2	Rash 25–50 % BSA	Bilirubin 3–6 mg/dL	Diarrhea 1000–1500 mL/day
3	Rash > 50 % BSA	Bilirubin 6–15 mg/dL	Diarrhea > 1500 mL/day
4	Erythroderma w/bullae formation	Bilirubin >15 mg/dL	Severe abdominal pain with or without ileus
Grade			
I	Stage 1-2	None	None
II	Stage 3 or	Stage 1 or	Stage 1
III		Stege 2–3 or	Stage 2-4
IV	Stage 4 or	Stage 4

Chronic GVHD

Chronic GVHD occurs in 30–80 % of allogeneic HSCT recipients and is the leading cause of non-relapse mortality in survivors more than 2 years after transplantation [10]. Skin involvement may progress directly from acute disease, following a period of disease quiescence, or *de novo* without a history of previous acute involvement. The greatest predictor of chronic GVHD is a history of prior acute GVHD [11]. Other risk factors include older patient age, female donor for male recipient, mismatched or unrelated donor, peripheral blood graft, T-cell replete graft, and use of donor lymphocyte infusions. A flare of chronic cutaneous GVHD may be triggered by a number of factors, most commonly tapering of immunosuppression, but may also occur following the development of a drug eruption or sunburn, or in the setting of a cutaneous or systemic infection.

One of the greatest hurdles to improving chronic GVHD management stems from the clinical and immunological complexity of the disorder. In an effort to facilitate clinical research in the field of chronic GVHD, the National Institutes of Health Chronic GVHD Consensus Project published a series of articles providing a standardized approach for diagnosis and staging [12], histopathology [13], disease biomarkers [14], response criteria [15], supportive care [16], and clinical trial design [17]. Traditionally, chronic cutaneous GVHD has been described as either "lichenoid" or "sclerodermoid" involvement. However, these terms do not accurately portray the variability in the currently recognized cutaneous manifestations of chronic GVHD [18]. The Consensus Project diagnosis and staging guidelines provide a classification system of the clinical manifestations of cutaneous GVHD (Table 38.3). Poikiloderma, lichen-planus-like lesions, and sclerotic skin changes including fasciitis are considered diagnostic features of chronic cutaneous GVHD when they occur in the setting of allogeneic HSCT. Other cutaneous features, such as ichthyosis, dyspigmentation, and alopecia are also well-recognized manifestations but are not considered diagnostic of skin involvement [12].

Given the variety of epidermal changes associated with GVHD, the term "lichenoid" is preferred as a histologic descriptor of GVHD rather than as a clinical disease classification. Discrete lichen-planus-like violaceous papules are relatively uncommon in chronic GVHD, but may be seen most commonly on the palms and soles (Fig. 38.4). In the past, the term "lichenoid" has been used most commonly to describe cutaneous GVHD which manifests as poorly defined interconnecting erythematous papules and plaques with overlying scale. This eruption may localize to sites of previous UV exposure, such as the posterior and lateral neck, and may spare UV-protected areas such as the buttocks. Underlying sclerotic changes resembling lichen sclerosus or morphea may also be present. Resolution of this manifestation of chronic GVHD often results in a distinct reticulate pattern of hyperpigmentation, reflecting the pigment incontinence induced by the epidermal-dermal interface reaction.

Sclerotic changes associated with chronic GVHD may develop at any layer of the dermal and subcutaneous tissue. Chosidow et al. [19] estimated the incidence of sclerodermatous GVHD to be 3.6 % based on a review of 196 HSCT patients. However, the true frequency of sclerotic changes associated with GVHD may be higher if all forms of sclerosis are included. In a large NIH cohort of 206 patients enriched for severe and refractory chronic GVHD, sclerotic changes were detected in 109 (53 %) [20]. Sclerosis may be present on multiple levels on a single patient and the changes may or may not occur in the presence of overlying epidermal involvement. The most superficial level of sclerotic changes resembles lichen sclerosus and consists of atrophic gray patches with epidermal atrophy, often distributed symmetrically on the upper back. Morphea-like GVHD mimics morphea with patchy areas of prominent dermal sclerosis, often with overlying pigmentation, that results in a decreased ability to pinch the skin. Morphea-like GVHD often occurs preferentially at sites of skin friction or pressure such as the waistband area (Fig. 38.5) [21]. Scleroderma-like GVHD represents full-thickness sclerosis with the complete inability to pinch skin and with a hidebound appearance. Involvement over joints may significantly limit range of motion. In contrast to scleroderma, scleroderma-like GVHD does not begin with symmetric distal hand involvement and proceed proximally and Raynaud's phenomenon is uncommon [18]. Chronic sclerosis may be complicated by bullae formation as well as spontaneous erosions and ulcerations (Fig. 38.6). Benign angiomatous papules and nodules may develop in patients with chronic disease (Fig. 38.7) [22].

The histologic of "lichenoid" chronic GVHD resembles that of lichen planus with a bandlike lymphoplasmocytic infiltrate. Sclerotic GVHD resembles scleroderma with homogenization of collagen and loss of adnexal structures. The level and degree of fibrosis observed histologically reflects the clinical type of sclerosis. In patients with primary rippling to the skin resembling eosinophilic fasciitis, sclerosis and inflammation will be seen primarily at the interface between the reticular dermis and the subcutaneous fat and the deeper fascia.

Chronic GVHD-Related Fasciitis

GVHD-related panniculitis and fasciitis represent sclerosis of the deep subcutaneous tissue and fascia [23]. Although GVHD-related fasciitis is thought to be an uncommon presentation, it may present in an insidious manner with resultant marked functional limitations. Patients with GVHD-related fasciitis often manifest overlapping features of both panniculitis and fasciitis and the histologic diagnosis may depend on the depth and extent of the tissue biopsy.

Table 38.3 Clinical manifestations of chronic GVHD

Dermatologic and mucosal features	
Skin	Alopecia
	Angiomatous papules
	Bullae
	Erythema
	Hypo- or hyperpigmentation
	Ichthyosis-like
	Keratosis-pilaris-like
	Lichen-planus-like[a]
	Lichen-sclerosus-like[a]
	Maculopapular
	Morphea-like[a]
	Poikiloderma[a]
	Scleroderma-like[a]
	Sweat impairment
	Ulceration
Nails	Brittleness
	Longitudinal ridging or splitting
	Onycholysis
	Pterygium unguis
Subcutaneous tissue	Fasciitis[a]
	Panniculitis
Oral mucosa	Erythema
	Gingivitis
	Hyperkeratotic plaques[a]
	Lichen-planus-like[a]
	Mucocele
	Mucosal atrophy
	Mucositis
	Pseudomembrane
	Restriction of oral opening from sclerosis[a]
	Ulcer
	Xerostomia
Genital mucosa	Lichen planus-like[a]
	Vulvar erosions/fissures
	Vaginal scarring/stenosis[a]
Other organ system involvement in chronic GVHD	
Cardiovascular	Pericardial effusion
Ophthalmologic	Cicatricial conjunctivitis
	Sicca symptoms
	Confluent punctuate keratopathy
	Photophobia
	Blepharitis
Gastrointestinal	Esophageal web
	Esophageal stricture/stenosis
Hematopoeitic	Thrombocytopenia
	Eosinophilia
	Lymphopenia
	Hypo- or hypergammaglobulinemia
	Autoantibodies
Hepatic	Elevated total bilirubin
	Elevated alkaline phosphatase
	Elevated transaminases

Table 38.3 (continued)

Musculoskeletal	Myositis or polymyositis
	Edema
	Myalgia

Neurologic	Peripheral neuropathy
	Myasthenia gravis
Pulmonary	Bronchiolitis obliterans ± organizing pneumonia
	Pleural effusion

[a]Diagnostic feature; other signs and symptoms listed are not considered sufficient to establish a diagnosis of chronic GVHD without further testing or other organ involvement

Fig. 38.4 Chronic GVHD; scaling violaceous papules and plaques on the hands

Patients may complain of muscle pain or weakness [24], or may demonstrate limited range of motion at affected joints at the time of presentation. GVHD-associated fasciitis shares many similarities with eosinophilic fasciitis, an uncommon disorder of unknown etiology first described by Shulman in 1974 [25]. GVHD-associated fasciitis presents with prominent induration and rippling of tissue, visible grooves demarcating fascial bundles or underlying superficial veins, and decreased range of motion (Fig. 38.8). The first indications of subcutaneous involvement may be edema of the affected limb. Magnetic resonance imaging may facilitate the diagnosis of subcutaneous involvement [26, 27].

Genital GVHD

Assessment of genital involvement is important in the management of GVHD patients. Genital involvement is most commonly associated with sclerotic cutaneous disease, but may occur with other forms of cutaneous involvement, or in the absence of other cutaneous involvement. Genital tract involvement may be present in as many as 49 % of female patients two years post-transplantation and may seriously impact the quality of life of affected individuals [28]. Manifestations include burning and irritation, discharge, erosions and fissures, or vaginal stricture (Fig. 38.9). In a recent review of 155 male allogeneic transplant recipients 1 year or more after transplant, 21 (13 %) manifested inflammatory lesions, most frequently balanoposthitis (12 patients), lichen-sclerosus-like lesions (6), and phimosis (5) [29].

Oral GVHD

The second most common organ system involved with chronic GVHD after the skin is the mouth. Chronic oral GVHD may affect the oral mucosa and salivary glands. Mucocele formation is very common but usually asymptomatic. Lichen-planus-like oral involvement manifests as erythematous hyperkeratotic plaques and erosions. Sclerosis of the skin surrounding the mouth or the frenulum can cause difficulty opening the mouth or protruding the tongue, respectively. Persistent erosions and fissures cause burning pain, particularly upon contact with acidic foods. Salivary

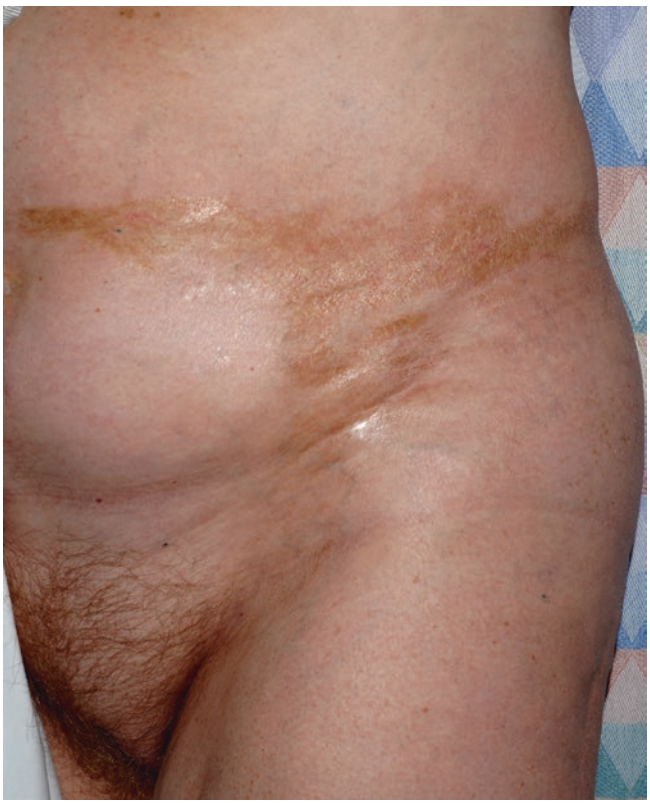

Fig. 38.5 Tan sclerotic plaques with koebnerization at site of waistband in patient morpheaform chronic GVHD

gland involvement from chronic GVHD results in decreased saliva production and sicca symptioms. Loss of taste is also commonly reported by patients [30].

Immunology of GVHD

Acute GVHD

Acute GVHD is a reaction of immunocompetent donor cells against the cells and organs of the host. Billingham [31] described three features necessary for the development of GVHD: (1) the transplanted graft must be immunologically competent; (2) the recipient must not be capable of rejecting the graft; (3) the recipient must express antigens that are recognized as foreign by the graft. Grafted cells recognize the host as foreign through differences between the donor and host in major and minor HLA expression.

Pro-inflammatory Environment

Ferrara and Reddy [32] proposed a three-step model for the immunopathophysiology of acute GVHD. The first phase occurs prior to transplantation of the graft during which time chemoradiotherapy, the underlying disease state, and other factors activate host antigen presenting cells (APCs). Total body irradiation in particular plays an important role in priming the immune response by inducing epithelial cell damage in the gastrointestinal tract,

Fig. 38.6 Hidebound sclerosis with skin ulceration in a patient with scleroderma-like chronic GVHD

Fig. 38.7 Numerous angiomatous papules and nodules in a patient with chronic sclerotic GVHD of the legs

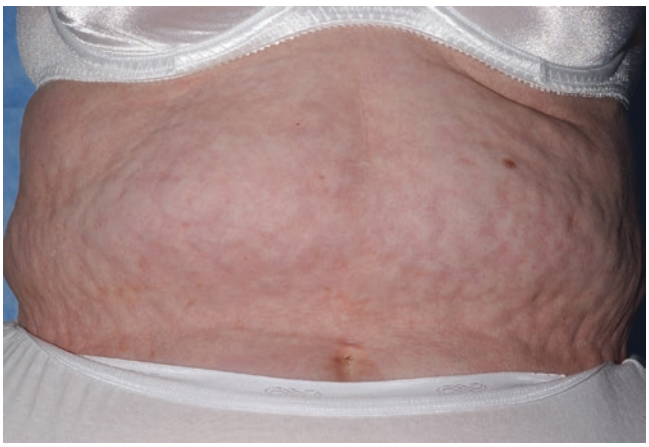

Fig. 38.8 Subcutaneous sclerosis from chronic GVHD; there is prominent rippling and nodularity of the subcutaneous tissue appreciable by deep palpation. The overlying skin is normal in texture and color

Fig. 38.9 Chronic vulvar GVHD; resorption of labia minora; pallor and sclerosis of vulvar vestibule; fissuring of the interlabial sulcus

which leads to host secretion of inflammatory cytokines (TNF-α and IL-1) and exposure to microbial products such as lipopolysaccharide. In fact, total body irradiation may contribute to chronic GVHD as well, particularly sclerotic skin disease, as pre-transplant conditioning was recently found to a be a risk factor for development of sclerotic chronic GVHD [20].

In the second phase of acute GVHD, host APCs expressing MHC class I and II molecules are recognized as foreign by donor T-cells. In murine studies, host dendritic cells are sufficient to activate donor T cells [33]. Differences in minor histocompatibility antigens (mHags), such as those encoded on the Y chromosome, may also play an important role in propagating acute GVHD, particularly in the setting of HLA-identical transplantation. Activation of natural killer (NK) cells, which eliminate APCs, abrogates the development of GVHD, suggesting a crucial role for host APCs in the propagation of acute GVHD [34]. The three major organ systems involved in acute GVHD – the skin, liver, and gut – contain large numbers of APC, which may in part be responsible for the localization of tissue damage to these organ systems [35].

In the final effector phase, inflammatory mediators and cell-mediated killing work together to induce the clinical effects typical of acute GVHD. $CD8^+$ cytotoxic T cells (CTLs) utilize perforin/granzyme mediated cytolysis, whereas $CD4^+$ T cells utilize Fas/FasL signaling, which may be particularly important for inducing hepatic damage [32]. TNF-α and IL-1 signaling play a prominent role in cellular damage in acute gastrointestinal GVHD. Cytokine gene polymorphisms may influence the expression of GVHD as a variance in the TNF-α gene has been associated with an increased risk of severe acute GHVD [36], whereas polymorphisms in IL-10, a potent suppressor of TNF-α, IL-1, and other inflammatory cytokines, has been associated with a decreased incidence of acute GVHD [37].

Regulatory T-Cells

Acute GVHD is mediated by donor T-cells that expand following transplantation in response to the recipient environment. Regulatory T-cells (T_{reg}) constitute a subset of the T-cell population which exert control over the allogeneic T-cell response against the host. T_{reg}s express FOXP3, a key transcription factor for T_{reg} function, as well as CD25, the IL-2 receptor α chain that is also expressed by activated T-cells. Donor grafts with a low percentage of CD4 + Foxp3+ T_{reg}s are associated with an increased risk of acute GVHD. In addition, the ratio of CD4 + FOXP3+ cells to CD4 + FOXP3-CD25+ in patients after transplant is significantly reduced in patients with acute GVHD, suggesting an important role for T_{reg}s in control of effector function [38]. Manipulation of specific T-cell subsets in donor grafts may allow for modulation of the GVHD and graft-versus-leukemia response.

Chronic GVHD

In contrast to acute disease, our understanding of the pathogenesis of chronic GVHD is somewhat incomplete. Chronic GVHD demonstrates a complex interplay of immunologic processes with features of alloimmunity, autoimmunity, and immunodeficiency. The heterogeneity of clinical manifestations and disease course in chronic GVHD makes identification of a murine model challenging. In addition, correlations between murine and human chronic GVHD are difficult because marked differences in immune reactions are observed by differences in the intensity of the conditioning regimen, disparity between strains, donor graft composition, and endogenous microbes of the animals [39]. The best characterized murine model of GVHD is the parent-into-F_1 mouse. In this model, parental lymphocytes are injected into the F_1 recipient offspring. Because the parental lymphocytes are genetically related to the recipient, they are not recognized as foreign. However, the donor lymphocytes recognize the F_1 mouse as foreign, inducing a GVHD reaction.

In chronic GVHD, autoreactive T-cells are thought to arise from impairment of negative thymic selection due to thymic damage incurred from chemotherapy, acute GVHD, or age-related atrophy [40]. The clinical similarity of chronic GVHD to autoimmune diseases such as Sjogren's syndrome and scleroderma and the reported benefit of treatment of chronic GVHD with anti-CD20 monoclonal antibody [41] also suggest a role for humoral immunity in chronic GVHD. Circulating autoantibodies were described in one of the first series describing the clinical features of chronic GVHD in 1980 [42]; however, the relevance of antibody formation to disease activity remains unclear. In a prospective study, the cumulative incidence of antinuclear antibodies (ANA) in patients with extensive chronic GVHD was 94 % after a median follow-up time of 26 months. The presence of nucleolar pattern ANA and other antibodies in association with ANA was associated with an increased risk of extensive chronic GVHD [43]. However, in this study, the presence and titer of specific autoantibodies did not predict the type of organ involvement, a finding in accord with a recent study comparing 106 patients with sclerotic GVHD to patients with GVHD without skin sclerosis which failed to find an association with ANA or other scleroderma-related antibodies [20, 43]. Nevertheless, antibodies targeting minor-HLA antibodies on the Y chromosome in male recipients of stem cell grafts from female donors correlate with the presence of chronic GVHD, suggesting a potentially important interplay between T and B cells in the pathogenesis of chronic GVHD [44].

Cytokine Dysregulation

Chronic GVHD is associated with elevated levels of IL-1 (β), IL-6, transforming growth-factor-β, TNF-α, and IFN-γ as well as decreased levels of IL-10 [45, 46]. TGF-β is the cytokine that has been most strongly implicated in GVHD-related fibrosis. Tissue fibrosis is a common manifestation in several organ systems involved with chronic GVHD, including the liver, pulmonary system (bronchiolitis obliterans), and skin. TGF-β is a pleiotropic cytokine that in the acute post-transplant period regulates donor engraftment and graft-versus-leukemia effect [47]. In the chronic period, TGF-β appears to the major driving force for collagen synthesis and the development of fibrosis. In the murine sclerodermatous GVH model, treatment with anti-TGF-β antibody prevented lung and skin fibrosis [48].

Platelet Derived Growth Factor

In scleroderma, platelet-derived growth factor (PDGF) appears to play a key role in the increased proliferative capacity of fibroblasts, an effect which is enhanced by the presence of transforming growth factor-β [49]. Increased gene expression of PGDF has been also detected in the skin in the murine sclerodermatous GVHD model [50]. Baroni et al. [51] reported stimulatory autoantibodies to the platelet-derived growth factor receptor (PDGFR) in a group of 46 patients with systemic sclerosis. Ten additional patients with scleroderma-like GVHD were also reported to have agonistic antibodies (this group was not further described in the paper). In this study, production of reactive oxygen species (ROS) and tyrosine phosphorylation was reversed with the use of PDGFR tyrosine kinase inhibitors, suggesting that agents such as imatinib mesylate with activity against the PDGFR may have potential utility for targeting this signaling pathway in the setting of scleroderma and sclerotic GVHD. However, to date the identification of stimulatory PDGFR antibodies in systemic sclerosis or GVHD has not subsequently been confirmed by other groups.

Donor Lymphocyte Infusion and Graft-Versus-Tumor Effect

An important barrier to the effective control of acute and chronic GVHD is the risk of inhibiting the activity of the stem cell graft against the donor's primary malignancy (graft vs. leukemia effect). Numerous studies have demonstrated that the risk of tumor relapse is lower in patients with GVHD than in those that do not develop GVHD [52]. Similarly, T-cell depletion of the donor graft and aggressive multiagent GVHD prophylaxis reduces the risk of developing GVHD, but does so at the expense of an antileukemic effect, resulting in an increased relapse rate [53]. Donor lymphocyte infusions (DLI) have been utilized to augment the antitumor response of the graft but are also associated with an increased rate of GVHD [54]. Ideally, our understanding of chronic GVHD will progress to the point where separation of the graft vs. host and graft vs. leukemia (tumor) effect

would be possible. In reality, it is a constant struggle to balance these competing forces in the management of these patients.

Treatment of Cutaneous GVHD

Acute GVHD

Acute GVHD is treated with systemic steroids, resulting in a 40–50 % response rate. There is no consensus as to the appropriate second-line agent in those patients who do not respond adequately to corticosteroid therapy. A variety of salvage therapies have been utilized in patients with steroid refractory GVHD, but no single agent has proven to be a superior option (Table 38.4) [110]. The major limitation of most acute GVHD therapies arises from the use of systemic immunosuppression and attendant risk of infection. Newer biological agents, such as those targeting tumor necrosis factor-α, have shown some benefit in acute GVHD but have been linked to invasive fungal infections [111].

Topical agents play a limited role in the management of acute cutaneous GVHD; however, high-potency topical corticosteroids may be of benefit in patients with limited skin involvement. Proper skin hygiene and surveillance for the development of cutaneous infections is needed.

For patients manifesting primarily cutaneous involvement, phototherapy is a potential treatment option in lieu of additional systemic immunosuppression. Psoralen in combination with UVA (PUVA) resulted in disease response of 15 out of 20 patients treated for acute skin GVHD [89]. Wetzig et al. [102] reported improvement with UVA1 in 5 out of 7 patients with acute skin GVHD. Complete response of steroid-resistant acute skin disease following narrowband UVB (NB-UVB) was reported in 7 out of 10 [107] and 8 out of 14 patients, respectively [108].

Extracorporeal Photopheresis

Extracorporeal photopheresis (ECP) is a leukopheresis procedure that has been approved by the US Food and Drug Administration for the treatment of cutaneous T-cell lymphoma. Following leukopheresis, the mononuclear cell sample is mixed with 8-methoxypsoralen and exposed to a UV-A light source before re-infusion into the patient. This procedure spares the patient of the risk of serious infection associated with systemic immunosuppression and is particularly effective for skin GVHD [71]. Greinix et al. [71] reported a 65 % complete response rate for acute skin GVHD after 3 months of treatment. In the pediatric setting, Messina et al. [72] reported a 76 % response rate for acute skin involvement in 33 patients. The optimal frequency and duration of ECP for GVHD is unclear. Apoptosis of alloreactive T cells is the presumed mechanism for the efficacy of ECP in GVHD, despite the fact that only a small percentage of circulating lymphocytes are treated at each ECP session [112]. ECP requires a large, double-lumen pheresis cathether and is not available at all medical centers. In addition, small children are not able to undergo this procedure because of the fluid volume extracted for the procedure. Recent modifications in the process are allowing the therapy be used more safely in small children by exchanging smaller fluid volumes.

Chronic GVHD

Skin-Directed vs. Systemic Therapy

Infection is the leading cause of death in patients with chronic GVHD. Patients are immunosuppressed from their disease state as well as from the immunosuppressive regimens required to treat their disorder. Treatment recommendations for chronic cutaneous GVHD must include a consideration of the type and extent of skin involvement, the potential for long-term morbidity (e.g. sclerotic disease), and the presence of other organ system involvement. Other important factors include the presence of high-risk features such as thrombocytopenia and progressive onset of disease, risk of infection, and the status of the underlying disease state/malignancy.

Limited cutaneous involvement in the absence of high-risk features or other systemic involvement may be addressed with topical measures. Non-sclerotic disease may respond to mid- to ultra-high potency topical steroids (triamcinolone 0.1 %-clobetasol 0.05 % cream/ointment), but may lead to skin atrophy with prolonged use [16]. Topical emollients and anti-pruritic agents may provide additional symptomatic relief. Choi and Nghiem [97] reported improvement in pruritus and erythema in 18 patients treated with tacrolimus 0.1 % ointment. However, all patients eventually required systemic therapy or phototherapy in order to control their skin disease. Subsequent reports have also described a modest benefit from tacrolimus ointment at 0.1 % and 0.03 % as well as with pimecrolimus [88, 98]. These agents may have utility for the treatment of superficial involvement, particularly in areas at high risk of skin atrophy with topical steroids. A response to topical tacrolimus 0.01 % has also been reported for oral GVHD [99]. However, intraoral use of tacrolimus 0.1 % ointment markedly elevated the serum drug level in a patient taking systemic tacrolimus [113]. Systemic toxicity after widespread application of topical tacrolimus was also reported in a pediatric patient with acute GVHD who was not on systemic tacrolimus [114]. The risk of cutaneous malignancy following long-term treatment with topical calcineurin inhibitors in the setting of chronic GVHD is unknown.

L lichenoid or erythematous skin involvement, *Sc* sclerotic skin involvement

[a]Type of chronic cutaneous GVHD not specified

[b]In this study, both lichenoid and sclerotic-type cutaneous GVHD was treated; however, none of the sclerotic patients responded to therapy

[c]Bath PUVA

[d]Narrowband UVB

Preventative strategies include sun avoidance, the use of sunblock, and protective clothing to decrease the risk of a UV-associated flare in symptoms. Surveillance for cutaneous malignancies should be performed at regular intervals. Diffuse or patchy post-inflammatory pigmentation is a frequent sequelae of chronic GVHD, particularly in darkly pigmented individuals. Following resolution of GVHD activity, this pigmentation fades gradually. Topical hydroquinone with or without retinoids or corticosteroid-containing compounds offer very limited benefit [16].

Treatment of eroded tissue and skin ulcerations in the setting of skin sclerosis is challenging. Aggressive wound management utilizing protective films, dressings, and wound healing products such as becaplermin may be beneficial [16]. Regular supervision in a dedicated wound care clinic may maximize the likelihood of achieving wound healing. As patients may be relatively immunosuppressed by the presence of GVHD or by therapies aimed at controlling GVHD, it is important to rule out an infectious source. Bacterial, viral, mycobacterial, and fungal cultures should be performed as indicated. Similarly, consideration should be given to non-infectious sources of skin breakdown other than GVHD, including vasculitis, bullous drug reaction, neuropathy, primary cutaneous malignancy, or metastatic disease.

Systemic treatment of chronic GVHD utilizes many of the same systemic modalities as for acute GVHD. Generally, first line treatment consists of continuation of the calcineurin inhibitor used for GVHD prophylaxis with prednisone initially at 1 mg/kg/day [115]. Similar to acute GVHD, there is no consensus regarding second line treatment. Therapeutic options include ECP, mycophenolate mofetil, rituximab, sirolimus, and imatinib mesylate. Unfortunately, interpretation of therapeutic responses in clinical trials is hampered by the lack of standardized evaluative indices for skin involvement. In addition, responses to epidermal (lichenoid) and sclerotic skin disease are sometimes reported together without the use of response criteria specific for the different skin manifestations [116].

Extracorporeal Photopheresis

Extracorporeal photopheresis has emerged as a major second-line treatment for patients with steroid refractory chronic GVHD. Rates of partial or complete remission of skin disease range from 31 to 100 % in clinical series [117]. However, in a randomized blinded comparison of standard chronic GVHD therapy (n = 47) vs. standard therapy + ECP (n = 48), the primary endpoint (total skin score) was not significantly different between the two groups [75]. The precise mechanism by which ECP treatment affects chronic GHVD is still unclear. ECP causes an increase in the plasmacytoid DC2 dendritic cell population and a corresponding decrease in the monocytoid DC1 population, which may result in a shift from a primarily Th1 to a Th2 cytokine profile [118]. Increased production of IL-10, in particular, may play an important role in the mitigation of the GVHD response through inhibition of antigen presentation and promotion of regulatory T cell differentiation [119, 120]. Although GVHD-related fasciitis resembles eosinophilic fasciitis the former does not respond well to steroid therapy and may result in significant long-term functional disability. ECP has been used successfully for the treatment of eosinophilic fasciitis [121], and also appears to be an attractive treatment option for GVHD-related fasciitis [122]. Several questions regarding ECP therapy remain unanswered, including the treatment schedule (weekly vs. every 2 weeks) and the potential for ECP as a first-line therapy in the management of chronic GVHD [117]. Nevertheless, several consensus groups now recommend ECP as second-line therapy, particularly for skin, oral and liver chronic GVHD [123–125].

Phototherapy

As with acute GVHD, chronic GVHD may respond to PUVA therapy. Lichenoid chronic GVHD has been reported to respond to psoralen plus UVA (PUVA) therapy in several small series [126]. Improvement in both lichenoid and sclerotic chronic GVHD has been reported in a small series following treatment with PUVA-bath therapy [90]. It must be kept in mind that chronic GVHD results in immunodeficiency that is often further compounded by iatrogenic immunosuppression and may result in an increased risk of skin neoplasia. Multiple squamous cell carcinomas have been reported following PUVA treatment for chronic GVHD [127]. The risk of melanoma in patients following HSCT is significantly elevated [128].

UVA1 is a form of phototherapy in which long wavelength (340–400 nm) UV light is used without a photosensitizer. UVA-1 radiation has the potential to reach the deeper layers of the dermis and even the subcutis. For this reason, UVA-1 has been employed for a number of sclerosing skin conditions, particularly localized scleroderma, with improvement in skin thickness in several small series [129]. Experience with UVA-1 for chronic GVHD is more limited, but has been effective in a small number of patients with lichenoid and sclerotic disease [102, 104, 105] although relapse after therapy has been seen in both types of cutaneous involvement [103]. UVA-1 is available at several major medical centers, but is not widely available in the community and questions remain regarding the optimal treatment frequency as well as whether the risk/benefit ratio supports use of low, medium or high dose therapy [129].

NB-UVB has also been reported in both the acute and chronic GVHD setting, primarily in small cases series.

NB-UVB shares with UVA-1 the advantage of avoiding exposure to oral or IV psoralen, is more easily performed in children, and is also more widely available in the community than UVA-1 phototherapy and ECP. Brazzelli et al. [109] reported an 80 % response in 10 pediatric patients with overlap acute/chronic GVHD or chronic GVHD.

Systemic Retinoids

Marcellus et al. [70] described the Johns Hopkins GVHD group's experience with etretinate for treatment-refractory sclerotic GVHD. Twenty out of 27 evaluable patients had a subjective response. Six patients could not tolerate the medication due to scaling and/or skin breakdown. Further prospective studies are needed to determine the utility of systemic retinoids for superficial disease.

Imatinib Mesylate

Imatinib mesylate is a multikinase inhibitor with activity against BCR-ABL, c-kit, and PDGFR, among other tyrosine kinases. The drug is FDA-approved for the management of Philadelphia chromosome + chronic myelogenous leukemia and has a significant track record of safety. In addition, imatinib mesylate has demonstrated significant anti-fibrotic properties in a number of murine models of lung [130] and skin fibrosis [131], suggesting that it may represent a 'targeted' anti-fibrotic therapeutic option in patients with sclerotic chronic GVHD. To date, several retrospective reviews [78, 79] and prospective studies [44, 77, 80] suggest that the drug may have efficacy in a subset of patients with steroid-refractory sclerotic skin disease. However, known side effects of imatinib mesylate, including cramping, fluid retention and fatigue, have been frequently reported in chronic GVHD patients and for this reason the drug is usually dosed at 100 mg and increased up to 400 mg if tolerated [77].

Treatment of Genital GVHD

As mentioned earlier, assessment of genital involvement by history and physical examination should be included in the dermatologic evaluation of all female patients. Standard recommendations in all female patients regardless of the presence of GVHD include the use of a vaginal topical estrogen to decrease atrophy of mucosal tissue, discussion of the risks/benefits of systemic hormonal therapies, education regarding self-examination, regular gynecological symptom review, pelvic examination, and cervical cytology. External genital involvement may be treated with high-potency topical glucocorticoids (betamethasone dipropionate cream 0.05 % gel or ointment) applied once or twice daily for up to 12 weeks [16]. Topical calcineurin inhibitors (cyclosporine, tacrolimus) are also beneficial in mild-moderate disease [16, 132]. The presence of vulvar disease and/or symptoms of vaginal involvement should prompt consultation with a gynecologist experienced in the evaluation and management of genital GVHD for a comprehensive internal examination. Hydrocortisone acetate rectal foam 100 mg/g for 4–6 weeks may be used for intra-vaginal application [28]. Severe vaginal stenosis may result in hematocolpos and requires the use of aggressive topical steroids and vaginal dilator insertion. Surgical lysis of extensive vaginal synechiae may be necessary in severe cases [16]. Transplant patients may also be at higher risk for cervical dysplasia and require close surveillance for the presence of vulvar HPV infection along with regular cervical cytology [133].

Treatment of Oral GVHD

Localized oral disease should be treated with alcohol-based high potency corticosteroid gels. Tacrolimus ointment is preferable for lip involvement due to the risk of atrophy with topical steroid use. Widespread oral disease may be treated with dexamethasone rinse formulation (0.5 mg/mL) 4–6 times/day. Cyclosporine [64] or azathioprine [57] rinses have been used in steroid-resistant cases. Oral phototherapy (PUVA, UVB, narrowband UVB) may be effective but the specialized equipment required for oral phototherapy is not readily available [16]. Patients with oral sicca symptoms are treated with salivary stimulants (e.g. sugar-free gum), saliva substitutes, and frequent sipping of water [16]. Patients with oral dryness are at increased risk of tooth decay thus meticulous oral hygiene is advised as well as surveillance for candidal infection. An increased incidence of squamous cell carcinoma of the oral cavity has been reported in patients with chronic GVHD following HSCT [134], and therefore, a high degree of suspicion is required for oral lesions that do not respond appropriately to therapy.

Questions

1. A 25 year old male with acute myelogenous leukemia requires hematopoietic stem cell transplantation. Which of the following donor/recipient characteristics is the most important risk factor for the development of GVHD?
   A. Female gender donor
   B. Advanced donor age
   C. Advanced recipient age
   D. Donor/recipient HLA incompatibility
   E. Recipient history of previous chemotherapy exposure

2. Which of the following manifestations are most consistent with acute GVHD?
   A. Lichen sclerosus-like changes, mucocele, esophageal stricture
   B. Alopecia, sclerotic skin changes, episcleritis
   C. Oral lichenoid changes, cutaneous lichenoid changes, nephritis
   D. Mucositis, bronchiolitis obliterans
   E. Hepatitis, erythema, diarrhea

3. Which of the following is NOT a diagnostic cutaneous feature of chronic GVHD?
   A. Morphea-like fibrosis
   B. Subcutaneous fibrosis
   C. Lichen planus-like changes
   D. Erythema
   E. Scleroderma-like fibrosis

4. Which is a potential complication of sclerotic skin changes of chronic GVHD?
   A. Restrictive lung disease
   B. Skin ulceration
   C. Range of motion restriction
   D. Alopecia
   E. All of the above

5. Which of the following treatment modalities has demonstrated the most potential for improvement in sclerotic skin disease?
   A. Oral PUVA
   B. Bath PUVA
   C. UVB
   D. NB-UVB
   E. UVA1

Iatrogenic Immunodeficiency and Skin Disease

39

Ramya Kollipara, Elizabeth Shane, Sheevam Shah, and Stephen K. Tyring

Abstract

Skin cancer in organ transplant recipients (OTR) is an ongoing problem as the number of living OTR grows due to an increasing number of transplants performed and longer patient and graft survival time. Kidney transplants, followed by liver transplants, account for the majority of cases. Chronic immunosuppression, along with other risk factors, places these patients at higher risk of developing malignancies, the most common being cutaneous malignancies. The dose and duration of immunosuppression are more important as risk factors than any one immunosuppressive agent in particular. It is thought that immunosuppressive drugs accelerate the development of skin cancer by being directly carcinogenic and by creating a state of compromised immune surveillance. Management of these patients requires a multifaceted approach involving the transplant team, dermatologists, other care providers and the patients. Treatment and follow up may then be determined on an individual basis on the patient's risk factors and the relative risk of the skin cancer. Patients should perform monthly skin self-examinations and have their skin examined by a physician annually.

Keywords

Immunosuppression • Organ • Transplant • Kidney • Liver • Skin • Cancer • Human Papillomavirus

Key Points

- The number of living OTR continues to grow due to an increased number of transplants performed and a longer patient & graft survival time, thereby increasing the number of patients on immunosuppression
- Immunosuppression required to maintain allografts leads to a significantly increased rate of both internal and cutaneous malignancies with skin cancer being the most common
- The skin cancer seen in immunosuppressed patients, primarily NMSC, occurs earlier and behaves more aggressively compared to NMSC in the general population
- Of the various types of skin cancers seen in OTR, SCC is the leading cause of mortality

- It is important to be aware of the associated risk factors so that OTR who are at increased risk can be identified and followed even more closely by dermatologists and the transplant physicians
- Immunosuppressive drugs accelerate the development of skin cancer by being directly carcinogenic and by creating a state of compromised immune surveillance
- HPV infection has been recognized as a putative risk factor in NMSC of OTR

Introduction

The number of living OTR continues to grow due to an increased number of transplants performed and a longer patient & graft survival time. As the number of organ transplant recipients (OTR) continues to increase so too does the need for a thorough understanding of these patients and the complications they are likely to encounter. There are over 140,000 OTRs currently living in the United States and between January and August 2009 there were 19,114 transplants performed [1]. Kidney transplants account for the majority of these, followed by liver transplants. Heart and lung are the two next most commonly transplanted organs [2]. The immunosuppression required to maintain these allografts leads to a significantly increased rate of both internal and cutaneous malignancies with skin cancer being the most common [3]. It is therefore likely that dermatologists will be caring for an increasing number of organ transplant recipients.

Types of Skin Cancer

Skin cancer is the most common malignancy for which OTR are at risk [4]. They are at particularly increased risk of nonmelanoma skin cancers (NMSC) with a rate of 50 times that of the general population [5]. Compared to immunocompetent individuals, transplant recipients are 15 years younger at the time of NMSC diagnosis [6]. Comparable results from various studies show that NMSC is diagnosed in 15–43 % of OTR 10 years post-transplantation [7]. These NMSC occur earlier and behave more aggressively compared to NMSC in the general population. The lesions are frequently multiple, have a more rapid rate of growth, and have an increased rate of recurrence and metastasis than seen in nontransplant patients [8]. The mean age of diagnosis of first NMSC since transplant varies with type of transplant but is reported as 4–9 years for kidney transplants. The most common location for NMSC in OTRs is the head, neck, and other locations include upper limbs, trunk and sun-exposed areas [9].

In the general population, basal cell carcinomas (BCC) occur approximately four times more frequently as squamous cell carcinomas (SCC). This ratio of BCC to SCC is reversed in OTRs [8]. In addition to increased rates of NMSC, studies have also found an increased risk of malignant melanoma, particularly in the pediatric population [10]. Kaposi's sarcoma incidence is increased by 84-fold in transplant recipients compared to the general population [11]. Merkel cell carcinoma, a rare neuroendocrine skin cancer, has also been found more commonly in OTR (approximately 24-times more common than in healthy patients) and is more aggressive than in the general population [12]. Of the various types of skin cancers seen in OTR, SCC is the leading cause of mortality. Data from the Cincinnati Tumor Registry showed that 63 % of deaths in OTR who died from skin malignancies were due to SCC [13].

Risk Factors

Several risk factors have been identified to help determine which patients are most likely to develop skin cancer post-transplantation. One clear contributor to the development of NMSC in both the general population and OTRs is ultraviolet radiation (UVR) [14]. This is supported by the tendency of lesions to develop in sun-exposed areas and by the increased risk of NMSC in OTRs reported in parts of the world with high levels of sun exposure [15]. The role of UVR as a risk factor is also supported by the fact that recipients with Fitzpatrick skin types I, II, or III have been shown to be at increased risk which is also true of the non-transplant population as well [16, 17]. Additionally, older patients are more likely to develop skin cancer which is in part attributed to greater cumulative sun exposure prior to transplantation [18, 19]. Finally, regular use of sunscreen and protective clothing has shown to reduce the incidence of NMSC in OTRs [20]. Ultraviolet radiation acts as both an initiator and promoter of skin cancer. It is directly mutagenic to epidermal keratinocytes and also has local immunosuppressive effects by reducing the number of Langerhans cells, thus impairing antigen presentation and recognition [21, 22].

Another well recognized important risk factor for NMSC is immunosuppression. An increasing number of patients are on long-term immunosuppression due to the increased number of organ transplants and the increasing survival of both the organs and their recipients. The duration and intensity of immunosuppression are directly related to the degree of cancer risk [23]. It is thought that immunosuppressive drugs accelerate the development of skin cancer by being directly carcinogenic and by creating a state of compromised immune surveillance [24–27]. The various immunosuppressive agents have different mechanisms of action which will be discussed later in this chapter.

Genetic polymorphisms have been shown to increase the risk of NMSC in OTRS. Variations in the methylenetetrahydrofolate reductase increase the risk of NMSC by increasing the sensitivity of DNA to ultraviolet radiation damage and by altering the DNA methylation process. Polymorphisms in glutathione-S-transferase have also been linked to increased incidence of NMSC in OTRs as they can interfere with the process of metabolizing reactive oxygen species. Other genes implicated include those that control melanin production, the interleukin-10 gene and the retinoblastoma gene [20].

Differences in skin cancer incidence have also been reported depending on type of organ transplantation, with heart and lung transplantation having the greatest risk due to older age at transplantation and a need for more intensive immunosuppression regimen [1]. Furthermore, the risk of a second SCC after an initial SCC post-transplantation is very high (reported at 80 % at 4 years in one study) [28]. Kidney transplant recipients and then liver recipients have a less significant risk [29]. The relative differences in risk may be due to a varying level of immunosuppression required to maintain each organ type [30]. In kidney transplant recipients, an effect of pretransplant end-organ disease has been identified. Incidence of NMSC was increased in patients who received a transplant for polycystic kidney disease and decreased in patients with diabetic nephropathy as primary cause of renal failure. This is hypothesized to be due to poor immunosuppressive drug absorption seen in diabetics due to gastroparesis and autonomic neuropathy [31].

It is important to be aware of these risk factors so that OTR who are at increased risk can be identified and followed even more closely by dermatologists and the transplant physicians. Knowledge and identification of these risk factors both before and after transplantation is vital to determining the appropriate level of follow up. In addition, discussion of these risk factors with the patients may encourage patients to practice safer sun habits and contact a physician earlier should they have a lesion of concern.

HPV and Its Role in Skin Cancer in Organ Transplant Recipients

It is known that OTR have an increased incidence of both viral warts and NMSC post-transplantation [32]. Identification of human papillomavirus (HPV) within these lesions suggests that HPV is pathogenic to the development of skin cancer in transplant recipients. Up to 90 % of transplant recipients have HPV-induced warts. Although considered benign lesions in immunocompetent individuals, warts in transplant patients have been shown both clinically and histologically to progress into dysplastic lesions and invasive SCC [33]. This implies that warts may be of prognostic significance to OTR [34].

An increasing number of HPV viral types are being identified in skin lesions of OTR. This is mostly attributed to the improved methods of detection of the virus using PCR with degenerate primers instead of consensus primers [34, 35].

Studies show that among the numerous HPV types that have been isolated from SCC of OTRs, there is a predominance of HPV types 5 & 8 [34]. Of note, these two types were also found to predominate in SCC of patients with epidermodysplasia verruciformis (EV). EV is a rare inherited disorder characterized by widespread warts and associated with a deficiency of cellular immunity. Approximately 30 % of EV patients develop skin cancers. A diverse range of HPV types have been identified in these lesions which is now referred to as the EV-HPV type supergroup which includes types 5 & 8 [35].

Studies have detected HPV DNA more frequently in SCC of OTRs compared to SCC of non-immunosuppressed individuals. In contrast, OTRs and non-immunosuppressed individuals had similar rates of detection of HPV DNA in BCC [34, 36]. The prevalence of HPV in BCCs of OTR and immunocompetent individuals has varied in several studies [37, 38]. Whereas, it was a common finding of all related studies among immunosuppressed patients, HPV DNA was more frequently detected in SCC than BCC. This indicates that HPV infection is more closely associated with SCC than BCC development.

The extent to which HPV plays a role in NMSC development in transplant patients is still unclear. A recent study found HPV DNA in the eyebrows and antibodies against HPV in the blood in OTRs with SCC [20]. In addition to SCC, HPV DNA has also been identified in benign tumors, normal skin of immunocompetent individuals, and normal skin of OTRs [39]. Immunosuppression may lead to a chronic state of HPV infection in these patients but is not alone sufficient to cause tumorgenesis. Current data shows that HPV and ultraviolet radiation are co-carcinogens as HPV interferes with cell-cycle arrest and DNA repair [20, 40].

One factor which might argue against the theory of HPV infection as a direct risk factor is the relatively low viral load found in skin cancers. Although a slightly higher amount of viral DNA was found in skin cancers of OTR compared to immunocompetent individuals, the level of viral DNA was still far lower than that seen in genital & cutaneous warts [34]. Additionally, long-standing warts in transplant recipients do not inevitably progress to skin cancers. Despite the strong association between the number of HPV-induced warts and the development of skin cancer, studies have shown an equally high prevalence of EV-HPV DNA in keratotic skin

lesions in transplant recipients both with and without cancer. The detection rate and spectrum of HPV infection between these same two groups in hyperkeratotic papillomas, actinic keratoses, and SCC was similar [41].

HPV and its role in cervical cancer has been well established [42]. It is generally accepted that integration of the viral genome into the host genome confers increased aggressiveness [43]. One study analyzed 181 specimens ranging in severity from condyloma to invasive cervical carcinoma. Only 3 % of biopsy specimens of cervical intraepithelial neoplasia showed integrated HPV DNA. In contrast, 81 % of cervical carcinomas ($P < 0.001$) showed integrated HPV DNA. All HPV 18-containing carcinomas had integrated HPV DNA which may be related to its greater transforming efficiency in vitro and its reported clinical association with more aggressive cervical cancers [44]. Studies have also shown that HPV16 DNA is not always present in the integrated form in tumors, suggesting that integration and subsequent inactivation of the transcriptional regulator, E2, are not essential steps for the development of HPV16 associated carcinoma [45]. Further studies specifically addressing the relative risk of episomal versus integrated viral DNA in the cutaneous malignancies of OTR would be of interest.

The recognition of HPV infection as a putative risk factor in NMSC of OTR has led to the investigation of synthetic immune response modifiers such as imiquimod as possible treatment of these lesions. A randomized, blinded, placebo-controlled study which looked at the safety and efficacy of 5 % imiquimod cream showed it to be a safe treatment in OTR on skin areas up to 60 cm^2. The study showed imiquimod 5 % cream may decrease cutaneous dysplasia and the frequency for squamous tumors to develop in high-risk patients. Of significance, renal graft function, assessed via serum creatinine measurement was unaffected. Furthermore, one study showed that imiquimod when used in conjunction with 5-fluorouracil led to complete clearance of SCC in situ in renal transplant patients. Of note, multiple studies have demonstrated that imiquimod does not decrease graft function even though it is an immune system stimulator [46]. Despite the promising effects of this drug, larger confirmatory studies are still necessary [47, 48].

Immunosuppressive Agents Used in Organ Transplant Recipients

The use of systemic immunosuppressive agents in organ transplant recipients is a well established risk factor for the development of NMSC. Multiple immunosuppressive agents exist and more are continuing to be developed. The impact of each agent in the development of NMSC is difficult to discern since more than one agent is usually used in each OTR. Intervening factors such as UVR exposure, skin type, and HPV burden among others exist, which further cloud the situation. The various immunosuppressive agents may contribute to NMSC development by two mechanisms: impairment of immune surveillance and direct carcinogenesis [24–27]. Studies show conflicting results indicating which agents seem to carry the greatest risk. However, there is a consensus that the dose and duration of immunosuppression are more important as risk factors than any one agent in particular [23]. This is supported by the fact that increased incidence of NMSC is seen in patients on normal dose immunosuppression compared to low-dose immunosuppression [49]. Additionally, patients receiving a triple regimen are at higher risk of NMSC development than those on double regimens [50]. Finally, reduction of immunosuppressant doses has been shown to be a reasonable adjuvant therapeutic strategy in OTRs with multiple or high risk skin malignancies [51].

Various trends in the use of the different immunosuppressants have developed over time. The Organ Procurement and Transplantation Network and Scientific Registry of Transplant Recipients Annual Report (OPTN/SRTR) has divided the use of immunosuppressants into several "eras" (see Table 39.1) [52]. During the "experimental era" (1954–1962) prednisone was the only available agent and the only routine transplants performed were those of kidneys of identical twins. The "azathioprine era" (1962–1983) began with the development of azathioprine (AZA) as an adjunct to prednisone and allowed for cadaveric renal transplants. The FDA approval of cyclosporine (CsA) in 1983 led to the "cyclosporine era" lasting until early 1990s. The use of CsA led to increased graft survival and routine extra-renal organ transplantation. The "modern era" (1990s to present) includes the development of new immunosuppressive agents with even greater survival rates.

Table 39.1 Immunosuppressants and organ transplantation

Immunosuppressant eras	Time period	Agent(s) used	Organs transplanted
Experimental era	1954–1962	Prednisone alone	Kidneys of identical twins
Azathioprine era	1962–1983	Prednisone & azathioprine	Cadaveric kidneys
Cyclosporine era	1983–1990	Cyclosporine	Extra-renal transplants
Modern era	1990–present	Tacrolimus & sirolimus	Extra-renal transplants with increased organ survival

Source: Helderman et al. [52]

Immunosuppressive agents can be divided into induction agents and maintenance agents. Induction agents are antibodies given peri-operatively to induce tolerance to the graft by depleting host T-cell activity. Newer agents, basiliximab and daclizumab, rabbit antithymocyte globulin and anti-interleukin-2 receptor antibodies, respectively, are used in the majority of inductions [53]. Maintenance immunosuppressives can be classified as antimetabolites, calcineurin inhibitors, and rapamycin each of which have different mechanisms of action allowing for synergistic effects when used in combination.

Azathioprine acts as an antimetabolite. AZA, a purine analog, blocks B and T-cell proliferation through the inhibition of purine synthesis and metabolism. Adverse effects of AZA such as bone marrow suppression and hepatitis result from its broad inhibition of purine synthesis [53]. AZA was recently reported to increase photosensitivity to ultraviolet A light (UVA), and also enables UVA to directly damage DNA [54]. Another antimetabolite, mycophenolate mofetil (MMF), is a prodrug that is metabolized into the active compound mycophenolic acid which inhibits de novo purine biosynthesis. MMF, approved in 1995 for use in renal transplant recipients, is now being used widely in place of AZA [55]. A switch to MMF can normalize photosensitivity to UVA and may contribute to reducing additional DNA damage and thus SCC [54]. In addition to bone marrow suppression, MMF also causes gastrointestinal distress. Improved gastrointestinal tolerability has been shown with the use of an enteric coated formulation in stable renal transplant recipients [56].

Cyclosporine (CsA), a calcineurin inhibitor, blocks activation of T-cells by preventing the expression of cytokine interleukin-2 (IL-2). CsA binds to cytoplasmic nuclear factor of activated T cells (NFAT), a family of transcription factors, preventing transcription of growth factors such as IL-2 [53]. CsA is also known to enhance the expression of transforming growth factor-β (TGF- β). TGFβ- is known to inhibit IL-2-stimulated T-cell proliferation and generation of cytotoxic T lymphocytes [55]. The carcinogenic effect of CsA has been shown in a study where patients treated with corticosteroids, azathioprine, and CsA had a three-fold increase in risk of skin cancer when compared to patients on corticosteroids and azathioprine alone [11]. Other studies have found lesions occur earlier in CsA-treated patients [11, 50]. CsA may have a direct cellular effect which promotes the progression of cancer independently from its effects on host immune cells. An ex vivo study showed that CsA-treated adenocarcinoma cells transformed non-invasive cells to invasive cells with pseudopodia and increased cell motility [24]. These changes were dose-dependent and reversible. Monoclonal antibodies directed against TGF-β prevented these changes indicating CsA-induced TGF- β production as a mechanism.

Tacrolimus (TAC), another calcineurin inhibitor, binds the cytoplasmic protein, FK-binding protein (FKBP), and prevents production of IL-2 by inhibiting phosphatase activity of calcineurin. TAC is 100 times more potent than CsA [57] and, in addition to nephrotoxicity, its side effects include glucose intolerance and reversible alopecia [55]. Tacrolimus has been shown in vitro to promote tumor growth in human hepatoma cells [58]. It has been suggested that tacrolimus may be less oncogenic than CsA based on a lower prevalence of enhanced TGF-β transcription [59].

Sirolimus, also known as rapamycin, is a relatively new antitumor agent, which shows promise in decreasing the risk of NMSC in OTRs. The cellular target of sirolimus, mTOR or mammalian target of rapamycin, is considered a member of P13K family kinases [60]. Sirolimus binds the intracellular protein FK-binding protein-12 (FKBP12) forming a high affinity complex which in turn binds mTOR. The binding of mTOR, also called FRAP (FKBP-rapamycin associated protein), ultimately results in cell cycle arrest at G1/S phase through the dephosphorylation and inactivation of p70 ribosomal protein S6 kinase. Consequently, this leads to the inhibition of IL-stimulated lymphocyte division and antibody production [55]. More specifically, sirolimus inhibits the response to interleukin-2 (IL-2) thereby blocking activation of T- and B-cells [56].

Sirolimus has been shown to have antineoplastic properties in both in vitro and in vivo studies [61–63]. Studies have shown a decrease in metastatic area in mice treated with rapamycin and an increase in tumoral area in mice treated with CsA. The decrease in tumor growth in mice treated with rapamycin is attributed to a decrease in neovascularization whereas the increase in tumor growth in CsA-treated mice was associated with extensive neovascularization. Sirolimus has been shown to inhibit vascular endothelial growth factor (VEGF) both in vitro and in vivo [63]. Another study using a human renal cell cancer pulmonary metastasis model showed sirolimus reduced, whereas CsA increased, the number of pulmonary metastases. Circulating levels of VEGF and TGF-B were found to be lower in rapamycin-treated mice than in control or CsA-treated mice [64].

Despite the relatively recent introduction of sirolimus, its use as an immunosuppressive agent in OTR has been studied. The incidence of skin cancer in sirolimus-treated organ transplant recipients was assessed at 2 years post-transplantation and comprised 1981 patients from five multi-center studies. All patients received CsA and corticosteroids and had varying combinations of sirolimus (SRL), AZA or placebo [65]. The study showed that patients receiving SRL immunotherapy without CsA have a lower incidence of malignancy than patients receiving both SRL and CsA. However the patients on combination therapy showed significantly lower incidence of skin cancer compared to CsA and placebo. The

study also found that use of SRL concentration-controlled immunotherapy and early elimination of CsA resulted in significantly lower rates of malignancy.

Sirolimus is well tolerated and has the advantage of less nephrotoxicity and elevating blood pressure compared to calcineurin inhibitors. Side effects of sirolimus include hyperlipidemia, thrombocytopenia, leucopenia, and anemia [66]. Although sirolimus, as well as preliminary data of its derivative CCI-779 (everolimus) look promising, it is important to recognize that further studies will need to take place to further assess its effects due to the relatively new development of the drug and the latency of onset of NMSC in OTRs.

HLA Subtypes and NMSC

Recipient HLA type has been suggested as a possible risk factor for NMSC in OTRs. Several theories on how HLA type may play a role in increasing the risk of NMSC exist. Studies investigating HLA types and the risk of NMSC in OTR have been done with conflicting results [67]. Two of the largest studies have found HLA-A11 to increase post-transplant risk of NMSC [67, 68]. Of these two studies, one was able to successfully identify a subset of Caucasian renal transplant recipients in a northern climate who were at increased risk at both short and long-term follow up after transplantation. This increased risk associated with HLA-A11 is only conferred in patients with lighter, sun-sensitive skin [67]. This study suggests a role for more aggressive monitoring in patients with HLA-A11 type. There are recurring findings in different studies showing HLA- DR1, HLA-DR4 and HLA- B27 and their association with non-melanoma skin cancer, but no definitive conclusions have been reached [69]. Further studies need to be conducted to confirm these findings and perhaps identify other HLA types which may have significance to OTRs and their risk of NMSC.

Treatment and Follow-Up Recommendations of NMSC in OTR

Management of OTR as a dermatologist is challenging due to the chronic immunosuppression and progressively increasing risk of NMSC. The American Society of Transplantation (AST) recommends that patients perform monthly skin self-examinations and have their skin examined by a physician annually [70]. A survey that weighed the advantages and disadvantages of various clinical settings of OTR concluded that regardless of the clinical design, certain principles are key to providing the best care [71]. The survey stressed the importance of: close communication with the transplant team, education of other care providers regarding OTRs' unique dermatologic concerns, patient education as a key to prevention, and close follow-up determined by the risk of skin cancer.

The International Transplant-Skin Cancer Collaborative (ITSCC) has combined data from many studies to develop useful clinical guidelines for the treatment of skin cancer in OTR [72]. Patients should be followed according to their individual risk factors. For low-risk individuals with no history of skin cancer, a yearly follow-up is recommended. For higher-risk individuals with a history of sunburns, fair skin type, or of older age, a 6–12 monthly schedule is advised. If there is any history of NMSCs, AKs or warts, then follow-up should be scheduled at 3–6-month intervals. For both high-risk SCCs and multiple NMSCs, a follow-up should be scheduled for every 3 months. Follow-up can be as frequent as once a month for patients with metastatic SCC [73, 74]. Precancerous lesions such as warts and actinic keratoses should be recognized and treated early to reduce the viral burden and the extent of intraepithelial neoplasia (See Figs. 39.1, 39.2, and 39.3). Treatment of precancerous lesions includes: cryosurgery, topical 5-fluorouracil, topical imiquimod, and electrodesiccation and curettage (ED&C). Photodynamic therapy may be used in OTRs for the treatment of actinic keratoses not responsive to conventional treatments, and superficial NMSC [20]. Topical and systemic retinoids may be used as chemoprevention of skin cancer but are only effective while the retinoid is being used [75, 76]. NSAIDs such as topical diclofenac are being used to treat AKs in those patients that prefer not to use 5-FU [73].

Some emerging treatments include epidermal growth factor (EGFR) inhibitors, ingenol mebutate (IM) and afamelanotide. There is increasing evidence showing amplification and overexpression of EGFR in SCCs. Cetuximab, a monoclonal antibody to the EGFR receptor, has been used primarily in metastatic SCC of the head and neck. Ingenol

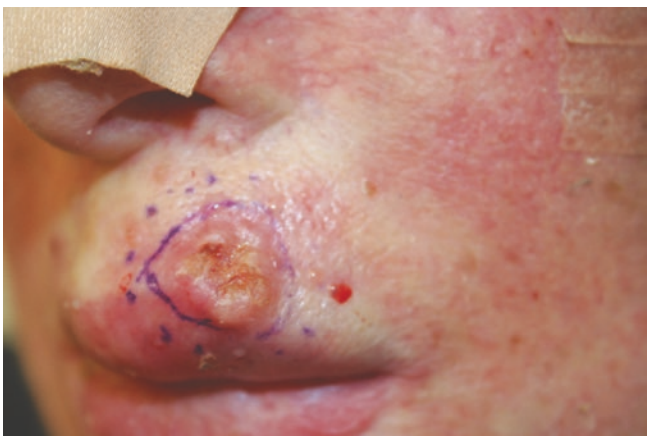

Fig. 39.1 Fifty-eight year old heart transplant patient who was previously treated with radiation to the circumoral area for multiple cutaneous squamous cell carcinomas. This is a recurrent moderately differentiated squamous cell carcinoma within the radiation field

Fig. 39.2 Fifty-eight year old heart transplant patient with multiple actinic keratoses of the dorsal hands

Fig. 39.3 Fifty-eight year old heart transplant patient with multiple actinic keratoses of the forehead and a lesion on the left nasal sidewall which was biopsied to reveal well-differentiated squamous cell carcinoma

mebutate (IM) is a new topical medication that has been recently approved by the FDA for treating AKs of the scalp, trunk and extremities. It has the added benefit of requiring fewer applications than 5-fluorouracil, diclofenac and imiquimod. The mechanism of action is not known, but two proposed mechanisms are direct damage to the mitochondrial membrane, leading to rapid cellular necrosis and the release of pro-inflammatory mediators. The other mechanism may involve the maturation of B cells that produce antibodies that lead to neutrophil-mediated, antibody-dependent cellular cytotoxicity. Afamelanotide is a synthetic analog of melanocyte stimulating hormone (α-MSH) that may protect skin from UVB damage [20].

Less aggressive SCC can be managed with destructive modalities such as: ED&C, cryosurgery, Mohs micrographic surgery, or excised with postoperative margin assessment (See Table 39.2).

Aggressive SCCs should be removed completely using excisional techniques including Mohs, excision with intraoperative frozen section control, or excision with postoperative margin assessment. Additional modalities may be useful in some instances. Radiation therapy may be considered as adjunctive therapy or as a primary modality for inoperable tumors (Fig. 39.1). Although not routinely used, small studies are beginning to support the role of sentinel lymph node biopsy (SLNB) in the evaluation of high risk NMSC [77].

Chemoprophylaxis with oral retinoids such as acitretin has been shown to be effective in reducing the rate of development of premalignant and malignant lesions in OTR [76, 78]. This effect is only exhibited while the patient is actively taking the retinoid. After cessation of the drug, the rate of development of lesions returns to baseline or may even exceed the prior rate of development. Retinoids have several side effects which are often very difficult for patients to tolerate on a

Table 39.2 Cutaneous squamous cell carcinomas in organ transplant recipients

Characteristic	Less aggressive SCC	More aggressive SCC
Size:		
'Mask' areas of face[a], genitals, hands, feet	<0.6 cm	>0.6 cm
Cheeks, forehead, neck, scalp	<1.0 cm	>1.0 cm
Trunk & extremities	<2.0 cm	>2.0 cm
Rate of growth	Static or slow-growing	Rapid
Ulceration	No	Yes
Clinical margins	Distinct, well-defined	Indistinct
Satellite lesions	No	Yes
Neurotropism	Absent	Present
Histology:		
Invasiveness	In situ/invasion limited to papillary dermis	Deep extension into subcutaneous fat
Perivascular or intravascular invasion	No	Yes
Differentiation	Well-differentiated	Poorly-differentiated

Source: Christenson et al. [71]

[a]Mask area includes: central face, eyelids, eyebrows, periorbital, nose, lips, chin, mandible, pre- & post-auricular areas, temple, ear

long-term basis. These side effects include: dry skin, dry lips, significant hair loss, pruritus and arthralgias [76].

Areas of multiple SCC, such as the dorsum of the hand, have been successfully treated with excision and split-thickness skin grafting. Although the grafted area remains lesion-free for an extended period, this procedure has significant morbidity and requires an extensive recovery [79, 80].

In cases of life-threatening skin-cancers, reduction of immunosuppression may be considered. Studies have shown that renal transplant recipients with very aggressive SCC have an improved prognosis following dose reduction compared to those whose immunosuppression was left unchanged [81]. It has also been shown that graft function may continue despite reduction of immunosuppression [82, 83]. It is important when considering reduction of immunosuppressive therapy that it is done in consultation with the transplant physician. If the need to reduce the level of immunosuppression is warranted, transplant physicians often prefer to lower the dose of AZA first as CsA confers better allograft survival [84]. Introducing mTOR inhibitors, or substituting them for a calcineurin inhibitor, may further reduce SCC formation [54].

Conclusion

Skin cancer in OTR is a continuing problem as the number of living OTR grows due to an increasing number of transplants performed and longer patient & graft survival time. This, in turn, has lead to a growing number of patients on chronic immunosuppression. Chronic immunosuppression, along with other risk factors, places these patients at higher risk of developing malignancies, the most common being cutaneous malignancies. Further investigation of these risk factors and the identification of others will hopefully lead to improved prevention, management and treatment of these patients. In addition, further investigation of current immunosuppressive regimens and the development of new immunosuppressive agents, will hopefully lead to decreased morbidity and mortality, particularly from cutaneous malignancies.

Management of these patients requires a multi-faceted approach involving the transplant team, dermatologists, other care providers and the patients. It is important as dermatologists to make all those involved in the care of these patients aware of their unique dermatologic concerns. Treatment and follow up may then be determined on an individual basis based on the patient's risk factors and the relative risk of the skin cancer.

Questions

1. Which of the following risk factors for the development of non-melanoma skin cancer is most important in both the general population and organ transplant recipients?
   A. Fitzpatrick skin type
   B. Ultraviolet radiation
   C. Family history
   D. Immunosuppression

Answer: B

Explanation: Lesions tend to develop in sun-exposed areas. There is also an increased risk of non-melanoma skin cancer in OTRs reported in parts of the world with high levels of sun exposure

2. Which of the following immunosuppressive agents inhibits the phosphatase activity of calcineurin?
   A. Tacrolimus
   B. Sirolimus
   C. Cyclosporine
   D. Azathioprine

Answer: A

Explanation: Tacrolimus binds FK-binding protein and prevents production of IL-2 by inhibiting phosphatase activity of calcineurin. Sirolimus binds FK-binding protein-12, forming a complex that binds mTOR. Cyclosporine blocks activation of T-cells by preventing the expression of cytokine IL-2. Azathioprine blocks B and T-cell proliferation through the inhibition of purine synthesis and metabolism

3. Which of the following HLA subtypes increases the risk of post-transplant non-melanoma skin cancer?
   A. HLA-DR1
   B. HLA-B27
   C. HLA-DR4
   D. HLA-A11

Answer: D

Explanation: Studies have found HLA-A11 to increase post-transplant risk of non-melanoma skin cancer. This increased risk is conferred in patients with lighter, sun-sensitive skin

Autoinflammatory Diseases

40

Haley B. Naik, Amanda K. Ombrello,
and Edward W. Cowen

Abstract

The term *autoinflammatory syndrome* was first proposed in 1999 to describe diseases with a lack of apparent provocation for inflammation and absence of high titer autoantibodies or antigen-specific T lymphocytes. The term *autoinflammation* was proposed in order to draw a distinction between diseases caused by dysregulation of the adaptive immune system (autoimmune) versus innate immune system (autoinflammation). Since that time, the definition of autoinflammatory diseases has evolved to include dysregulatory disorders characterized by significant excessive inflammation mediated predominantly by components of the innate immune system. As our understanding of immune dysregulatory diseases evolves, we are now beginning to understand that diseases characterized by excessive inflammatory response lie on an immunological disease continuum, in which both innate and adaptive immune system components may play pivotal roles in disease propagation.

Introduction

The term *autoinflammatory syndrome* was first proposed in 1999 to describe diseases with a lack of apparent provocation for inflammation and absence of high titer autoantibodies or antigen-specific T lymphocytes [1]. The term *autoinflammation* was proposed in order to draw a distinction between diseases caused by dysregulation of the adaptive immune system (autoimmune) versus innate immune system (autoinflammation). Since that time, the definition of autoinflammatory disease has evolved to include dysregulatory disorders characterized by significant excessive inflammation mediated predominantly by components of the innate immune system (Table 40.1). As our understanding of immune dysregulatory diseases evolves, we are now beginning to understand that diseases characterized by excessive inflammatory response lie on an immunological disease continuum, in which both innate and adaptive immune system components may play pivotal roles in disease propagation.

Innate Immunity

The innate immune system provides an immediate and non-specific host defense against infection while the adaptive immune system provides a more complex, antigen-specific

Table 40.1 Clinical features of autoinflammatory disorders

Autoinflammatory disease	Inheritance	Gene/Protein	Age of onset	Flare duration	Mucocutaneous manifestations	Musculoskeletal manifestations	Systemic manifestations	Treatment
FMF	AR	*MEFV*/pyrin	First three decades of life	1–3 days	Erysipeloid-like rash on dorsal hands and feet	Arthritis	Fever Polyserositis AA amyloidoisis	Colchicine IL-1 antagonists
TRAPS	AR	*TNFRSF1A*/TNFR1 receptor	Childhood or adolescence	7–14 days	Migratory erythema Periorbital edema Conjunctivitis	Arthralgia, arthritis	Fever Pleuritis Abdominal pain AA amyloidosis	TNFα antagonists IL-1 antagonists
MKD	AR	*MVK*/mevalonate kinase	First year of life	3–7 days	Urticaria-like eruption Morbiliform eruption Petechiae Vasculitic purpura	Arthralgia, arthritis	Fever Cervical lymphadenopathy Abdominal pain Vomiting, diarrhea Splenomegaly	NSAIDs TNFα antagonists IL-1 antagonists
FCAS	AD	*NLRP3/CIAS1*/NLRP3	Usually in childhood	24 h	Cold-induced neutrophilic urticaria Conjunctivitis	Arthralgia	Fever Rare secondary amyloidosis	IL-1 antagonists
MWS	AD	*NLRP3/CIAS1*/NLRP3	Childhood	1–3 days	Neutrophilic urticaria Conjunctivitis Uveitis Scleritis	Arthralgia	Fever Sensorineural deafness Papilledema Aseptic meningitis AA amyloidosis	IL-1 antagonists
NOMID	AD	*NLRP3/CIAS1*/NLRP3	First weeks of life	Continuous	Neutrophilic urticaria Conjunctivitis Uveitis	Erosive arthritis Joint deformities	Fever AA amyloidosis Papilledema Aseptic meningitis Seizures Cognitive impairment Sensorineural deafness	IL-1 antagonists
DIRA	AR	*IL1RN*/IL1RA	At birth or within first weeks of life	Continuous	Sterile pustulosis Oral ulcerations	Joint swelling Hyperostosis Osteolysis	Low-grade fever Premature birth HSM Respiratory insufficiency Thrombosis	Anakinra
DITRA	AR	*IL36RN*/IL36RA	Childhood, adulthood, Peri-partum	Days to weeks	Sterile pustulosis	Arthralgias	Fever	Acitretin IL-1 antagonists
SAPHO/CRMO	Unknown	Unknown	Childhood or young adulthood usually	Weeks	Palmoplantar pustulosis (60%) Acne (25%) Neutrophilic dermatoses	Hyperostosis Osteolysis Synovitis	Fever	NSAIDs Bisphosphonates Methotrexate TNFα antagonist IL-1 antagonists

Autoinflammatory disease	Inheritance	Gene/Protein	Age of onset	Flare duration	Mucocutaneous manifestations	Musculoskeletal manifestations	Systemic manifestations	Treatment
Majeed syndrome	AR	*LPIN2*/lipin-2	Neonatal	Continuous	Neutrophilic dermatoses	Hyperostosis Osteolysis	Congenital dyserythropoetic anemia	IL-1 antagonists
CAMPS	AD	*CARD14*/CARD14	Infancy	Continuous	Generalized pustulosis	Arthralgia	Fever	IL-12/23 antagonist
PAPA	AD	*PSTPIP1*/PSTPIP1	Childhood	Weeks	Pyoderma gangrenosum Acne	Pyogenic arthritis	Fever	TNFα antagonist IL-1 antagonists
PRAAS	AR	*PSMB8*/PSMB8	First weeks of life	Days to weeks	Violaceous annular plaques Heliotrope rash, periorbital swelling Lipodystrophy	Variable arthritis Myositis	Fever HSM Microcytic anemia Lymphadenopathy Metabolic abnormalities	No established therapy
PLAID	AD	*PLCG2*/phospholipase Cγ_2	Early childhood	Hours	Cold-induced urticaria Atopy Granulomatous rash	None	Autoimmune thyroiditis Sinopulmonary infection	No established therapy
APLAID	AD	*PLCG2*/phospholipase Cγ_2	Infancy	Continuous, triggered by sun and heat exposure	Recurrent vesiculobullae Corneal bullae and ulcerations	Arthralgia	Recurrent sinopulmonary infection Enterocolitis	No established therapy Corticosteroids, IL-1 antagonists have been used
DADA2	AR	*CECR1*/ADA2	Early childhood	Continuous	Livedo racemosa	None	Fever Vasculopathic changes HSM Ophthalmologic involvement Mild immunodeficiency	No established therapy

immune response. Effector cells of innate immunity include phagocytes, such as macrophages, dendritic cells and other antigen presenting cells, whereas in autoimmune diseases, B and T lymphocytes are the primary mediators of the inflammatory response.

The innate immune system acts through pattern recognition receptors (PRR) which recognize highly conserved pathogen motifs called pathogen-associated molecular patterns (PAMPs) and damage motifs known as damage-associated molecular patterns (DAMPs). There are three recognized types of PRRs employed by the innate immune system: Toll-like receptors (TLRs), NOD-like receptors (NLRs) and retinoic-acid-inducible-gene-1-like receptors (RLRs). Recognition of foreign material by PRRs leads to activation of signal transduction pathways which signal gene expression of pro-inflammatory cytokines, including interleukin-1 (IL-1) family cytokines, interferon α (IFNα), interferon γ (IFNγ), and tumor necrosis factor α (TNFα). Chronic, prolonged, unmitigated, excessive activation of PRRs can lead to autoinflammation and autoinflammatory diseases [2].

The Inflammasome

The first-described autoinflammatory diseases, the classic periodic fevers syndromes and the cryopyrin-associated periodic syndromes (CAPS) – were characterized by dysregulation of inflammasome activation. Activation of the NLRs leads to the formation of large multimeric complex protein structures, known as inflammasomes, which are critical for host defense against infection. Two main inflammasomes have been described: the NALP1 inflammasome and the NALP3 inflammasome, also known as the cryopyrin inflammasome [3]. In response to microbial components or endogenous metabolic stress, inflammasomes mediate procaspase activation which in turn catalyzes the cleavage of pro-IL-1β and pro-IL-18 into activated IL-1β and IL-18, respectively. IL-1β is produced primarily by myeloid cells and is the primary cytokine implicated in several autoinflammatory diseases. The IL-1 receptor (IL-1R) is ubiquitously expressed, and binding of IL-1β to the IL-1R results in proinflammatory signaling through NFkB-mediated transcription of proinflammatory genes [4]. The most well-described inflammasome, the NALP3 inflammasome, plays a key role in the pathogenesis of Familial Mediterranean Fever (FMF), the TNF receptor-associated periodic syndrome (TRAPS) and CAPS [3] (Fig. 40.1).

Since the initial characterization of the cryopyrin-associated fever syndromes, numerous other monogenic autoinflammatory disorders have been described, including those which lead to pustular and other neutrophilic skin manifestations, and which further contribute to our understanding of IL -1 and non-IL-1-mediated innate immune pathways driving inflammatory skin disease. Characterization of several monogenic diseases has also led to use of targeted therapeutics for their management. Importantly, these insights have also helped to begin to dissect pathogenic mechanisms of phenotypically similar autoinflammatory diseases with as yet no known genetic etiology, and identify appropriate targeted therapeutics for their management, thereby improving human health.

This chapter will introduce monogenic autoinflammatory diseases and discuss pathogenic mechanisms, clinical features and therapeutic options for these disorders.

Classic Fever Syndromes

Familial Mediterranean Fever

The term Familial Mediterranean Fever (FMF) was first proposed in 1958 to describe a periodic fever syndrome which predominated in individuals of Eastern Mediterranean descent [5]. It is the most prevalent autoinflammatory disease worldwide [6]. Although FMF is classically recessively-inherited [7, 8], dominant inheritance and clinically symptomatic heterozygotes have been reported [9]. Genetic mutations in the *MEFV* gene are responsible for FMF and were first reported in 1997 [7, 8]. Almost one-half of the mutations described to date have been identified on exon 10, underscoring the importance of this exon in the function of *MEFV* [10].

The *MEFV* gene encodes the protein pyrin which binds the apoptotic speck (ASC) adaptor protein in the NALP3 inflammasome. Binding of wildtype pyrin and ASC inhibits assembly of the NALP3 inflammasome [11]. Mutations in *MEFV* are gain-of-function mutations affecting pyrin, thereby leading to increased inflammasome activity and subsequent IL-1β production. This hypothesis has been confirmed in a pyrin knock-out murine model as well as a murine model with truncated pyrin protein in which increased caspase-1 activation and increased IL-1β maturation is observed [12]. In a pyrin knock-in murine model, it was demonstrated that pyrin could form an inflammasome of its own, independent of NALP3, which could activate proinflammatory cytokine IL-1 [13].

Individuals with FMF typically present within the first three decades of life with acute episodes of fevers, erysipelas-like rash, arthritis and polyserositis. Flares can last 1–3 days in duration, and occur as frequently as weekly or as rarely as every few years [14, 15]. The erysipelas-like rash of FMF tends to involve the hands and dorsal feet, lasting up to 72 hours and recovering with recrudescence of fever (Fig. 40.2a). Approximately 30% of affected individuals will experience acute nonerosive arthritis during flares. The majority of patients develop monoarthritis (70%), and fewer develop oligo- (26%) and polyarthritis (4%). The most commonly affected joints include the knees, followed by ankles and hips. Arthritis is typically self-limited and not associated with permanent periarticular or cartilage damage [16]. Polyserositis can manifest as an acute abdomen, pleuritis, pericarditis, scrotal pain and more rarely, aseptic meningitis [17]. Gastrointestinal disease

manifestations, ranging from mild abdominal pain to noninfectious peritonitis, occur in 95 % of FMF patients [18]. Prolonged myalgias in the setting of fevers [19], elevated inflammatory markers likely secondary to vasculitis [20], as well as HLA-B27-independent sacroiliitis have also been reported [21].

Secondary AA amyloidosis is a prominent feature of chronic and uncontrolled FMF [22]. In the setting of chronic inflammation, AA amyloid is subject to protein misfolding and subsequent deposition in extracellular matrices of various tissues leading to organ impairment. In FMF, amyloidosis typically involves the kidneys. Affected individuals present with proteinuria and subsequently develop nephrotic syndrome and uremia, ultimately leading to renal impairment and death. Biomarkers for FMF include elevated serum amyloid A as well as elevated levels of DAMP protein S100A12. The latter has been shown to correlate with joint disease severity [23, 24]. Elevated systemic inflammatory markers have been during attacks as well as persist during attack-free periods [25].

Skin histopathology of FMF erysipelas-like erythema demonstrates superficial dermal edema and sparse perivascular infiltrate composed of neutrophils and few lymphocytes. Deposits of C3 in the vessel walls of the superficial vascular plexus can be seen on direct immunofluorescence [26–30]. Synovial fluid from affected joints ranges from non-inflammatory to septic-appearing [16].

Oral colchicine is the mainstay of therapy for the management of recurrent attacks and secondary amyloidosis associated with FMF [31]. In addition to achieving remission of inflammatory flares in the majority of patients, oral colchicine 1–2 mg daily has been associated with improvement of renal function in 95 % of affected individuals with proteinuria but not nephrotic syndrome. Furthermore, colchicine use has been shown to prevent the development of amyloid renal disease in

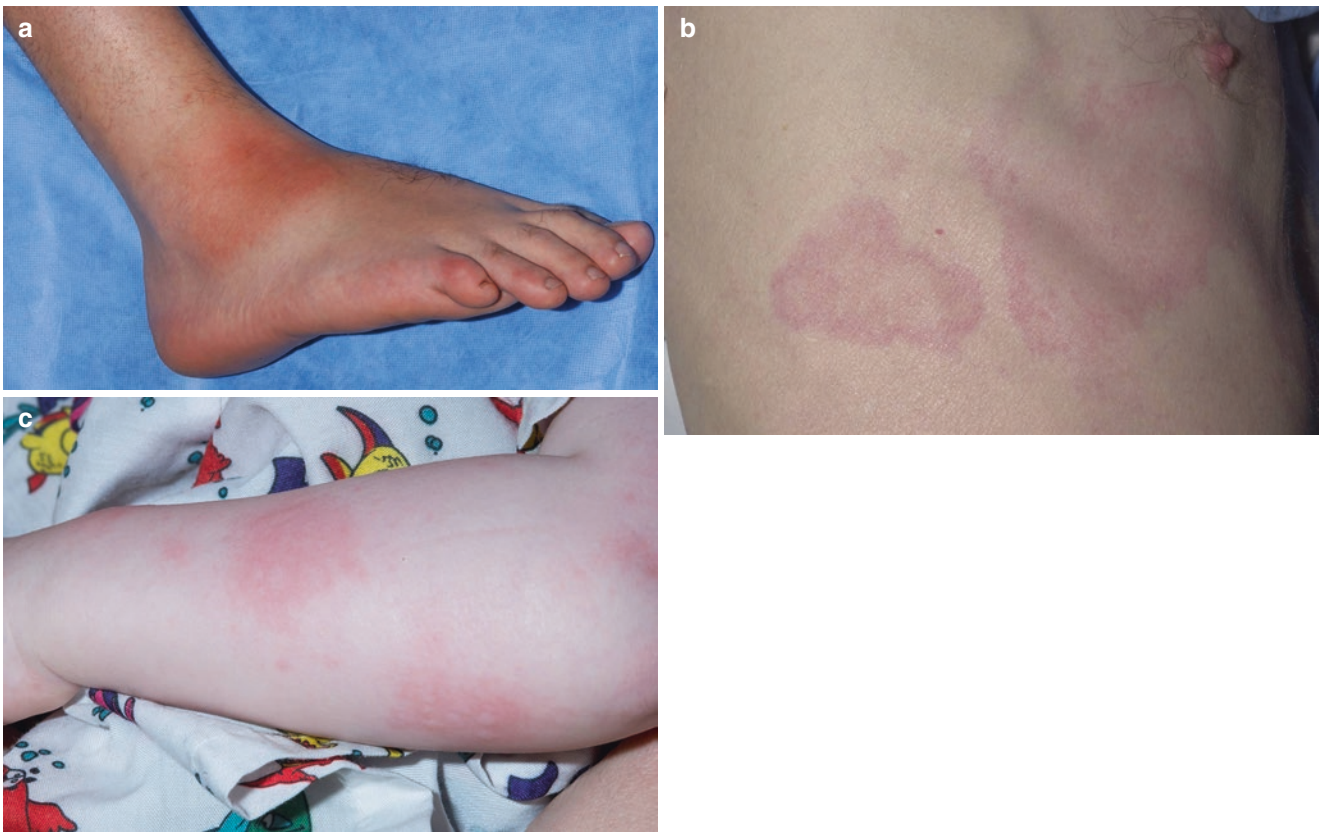

Fig. 40.2 Dermatologic manifestations of classic periodic fever syndromes. (**a**) Erysipeloid erythema involving the anterolateral ankle of a child with Familial Mediterranean Fever (FMF). (**b**) Migratory erythema with serpiginous borders and central clearing on the right lateral chest of a young man with TNF receptor-associated periodic syndrome (TRAPS). (**c**) Urticaria-like plaques involving the left arm of a child with mevalonate kinase deficiency (MKD)

FMF patients [16]. IL-1 antagonists should be considered in individuals who do not respond to or continue to have progressive renal amyloidosis despite oral colchicine therapy, as well as in patients who are intolerant to oral colchicine [32–36].

TNF Receptor-Associated Periodic Syndrome

Shortly after the discovery of the genetic cause of FMF, the genetic basis of TNF receptor-associated periodic syndrome (TRAPS) was reported in 1999 [37]. TRAPS is a dominantly-inherited disorder caused by mutations in the *TNF receptor superfamily member 1A (TNFRSF1A)* gene which encodes the TNFR1 receptor protein. Over 100 different mutations in *TNFRSF1A* have been reported to date [38].

The TNFR1 receptor is ubiquitously expressed. Mutations in *TNFRSF1A* lead to TNFR1 receptor protein misfolding. As a result, TNFR1 is unable to be transported to the cell membrane and therefore is sequestered in the endoplasmic reticulum at levels tenfold higher than the wild type protein [39, 40]. Mutations in TNFR1 lead to constitutive activation of MAP-kinases with subsequent uncontrolled production of IL-1 and TNFα.

The majority of TRAPS patients present in childhood or adolescence with a constellation of symptoms that can include recurrent fevers, abdominal pain, pleuritis, arthralgias, myalgias and periorbital edema and/or conjunctivitis. Attacks last for approximately 7–14 days but they may persist for up to 4 weeks. Abdominal pain occurs in 88 % of TRAPS patients, ranging from mild to moderate pain to acute abdomen [41]. Cutaneous manifestations occur in 69-87 % of TRAPS patients, most commonly as centrifugal migratory erythematous patches overlying sites of myalgia. Serpiginous patches and plaques and urticaria-like eruptions are less common [42] (Fig. 40.2b). The rash tends to progress from proximal to distal sites concurrent with myalgia symptoms. Arthralgia occurs in two-thirds of patients, involving peripheral joints in a monoarticular or oligoarticular pattern. Arthritis is less common [43, 44]. Periorbital edema is a hallmark feature of TRAPS, and conjunctivitis and uveitis has also been reported in approximately one-half of affected individuals [45]. Like FMF, renal deposition of AA amyloid, and subsequent renal impairment, is a prominent feature of TRAPS, affecting 8–10 % of patients with TRAPS [23]. Serum amyloid A (SAA) can be used as a biomarker in TRAPS [23].

Skin histopathology of the migratory rash associated with TRAPS is notable for superficial and deep perivascular and interstitial infiltrate of lymphocytes and monocytes. Small vessel vasculitis and recurrent panniculitis have also been

reported [42]. Myalgias have been associated with monocytic fasciitis [46].

Definitive management of TRAPS remains elusive. Initially, it was thought that utilization of TNFα antagonists would be highly successful in ameliorating the signs and symptoms of disease. A prospective study demonstrated that etanercept, the soluable p75 TNFR:Fe fusion protein, reduced the frequency and intensity of attacks but did not lead to complete resolution [47]. Furthermore, a diminished effect of etanercept over time has been reported [47]. Paradoxically, anti-TNFα monoclonal antibodies have also been reported to cause an acute worsening of a patient's clinical disease [48–51]. The IL-1 antagonists anakinra and canakinumab have also been used for the management of TRAPS with variable response [52, 53].

Mevalonate Kinase Deficiency

Mevalonate kinase deficiency (MKD) (formerly known as *Hyperimmunoglobulinemia D and periodic fever Syndrome (HIDS)* and *Hibernian fever*) is a recessively inherited condition caused by mutations in the *mevalonate kinase (MVK)* gene which encodes the mevalonate kinase protein [54, 55]. The most commonly reported mutation is V377I but however more than 30 distinct mutations have been reported [56].

Mevalonate kinase catalyzes the conversion of mevalonic acid to 5-phosphomevalonic acid in the biosynthesis of cholesterol and nonsterolisoprenoids. Mutations in *MVK* lead to decreased mevalonate kinase enzymatic activity which leads to reduction in isoprenoids, products of cholesterol biosynthesis pathways [57]. In vitro data from MKD patients demonstrate that isoprenoid biosynthesis leads to decreased IL-1β secretion in MKD leukocytes [58]; however, the mechanism by which depletion of isoprenoids results in increased circulating proinflammatory IL-1β is an area of ongoing investigation.

Affected individuals present within the first year of life with recurrent fevers, rash and arthralgias that can last 3–7 days and recur every 4–6 weeks. Flares can be triggered by childhood vaccinations, trauma, infection and stress. Cutaneous manifestations include an urticaria-like eruption, morbiliform eruption, petechiae and vasculitic purpura [59, 60] (Fig. 40.2c). Approximately two-thirds of affected individuals develop polyarthralgias and/or a nonerosive polyarthritis but it is not uncommon for only a single joint to be involved. The most commonly affected sites of joint involvement are large joints such as the knees and ankles [43, 44]. Bilateral cervical lymphadenopathy is a prominent feature of HIDS. Abdominal pain, vomiting, diarrhea, mucosal ulcerations and splenomegaly can also been seen. Unlike FMF and TRAPS, amyloidosis is an atypical finding [60].

Elevated serum ESR, CRP, IgA, IgD and urine mevalonic acid levels can be detected during disease flares. Urine mevalonic acid levels are currently used for diagnosis of MKD. Elevated IgD levels can also be seen in FMF and TRAPS and, therefore, should not be used for diagnosis [18]. Patients with MKD may also have normal IgD levels. Histologic examination of skin lesions reveal perivascular lymphocytic infiltrate, and may demonstrate vasculitic features and a neutrophilic infiltrate [59, 60].

The management of MKD is primarily supportive. NSAIDs may be used for the management of mild disease. Colchicine is of little utility in managing MKD. Successful management of MKD with TNFα antagonists [61] and IL-1β antagonists [62, 63] in individual cases has been reported.

IL-1 Family-Mediated Autoinflammatory Diseases

Cryopyrin-Associated Periodic Syndromes

Cryopyrin-associated periodic syndromes (CAPS), or the *cryopyrinopathies,* comprise a spectrum of 3 disorders characterized by autosomal dominant gain-of-function mutations in the *NLRP3/CIAS1* gene which encodes the NLRP3 protein [64]. Ranging from mildest to most severe in presentation, the three disorders include familial cold-induced autoinflammatory syndrome (FCAS), Muckle-Wells syndrome (MWS) and neonatal onset multisystem inflammatory disorder/chronic infantile neurologic, cutaneous and articular syndrome (NOMID/CINCA).

The majority of MWS and FCAS cases are familial [64], while the majority of NOMID cases reported are sporadic [65, 66]. The latter is thought to be due to the severity of the NOMID phenotype with death prior to reproductive age. Among approximately 130 mutations identified in *NLRP3/CIAS1*, greater than 90% have been associated with exon 3 [38, 64]. Mutations in NLRP3 result in inappropriate activation of the inflammasome and elevated IL-1 production. Approximately 50% of NOMID patients have germline mutations in NLRP3 by Sanger sequencing while far fewer germline mutations have been found in MWS and FCAS. In those for whom germline mutations cannot be identified, approximately 70% have somatic mosaicism identified through deep sequencing methods [67]. Given this information, diagnosis of CAPS is made on a clinical basis, with rapid response to trial with an IL-1 antagonist used for confirmation of clinical diagnosis. Genetic testing may be used for confirmation of diagnosis.

Common features in patients with CAPS include fever, leukocytosis, transient neutrophilic urticaria, conjunctivitis, arthralgias, and elevated inflammatory markers. The urticaria-like rash tends to be non-pruritic and presents as rose-colored flat macules or slightly raised plaques on the trunk and extremities that resolve within 24 hours. Lesional skin histopathology is characterized by neutrophilic infiltrate with interstitial and perivascular neutrophils and lymphocytes without dermal edema or vasculitis [68, 69]. Disease

onset, severity, multiorgan involvement, morbidity and mortality differ between these three diseases.

FCAS

FCAS is the mildest of the 3 cryopyrinopathies. Patients usually present early in childhood, but presentations later in adulthood have been described. Febrile attacks are triggered by cold exposure, with development of fever and rash within 2 hours of exposure, peaking at 2–6 hours, and lasting 12–24 hours. Amyloid deposition is infrequent, and is found in only 2% of patients [23, 70].

Muckle-Wells Syndrome

Muckle-Wells syndrome is characterized by intermediate severity. Unlike FCAS, disease manifestations are not associated with cold exposure and febrile attacks tend to occur with greater frequency, with the characteristic rash often noted in the early afternoon [71]. Ocular inflammation is characterized by inflammation of the conjunctiva, sclera, and anterior chamber. Patients can present with headache secondary to papilledema and aseptic meningitis. In the second or third decades of life, patients can develop sensorineural deafness due to damage of the Corti organ secondary to chronic ear inflammation. Sensorineural deafness occurs in approximately 75% of untreated cases [72, 73]. AA amyloidosis is frequently seen in MWS, occurring in 25% of untreated cases [74].

NOMID/CINCA

NOMID/CINCA is the most severe of the cryopyrinopathies. NOMID is characterized by chronic systemic multiorgan inflammation and persistently elevated inflammatory markers. Patients present within the first few weeks of life with persistent low-grade fevers, neutrophilic urticaria, painful arthropathy and elevated inflammatory markers (Fig. 40.3a). Aseptic meningitis and subsequent elevated intracranial pressure leads to irritability, headaches, nausea, vomiting and seizures. Although the aforementioned symptoms can wax and wane, inflammatory markers in patients with NOMID tend to remain persistently elevated [75].

In untreated NOMID, significant end-organ damage is observed early in life [76]. Chronic aseptic meningitis leads to increased intracranial pressure, hydrocephalus and papilledema. Furthermore, chronic aseptic meningitis in combination with central nervous systemic inflammation can contribute to cognitive impairment. Chronic papilledema can result in optic nerve atrophy, leading to gradual vision loss in the third decade of life. Uveitis may also contribute to vision loss [75]. Sensorineural deafness due to chronic inflammation of the cochlea may develop within the first few years of life. Persistent joint inflammation resulting in premature and aberrant ossification, osteolytic lesions and cartilage hypertrophy can lead to permanent joint deformities in 50–70% of untreated NOMID patients [65, 77–79].

All cryopyrinopathies respond rapidly and completely to IL-1 blockade [75, 80–86]. To date, three IL-1 antagonists – short-acting anakinra and the longer-acting rilonacept and canakinumab – have been FDA approved for the management of CAPS. IL-1 antagonists should be initiated early in life to prevent end-organ damage in these conditions and doses should be titrated to resolution of CNS and cochlear inflammation as continued benefit has been seen with prolonged use of these agents [4, 76, 79, 80, 83–85, 87, 88].

DIRA

Deficiency of the IL-1 receptor antagonist (DIRA) was first described in 2009 [89, 90]. Since that time, approximately 25 affected individuals in United States (including Puerto Rico), Canada, the Netherlands, and Brazil have been described [89–95]. Homozygous loss-of-function nonsense and missense mutations in the *IL1RN* gene, which encodes the IL-1 receptor antagonist (IL1RA), are responsible for the DIRA phenotype.

IL1RN is constitutively expressed in healthy human hosts and serves to inhibit proinflammatory IL-1-mediated signaling by competitively binding the IL-1 receptor. In DIRA, *IL1RN* mutations result in nonfunctional IL1RA, leading to unopposed IL-1 proinflammatory signaling and widespread systemic inflammation [96]. Because the IL-1 receptor is ubiquitously expressed, the disease manifestations of this condition are seen in multiple organ systems.

Affected individuals present at birth or within the first few weeks of life with fetal distress, pustulosis, oral ulcerations, joint swelling, and pain with movement (Fig. 40.3b). Premature birth has been observed. The pustular eruption of DIRA resembles pustular psoriasis, ranging from discrete crops of pustules to generalized pustulosis. The spectrum of bony changes seen includes epiphyseal ballooning of long bones, anterior rib-end widening, periosteal elevation of long bones and multifocal osteolytic lesions. High fevers are not a typical feature of DIRA. Leukocytosis and markedly elevated systemic inflammatory markers are found [89, 90]. Stomatitis, hepatosplenomegaly, respiratory insufficiency and thrombotic events have been less commonly observed. In untreated patients, mortality secondary to multiorgan failure in the setting of systemic inflammatory response syndrome (SIRS) and pulmonary hemosiderosis with progressive interstitial fibrosis has been reported.

Affected skin histopathology demonstrates epidermal acanthosis, hyperkeratosis and extensive epidermal and dermal neutrophilic infiltrate with pustule formation along hair follicles [89].

DIRA responds dramatically to IL-1 antagonist therapy, which effectively provides a recombinant replacement of the dysfunctional protein. Anakinra, a recombinant IL-1 recep-

tor antagonist, leads to rapid improvement in skin manifestations, normalization of acute phase reactants and resolution of bony inflammation [89]. Given the severity of the disease and the availability of effective therapy, early disease recognition and prompt implementation of IL-1 blockade therapy prior to development of bony deformities, pulmonary sequelae and SIRS is critical.

DITRA

Deficiency of the IL-36 receptor antagonist (DITRA) was first described in 2011 in familial and sporadic cases of pustular psoriasis in 9 Tunisian families [97] and 3 unrelated English patients [98]. DITRA is an autosomal recessive condition caused by homozygous and compound heterozygous inactivating mutations in the *IL36RN* gene, which encodes the IL-36 receptor antagonist protein (IL36RA). Following the initial description of DITRA, *IL36RN* mutations have also been reported in individuals of varied ancestry, including European [99], Chinese [99], Japanese [100] and Lebanese [101], suggesting that these mutations may be found in other populations.

IL-36 is an IL-1 family cytokine that binds to the IL-36 receptor, enabling the recruitment of the IL-1 receptor accessory protein and subsequent signal transduction involving nuclear factor kappa-light chain-enhancer of activated B cells (NFkB) and mitogen-activated protein (MAP) kinases. The IL-36 receptor antagonist is encoded on chromosome 2 and competitively binds the IL-36 receptor, thereby providing negative feedback to IL-36 signaling [97, 98]. In DITRA, mutations in the IL36RN gene result in dysfunctional IL36RA protein, leading to unopposed proinflammatory signaling through the IL-36 receptor. Deficiency of the IL-36 receptor antagonist leads to an exaggerated inflammatory response by a mechanism analogous to that observed with dysfunctional IL-1 receptor antagonist protein in patients with DIRA. Unlike the IL-1 receptor in DIRA expression of the IL-36 receptor is limited to epithelial surfaces that have contact with the outside environment [98], thus limiting the disease phenotype predominantly to mucocutaneous surfaces.

The age of onset of DITRA is quite variable, ranging from onset in infancy through adulthood. Two cases of onset during pregnancy have also been reported [97]. Clinical characteristics include recurrent and sudden onset pustular eruptions on a background of erythematous plaques, with associated fevers, neutrophilia, leukocytosis and elevated inflammatory markers. While clinical features of DITRA are confined to the mucocutaneous surfaces, the spectrum of cutaneous involvement can be quite varied. While many reported cases demonstrate generalized pustulosis, patients have also been reported to have limited involvement including acrodermatitis continua of Hallopeau, palmoplantar pustulosis and migratory glossitis [97, 98], suggesting that the same gene may be responsible for a spectrum of phenotypes. Patients may have a history arthropathy, cholangitis, or plaque psoriasis [97]. Skin histopathology demonstrates epidermal acanthosis with elongation of rete ridges, parakeratosis and spongiform pustules [97].

Targeted therapeutic options for DITRA do not exist. The majority of reported DITRA patients have been managed with systemic and topical corticosteroids and systemic retinoids with variable success. Methotrexate and biologic agents, including adalimumab, infliximab and etanercept, have also been utilized with variable success [97, 98]. Recent reports of successful management of DITRA patients with IL-1 antagonists suggest that IL-1 might play an important role in disease pathogenesis [102, 103].

PAPA

Pyogenic arthritis, pyoderma gangrenosum and acne (PAPA) was first coined in 1997 [104]. It is an autosomal dominant disease with incomplete penetrance. Disease-causing mutations in PAPA syndrome are due to gain of function mutations in the *proline-serine-threonine-phosphatase-interacting-protein-1* (*PSTPIP1)* gene, also known as *CD2BP1*.

PSTPIP1 is a cytoskeletal protein that interacts with PEST-type protein tyrosine phosphatases (PEST-PTPs), Wiskott-Aldrich syndrome protein (WASP), and pyrin. While the pathogenesis of PAPA syndrome is not completely understood, mutations in *PSTPIP1* are thought to decrease the interaction of PSTPIP1 with PEST-type proteins, thereby increasing phosphorylation of *PSTPIP1* and increasing *PSTPIP1* interaction with pyrin, ultimately leading to unopposed IL-1 proinflammatory signaling [105].

PAPA patients typically present within the first decade of life with aseptic monoarthritis of the large joints such as knees, elbows and ankles. Persistent untreated chronic inflammation can lead to joint destruction. Cutaneous features of PAPA include acne and pyoderma gangrenosum. Although pyoderma gangrenosum lesions can present early in childhood, cystic acne tends to manifest at puberty (Fig. 40.3c). Hidradenitis suppurativa, psoriasis and rosacea have also been described [106–108]. Given the incomplete penetrance of this disease, a spectrum of disease severity is seen with PAPA, ranging from mild acne to explosive acne fulminans, pyoderma gangrenosum, and debilitating erosive joint disease. Pathergy is a prominent feature of PAPA.

Laboratory studies reveal persistently elevated systemic inflammatory markers and leukocytosis but are otherwise nonspecific. Histopathology of cystic acne lesions is similar to that seen with cystic acne in other settings: distended

follicles with cystic spaces and follicular openings filled with keratinaceous debris and numerous bacteria. Ruptured cystic contents induce a brisk perifollicular neutrophilic inflammatory infiltrate. The histopathology of pyoderma gangrenosum is similar to that of pyoderma gangrenosum in other settings. Early lesions are characterized by a neutrophilic vascular infiltrate. Actively progressing lesions demonstrate neutrophilic infiltrates with leukocytoclasia. Pyoderma gangrenosum ulcers demonstrate marked tissue necrosis with surrounding mononuclear cell infiltrates. The synovial fluid from affected joints is characterized by sterile neutrophil-predominant infiltrate [108].

Management of PAPA with biologic agents has been met with mixed results. TNFα antagonists appear to be more effective for cutaneous manifestations while IL-1 antagonists seem to be more effective for managing articular disease manifestations. The reason for this is not known. Systemic and intra-articular corticosteroids have been used for articular disease, but steroid use can exacerbate acne so should be used with caution. Severe acne in PAPA patients can be managed with tetracycline antibiotics or isotretinoin. Effective management of PAPA syndrome is often a challenge and patients may require multiple systemic agents, including multiple biologic agents [109]. Patients should be closely monitored for infection when on multiple immunosuppressive agents.

SAPHO/CRMO

Although reports of acne and osteoarticular manifestations date back to the 1960s, the unifying term Synovitis Acne Pustulosis Hyperostosis Osteitis (SAPHO) was first described in 1987 [110, 111]. SAPHO is a rare disease, with a prevalence of fewer than 4 in 10,000 [112] and a female predilection [113–116]. This condition usually presents in childhood or young adulthood. Chronic Recurrent Multifocal Osteomyelitis (CRMO) was first described in 1972 and predominates in children [117]. It is unclear if SAPHO and CRMO are distinct diseases – many consider them to be the same entity. The genetic etiology of SAPHO/CRMO is unknown; however, a CRMO murine model does exist caused by homozygous mutations in the murine gene *pstpip2* [118].

The etiology of SAPHO is poorly understood. A number of familial cases have been reported, suggesting a genetic component in disease pathogenesis [119–123]. In addition, SAPHO shares some clinical features with several monogenic autoinflammatory diseases, including DIRA and PAPA, in which pro-inflammatory IL-1 pathways are thought to play a critical role. The efficacy of IL-1 blockade in these other diseases suggests that IL-1 pathways may play an important role in SAPHO pathogenesis. *Propionibacterium acnes,* a skin saprophyte, has been isolated in bone biopsies of affected bone lesions [124–126], suggesting a possible role as an opportunistic pathogen that activates innate and T-cell immunity through increased complement, IL-1 [127], IL-8, and TNFα levels [128, 129].

Cutaneous manifestations of SAPHO and CRMO may present concomitantly with, prior to, or after the onset of osteoarticular disease. Approximately 85 % of adults with SAPHO develop cutaneous manifestations of disease while only 30 % of children with CRMO manifest cutaneous disease [130]. Cutaneous features are predominantly neutrophilic in etiology, with palmoplantar pustulosis predominating in 60 % of affected individuals, followed by acne seen in 25 % of patients [115] (Fig. 40.3d). Other reported cutaneous disease manifestations include hidradenitis suppurativa, dissecting cellulitis of the scalp, pilonidal cyst/sinus, generalized pustular psoriasis, psoriasis vulgaris, subcorneal pustular dermatosis, erythema nodosum, and more rarely, pyoderma gangrenosum or Sweet's Syndrome [113, 131–134].

Osteoarticular manifestations are the hallmark of SAPHO/CRMO and are required for diagnosis. The osteoarthropathy is characterized most prominently by osteitis and hyperostosis. In adults, anterior chest wall osteitis is most common, affecting 65–90 % of individuals. The next most commonly affected site is the spine, affecting approximately 30 % of individuals, with the thoracic spine most frequently involved. Sacroiliitis develops in approximately 52 % of affected individuals. In adults, appendicular skeleton abnormalities are rarely seen, with long bone involvement in 5–10 %, and mandibular involvement reported in 1–10 % [135, 136]. In contrast, long bones are commonly involved in children, with distal and proximal tibia being most commonly involved, followed by proximal and distal femur [137, 138] (Fig. 40.3e). Affected individuals may have arthritis at joints adjacent to bony lesions. In adults, distant synovitis can also be seen.

Systemic features of SAPHO/CRMO include fevers and malaise. Elevated inflammatory markers can sometimes be seen. Inflammatory bowel disease, most often Crohn disease, has been reported in 10 % of patients with SAPHO syndrome [115].

First-line therapy for SAPHO/CRMO-related bony disease includes NSAIDs [139]. In the setting of NSAID failure, bisphosphonates [140–143] or methotrexate [139] should be considered for management of bone inflammation. Bisphosphonates are quite effective for the management of osteoarticular inflammation, but must be used with caution in females of childbearing age given the potential risks of fetal skeletal defects. In addition to efficacy in the management of bone inflammation, methotrexate has also demonstrated efficacy for skin manifestations. TNF-α antagonists [144] and IL-1 antagonists [145, 146] have also

been shown to be highly effective for the management of refractory cases of SAPHO/CRMO skin and bone lesions in case reports and case series, however neither have been systematically studied and neither are FDA-approved for this indication.

Majeed Syndrome

Majeed syndrome was first described in a Jordanian family in 1989 [147]. It is a rare, autosomal recessive condition resulting from loss of function mutations in the *LPIN2* gene [148, 149]. To date, 3 families with Majeed syndrome and 4 distinct *LPIN2* mutations have been reported [147, 150–152].

The *LPIN2* gene encodes lipin-2, a phosphatide phosphatase important in glycerol biosynthesis which acts as a transcription co-activator regulating lipid metabolism genes [153]. Although the function of lipin-2 is not fully understood, it may also play an important role in mitosis and cellular response to oxidative stress [154, 155]. The *LPIN2* mutations in Majeed syndrome abolish the enzymatic activity of lipin-2 [156, 157]. How loss of lipin-2 function leads to cutaneous and osteoarticular inflammation and hematologic abnormalities in Majeed syndrome is not fully understood. It has been hypothesized that loss of lipin-2 activity might lead to diminished IL-1RA production, as the latter has been observed in one described Majeed patient to date [152], however this remains an area of ongoing investigation.

Affected individuals present with the triad of: neutrophilic dermatosis, neonatal onset recurrent multifocal osteomyelitis (CRMO), and congenital dyserythropoeitic anemia (CDA) [158]. The most common cutaneous manifestation described is Sweet's Syndrome [147], however pustular dermatosis and psoriasis-like lesions have also been reported. CRMO in these patients develops in infancy and persists relentlessly, resulting in painful bone inflammation, erosive joint disease and joint contractures. The most common sites of bony inflammation include the clavicles, sternum, and long bones. Unlike isolated CRMO, mandible and vertebral body involvement is rare. The CDA associated with Majeed syndrome is characterized by microcytosis and both peripheral and bone marrow involvement, which is unique among the described types of CDA, however the severity of CDA in Majeed syndrome is variable [147, 150, 151]. Elevated proinflammatory cytokines IL-1β, IL-6, IL-8 and TNF-α have been reported in affected patients [152].

Majeed syndrome has been treated with NSAIDs [149], corticosteroids [147], colchicine [159], interferon gamma, bisphosphonates [160] and TNF antagonists [152] with variable success. Recent case reports have demonstrated resolution of cutaneous and bony inflammation as well as inflammatory markers and anemia with IL-1 inhibition with both anakinra and canakinumab, confirming that IL-1 pathways may play a critical role in the pathogenesis of Majeed, and by extension, potentially also in SAPHO/CRMO [152].

NFkB-Mediated Autoinflammatory Diseases

CARD14-Mediated Pustular Psoriasis

Rare, highly-penetrant, autosomal dominantly-inherited, gain of function mutations in the *caspase recruitment domain 14 (CARD14)* have recently been reported in familial and sporadic cases of psoriasis vulgaris [102, 103, 161, 162] and familial cases of pityriasis rubra pilaris (PRP) [163]. A sporadic *de novo* mutation in exon 4 of *CARD14* has also been reported in a 3 year-old Haitian child with generalized pustular psoriasis (GPP), termed *CARD14*-mediated pustular psoriasis (CAMPS) [162]. These reports suggest that *CARD14* mutations can be associated with clinical and histological features of plaque psoriasis, pityriasis rubra pilaris and pustular psoriasis, indicating that these phenotypes may lie on a spectrum and share common pathogenic pathways.

The *CARD14* gene resides at the PSORS2 psoriasis susceptibility locus on chromosome 17. The CARD14 protein is thought to play a role in NFkB activation. *CARD14* mutations found in the reported psoriasis, PRP and CAMPS patients have been associated with upregulation of IL-8, a neutrophil chemotaxin, and CCL20, a chemotactic factor for CCR6+ immature dendritic cells and T cells [164–166]. The novel mutation found in CAMPS additionally led to upregulation of *IL36G*, a proinflammatory gene, and *SOD2*, a potential antinecroptosis gene [162]. These genes have previously been shown to be upregulated in response to injury, suggesting that CARD14 may play a role in maintaining skin homeostasis in the setting of injury [164].

In the single case of CAMPS reported, disease onset occurred at 6 months of age. Clinical features of CAMPS included generalized pustulosis, palmoplantar keratoderma, fevers and nail dystrophy. Neither arthropathy nor arthritis was present. Clinical laboratory assessments were notable for leukocytosis and elevated inflammatory markers. The patient's disease was refractory to therapy with systemic corticosteroids, cyclosporine, infliximab and anakinra [162]. Ultimately, her disease responded to IL-12/23 inhibition with ustekinumab, suggesting that IL-12/23 may play an important role in driving the clinical phenotype seen in

CAMPS. Furthermore, ustekinumab may play an important therapeutic role in managing other CARD14-mediated dermatoses.

Autoinflammatory Diseases Mediated via Other Pathogenic Pathways

Proteasome Associated Autoinflammatory Syndrome

Proteasome-associated autoinflammatory syndrome (PRAAS) was first described in 1939 by Nakajo and colleagues. Since that time, this disorder has been known by various names including Nakajo-Nishimura syndrome (NNS) [167, 168]; Japanese autoinflammatory syndrome with lipodystrophy (JASL) [169]; joint contracture muscular atrophy, microcytic anemia and panniculitis like lipodystrophy (JMP) [170]; and chronic atypical neutrophilic dermatosis with lipodystrophy and elevated temperature (CANDLE) [171]. PRAAS is characterized by autosomal recessive mutations in proteasome subunit b type 8 (*PSMB8*). Four disease-causing mutations (T75M, A92T, C135X, and G201V) have been described to date [172].

Proteasomes are evolutionarily-conserved, ATP-dependent protein structures that are critical for protein degradation. Proteasomes target intracellular polyubiquitinated proteins and cleave them into peptides which are then available for antigen presentation [173, 174]. PSMB8 encodes the inducible β5i subunit of the proteasome. In the setting of interferon (IFN) stimulation, the critical β1, β2 and β5 proteasome subunits are replaced with inducible subunits β1i, β2i and β5i forming immunoproteasomes [175]. Immunoproteasomes generate peptides for antigen presentation and also help to maintain homeostasis by removing accumulating proteins from cells [176, 177]. Patients with PRAAS have a persistent dysregulated IFN signature on microarray analysis and increased STAT-1 phosphorylation in monocytes, suggesting cellular stress. Mutations in *PSMB8* lead to defective assembly of the proteasome complex, which in turn leads to accumulation of polyubiquitinated proteins in the cells, and subsequent cellular stress resulting in further increased IFN signaling [172]. Cytokine studies have demonstrated that PRAAS patients have increased levels of IL-6, IL1RA, and IFN-inducible chemokines CXCL10 and CCL2 [172, 178].

Onset of PRAAS occurs within the first weeks of life and is characterized by fever and erythematous and violaceous annular eruptions involving the trunk and extremities which persist for several days or longer and may leave residual purpura. Later in infancy, patients develop periorbital erythema resembling a heliotrope rash but with prominent associated edema (Fig. 40.4a). Violaceous nodules and plaques of variable morphology are common on the trunk and extremities, as well as hepatosplenomegaly and elevation in inflammatory markers. Within the first years of life, individuals with PRAAS develop progressive lipodystrophy predominantly involving the face and extremities, failure to thrive, microcytic anemia and lymphadenopathy (Fig. 40.4b). Other reported features include widening of the digits, arthritis, joint contractures, myositis, basal ganglia calcification, dyspnea, seizures, short stature and low body weight [167, 168, 171, 172, 179, 180]. Truncal obesity and hyperlipidemias, insulin resistance, and acanthosis nigricans suggest additional metabolic abnormalities [172, 179]. Severe inflammatory attacks can result in systemic inflammatory response syndrome (SIRS), organ failure, and death. Calcifications in vessels and soft tissues, as well as cardiomyopathy and cardiac arrhythmia, have also been reported [179]. Skin histopathology of PRAAS is distinct from other autoinflammatory diseases and demonstrates dense perivascular and interstitial infiltrates comprising atypical mononuclear cells and neutrophils in the papillary and reticular dermis.

Systemic therapies for PRAAS, including systemic steroids, NSAIDs, colchicine, methotrexate, azathioprine and tacrolimus have been met with mixed results [172]. Partial responses have been seen with biologic agents including TNF-α, IL-1, and IL-6 antagonists [172]. Lipodystrophy remains a prominent and persistent disease characteristic despite therapeutic intervention [172]. Dysregulation of IFN pathways suggests that this pathway may be a promising therapeutic target for future intervention.

PLCG2-Associated Diseases

PLCG2-associated antibody deficiency and immune dysregulation (PLAID) and *PLCG2*-associated antibody deficiency and immune dysregulation (APLAID) are two recently described autoinflammatory diseases which are paradoxically characterized by both immune activation and immunodeficiency. Both PLAID and APLAID are dominantly inherited [181, 182].

PLCG2 encodes phospholipase $C\gamma_2$, a phospholipase responsible for cleaving phosphatidylinositol-4,5-bisphosphate (PIP2) into inositol triphosphate (IP3) and diacyloglycerol (DAG). Phospholipase $C\gamma_2$ regulates inflammatory and immune signaling pathways in hematopoietic cells. The carboxy terminal SRC-homology 2 (cSH2) domain of *PLCG2* is evolutionarily conserved and plays a critical role in the regulation of the gene as it contains the elements of gene autoinhibition. Mutations affecting this region may directly destabilize the region and affect ligand binding and interaction of residues interacting with the domain. Mutations in the autoinhibitory cSH2 component of the *PLCG2* gene are responsible for

Fig. 40.4 Dermatologic manifestations in PRAAS. (**a**) Periorbital erythema and deep red round and annular plaques involving the upper extremity and trunk in a child with proteasome associated autoinflammatory syndrome (PRAAS). (**b**) Lower extremity lipodystrophy in a child with PRAAS

development of both PLAID and APLAID. In PLAID, large activating in-frame heterozygous deletions of the *PLCG2* cSH2 domain cause failure of autoinhibition and result in constitutive phospholipase activity. This results in temperature-dependent function of the phospholipase $C\gamma_2$ enzyme. Specifically, at 37 °C, mutant *PLCG2*-expressing cells are anergic, however when cooled, these cells are activated [181]. In APLAID, a missense mutation in the *PLCG2* cSH2 domain leads to a Ser707Tyr substitution which directly affects the autoinhibitory function of this region [182].

PLAID was first reported in 2012 in 3 families of PLAID patients and is clinically characterized by familial cold-induced evaporative urticaria [181, 183]. Other disease manifestations that were described include atopy, granulomatous rash, autoimmune thyroiditis, sinopulmonary infection, antinuclear antibodies and common variable immunodeficiency and variable B cell immunodeficiency. Affected individuals had low levels of serum IgM and IgA, circulating CD19+ B cells, IgA+ and IgG+ class-switched memory B cells, and natural killer cells. In contrast, IgE levels were elevated.

APLAID was initially reported in one family in 2012 and is clinically characterized by recurrent inflammation of multiple organ systems including the skin, eyes and lungs. The reported individuals presented in infancy with an epidermolysis bullosa-like eruption which progressed to erythematous and vesicopustular lesions in childhood. Systemic features included corneal bullae, arthralgia, sinopulmonary infections, enterocolitis, absence of autoantibodies, and mild immunodeficiency. B cells in these patients were notable for enhanced surface ligand mediated cellular signaling and absence of cold sensitivity, in contrast to PLAID patients. These patients had a paucity of circulating IgA and IgM antibodies and also lacked peripheral class-switched B cells. Skin histopathology demonstrated a dense dermal mixed inflammatory cell infiltrate composed of lymphocytes, histiocytes, eosinophils, and karyorrhectic debris [182].

Management of PLAID has been largely supportive, including prophylaxis and treatment of recurrent infections in immunocompromised individuals. NSAIDs and TNF-α antagonists were ineffective in both APLAID patients, however both had partial disease response to

IL-1 antagonists. These individuals also had significant improvement of systemic inflammation with corticosteroids, but side effects limit the use of these agents [182]. It has been hypothesized that phospholipase inhibitors might be beneficial for the management of PLAID and APLAID [184].

Deficiency of Adenosine Deaminase 2

Deficiency of Adenosine Deaminase 2 (DADA2) (also known as fever with early onset of stroke (FEOS)) was first described in 2014 in 9 individuals [185]. Recessively-inherited loss of function mutations in cat eye syndrome chromosome region, candidate 1 (*CECR1*), which encodes adenosine deaminase 2 (ADA2), are responsible for this condition.

The ADA2 enzyme is expressed predominantly in myeloid cells and secreted into the blood. It acts by converting adenosine to inosine and 2′-deoxyadenosine to 2′-deoxyinosine. Loss of function missense mutations in *CECR1* in DADA2 affect the stability and impact the catalytic and dimerization domains of ADA2. This leads to reduced ADA2 levels and enzyme activity in the blood. Studies in zebrafish paralog *cecr1b* suggest that mutations in this gene affect endothelial integrity and lead to a near complete absence of neutrophils [185]. Studies in both humans and zebrafish indicate that ADA2 may be necessary both for vascular integrity and leukocyte development in the zebrafish, and that the near absence of ADA2 in humans may lead to strokes and autoinflammation by similar mechanisms.

Patients with DADA2 present in early childhood with recurrent fevers and a spectrum of vasculopathic features including livedo racemosa, strokes, and polyarteritis nodosa (Fig. 40.5). Ischemic and hemorrhagic lacunar strokes occurred during episodes of inflammation with onset typically before the age of 5. Hepatosplenomegaly, portal hypertension, ocular inflammation, recurrent bacterial and viral infections, hypogammaglobulinemia, lymphopenia, low IgM levels, and anti-nuclear antibodies were variably seen in affected individuals. Positive lupus anticoagulant developed over time but anti-phospholipid antibodies were not detected. Skin histopathology predominately demonstrated perivascular lymphocytes and interstitial infiltrate comprising neutrophils and macrophages. Cutaneous vasculitis was observed in one individual [185].

Corticosteroids partially controlled episodes of inflammation and fever. Despite aggressive management with corticosteroids, cyclophosphamide and cytokine inhibitors, one affected individual continued to have stroke events into adulthood. Effective targeted therapeutic strategies for DADA2 require further investigation.

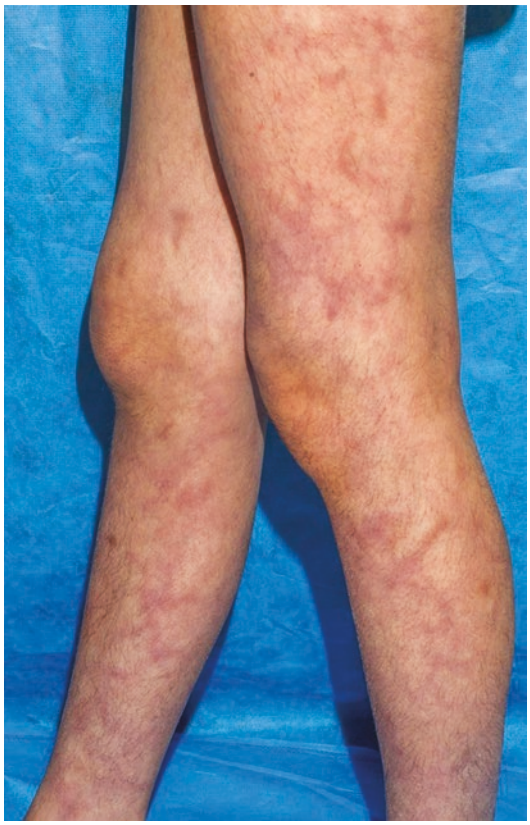

Fig. 40.5 Livedo racemosa in a patient with deficiency of adenosine deaminase 2 (DADA2)

Summary

Recent genetic insights into several rare monogenic autoinflammatory disorders have elucidated pathogenic mechanisms of debilitating diseases resulting from dysregulation of the innate immune system. The study of these molecular pathways of sterile inflammation has pointed to potential targeted therapeutic strategies for these enigmatic diseases. The identification of novel autoinflammatory syndromes continues to provoke investigation for novel targets for therapeutic intervention.

Questions

1. Dysregulation of the NALP3 inflammasome is thought to play an important pathogenic role in which autoinflammatory diseases?
2. Osteoarticular inflammation and neutrophilic dermatoses are clinical features shared by which autoinflammatory diseases thought to be mediated by IL-1 pathways?
3. Mutations in which gene is responsible for a spectrum of pustular and papulosquamous dermatoses?
4. Dysregulation of what signaling pathway is thought to play an important role in PRAAS pathogenesis?

5. Which two recently-described diseases are paradoxically characterized by both autoinflammation and immunodeficiency?

Answers

1. Cryopyrin-associated periodic syndromes; familial Mediterranean fever; TNF-receptor-associated-periodic syndrome
2. SAPHO/CRMO
3. LPIN2
4. PSMB8
5. PLAID and APLAID

Cutaneous T-Cell Lymphoma

41

Sasha Stephen, Ellen J. Kim, Camille E. Introcaso, Stephen K. Richardson, and Alain H. Rook

Abstract

Cutaneous T-cell lymphomas (CTCLs) are a group of extranodal non-Hodgkin's lymphomas (NHLs) that present primarily in the skin. The most common type of CTCLs, mycosis fungoides (MF) and Sézary Syndrome (SS), were first described over two centuries ago, and since that time, the clinical characteristics, pathophysiology, and immunobiology have been characterized in detail. Derived from skin-homing, mature, effector T-cells that usually express CLA/CD4/CCR4/CCR10 and lack T-cell markers CD7 and/or CD26, the malignant MF/SS cells typically have a Th2 phenotype. With more advanced disease, Th2 cytokines predominate and result in decreased host cell-mediated immunity that likely contributes to increased susceptibility to infection and disease progression. Early aggressive systemic chemotherapy has not been shown to improve overall survival in MF/SS and over the past 40 years [1] the therapeutic approach has undergone a paradigm shift, such that skin-directed therapies (SDTs) and systemic immune-modifying biologics play a central role in initial MF/SS management. This chapter will review MF/SS clinical presentation, staging work-up, pathophysiology, immunobiology, and how these have shaped current treatment strategies. In particular, MF/SS chemokine biology, immune defects, and immune modifying therapies, including the new frontier of hematopoietic stem cell transplantation will be specifically highlighted.

Clinical Presentation

CTCLs are a heterogeneous group of extranodal lymphomas and were the subject of a new joint classification system in 2005 by the World Health Organization-European Organization for Research and Treatment of Cancer (WHO-EORTC) (Table 41.1) [2]. MF/SS is relatively uncommon and comprises approximately 3.9% of all NHLs [3]. The incidence of CTCL has increased since 1973 with an annual age-adjusted incidence of 6.4–9.6 cases per million people in the United States [4]. The cause of the vast majority of MF/SS cases are unknown, despite numerous environmental and infectious etiologies having been investigated as potential sources of chronic antigenic stimulation. These include human T-cell lymphotrophic virus (HTLV), cytomegalovirus (CMV), Borrelia burgdorferi, human herpes virus-8 (HHV-8), *Staphylococcus aureus*, *Chlamydia* species, and chemical exposures such as aromatic or halogenated hydrocarbons [5, 6].

MF classically presents as scaly oval or annular patches/plaques (T1-2 tumor designation) on sun-protected areas such as the trunk, buttocks, axillae, groin, and proximal extremities, ("bathing trunk" distribution) with or without pruritus (Fig. 41.1a–c). Typically, it has indolent behavior and in early disease when host immunity is intact and lesions may wax and wane spontaneously. Because of this, early disease may take years before definitive diagnosis is made and skin biopsies may demonstrate non-specific dermatitis. Lesions may also less commonly affect sun exposed areas such as the face and can also result in localized hair loss (as seen in the follicular variant). They may also progress to thicker, more infiltrated plaques (Fig. 41.1c), ulcerated tumors (T3 disease) (Fig. 41.1d), or coalesce into a confluent erythema >80% body surface area ("erythroderma" or T4 disease) (Fig. 41.1d). In these cases, the disease can cause more symptoms and behave more aggressively.

In addition to the classic presentation, MF has myriad other clinical morphologies and histological variants (classic Alibert-Bazin subtype, erythrodermic/Sezary Syndrome, unilesional, hypopigmented, pagetoid reticulosis, follicular/follicular mucinosis, syringotropic, granulomatous/slack skin, bullous/vesicular, palmoplantar, pigmented purpuric dermatosis-like, interstitial, icthyosiform, hyperkeratotic/verrucous, vegetating/papillomatous) [7] and has been referred to as one of the great clinical imitators, similar to cutaneous syphilis and sarcoidosis. Subtypes may be characterized by more indolent behavior (hypopigmented MF) or by more aggressive behavior (follicular, granulomatous), depending on their clinical course. Follicular MF, even with limited lesions, can be recalcitrant to therapy given the depth of the malignant infiltrate.

SS typically has a more aggressive course than MF from its onset, and typically presents as de novo erythroderma with leukemic peripheral blood involvement by the atypical, hyperconvoluted, cerebriform, malignant T-cells known as Sézary cells (also previously referred to as Lutzner cells or cellules monstrueuses). This is in contrast to patients who have MF that evolves into erythroderma over time (erythrodermic MF). Originally, SS was described with the clinical triad of erythroderma, lymphadenopathy, and palmoplantar keratoderma (Fig. 41.1e). SS patients may also have severe pruritus, active scaling/desquamation, prominent conjunctival eversion of the eyelids (referred to as ectropion), diffuse alopecia, chills, low grade fevers, night sweats, or fatigue.

MF/SS patients, particularly erythrodermic patients, are heavily colonized by skin bacteria and are susceptible to recurrent infections with correct *Staphylococcus aureus*, which often are methicillin-resistant (MRSA). Patients with ulcerated tumors are also at high risk for bacterial sepsis and in general, infections have previously been the leading cause of mortality in MF/SS patients [8].

MF/SS patients may also present with other concomitant skin conditions, such as the chronic, recurrent primary cutaneous CD30+ lymphoproliferative disorders (LPDs) such as lymphomatoid papulosis (LyP) or CD30+ primary cutaneous anaplastic large cell lymphoma (ALCL) [9]. Patients with MF/SS may also be at higher risk for having secondary malignancies, such as other skin cancers (nonmelanoma and

melanoma) and secondary lymphomas [10]. Young patients with MF/SS diagnosed before 30 years of age may experience an increased risk of secondary malignancies, particularly melanoma and lymphoma, but, despite this risk, have a favorable prognosis [11].

Diagnosis

Early diagnosis of MF can be elusive, as the clinical and histopathology of early MF lesions can mimic benign dermatoses, such as eczematous dermatitis, allergic contact dermatitis, psoriasis and parapsoriasis. Traditionally, the diagnosis is made when a patient presents with typical lesions and skin biopsy reveals atypical lymphocytes (with large, hyperchromatic and hyperconvoluted nuclei) within the epidermis, in the absence of epidermal spongiosis, and often associated with epidermal dendritic cells (DCs) to form the pathognomonic "Pautrier's microabcesses." Currently there are sophisticated laboratory tools to aid in diagnosis, which include tissue immunohistochemistry and flow cytometry (which can demonstrate CD3 expression, CD4>CD8 expression of greater than 4:1, as well as characteristic T-cell lineage antigen loss of CD5, CD7, CD26, and less often CD3). Molecular detection of clonal T-cell receptor (TCR) gene rearrangements (β and γ chains) in the skin or other tissue (such as the blood or lymph node) can also further strengthen the diagnosis [12]. These days, the standard evaluation of early MF often involves assessment of multiple criteria (clinical, histopathological and molecular) [13]. However, it must be noted that T-cell clonality can also be detected in benign and autoimmune inflammatory dermatoses and should not be automatically equated with neoplasia [14, 15]. Diagnosis ultimately rests on accurate clinicopathologic correlation with adjunctive molecular studies, if appropriate.

In SS, leukemic blood involvement was traditionally measured by the Sézary prep, visual examination of a peripheral blood buffy coat smear for the atypical Sézary cells (Sézary count >5 % total lymphocytes was considered significant). However, this method was laborious and was subject to considerable inter-observer variability. More sensitive and specific tools to measure peripheral blood involvement include anti-TCR Vβ-specific monoclonal antibodies, or T-cell surface marker antibodies (CD3, CD4, CD7, CD8, CD26) using fluorescence-activated cell-sorting (FACS) analysis/flow cytometry.

The identification of a clonal malignant TCR Vβ population aids in the diagnosis and allows for monitoring of the disease course in SS patients. However, as SS cells express molecules also present on normal activated CD4 T cells, diagnosis based on the phenotype of circulating malignant cells can be difficult [6]. SS patients without an identifiable circulating clone pose a particular diagnostic and therapeutic monitoring challenge, as loss of CD26 is suggestive but not definitive of the malignant population [16].

To that end, much work has been performed recently to identify additional diagnostic markers for SS. Wysocka and colleagues identified CD164 as a novel early detection marker for SS in patients with low-to-high tumor burden, demonstrating a statistically significant correlation between CD164 acquisition and loss of CD26 expression [17]. The studies further showed that while CD164 is present on CD4 T cells of SS patients with a wide range of tumor burdens, it is absent on CD4 T cells of healthy controls and patients with atopic dermatitis. Additionally, morphological examination of purified CD4+CD164+ T cells demonstrates the morphology of malignant Sézary cells. Lastly, CD4+CD164+ T cells were noted to disappear in SS patients who experienced clinical remission as a result of treatment, underscoring the potential for CD164 to serve as a marker for malignant cells in SS.

Other markers recently reported useful in flow cytometric analysis include vimentin, CD158k [18], T-plastin (PLS3) [19], Twist [20], and NKp46 [21]. Michel and colleagues demonstrated that combination of CD158k, PLS3, and Twist gene expression profiling by quantitative PCR can be used for an efficient molecular diagnosis of SS [22]. The authors showed that $CD4^+$ T cells from SS patients expressed significant PLS3, Twist, CD158k, and NKp46 mRNA levels and that analysis of expression of these four markers accurately classified 100 % patients in the study.

In SS, molecular testing for T-cell receptor gene rearrangements can often detect the identical clonal T-cell population in the blood and the skin. In general, matching T-cell monoclonality detectable in several different skin lesions or tissues (skin, nodes, blood) in a patient over time is suggestive of CTCL [23].

Disease Staging

Since 1979, a tumor-node-metastasis-blood (TNMB) classification and staging system has been used for MF/SS and TNMB stage has proven to be an important prognostic measure (Tables 41.2 and 41.3) [24]. In 2007, modifications were proposed by the International Society for Cutaneous Lymphomas (ISCL) regarding further stratification of blood involvement parameters to reflect the newer and more sensitive assays [25, 26]. The current B classification proposed by the ISCL includes B0 (no clinically significant blood involvement), B1 (clinically significant "minimal" blood involvement with Sézary cells <1.0 K/ul) and B2 (leukemic blood involvement detectable either as (a) Sézary cells >1.0 K/ul; (b) CD4/CD8 ratio >10 and CD4+CD7- population >40 % or CD4+CD26- population >30 %, (c) lymphocytosis with

Table 41.2 TNMB classification for mycosis fungoides and Sézary syndrome, 2014 National Comprehensive Cancer Network guidelines

T (skin)	
T1	Limited patch/plaque (<10 % body surface area)
T1a	Patches only
T1b	Presence of plaques with or without patches
T2	Generalized patch/plaque (≥10 % body surface area)
T2a	Patch only
T2b	Presence of plaques with or without patches
T3	≥1 tumors (≥1 cm in diameter)
T4	Generalized erythroderma (≥80 % BSA)
N (lymph node)	
N0	No clinically abnormal (palpable; ≥1.5 cm diameter) peripheral LNs
N1	Clinically abnormal LNs; histopathology Dutch grade 1 or NCI $LN_{0\text{-}2}$
N1a	Clone negative
N1b	Clone positive
N2	Clinically abnormal LNs; histopathology Dutch grade 2 or NCI LN_3
N2a	Clone negative
N2b	Clone positive
N3	Clinically abnormal LNs; histopathology Dutch grade 3–4 of NCI LN_4; clone positive OR negative
M (viscera)	
M0	No visceral involvement
M2	Visceral involvement (pathology confirmation of specific organ involved)
B (blood)	
B0	Absence of significant blood involvement (≤5 % of peripheral blood lymphocytes are atypical/Sézary cells)
B0a	Clone negative
B0b	Clone positive
B1	Low blood tumor burden (>5 % of peripheral `blood lymphocytes are atypical/Sézary cells but does not meet criteria of B2
B1a	Clone negative
B1b	Clone positive
B2	High blood tumor burden defined as one of the following: ≥1000 Sézary cells/μL with positive clonal rearrangement of TCR; CD4:CD8 ratio ≥10 with positive clone; or $CD4^+CD7^-$ cells ≥40 % or $CD4^+CD26^-$cells ≥30 % with positive clone

Table 41.3 Clinical staging system for mycosis fungoides and Sézary syndrome, based on the 2014 National Comprehensive Cancer Network guidelines

Clinical stages	T	N	M	B
IA	1	0	0	0 or 1
IB	2	0	0	0 or 1
IIA	1 or 2	1 or 2	0	0 or 1
IIB	3	0–2	0	0 or 1
IIIA	4	0–2	0	0
IIIB	4	0–2	0	1

IVA_2	1–4	3	0	0–2
IVB	1–4	0–3	1	0–2

molecular genetic evidence of a clonal T-cell population; or (d) chromosomally abnormal T-cell clone). The updated blood involvement parameters may affect staging and prognosis of patients. Currently, the ISCL proposes that in patients with erythroderma (T4 skin classification), the B2 classification be considered the equivalent to nodal involvement (hence T4N0-1M0B2 would be upgraded from Stage III to Stage IVA1). A retrospective study by Vonderheid et al. demonstrated that using modified B criteria improved prognostication in erythrodermic patients [26]. Several large studies have since validated the 2007 ISCL staging classification for prognosis and risk stratification [27–29]. National Comprehensive Cancer Network Clinical Practice Guidelines for MF/SS have been available since 2008 and include

recommendations for diagnostic and staging work up as well as current established treatments and treatment algorithms, and are updated yearly [30].

Once patients have an established diagnosis of MF/SS, a typical staging workup includes complete skin and physical examination, bloodwork including complete blood count with differential, comprehensive metabolic panel, lactate dehydrogenase, and either peripheral blood flow cytometry or Sézary cell prep (flow optional in T1a, limited patch disease with no high risk clinical or histologic characteristics). Computed tomography (CT) or positron emission tomography scanning (PET) is appropriate for patients with systemic symptoms, clinically palpable lymphadenopathy (>1.5 cm), or more advanced T classification (T1b follicular MF, extensive T2a/b, T3/tumors or T4/erythrodermic disease, patients with B symptoms). These tests are useful to assess nodal or visceral involvement by MF/SS. The role of staging bone marrow biopsy remains controversial [31]. In the United States, bone marrow biopsy is typically reserved only for patients with advanced disease with some evidence of other hematological abnormalities (i.e.: other cytopenias).

Overall survival in MF/SS is highly dependent on initial disease stage. Several studies have demonstrated that early stage disease (i.e.: skin disease only, limited to <10 % body surface area) if treated has overall median survival comparable to healthy control populations. However, with more advanced disease, overall survival also decreases with Stage IV disease having a 27 % 5-year survival and Sézary Syndrome patients having a 30 % 5-year survival [32]. In retrospective studies, the risk of disease progression ranged from 10 % (Stage IA) to 25 % (Stages IB or higher) over a 30 year period [33, 34]. While a 2003 study by Kim and colleagues [32] reported an overall survival (OS) of only 2.5 years in patients with SS, a study by Agar and colleagues [27] in 2010 reported a 3.1 year OS, and a study by Talpur and colleagues [28] from 2012 showed an OS of 4.64. As the major cause of death in patients with SS is line sepsis, which is often caused by *Staphylococcus aureus*, Talpur et al. report that *Staphylococcus* was prospectively cultured and was aggressively treated and prevented with antibiotics and skin care [35]. The authors thus postulate that the improved survival may have resulted in part from early treatment of coexisting infections, as well as earlier diagnosis of disease and advent of new therapies.

Various clinical prognostic factors have been demonstrated including patient age, initial stage, T classification, visceral disease, elevated LDH, eosinophilia, presence of Sézary cells, and B0b blood classification [27]. Important histological factors that indicate poor prognosis include "large cell transformation" (LCT, presence of >25 % large atypical T-cells in the infiltrate seen in the skin or lymph node or blood, may be either CD30+ or CD30-, with CD30- transformation having worse prognosis than CD30+) [36], folliculotropic or granulomatous infiltrate; in contrast, the presence of CD8+ tumor infiltrating cytotoxic lymphocytes (TILs) in the infiltrate has been demonstrated to be a favorable prognostic marker.

Recently, a new cutaneous lymphoma international prognostic index (CLIPi) for early and late stage CTCL has been developed and validated to aid with patient risk stratification [37]. Based on the proposed index, significant adverse prognostic factors at diagnosis included male gender, age >60, presence of plaques, folliculotropic disease, and stage N1 for early stage disease, and male gender, age >60, stages B1/B2, N2/3 and visceral involvement for late stage disease. Using these variables 3 distinct groups are designated for early and late stage patients: 0–1 (low risk), 2 (intermediate risk), and 3–5 factors (high risk). Using this prognostic index a 10 year OS for each group may be obtained (in the early stage model was 90.3 % (low), 76.2 % (intermediate) and 48.9 % (high) and 53.2 % (low), 19.8 % (intermediate) and 15.0 % (high) for the late stage model).

CLIPi thus supplements the current NCI Staging System and is a useful tool for individual prognostication and for making comparisons between different groups of patients in clinical trials.

Perhaps the most potentially powerful prognostic tool currently being developed in MF/SS is cDNA microarray analysis. Previously, MF/SS patients were shown to have a distinct gene expression profile that was distinguishable from other benign inflammatory dermatoses [38]. In addition, such profiles could also identify high risk patients with <6 month survival. The panel of genes identified included upregulated GATA3 (involved in Th2 differentiation), downregulated STAT4 (involved in Th1 differentiation), and CD26 (dipeptidylpeptidase IV, which regulates T-cell entry into the epidermis, see section "Chemokines"). Recently, several studies have confirmed that a similar panel of genes has been shown to be capable of molecularly diagnosing MF/SS patients [39, 40].

Pathophysiology

Chemokines and Their Receptors in CTCL

As mentioned previously, CTCL is a malignancy in which tumor cells exhibit an affinity for the skin. This affinity is dependent upon their expression of cell surface "trafficking" molecules which mediate their migration to the cutaneous microenvironment. Chemokines and their receptors are included in this family of molecules and play a critical role in mediating tissue-specific trafficking of leukocytes to the skin.

Chemokines are chemotactic cytokines that are produced by a wide array of tissues and range from 8 to 17 kDa in size.

They are divided into families in accordance with the positioning of cysteine residues in their chemical structure. Aside from their role in cell migration, they have also been shown to play a role in the mediation of inflammatory responses, angiogenesis, and cellular proliferation [41].

Chemokine receptors are seven transmembrane-spanning G-protein coupled proteins that are capable of recognizing more than one chemokine. Several chemokines and their receptors have been identified to play a critical role in the trafficking of immune cells to the skin, more specifically, thymus and activation-regulated chemokine (TARC), macrophage-derived chemokine (MDC), stromal derived factor-1 (SDF-1), and cutaneous T-cell-attracting chemokine (CTACK). These chemokines have been shown to be produced by multiple cell types (including keratinocytes, fibroblasts, and endothelial cells) and are upregulated at sites of cutaneous inflammation. Skin-trafficking T-cells have been shown to express receptors for these chemokines.

Lymphocyte trafficking to the skin requires that the cell undergo a sequential series of events that begins with an initial tethering interaction with the endothelial surface, followed by rolling, activation, firm adhesion, and diapedesis into the dermal microenvironment. The tethering and rolling events are mediated by interactions between cutaneous lymphocyte associated antigen (CLA) and E-selectin [42]. CLA is expressed on the surface of skin-trafficking T-cells and E-selectin is expressed by endothelial cells at sites of cutaneous inflammation.

Activation of the arrest stage of lymphocyte trafficking is mediated by interactions between chemokines and their receptors. Upon engagement of the chemokine receptor, signals are transduced which activate downstream events that include a change in cellular morphology, such that integrins on the surface of the leukocyte are sufficiently exposed to contact their ligands on the dermal microvasculature (e.g. LFA-1 binding to ICAM-1). This leads to the arrest of the rolling cell, which may then migrate into the dermis along a chemotactic gradient generated by chemokines produced in the skin.

The malignant cells in CTCL have been shown to express skin-trafficking molecules and includes CLA and an array of chemokine receptors. Although frequently elevated, we and others have observed that CLA expression may be more variable among circulating malignant cells [43], whereas chemokine receptors involved in skin-trafficking are more consistently expressed at high levels among this population.

It appears somewhat counterintuitive that cells expressing skin-trafficking molecules may remain confined to the circulation, as is noted among patients with advanced disease such as in SS. This confinement of malignant cells to the blood compartment may in part be accounted for by significantly elevated chemokine levels (such as TARC) in the skin and circulation of patients. It is plausible that TARC levels in the blood may exceed a threshold concentration required for effective chemotaxis, and thus abolish a skin-derived chemotactic gradient. This idea is supported by the work of Poznansky et al. who reported the potential for T-cells to exhibit movement away from a chemotactic gradient established at concentrations above which normal directional migration is detected [44]. This finding, in combination with the variable expression levels of other skin-trafficking molecules (such as CLA) among the malignant population in CTCL may provide an explanation for the high percentage of neoplastic cells detected in the circulation of patients with advanced disease.

Several studies have evaluated the expression of chemokine receptors by malignant cells in the skin and circulation of CTCL patients. Flow cytometric analysis and immunohistochemical studies revealed preferential expression of the chemokine receptors CCR4, CXCR3 and CXCR4 among MF cells and the surrounding reactive T cells in patients with early patch and plaque stage disease. Interestingly, patients with tumor stage disease exhibit a loss of CXCR3 (and rarely CCR4), while expressing high levels of the chemokine receptor CCR7 [45]. CXCR4 and CCR4 have both been shown to play a role in lymphocyte migration to the skin, while CCR7 mediates the migration of T cells to lymphatic tissue and may account for the nodal disease observed among patients with advanced disease. CCR7 recognizes secondary lymphoid tissue chemokine (SLC/CCL21) produced within the nodal microenvironment. Preferential expression of CCR10 has also been reported among tumor cells of MF patients. CCR10 is the receptor for the cutaneous T-cell attracting chemokine (CTACK/CCL27) which is constitutively produced by epidermal keratinocytes [46].

Similar to the MF cells in tumor stage disease, the malignant cells in patients with peripheral blood disease have been shown to express elevated levels of CCR4, CCR7, CXCR4, and CCR10 [47]. In addition, the circulating malignant cells are also characterized by their loss of the cluster of differentiation markers CD7 and/or CD26 [48]. The absence of CD26 is believed to contribute to the accumulation of malignant cells in the skin of Sézary syndrome patients [49].

Campbell and colleagues have recently demonstrated that MF and SS may arise from two distinct T-cell subsets. Their studies show that clonal malignant T cells from the blood of SS patients universally coexpress the lymph node homing molecules CCR7 and L-selectin as well as the differentiation marker CD27, a phenotype consistent with central memory T cells (T_{CM}) [50]. The authors also note that CCR4 was universally expressed at high levels, while there was variable expression of CCR6, CCR10, and CLA. In contrast, T cells isolated from MF skin lesions lacked CCR7/L-selectin and CD27, but strongly expressed CCR4 and CLA, a phenotype of skin resident effector memory T cells (T_{EM}).

Additionally, genomic analysis reveals differing molecular profiles characteristic of MF and SS. MF is characterized

by increased expression of FASTK and SKAP1 genes, and diminished expression of the RB1 and DLEU1 tumor suppressor genes [51], while SS is characterized by amplification of MYC oncogene in 75 % of patients with SS, which was detected in only a minority of patients with MF [52].

Although MF and SS were originally thought to represent points of progression in a disease continuum, the recent data suggest that these two entities might best be considered as separate lymphoproliferative diseases which originate from distinct T-cell subsets and have different genetic signatures.

CD26 is a dipeptidyl transferase expressed as both a soluble factor in the circulation and as a cell surface protein expressed by lymphocytes. CD26 mediates the cleavage of the chemokine stromal derived factor-1 (SDF-1), produced by inflamed skin (Fig. 41.2a). SDF-1 is the natural ligand for the chemokine receptor CXCR4, which is expressed by the malignant population in Sézary syndrome. The absence of CD26 leads to elevated levels of SDF-1, which in turn, contributes to the trafficking of malignant cells to skin (see Fig. 41.2b).

A CD26 negative population of greater than 30 % among erythrodermic patients is believed to be sufficient to support a diagnosis of Sézary syndrome, and thus differentiate such patients from individuals suffering from benign inflammatory dermatoses [16]. We have recently reported a correlation between the percentage of circulating CD4 + CD26- T-cells and changes in clinical status among Sézary syndrome patients. More specifically, a reduction in this population typically heralds improved clinical status, whereas, an increase frequently precedes disease progression characterized by a greater than 20 % increase in affected body surface area, or a greater than 10 % increase in body surface area accompanied by progressive lymphadenopathy and/or hepatosplenomegaly [53].

While chemokine receptors are necessary for tissue-specific lymphocyte trafficking to the skin, expression of their chemokine ligands plays an essential role in this process. In the absence of chemokines, engagement and activation of the chemokine receptor will not occur. The epidermotropism exhibited by neoplastic cells in CTCL has been attributed, in part, to the production of chemokines by epidermal cells. Whether their production arises secondary to the accumulation of malignant cells in the skin or precedes the infiltration has not be en established.

Elevated levels of the chemokine, cutaneous T-cell attracting chemokine (CTACK/CCL27), has recently been reported in the serum of patients with CTCL. The highest levels were detected among patients with more advanced disease (tumor stage and erythroderma), and improved in response to successful treatment [54]. CTACK has been shown to be produced by epidermal keratinocytes and is presented on the surface of dermal endothelial cells [46, 55]. It is recognized by the chemokine receptor, CCR10, which, as mentioned previously, is expressed by the malignant population [56].

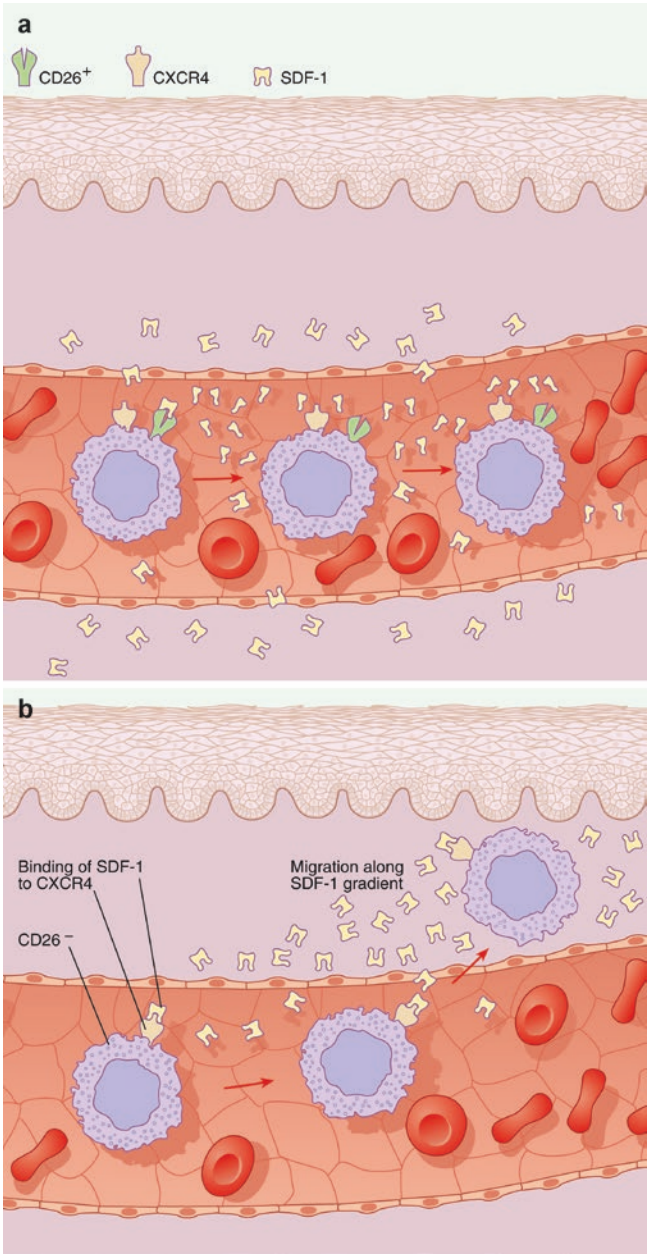

Fig. 41.2 (**a**) CD26 is a bipeptidyl transferase expressed by normal T lymphocytes that induces the cleavage and inactivation of the chemokine stromal-derived factor-1 (SDF-1). This cleavage prevents the binding of SDF-1 to its receptor, CXCR4, thus interfering with SDF-1/CXCR4-mediated chemotaxis into the skin. CD26+ T cells are resistant to the chemotactic effects of SDF-1 via CD26-mediated inactivation (*top*). (**b**) The absence of CD26 is reported among circulating malignant cells in Sézary syndrome. In the absence of CD26, SDF-1 may efficiently establish a chemotactic gradient that promotes the migration of malignant cells into the skin via engagement of CXCR4. Engagement of CXCR4 by SDF-1 in the cutaneous microvasculature and subsequent chemotaxis of the cell into the dermal microenvironment are demonstrated (*top*)

Thymus and activation-regulated chemokine (TARC/CCL17), the ligand for CCR4, was shown to be elevated in CTCL patients relative to normal individuals and patients with psoriasis vulgaris [57]. More specifically, an increase in serum TARC levels was shown to correlate with more advanced disease, being greatest among tumor stage patients as compared to patch and plaque stage patients. Immunohistochemistry revealed TARC expression by lesional keratinocytes at all stages of disease. These findings support a functional role for CCR4 in the accumulation of malignant cells in the skin of CTCL patients.

Preferential expression of mRNA for the chemokine interferon-gamma inducible protein 10 (IP-10) has been reported in the epidermis of patients with early stage epidermotropic CTCL [58]. IP-10 is the ligand for CXCR3, which is expressed by MF cells in early patch/plaque stage disease [45]. CXCR3 and its ligand, IP-10, are considered to be Th1 associated molecules given their ability to recruit Th1 cells to sites of inflammation. Thus, levels of IP-10 and CXCR3 positive cells may reflect the host anti-tumor response. Patients with more advanced disease exhibit a depression in CXCR3 levels, whereas, expression of the Th2 associated chemokine-receptor, CCR4, and its ligand (TARC), remain elevated and skew the cutaneous cytokine milieu in favor of Th2 cytokine production, which likely contributes towards the pathogenesis of disease in CTCL.

Once the malignant T-cells have been recruited to the skin, their growth appears to be supported by the in situ production of cutaneous cytokines. Yamanaka and colleagues have demonstrated that lesional skin of CTCL patients over produces interleukin-7 [59]. IL-7 itself clearly exhibits pro-proliferative effects on malignant T-cells derived from CTCL patients.

Chromosomal and Genetic Abnormalities

MF/SS is not considered a primary genetic disorder attributable to discrete mutation(s), however with disease progression, several genetic abnormalities have been detected. Cytogenetic studies have demonstrated chromosomal deletions (1p, 17p, 10q, 19) and gains (4q, 18, 17q) [60]. Even early MF lesions have been shown to have STAT 3 constitutively activated or defects in their apoptosis pathways (decreased Fas expression) [61–63]. In more advanced disease, such as tumor-stage MF or SS, other genetic perturbations include p15/16 and p53 defects, microsatellite instability, hypermethylation of tumor suppressor genes (p14, p15, p16, BCL7a, PTPRG, p73) [64, 65], and constitutive activation of NF-kB [66]. In addition to these, epigenetic factors (which affect gene expression through modification of histones and other chromatin-associated proteins) appear to play a role in CTCL development/progression, given the clinical activity of histone deacetylase inhibitors (HDACi) in CTCL [67].

MF/SS malignant T-cells also can variably express the interleukin-2 receptor (IL-2R) that binds the cytokine IL-2. IL-2R is comprised of 3 subunits: IL-2Rα (CD25/p55), IL-2Rβ (CD122/p75) and IL-2Rγ (CD132/p64). IL-2Rα has been viewed as a marker of cell activation and is significantly expressed in approximately 20 % of MF/SS patients, particularly in later stage disease [68], and soluble IL-2R can be detected in the peripheral blood [69]. The T-cells can also express other activation markers such as CD45RO and/or proliferating-cell nuclear antigen (PCNA).

Immunobiology

Immune Dysregulation in CTCL: Clues to Understanding Disease Progression

It has long been known that patients with advanced MF/SS typically exhibit abnormalities in a variety of parameters of cell-mediated immunity. Moreover, the malignant T-cells have been implicated as the cause of the endogenous immune deficiency. Earlier observations by Vowels and colleagues demonstrated that the malignant $CD4^+$ T cells observed in most cases of MF/SS appear to exhibit a Th2 phenotype (Fig. 41.3). In vitro stimulation of peripheral blood cells derived from SS patients routinely results in increased levels of measurable IL-4 expression [70]. Furthermore, Vowels et al. demonstrated levels of IL-4 and IL-5 mRNA in clinically involved skin, even among patients with early patches or plaques while uninvolved skin and the skin of normal volunteers did not have detectable levels of Th2 cytokine mRNA [71]. Increasing levels of IL-10 mRNA in parallel with an increasing density of the malignant T cell infiltrate as lesions progressed from patch to plaque to tumor has also been demonstrated [72]. cDNA microarray analysis of the malignant T-cells isolated from patients with SS have shown that the Th2 cell–specific transcription factors such as GATA-3 and Jun B are highly overexpressed [38]. Thus, despite evidence of a vigorous host response in skin lesions in early disease, characterized by the presence of IFN-γ–secreting $CD8^+$/TiA-1^+ T cells [73], the chronic production of Th2 cytokines such IL-4, IL-5 and IL-10 by the malignant T cell population likely represents one mechanism by which the tumor cells circumvent the anti-tumor immune response.

The host anti-tumor response, although effete, may play a role, albeit small, in containment of disease progression, even among those with advanced disease. This is supported by the observation of rapid progression of SS associated with the use of immunosuppressive agents such as cyclosporine [74]. In addition to enhanced Th2 cytokine production during disease progression, patients with circulating malignant

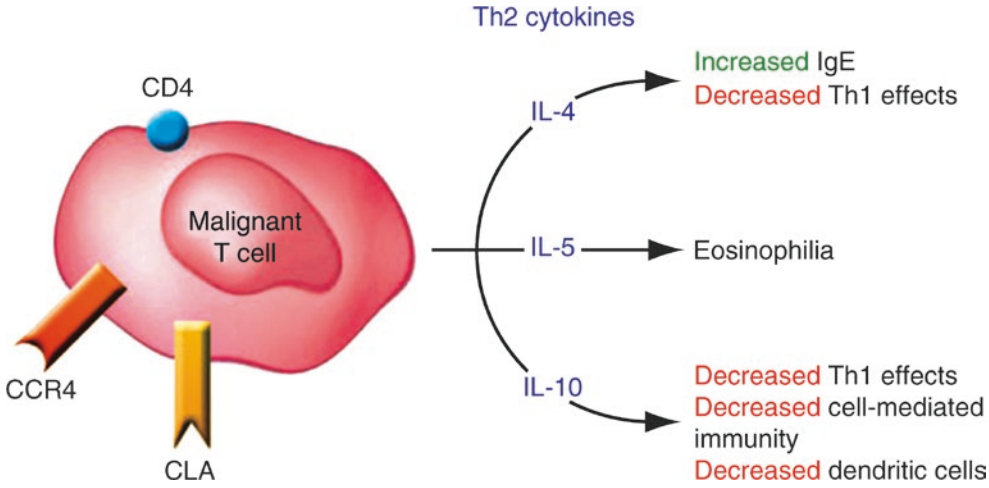

Fig. 41.3 The malignant T cell in MF/SS expresses CD4/CLA/CCR4/CCR10 and produces the cytokines IL-4/IL-5/IL-10, which results in Th2 predominance and subsequent multiple abnormalities in cellular immunity (From Kim et al. [5] with permission of the American Society for Clinical Investigation. Copyright 2005)

T cells also manifest defects in Th1 cytokine production. Wysocka et al. observed a progressive decline in the production of IL-12 and IFN-α by peripheral blood cells that correlated with an increase in the peripheral blood burden of malignant T cells [75]. Furthermore, the decline in production of these cytokines appeared to be linked to a decline in the numbers of peripheral blood myeloid and plasmacytoid DCs, respectively. Accompanying the decrease in DCs and a defect in IL-12 production is a deficit in production of other products of myeloid DCs, including IL-15 which is an important IFN−γ–stimulating agent and powerful booster of Th1 responses. In contrast, Yamanaka et al., observed increased serum IL-18 and IL-18 mRNA within CTCL skin samples suggesting alternative potential sources for this interferon inducing cytokine [76] Nevertheless, peripheral blood cells of SS patients clearly manifest marked decreases in IFN-γ production [70].

Intense recent interest has focused on the possible contributory role of regulatory T-cells (Tregs) in the endogenous immunosuppression in advanced CTCL. Berger and colleagues have demonstrated that under certain *in vitro* conditions that malignant T-cells may assume properties of Tregs, including the expression of Foxp3 and production of TGF-β and IL-10 [77]. Similarly, Walsh et al., was able to demonstrate increased Foxp3 expression among the peripheral blood cells of some patients with SS and among the circulating cells of all patients with HTLV-1 associated CTCL [78]. The cells of such patients were found to produce increased concentrations of TGF-β. Wong et al. has observed increased expression of CTLA-4 upon activation of the circulating cells of patients with CTCL, indicating that this molecule, which is typically associated with Tregs, was upregulated and a sign of increased numbers of Treg cells [79]. These findings remain controversial as Tiemessen observed that the Foxp3 positive Tregs of some CTCL patients are dysfunctional and exhibit a reduced ability to inhibit the proliferation of CD4+/CD25- T-cells [80] while Yamano and colleagues have made similar observations in regard to HTLV-1 infected CD4+ cells [81]. Despite these disparate findings, many investigators involved in studies of the immunobiology of CTCL feel that Tregs likely play some role in the pathogenesis of the immune suppression. Thus, as discussed below, elimination of Tregs is just one of several new therapeutic strategies under investigation.

Other mechanisms that could account for abnormalities in DC maturation, and thus, for diminished IL-12 production have been highlighted by recent studies by French et al., which demonstrated a defect in expression of CD40 ligand upon activation of malignant T cells derived from patients with SS [82]. CD40 ligand is not expressed on resting T cells but is normally upregulated on the cell surface upon engagement of the TCR. By contrast, malignant CD+/CD7- T cells fail to express CD40 ligand upon engagement of the TCR by anti-CD3. Clearly, the absence of CD40 ligand interaction with CD40 on APCs during an immune response can lead to a profound reduction in DC activation and cytokine production. Through the in vitro addition of recombinant hexameric CD40 ligand, French and colleagues demonstrated reconstitution of IL-12 and TNF production by the cells of patients with SS. These findings provide obvious insights regarding potential strategies for correcting defects in immune dysregulation related to diminished numbers and function of DCs associated with advancing MF/SS.

Derangements in T-cell diversity may also play a role in the immune suppression of CTCL. Yawalkar et al., using beta-variable complementarity-determining region 3 spectratyping determined that patients with both early as well as late disease exhibit loss of the normal T-cell repertoire [83, 84]. These findings are reminiscent of a chronic retroviral infection as similar observations have been made in HIV infection. Loss of T-cell repertoire may partially account for the failure of advanced stage CTCL patients to respond normally to a variety of antigens.

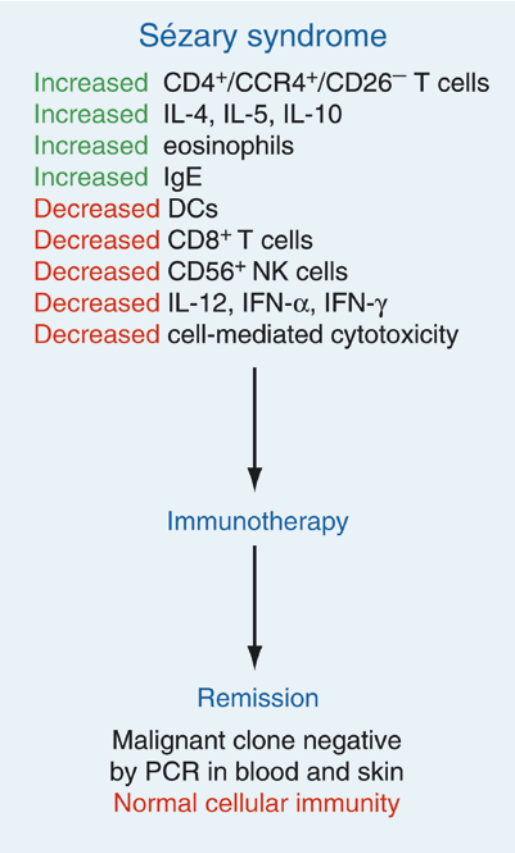

Fig. 41.4 Elimination of the malignant T-cell clone during immunotherapy leads to a restoration of a normal immune response. Studies of numerous patients with SS have demonstrated that induction of complete remission with clearing of the malignant T-cell clone during multimodality immunotherapy leads to a restoration of normal host immune function (From Kim et al. [5] with permission of the American Society for Clinical Investigation. Copyright 2005)

The result of the diverse abnormalities of DC and T-cell function during progressive MF/SS are multiple abnormalities in cellular immunity (Fig. 41.4). Marked defects in cellular cytotoxicity occur that correlate with the burden of circulating malignant T cells [85]. Progression from early to more advanced MF/SS is typically associated with a marked decline in NK cell numbers and activity which could partially be due to a decline in myeloid DC production of IL-15 which is critical for the normal growth of these cells. Similarly, a decline in the number of peripheral blood $CD8^+$ T cells accompanies an increasing burden of circulating malignant T cells. Furthermore, the percentage of these cytotoxic cells that express activation markers, such as CD69, is also significantly reduced compared to NK and $CD8^+$ T cells from MF patients without overt peripheral blood involvement [86]. A reduction in the number of functioning NK and $CD8^+$ T cells is almost certainly associated with a deterioration of both host anti-tumor immunity and immune surveillance against microbial organisms. Examples of these phenomena include infections such as disseminated herpes simplex/zoster or progressive multifocal leukoencephalopathy among SS patients who have never been iatrogenically immunosuppressed by chemotherapy or other immunosuppressive medications [8, 87, 88]. As mentioned earlier, other malignant neoplasms, including melanoma and non-melanoma skin cancers as well as Hodgkin's lymphoma, also appear to be more common in MF/SS patients independent of the history of previous predisposing therapy (such as phototherapy or radiation therapy) [10, 89, 90]. These findings reflect an overall impairment in immune surveillance against cancer.

Other characteristic immunological findings associated with the progression of MF/SS include development of peripheral eosinophilia and elevated levels of serum IgE [70, 91]. Peripheral eosinophilia has been determined to be an independent marker for poor prognosis and disease progression [92]. In one study, peripheral blood cells from patients with SS and eosinophilia produced markedly higher levels of IL-5 upon stimulation than did cells of patients or normal volunteers without eosinophilia [93]. A finding of importance in this study indicated that culture of the patients' cells with either recombinant IFN-α or IL-12 significantly inhibited the excess production of IL-5. These observations suggest that these cytokines could be useful therapeutic tools to prevent continued proliferation of eosinophils under the influence of IL-5, thus, possibly preventing at least some of the adverse effects associated with high eosinophil counts.

It is particularly noteworthy that after successful treatment of SS with immunotherapeutic agents, with resolution of evidence for skin disease and disappearance of the malignant clone from the blood, virtually all abnormal immune parameters are restored to normalcy (Fig. 41.4) [85]. One implication of these observations is that the malignant clone is likely responsible for much of the immune dysregulation that occurs in SS. Moreover, these findings indicate that SS patients who experience remission will have their immune system at least partially reconstituted. Thus, such patients should be less likely to experience severe consequences of microbial infection in comparison to those with advanced SS.

Treatment

Treatment of MF/SS can be divided into 2 major categories: skin directed therapies (SDTs) and systemic therapies. As listed in Table 41.4, there are numerous options. Therapeutic approaches can vary widely from center to center, and the availability of many newer therapies varies among countries. It is useful to divide the discussion of therapies in regard to early stage vs. late stage disease (Table 41.5).

Table 41.4 Treatment options in MF/SS

Skin directed therapy	Mechanism of action
Topical corticosteroids	Tumor cell apoptosis, decrease skin LCs
Topical chemotherapy (nitrogen mustard, BCNU)	Tumor cell apoptosis
Topical retinoids (bexarotene, tazarotene)	Tumor cell apoptosis
Topical imiquimod	TLR7 agonist, triggers innate & adaptive anti-tumor immunity
Phototherapy (UVB, PUVA, excimer laser)	Tumor cell apoptosis Decrease skin LCs
Electron beam therapy (EBT)	Tumor cell apoptosis
Biological therapy	
RXR retinoid (bexarotene)	Tumor cell apoptosis Inhibit tumor cell IL-4 production
RAR retinoid (isotretinoin, all-trans retinoic acid)	Tumor cell apoptosis Induce interferon-γ
Interferons (alpha, gamma)	Enhanced cell-mediated cytotoxicity Inhibit tumor cell Th2 cytokine production
GM-CSF	Enhanced circulating dendritic cell numbers and function
Extracorporeal photopheresis	Circulating tumor cell apoptosis Induction of DC differentiation
Fusion protein/toxin (denileukin diftitox[a])	Targets and kills CD25 (IL2 receptor) expressing tumor cells.
Histone deacetylase inhibitors (vorinostat, romidepsin)	Affects tumor cell gene transcription, non-histone effects.
Other systemic therapy	
Cytotoxic chemotherapy (MTX, pegylated doxorubicin, gemcitabine, etoposide, pentostatin)	Cytotoxic agents
Hematopoeitic stem cell transplantation (allogeneic)	Cytotoxic agents (induction)
	Graft-vs-tumor effect
Experimental therapy	
Transimmunization ECP	Enhances DCs antigen processing of apoptotic tumor cells
Targeted monoclonal antibodies (CD4, CD52, CD40, CCR4)	Targets tumor cells (CD4, CD52, CCR4) Activated dendritic cells (CD40)
Cytokines (IL12, IL2, IL15)	Augments cell mediated anti-tumor immunity
Toll-like receptor agonists (CpG-ODN, imidazoquinolones)	TLR agonists, augment innate and adaptive anti-tumor immunity
Tumor vaccines	Clonotypic TCR as antigen Dendritic cell based vaccines

Early MF

It has become quite clear during the past several decades that traditional systemic chemotherapy has not resulted in durable remissions in MF/SS [1]. As a consequence, emerging therapeutic efforts have focused upon targeted biological agents and immune modifications using a multimodality approach. Numerous arms of the immune system must cooperate to generate a sufficient host anti-tumor response such that the proliferation of the malignant T cell population in MF/SS patients can be controlled and, ideally, eradicated (Fig. 41.5).

Patients with patches or plaques limited to less than 10% skin surface area (stage IA or T1 disease) tend to exhibit normal cellular immune responses. Therefore, use of skin-directed therapies, including topical chemotherapy [94, 95], superpotent topical corticosteroids, topical retinoid application [96], psoralen plus ultraviolet A phototherapy (PUVA) [97, 98], or electron beam radiation therapy [99], which target the tumor burden in the skin by directly inducing apoptosis of malignant T cells, is often sufficient to induce complete clearing of disease. At this stage, the systemic immune response is intact and it may contribute to controlling disease burden from going beyond the skin. In the event that clearing is not complete, the addition of a single agent systemic immunomodulator, such as recombinant IFN-α or the retinoid bexarotene (Targretin (R)), typically leads to a better clinical response.

For patients who do not yet manifest overt peripheral blood disease but who exhibit more extensively infiltrated cutaneous plaques or a greater extent of skin surface area involvement, multimodality therapeutic approaches appear to result in more rapid responses [100–103]. IFN-α, produced by plasmacytoid DCs, is a product of the innate

Table 41.5 Treatment of MF/SS by clinical stage

Stage	Initial therapy	Subsequent therapy	Therapy for refractory disease
IA (early stage)	Skin directed therapies		
IB/IIA	Topical chemotherapy Phototherapy Electron beam therapy (± low dose biological agents)	Interferons Retinoids Multimodality rx Topical chemo + biological agent Phototherapy + biological agent 2 biological agents Denileukin diftitox[a] Histone deacetylase inhibitors	Experimental therapies
IIB (advanced stage)	Few tumors Localized EBT Intralesional IFN Topical chemotherapy + biological agent Generalized tumors Total skin EBT Denileukin diftitox Multimodality therapies	Multimodality therapy Denileukin diftitox Histone deacetylase inhibitors Single agent chemotherapy	Experimental therapies
IIIA, B	PUVA Retinoids Interferons Methotrexate ECP Histone deacetylase inhibitors Multimodality therapies	Multimodality therapies Denileukin diftitox Histone deacetylase inhibitors Single agent chemotherapy	Experimental therapies
IVA, B	Single agent systemic therapy Multimodality therapy (+skin directed therapy)	Adjuvant palliative local radiation for extracutaneous disease Bone Marrow/Stem Cell Transplant Chemotherapy	Experimental therapies

immune response, and appears to be one of the most highly active biologic agents used in the therapy of MF/SS [104]. It is now well accepted that PUVA plus IFN-α administration can produce higher clinical response rates than the use of PUVA alone [103, 105, 106]. Several small studies have also suggested that a combination of IFN-α with oral retinoids, including bexarotene or 13-cis retinoic acid, may induce rapid responses among patients with extensive skin lesions [100, 107].

Mechanistically, IFN-α induces a variety of beneficial effects on the host immune response that may lead to disease clearing. IFN-α directly enhances cell-mediated cytotoxicity; both $CD8^+$ T cells and CD56+ NK cells exhibit rapid activation as assessed by upregulation of CD69, and the cytotoxic effects of NK cells are significantly boosted [86]. IFN-α also suppresses Th2 cytokine production by malignant T cells, which may lead to abrogation of the suppressive effects of IL-4 and IL-10 on antitumor immunity. Recently Wood and colleagues demonstrated that methotrexate and IFN-α synergistically upregulates Fas expression on CTCL cells (methotrexate demethylates the Fas promoter and IFN-α increases Fas levels via STAT1) resulting in enhanced tumor cell apoptosis [108]. This is one potential mechanism to explain the clinical efficacy of this combination [109].

Bexarotene, a recently FDA approved retinoid X receptor–specific compound has also been determined to have valuable immunomodulatory effects that are of benefit in the treatment of MF/SS, particularly when used in combination therapy. Bexarotene has the ability to induce apoptosis within the malignant population of T cells [110, 111]. This effect may account for the nearly 50 % response rate of MF/SS patients when high-dose, single-agent oral bexarotene is administered [112]. Nevertheless, Budgin et al. have demonstrated that although the malignant cells of most patients with SS are susceptible to the apoptotic effects of bexarotene in vitro, purified Sézary cells from approximately one-third of patients demonstrate significant resistance to apoptosis [111]. This finding may account for the failure of a subset of patients to respond clinically to this compound. Furthermore, recent observations suggest that chronic bexarotene use may be associated with emergence of malignant clones of T-cells that lack the specific RXR-responsive receptor and which exhibit resistance to the apoptotic effects of this retinoid [113]. In regard to cytokine production, bexarotene has the capacity to inhibit IL-4 production, and

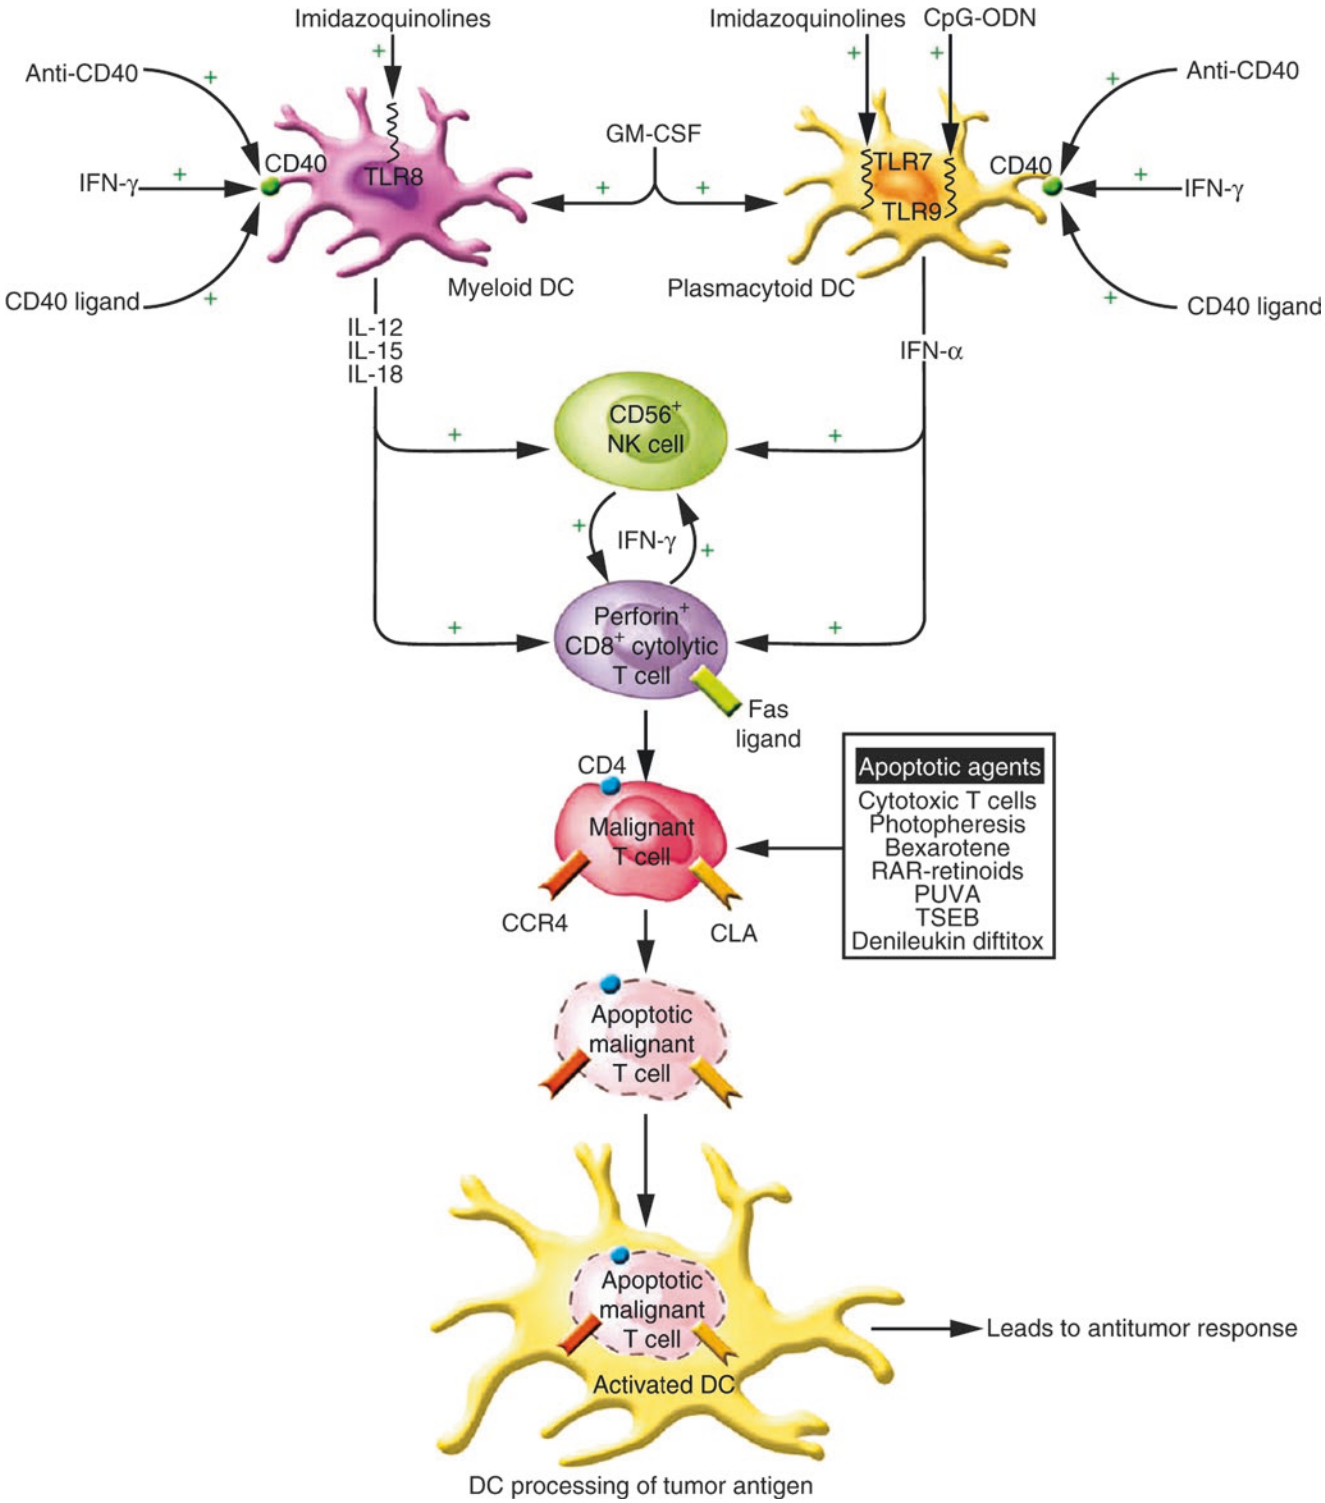

Fig. 41.5 Multimodality strategy for enhancing the antitumor response using immunotherapeutics. A multimodality approach encompasses the activation of multiple arms of the immune response through the use of agents to activate DCs, CTLs (CD8+), and NK cells (CD56+). Granulocyte-macrophage colony-stimulating factor (GM-CSF) may enhance the numbers of DCs while agents that enhance CD40 expression (IFN-γ) and activation (CD40 ligand; activating anti-CD40 antibody) and TLR ligands (CpG-ODNs; imidazoquinolines) lead to DC cytokine production and to enhanced DC processing of apoptotic malignant T cells. Cytokines produced by DCs as well as exogenously administered cytokines augment CD8+ T-cell cytokine production. Proapoptotic agents, including bexarotene, RARspecific retinoids, PUVA, photopheresis, topical chemotherapy, total skin electron beam irradiation (TSEB), and denileukin diftitox can assist in the development of an antitumor immune response by reducing the overall tumor burden and by providing a source of apoptotic malignant cells and tumor antigens for uptake by DCs. (From Kim et al. [5] with permission of the American Society for Clinical Investigation. Copyright 2005)

possibly other Th2 cytokines, in vitro by stimulated peripheral blood cells of SS patients. The net effect would be to negate the suppressive effects of these cytokines on cellular immunity.

In contrast to bexarotene, retinoic acid receptor (RAR)-specific retinoids may have modest direct immune potentiating properties. Using a number of different RAR-specific retinoids, including all-*trans*-retinoic acid and 13-*cis*-retinoic acid, Fox et al., demonstrated that these compounds exhibited the capacity to induce IL-12–dependent IFN-γ production [114]. Moreover, synergistic production of IFN-γ occurred when low concentrations of IL-2 were added to the RAR-specific retinoids. In contrast, bexarotene does not induce IFN-γ production [111]. These findings support the use of an RAR-specific retinoid as another component of the combined therapeutic approach.

Toll-like receptors (TLR) are a family of specialized immune receptors that induce protective immune responses when they detect highly conserved pathogen-expressed molecules. The major populations of human dendritic cells include myeloid dendritic cells (mDCs) which express TLR8 and plasmacytoid dendritic cells (pDCs) which express TLRs 7 and 9. Over the past decade, TLR agonists have been used to stimulate an antitumor immune response by activating and bridging the innate and adaptive immunity [115]. Substantial data has now emerged to suggest that TLR agonists may have a significant role in the therapy of MF/SS.

Wysocka and colleagues have demonstrated TLR 7, 8, and 9 have the capacity to potently activate innate immune cells of patients with advanced, refractory CTCL and that these effects can be synergistically enhanced in vitro by addition of IFNγ or IL-15 [116].

Imiquimod, a member of the imidazoquinoline family, which is FDA approved to treat basal cell carcinoma, actinic keratoses, and condyloma, can induce local immune activation that can be associated with lesion regression when applied as a cream directly to CTCL skin lesions [117, 118]. Imiquimod potently triggers TLR7, expressed on pDCs, which results in IFN-α and TNF-α production [119, 120]. Imiquimod may also directly induce cells of some tumor types to undergo apoptosis [121] and is currently listed as a standard of care skin directed therapy in current National Comprehensive Cancer Network clinical practice guidelines for MF/SS. However, it has a low bioavailability leading to unreliable clinical responses, which are dependent on numbers of resident pDCs within lesions that can be activated by imiquimod. Numerous factors can lead to diminished numbers and function of pDCs in the skin of CTCL patients including the use of potent topical steroids and administration of ultraviolet light, which can induce apoptosis of dendritic cells. In addition, application of topical tacrolimus may inhibit the ability of resident pDCs to further activate surrounding normal T cells which are necessary for the induction of an adaptive immune response against the tumor cells [122].

Advanced MF/SS

Current Therapies

In contrast to patients with early MF, patients with advanced MF/SS exhibit a broad array of abnormalities affecting every arm of the immune response that participates in anti-tumor immunity ($CD8^+$ T cells, NK cells, and DCs). Thus, more aggressive therapy is required at these later stages of MF/SS to adequately restore the host immune response. Accordingly, evidence is now emerging indicating that multimodality immunotherapy can frequently induce complete clinical responses in advanced disease that are both durable and sufficient to eradicate the malignant clone [85, 123, 124].

Central to the strategy for elimination of the malignant T cell population is the use of agents that can induce apoptosis of these cells while simultaneously enhancing the host's ability to process the apoptotic cells so that a robust cytotoxic T cell response can be generated. For patients with circulating malignant T cells, extracorporeal photopheresis (ECP) can result in massive apoptosis of cells within this compartment [125, 126]. ECP is a leukapheresis procedure FDA approved for the treatment of SS in which approximately 10^{10} peripheral blood mononuclear cells are collected from the patient, treated with 8-methoxypsoralen, exposed to 1–2 J of ultraviolet A light in the photopheresis machine, and re-infused back to the patient. In addition to inducing malignant T-cell apoptosis, ECP also induces monocyte differentiation into DCs capable of phagocytosing and processing the apoptotic tumor cell antigens [127]. Repeated cycles of ECP for 2 consecutive days every 3–4 weeks with re-administration of the treated cells is occasionally sufficient to induce a complete clinical response in SS. One potential modification to ECP called transimmunization involves prolonged co-incubation of the apoptotic malignant T-cells and the newly formed DCs prior to reinfusion to optimize the above antigen processing and more efficient induction of tumor targeted immunity [127].

Nevertheless, administration of large numbers of apoptotic cells as generated by ECP can compromise dendritic cell functions, including cytokine production, and therefore has the potential to exacerbate the pre-existing immune depressed state [128]. Such observations support the rationale for the adjunctive use of multiple agents that can enhance both the afferent immune response (events related to processing of apoptotic malignant cells) as well as the efferent response (direct cytolytic attack on the tumor cells).

In support of this approach, our group at Penn has recently demonstrated high response rates of SS patients when ECP was combined with the administration of multiple immune

adjuvants [123, 129]. As part of this regimen, IFN–α and bexarotene were routinely used in combination with ECP. In some cases, GM-CSF was administered following each ECP treatment to enhance APC function. The monthly administration of 125 μg of GM-CSF on 2 consecutive days resulted in significant increases in circulating DC numbers compared to DC numbers in ECP-treated SS patients who did not received GM-CSF [75]. In one patient, administration of GM-CSF three times per week for 6 months resulted in the persistent normalization of DC numbers indicating that APC functions might be markedly augmented in this patient population with the long-term use of GM-CSF.

In addition to IFN-α, additional approaches to enhance the effector phase of anti-tumor immunity are presently being utilized. Although limited results have been reported following the administration of recombinant IFN-γ, recent evidence suggests that it has significant potential for the treatment of MF/SS and it is clearly well tolerated, particularly by the elderly who experience frequent cognitive dysfunction and fatigue with IFN-α treatment [130–132]. In addition to enhancing the cytolytic lymphocyte function of patients with MF/SS, IFN-γ suppresses the excess Th2 production, enhances CD40 expression, and primes their abnormal DCs for IL-12 and IL-15 production, particularly in response to CD40 ligation [75] and Toll like receptor agonistic stimulation [133]. In our Cutaneous Lymphoma Program at the University of Pennsylvania, when possible we are presently routinely using IFN-γ for SS patients who appear to be refractory to IFN-α. In several cases, addition of IFN-γ to a multimodality regimen that included photopheresis and bexarotene appeared to be associated with the induction of a sustained complete clinical response [131, 132].

Alternative routes exist for the administration of IFN-γ. In a small pilot study, Dummer and colleagues demonstrated clinical efficacy of IFN-γ cDNA administered subcutaneously in an adenoviral vector [134]. The local intralesional injection resulted in significant responses rates of individual lesions in both MF and SS patients. Moreover, elevated serum levels of IFN-γ were observed and appeared to be associated with regression of lesions distant from the injection sites. This study further suggests that elevation of IFN–γ levels can beneficially alter disease progression.

Removal of the Immunological Brake: Elimination of Treg Activity

As indicated above, increasing evidence exists for the role of enhanced $CD4^+CD25^+$ Treg function in CTCL as a contributory mechanism for depressed cellular immunity [77, 78]. Although strategies for the elimination of suppressor activity in MF/SS remain untested, several potential approaches are possible. Previously, denileukin diftitox (Ontak), a diptheria toxin–IL-2 protein conjugate, was available for targeting IL-2 receptor–bearing T cells but currently is unavailable [135]. After binding to the IL-2 receptor, it undergoes endocytosis followed by release of the diptheria toxin, which results in arrest of protein synthesis and, ultimately, apoptosis of T cells. Intravenous administration of denileukin diftitox to patients with MF results in the regression of plaques and tumors [136]. Its major mechanism of action is thought to be mediated by direct killing of malignant T cells. However, it is entirely possible that at least a portion of its activity is mediated through the elimination of CD25-bearing Tregs as suggested during recent studies of ovarian cancer treatment [137].

Because Tregs express CTLA-4, another potential approach to their inhibition is through the use of anti–CTLA-4 antibody [138]. This therapeutic approach, although promising for metastatic melanoma [139], remains untested so far for CTCL. Tregs may also suppress immunoreactivity by production of IL-10 or TGF-β. Antibodies with neutralizing activity for these factors could be utilized to reverse their inhibitory effects on the immune response.

Monoclonal Antibodies

Alemtuzumab

Alemtuzumab (Campath) is a humanized monoclonal antibody directed against CD52 expressed on malignant and benign T cells, B cells, monocytes, and dendritic cells. It is currently approved for the treatment of chronic lymphocytic leukemia, and several studies have investigated its efficacy in CTCL. In an open-label trial of alemtuzumab in 19 pretreated patients with advanced erythrodermic CTCL (i.e., erythrodermic MF and SS) with a median follow-up of 24 months, the overall response rate was 84 %, with 47 % complete and 37 % partial remissions [140]. Several studies have recently shown that alemtuzumab can preferentially induce significant clinical responses in SS but not MF patients [141, 142]. Based on these observations, Clark and colleagues have proposed that human cutaneous T_{CM} recirculate into the blood, whereas T_{EM} are a non-recirculating skin resident population, postulating that the skin resident T_{EM} cells escape alemtuzumab-induced cell-dependent cytotoxicity due to absence of potential cytotoxic effectors such as monocytes, neutrophils, and natural killer cells in the skin [141]. Interestingly, the authors also report a marked lack of cutaneous infections in low dose (10 mg subcutaneously three times weekly for at least 6 weeks) alemtuzumab-treated SS patients despite profound lymphopenia, suggesting that skin resident T_{EM} cells can protect the skin from pathogens even in the absence of T cell recruitment from the circulation.

In contrast, in a retrospective analysis of long-term efficacy and safety of higher dose alemtuzumab (30 mg two to three times weekly in the induction phase followed by 30 mg weekly during the maintenance phase) in 39 patients, De Masson and colleagues again report profound lymphopenia in the majority of patients during a median follow-up of 24 months, associated with a 62 % rate of infections including

cytomegalovirus viremia, tuberculosis, *Mycobacterium chelonae* cutaneous infection, bacterial infection, toxoplasmosis, aspergillosis, and unspecified pulmonary infection [142]. Additional adverse effects included grade 3 or higher cytopenias, acute coronary syndrome, ischemic colitis, deep-vein thrombosis, serum-sickness-like reaction, and infusion reactions. These adverse events led to treatment discontinuation in 44 % of cases and death in 5 % of cases. There was no significant difference in terms of effectiveness and safety between patients treated with subcutaneous and intravenous alemtuzumab. Additionally, Faguer et al. reported LCT in the skin of a patient with CTCL treated with alemtuzumab, suggesting a lack of immune surveillance associated with alemtuzumab-related lymphopenia [143]. Furthermore, in some cases, CD52 may become down-regulated on the malignant cells after alemtuzumab therapy [144], therefore a flow cytometric evaluation of CD52 expression may be considered before starting alemtuzumab treatment, and particularly before re-treatment with alemtuzumab after good initial response followed by relapse.

Brentuximab Vedotin

CD30 is a pro-survival receptor, which belongs to the tumor necrosis factor receptor superfamily [145]. Initially identified on Reed–Sternberg cells in Hodgkin's Lymphoma (HL), and later systemic ALCL, it is now known that CD30 is also expressed in other B cell and T cell NHLs, including CTCLs, such as primary cutaneous ALCL (pcALCL), LyP, and LCT MF.

Brentuximab vedotin (BV) is an antibody-drug conjugate of anti-CD30 monoclonal antibody and the proapoptotic antitubulin agent monomethyl auristatin. It has been approved as a second-line treatment for HL and ALCL, with investigation of its use in other malignancies, including CTCL currently ongoing. Results from a Phase II open-label trial of BV in CD30+ CTCLs (LyP, pcALCL, and CD30+ MF) showed a 100 % in LyP/pcALCL, and 44 % in CD30+ MF which varied based on degree of CD30 expression [146]. A Phase III trial in CD30+ CTCL is currently recruiting patients.

Several cases of progressive multifocal leukoencephalopathy (PML), a frequently fatal JC virus-induced central nervous system infection, have been reported in association with BV therapy [147]. Prior immunosuppressive therapy and compromised immune system function were the initial postulated risk factors; however, later reports described two CTCL patients treated with BV who had developed PML who had not previously received chemotherapy [148]. Therefore, the decision to administer BV in patients with CTCL should be based on consideration of risk-benefit profiles and alternative therapeutic options.

Histone Deacetylase Inhibitors

Histone deacetylase inhibitors (HDACi) represent a novel class of anticancer drugs, with two members of the group, vorinostat and romidepsin, approved for the therapy of CTCL. HDACi modulate chromatin structure has been shown to promote growth arrest, differentiation, and apoptosis of tumor cells [149]. While HDACi have been shown to have a significant response rate and a high rate of pruritus relief with vorinostat in particular in heavily pretreated, refractory CTCL patients [150], there is also emerging evidence for the potent immunosuppressive properties of HDACi. Studies have shown that HDACi can have therapeutic benefit in autoimmune disease models [151–153] perhaps owing to the enhancement of regulatory T-cell functions [154]. Moreover, we have previously reported a patient with CTCL with refractory bullous pemphigoid, who experienced rapid resolution of her autoimmune disorder following initiation of therapy with vorinostat [155]. Furthermore, *in vitro* studies have shown anti-inflammatory properties of HDACi via suppression of cytokines such as TNF-α and IL-1β [156]. Our group has reported significant blunting of functional NK activity in a SS patient treated with vorinostat, as well as potently suppression of multiple arms of the immune system by vorinostat in vitro [157]. Kelly-Sell and colleagues serially examined the cellular immune function of eight CTCL patients undergoing treatment with romidepsin, showing similarly decreased NK cell cytolytic activity and DC activation, as well as increased specificity for romidepsin induced CD4+ tumor cell apoptosis and dose dependent increases in cellular apoptosis of healthy cells in multiple lineages [158].

These findings have raised concern that HDACi may suppress immune function in CTCL patients, may lead to greater susceptibility to opportunistic infections [159], and support the concurrent use of multiple immune stimulatory agents to preserve the host immune response. In particular, addition of interferon gamma to HDACi has been reported to be a safe, well tolerated, and successful combination in several case reports [160, 161]. The proposed mechanism of action supporting use of this combination therapy involves stabilization of Th1 cytokine profiles by interferon gamma by enhancing cytotoxic T-cell activity and promoting a more robust antitumor response to counteract the immunosuppressive effects of HDACi. As attempts at preservation of cellular immunity are critical in the management of CTCL, the recent data highlight the complexity of the effects of HDACi and the need to balance their anti-tumor effects and immunosuppressive capabilities.

Experimental Therapy

Resiquimod, which activates both TLR7 expressed on pDCs, and TLR8 expressed on mDCs, is a promising member of the imidazoquinoline family which is currently in a clinical trial for therapy of CTCL. Its activity results in production of a more extensive array of immune activating cytokines, including IL-12, 15, 18, and IFN-α. Because Tregs also express TLR8, activation of this receptor can lead to inhibition of these suppressive cells, resulting in further immune augmen-

tation. Additionally, as the bioavailability of resiquimod as a topical gel is tenfold greater than that of imiquimod cream, and its potency may be up to 100 times higher, it may have great enough efficacy to induce systemic immune activation after cutaneous application, to potentially be used as a single agent in treatment of patch to plaque stage lesions of CTCL. Use in combination with IFNγ with which it can synergize to broadly activate Th1 type cellular immunity might be particularly efficacious.

Additionally, recent clinical trials have continued to test the effects of an alternative class of DC activating agents, synthetic oligodeoxynucleotides that contain CpG motifs (CpG-ODNs). CpG-ODNs have been recognized as immune stimulatory agents through their activation of DCs following binding to TLR9 expressed on plasmacytoid DCs [162]. The immunostimulatory potential of CpG-ODNs has been tested in murine tumor models and has been observed to lead to the generation of strong antitumor T cell responses resulting in complete remission of certain established solid tumors [163]. Thus, there is substantial rationale to study the activity of CpG-ODNs in human tumor systems. In this regard, in vitro data indicate that CpG-ODNs can potently activate CTCL patients' DCs, leading to IFN-α production, increased expression of critical immune accessory molecules, and enhanced cell-mediated cytotoxicity [86]. Moreover, Kim and colleagues have shown in a phase I clinical trial for refractory advanced CTCL that CpG-ODNs administered subcutaneously as a single agent led to significant clinical responses in 32% of patients, with three patients having complete responses. The majority of responses were maintained long after study conclusion [164]. A subsequent trial by the same authors showed promising results of intratumoral vaccination of intralesional, subtherapeutic dosing of CpG-ODNs combined with local radiation therapy in 15 patients with relapsed or refractory MF [165]. Following the administration of a previously demonstrated subtherapeutic dose of CpG, nonirradiated skin lesions regressed in one-third of patients, suggesting that CpGs prime the local APCs to be more efficient. It was also noted that skin lesions of responding patients demonstrated decreased numbers of CD25+ Foxp3+ T-regs cells. Therefore, application of CpG-ODNs in a multimodality therapeutic approach that uses photopheresis might also yield significant therapeutic benefit. It is noteworthy that anti-viral vaccination strategies that incorporate the use of CpG-ODNs along with viral antigen appear to be markedly superior to those that use antigen alone [166]. Since ECP represents an immunization procedure utilizing apoptotic tumor cells, such findings support the use of CpG-ODNs at the time of re-infusion of the treated tumor cells in an effort to directly target the tumor antigens to DCs for processing.

Other mechanisms for activating the DCs of patients with MF/SS that are under pre-clinical investigation include strategies for the engagement of CD40. As stressed above, there is substantial evidence that a defect in CD40 ligand expression by malignant T cells plays some role in the depressed production of DC-dependent cytokines [82]. Furthermore, co-culture of peripheral blood cells of SS patients with hexameric recombinant CD40 ligand resulted in substantial production of IL-12. Clinical trials using this approach have yet to be undertaken. Another strategy that appears promising for the treatment of solid tumors but which awaits clinical testing for CTCL, involves the use of an activating anti-CD40 antibody. Animal models using this approach indicate that enhanced generation of tumor-specific T cells can occur [167, 168].

IL-12 is a cytokine known to induce IFN-γ release and to enhance cytolytic T cell and NK cell activities, and thus has the potential to enhance the anti-tumor immune response of MF/SS patients. In a small phase I study followed by a limited phase II study, the subcutaneous administration of recombinant IL-12 to a total of 32 patients with MF resulted in approximately a 50% response rate [169, 170]. Since malignant T cells lack the IL-12 β2 receptor [171] and are thus incapable of signaling in response to IL-12, it is presumed that the clinical response was not due to the direct effects of the cytokine on the malignant cells. Indeed, serial biopsies of cutaneous plaques during treatment revealed dense infiltrates of $CD8^+$ T cells that appeared near the time of initial signs of lesional regression [169]. Thus, it is believed that $CD8^+$ T cells with augmented cytolytic activity are the predominant "work-horses" activated in response to IL-12. Whether IL-12 administration has advantages over IFN-γ use is presently unknown, but it is hoped that in the future, IL-12 will also find its place in a multimodality therapeutic approach. Currently it is being studied in a phase 2 clinical trial for refractory CTCL using IL-12 DNA delivered by electroporation (Oncosec).

Future Strategies for Enhancing the Host Immune Response

Tumor Vaccines

Most vaccination strategies for MF/SS utilize the clonotypic TCR as a source of tumor-specific antigen. Immunogenic epitopes are found within both the variable (V-region) and the constant (C-region) regions of the clonotypic TCR-α and TCR-β receptor [172, 173]. In some experiments, immunogenic peptides have been directly isolated from the MHC class I molecules on the surface of the malignant clone. This confirms that the antigen-processing pathway for endogenous proteins remains intact in the malignant clone, and that the clonotypic TCR is subjected to antigen processing and presentation by MHC class I. Consequently, the TCR peptide-MHC complex on the surface of a malignant cell can serve as a target for recognition by CD8+ CTL's. This has been demonstrated in both normal donors and patients with MF/SS, where immunogenic peptides derived from the clo-

notypic TCR induced tumor-specific CD8+ T-cells which were capable of secreting TNF-α [172], as well as lysing autologous tumor cells *in vitro* [173].

Dendritic-cell based vaccines have also been developed for CTCL [174]. Sources of antigen used to pulse DC's prior to vaccination may include tumor-cell lysates, peptides, "mimotopes," tumor-derived DNA or RNA, apoptotic tumor cells and even tumor cell-DC fusions. Maier et al. reported on ten CTCL patients treated with weekly intra-nodal injections of autologous DC's pulsed with tumor lysate [175]. In this study, 50 % of patients had a clinical response to the vaccine, accompanied by an infiltration of CD8+ and TIA+ cytotoxic cells at the site of regressing lesions as well as molecular remission in some cases. Of note, clinical responses in this study were associated with a low tumor burden, which underscores the importance of instituting immunotherapy early in the course of the disease and prior to the development of significant immune dysregulation [175].

The addition of an immune adjuvant(s) may be used in an attempt to enhance the efficacy of the vaccine. Cytokines such as IL-12 [169, 176], IL-15 [86, 177], IL-18 [178], and IL-21 [179], can augment the development, the effectiveness, and/or the maintenance of anti-tumor CTL responses. Moreover, these same cytokines have also been shown to enhance NK-cell activity which may play an important role in controlling tumor growth *in vivo*. GM-CSF is another cytokine which has been used as a cancer vaccine adjuvant to enhance both the number and function of dendritic cells [180, 181]. As discussed earlier, other immune activating agents including TLR agonists (i.e. imidazoquinolines, CPG-ODN's), anti-CD40, and anti-CTLA-4 could be used in conjunction with a tumor vaccine for patients with CTCL.

Programmed Cell Death 1

Programmed cell death 1 (PD-1) is an inhibitory receptor expressed by activated T cells. Engagement of PD-1, a member of the B7-CD28 family, by its ligands (PD-L1 and PD-L2) transduces a signal that leads to inhibition of T-cell function, including proliferation and cytokine production, therefore leading to attenuation of the immune response [182]. PD1 is expressed in activated T cells, B cells and antigen-presenting cells, and the expression of its ligands has been described in aggressive solid tumors [183].

Recent evidence suggests that CTCL may have differential PD-1 expression in MF and SS. Kantekure and colleagues have shown that PD-1 was frequently expressed at the early, patch and plaque stages of MF, but that expression seemed to decrease with disease progression [184]. Several other studies have shown that PD-1 expression is upregulated on malignant T-cells in the skin and CD4 T-cells of SS patients to a greater extent than in MF patients [185, 186].

Blockade of PD-1 can increase immune activating cytokine production and may enhance functioning of cytotoxic T cells, which would lead to enhanced disease eradication. Samimi et al. have shown that blockade of the PD-1/PD-L1 pathway yielded a relative increase in IFN-γ production by PBMCs of patients with CTCL, suggesting improved antitumor immunity. Furthermore, a strong decrease in PD-1 expression with improvement of disease was observed.

In studies of metastatic melanoma, it has been shown that PD-1 blockade can mediate tumor regression in a substantial proportion of patients, and more recently a favorable survival, durable tumor remission, and long-term safety has been demonstrated in patients with advanced melanoma receiving a PD-1 antagonist nivolumab [187]. Clinical trials of PD-1 antagonists in CTCL are needed to evaluate efficacy of this promising targeted therapy in this patient population.

Chemokines

Chemokine receptors and their ligands may serve as potential targets for anti-tumor therapy in MF/SS. Antibody-based therapeutics targeting chemokine receptors and compounds with the potential to down-regulate chemokine receptor expression hold great promise as potential therapies. A novel humanized-CCR4 monoclonal antibody has recently been developed that has been approved for use in Japan for adult T-cell leukemia, lymphoma and is currently being investigated as a potential therapeutic for the treatment of patients with CCR4+ T-cell leukemia/lymphoma [188]. The CCR4+ cells in these conditions have been shown to exhibit features of regulatory T-cells with the ability to suppress anti-tumor immune responses. In addition to lysing $CCR4^{+}$ T cells in vitro, this antibody reduced the expression of Foxp3 mRNA suggesting a possible role in depleting Tregs [189]. It is currently being studied in a large Phase 3 randomized two-armed cross over trial in refractory MF/SS.

As mentioned earlier, IFN-γ can be combined with other biologic response modifiers to achieve high clinical response rates among SS patients [123]. In addition to its ability to enhance cell-mediated cytolytic activity and suppress Th2 cytokine production, IFN-γ may also significantly increase production of the Th1 associated chemokine, monokine induced by gamma-interferon (Mig), a CXC chemokine recognized by CXCR3 [190]. Aside from its expression by MF cells in early stage disease (as discussed earlier), it is also expressed by cytotoxic T-cells, and thus contributes towards the accumulation of tumoricidal cytolytic T-cells in lesional skin.

In recent work, we have observed the ability of the retinoid bexarotene to preferentially decrease CCR4 levels among malignant cells in-vitro [191]. This reduction was associated with a decrease in malignant cell chemotaxis in response to TARC. Our findings, may in part, explain the marked clearing of cutaneous erythroderma we have noted among patients treated with this therapeutic agent [192], and suggest a potential role for such compounds in the management of inflammatory and neoplastic diseases of the skin in the near future.

Interleukin-31

CTCL patients often suffer from intense pruritus, which can cause significant morbidity and decreased quality of life [193]. IL-31, is a Th-2 cytokine, found in pruritic conditions such as atopic dermatitis [194] and mastocytosis [195], and has been shown to be associated with the level of pruritus and severity of disease. Increased IL-31 protein was recently identified in the serum of patients with CTCL [196]. Subsequently, Singer et al. demonstrated that IL-31 is specifically produced by $CD4^{+}CD26^{-}$malignant cells in CTCL patients [197]. Additionally, the authors showed that in this patient population, IL-31 mRNA levels significantly correlate with pruritus severity, and that clinical resolution of pruritus correlates with decreased IL-31 levels in the circulation [197]. Given this strong association, IL-31 may be considered as a potential therapeutic target for anti-itch treatment in CTCL. Current established systemic medications used for pruritus include antihistamines, gabapentin, mirtazapine and other SSRIs, naltrexone.

Hematopoietic Stem Cell Transplant Therapy

Despite numerous therapeutic strategies reviewed above, no regimen has been shown to increase survival of patients with CTCL [198], therefore younger patients with advanced disease, with multiple tumors, erythroderma, or involvement of the reticuloendothelial system who are refractory to the above therapies are increasingly being considered for allogeneic hematopoietic stem cell transplantation (HSCT).

Originally, HSCT was conceived as a replacement for a patient's own diseased hematopoietic system, which theoretically had been destroyed by a pre-transplant regimen of chemoradiation. This concept of eliminating the abnormal cells and supporting hematopoiesis with transplanted stem cells continues to be the basis for autologous stem cell transplants, in which patients' own reserved stem cells are returned after chemoradiation. In fact, some authors support "high-dose chemotherapy with hematopoietic progenitor cell support" as a more appropriate term for autologous stem cell transplant [199].

However, allogeneic HSCT has evolved conceptually into an immunologic therapy with the observation that donor transplanted T-cells can elicit a graft-versus-tumor effect against the host's tumor cells [200]. The immunologic basis of the disorder graft versus host disease (GVHD), which causes a significant amount of transplant-related morbidity and mortality, also supports the concept that the engrafted immune system, even when HLA-matched, is active against host tissue [199]. Based on this model, investigators have employed strategies of pre- and post-transplant immunosuppression that are less toxic to the hosts' other organ systems and have had success with nonmyeloablative conditioning regimens for allogeneic stem cell transplants [201]. A truly nonmyeloablative conditioning regimen results in mixed chimerism of both donor and host hematopoiesis post-transplant, and allows for transplantation in elderly patients and those with co-morbidities who would otherwise not be candidates for myeloablative transplant.

Stem cell transplants have achieved long-term complete responses in many types of hematologic malignancies, and several case studies and retrospective analyses of autologous and allogeneic, as well as myeloablative and nonmyeloablative, stem cell transplants for advanced CTCL have been published. In the two largest series of advanced MF and SS patients undergoing autologous stem cell transplant, almost all patients did achieve a complete response. However, out of 13 reported patients with a complete response, 12 relapsed, with the longest time to relapse being 14 months, and the median time to relapse in the larger study being 7 months [202, 203]. Several other case reports of autologous stem cell transplant for advanced CTCL have been published, and although overall, patients do achieve a safe and complete response, more than half of reported cases have relapsed within 6 months [199].

In contrast to autologous stem cell transplant, retrospective analyses of allogeneic bone marrow transplant in advanced CTCL suggest that if the patient and the graft are able to survive the transplant period, complete responses can be achieved and sustained [204–209]. A patient-level meta-analysis performed by Wu et al. to compare the outcome of allogeneic versus autologous SCT in patients with MF/SS using 39 cases from the literature showed favorable overall and event free survival, and a more durable response in patients who received allogeneic SCT [210]. In this group, the majority of patients experienced persistent GVHD, mostly with mild to moderate severity. Meanwhile, the majority of the deaths in the autologous group were due to progressive disease.

A retrospective analysis by Duarte and colleagues of allogeneic SCT in advanced CTCL patients showed decreased relapse rates (38 % after 1 year, 47 % after 3 years post-transplantation) and increased overall survival (66 % after 1 year, 53 % after 3 years post-transplantation) when compared to published data of conventional treatments [211]. Duvic and colleagues have reported that 11 of 18 advanced CTCL patients who underwent total skin electron beam therapy followed by non-myeloablative allogeneic stem cell transplant were in complete remission after median follow up of 19 months, with morbidity and mortality attributable to sepsis and infections, as well as acute and chronic GVHD [212].

These responses are evidence for a graft versus tumor effect, which in most cases is accompanied by some degree of GVHD. In all allogeneic stem cell transplant patients, a balance between disease relapse and GVHD must be achieved using some degree of post-transplant immunosuppression. Disease relapse can thus often be controlled by reducing the level of immunosuppression, or by administration of donor lymphocyte infusions. In some cases, patients have been able to discontinue immunosuppression entirely, without evidence of recurrent CTCL or GVHD [208].

Nonetheless, treatment-related mortality (i.e., life-threatening infections and GVHD) occurs in approximately 30 % of cases [213]. Thus, more extensive studies are needed to optimize conditioning regimens, donor types, disease status and timing of allogeneic SCT for advanced CTCL, which would be considered the ultimate immunotherapy.

Questions

Question 1: Advanced mycosis fungoides/Sezary Syndrome results in increased serum levels of:
A. Th1 cytokines
B. Th2 cytokines
C. Th17 cytokines
D. IgE
E. B and D

Question 2: Advanced MF/SS patients are at increased risk for which infections?
A. Atypical Mmcobacterial
B. Gram negative bacterial
C. HSV and VZV reactivation
D. Syphillis
E. Tuberculosis

Question 3: An initial treatment approach for newly diagnosed Sezary Syndrome includes all EXCEPT
A. Extracorporeal photopheresis
B. Interferons
C. TNF alpha inhibitors
D. Retinoids
E. Skin directed therapies

Answer key
Question 1: E
Question 2: C
Question 3: C

Immune Environment of Cutaneous Malignancies

42

Channa G. Ovits and John A. Carucci

Abstract

The ability of cutaneous malignancies to develop and progress involves a complex interplay with the local immune environment. Multiple immunomodulatory mechanisms underlie the ability of squamous cell carcinoma, basal cell carcinoma and melanoma to evade immune detection. These mechanisms include a modulation of the gene profiles of these cancers, which populations of immune cells are present and which cytokines are produced in the immune microenvironment. With squamous cell carcinoma, the gene expression and cytokine profile show an immunosuppressed microenvironment, along with functionally compromised dendritic cells and tumor-associated macrophages being present in the tumor microenvironment. Basal cell carcinoma also achieves immune evasion with an immunosuppressed microenvironment, as seen by the Th2 dominant cytokine profile and the presence of regulatory T cells. Immunosuppressed transplant patients have increased incidence of and more aggressive non-melanoma skin cancers due to the altered immune microenvironment, with modified T cell populations and ratios and pro-tumoral cytokines. Melanoma, despite its immunogenicity, displays a number of immune suppressive mechanisms, such as impaired antigen-presenting cell maturation, T cell anergy, the induction and recruitment of regulatory T cells and myeloid-derived suppressor cells. The understanding of the immune microenvironment of cutaneous malignancies is crucial, as it affords many potential targets for therapeutic options.

Keywords

Basal cell carcinoma • Squamous cell carcinoma • Melanoma • Macrophages • Regulatory T cells • Dendritic cells • Langerhans cells • Imiquimod • Th1 immune response • Th2 immune response

Cutaneous malignancies are the most common human cancers, with basal cell carcinoma (BCC), squamous cell carcinoma (SCC) and melanoma comprising the majority of skin cancers. The public health burden of these cancers is significant, with basal cell carcinoma being the most common human cancer, squamous cell carcinoma being the second most common and melanoma being the fifth and sixth most common cancer in men and women respectively [1, 2]. Each year in the US, about 5 million people are treated for skin cancer and the cost of this treatment is approximately 8.1 billion dollars. 2.8 million cases of BCC alone are diagnosed each year in the US [3]. Understanding these cancers and their context within the immune environment can lead to better treatment options and novel therapeutic approaches being developed for the patients diagnosed each year.

The development and progression of these malignancies involves complex interactions with the local immune

microenvironment. The tumor microenvironment includes tumor and non-tumor cells at the dynamic interface of neoplasia [4]. The immune cells include Langerhans cells, dermal dendritic cells, CD4 and CD8 T-cells, T-regulatory cells, macrophages, natural killer cells and mast cells. T cells, both CD4 and CD8, and dendritic cells are often shown to be infiltrating various tumors, and tumor-associated macrophages are often found surrounding and infiltrating the tumor as well. These cells, when functioning properly, work both in concert and independently towards immunosurveillance, the prevention of malignant progression and regression of primary malignancies. Immunosuppression, such as in transplant recipients, increases the risk of skin cancer, in particular the non-melanoma skin cancers. Additionally, melanoma behaves more aggressively in immunosuppressed patients. The malignancy's ability to evade immunosurveillance, progress and metastasize is the result of multiple immunosuppressive mechanisms.

Our understanding of cutaneous cancers' interaction with the immune environment has grown over recent years and continues to be explored. The attempts to translate these basic science developments into clinical applications have had varying levels of success, with immunotherapeutic agents, such as cytokines, anti-cytokine antibodies and vaccines, proposed, tested and sometimes approved for use. These treatments options for melanoma are outlined and discussed in Chapter 51.

Nonmelanoma Skin Cancer (NMSC)

Squamous Cell Carcinoma

Cutaneous SCC is the second most common human cancer, affecting greater than 300,000 individuals in the US annually [1, 5]. While most cases are treated successfully with local removal, aggressive cases can metastasize to local lymph nodes and distant organs. These aggressive cases are responsible for the approximately 10,000 non-melanoma skin cancer deaths in the US each year [1].

SCC is a malignant proliferation of the keratinocyte that tends to occur on sun-damaged skin. It often progresses from noninvasive precursor lesions, such as actinic keratosis (AK). It presents in a variety of forms, from a crusted patch or nodule, to an ulcer, to a hyperkeratotic indurated papule.

SCC Gene Expression and Immune Cell Profile

The immune microenvironment of SCC is unique, both in the cells that are local to the tumor and their ability to be stimulated, as well as the presence of various cytokines (Fig. 42.1). The gene expression profile of SCC shows a relatively immunosuppressed microenvironment [6]. In studies of immune response gene expression in SCC as compared to normal skin and psoriasis, a number of stimulatory genes are downregulated. These genes include the gene for cytotoxic T cell product granzyme B, the activated T-cell marker CD69 and the proinflammatory mediator inducible nitric oxide synthase (iNOS), an enzyme that is key in tumor immunity [6]. Additionally, invasive SCC showed a change in cytokine gene expression, with an increase in IL-24 expression as compared to AK or SCC in situ. SCC was also found to have increased expression of protumoral factor matrix metalloprotease 7 (MMP-7), which was shown to be induced by IL-24 in culture. IL-24 is thought to contribute to SCC invasion through the upregulation of MMP7 [7].

The evidence of immunosuppression in SCC continues with the lack of particular immune cells in the local environment; NK cells, B cells and monocytes are rarely detected around SCC [8]. Each of these cells has been shown to play a role in tumor cell eradication. NK cells are lymphocytes that were first identified for their ability to kill tumor cells without deliberate immunization or activation [9]. Monocytes exhibit considerable selective cytocidal activity against tumor cells through the generation of reactive oxygen species (ROS) [10]. Though some studies have shown resting B cells to inhibit T-cell mediated regression of tumor cells, other studies have shown the key role that activated B cells play in T cell activation and creation of long term responses against cancer [11]. The collective scarcity of these cells in SCC may play a role in SCC's ability to establish itself, as well as grow and metastasize.

The presence of the myeloid-derived suppressor cells (MDSCs) provides further evidence and mechanisms for SCC- related immunosuppression. MDSCs are potent suppressors of T-cell mediated responses, partially due to the downregulation of E-selectin on vascular endothelial cells. The lack of E-selectin on endothelial cells restricts T-cell entry into tumors and is caused by the presence of nitric oxide (NO) in the microenvironment. SCC-infiltrating MDSCs have been shown to produce NO, thus contributing to the immune evasion of the tumor. A possible therapy of suppressing NO production through inhibiting inducible NO synthase (iNOS) has been shown to induce E-selectin expression in vitro and may be effective as a future therapy for SCC [12].

Tumor-Associated Macrophages in SCC

Macrophages are a major population of leukocytes that are found surrounding and infiltrating solid tumors [13]. In SCC, macrophages have been shown to be far more abundant than in normal skin [14]. These peritumoral and penetrating

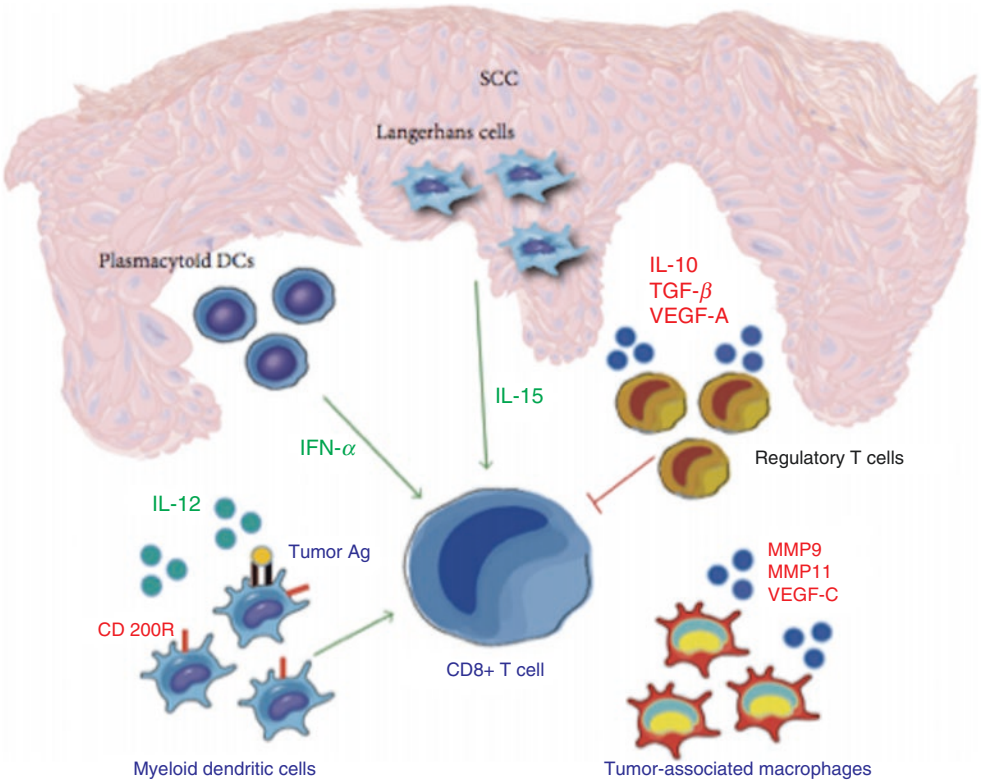

Fig. 42.1 The SCC immune microenvironment. The SCC microenvironment involves a complex interplay of immunoinhibitory and immunostimulatory cells and cytokines. While Langerhans cells and plasmacytoid DCs are producing proinflammatory cytokines IL-15 and IFN-α respectively to enhance the immune response, the presence of tumor associated macrophages and regulatory T cells contribute to immune dysfunction and tumor invasion through the production of matrix metalloproteases (MMP9 and 11), pro-angiogenic factors (VEGF-C) and immunoinhibitory cytokines (IL-10, TGF-β, VEGF-A). These protumoral cytokines can also functionally compromise the other immune cells of the microenvironment, leading to immature myeloid dendritic cells, which express CD200, and Langerhans cells which express a mixed gene profile of immune activation and immune tolerance genes

macrophages, as mentioned earlier, are defined as tumor-associated macrophages (TAMS) [15]. TAMS play a significant role in tumor behavior, with potential to inhibit or stimulate tumor growth. Some studies have shown TAMs are capable of eradicating tumor cells in vitro, yet others have correlated a poor prognosis with increased numbers of TAMS [16–18]. In their role in aiding and abetting the tumor, TAMS can fail to identify tumor antigens and can release angiogenic and tumor stimulating factors [19, 20]. It is suspected that the tumors themselves may be creating a dynamic microenvironment that transforms the TAMS into macrophages that allow for tumor growth [21].

Despite the potential ability of TAMS to inhibit tumor progression, an increased number of TAMS is correlated with a negative prognosis. This can be explained by a number of factors. In studies, TAMS have been shown to make matrix metalloproteinases (MMP)9 (gelatinase B) and 11 (stromelysin-3), zinc-dependent proteinases that participate in extra-cellular matrix degradation, which allow direct tumor invasion, as well as release pro-angiogenic factors otherwise sequestered within the extra-cellular matrix [14, 22]. This is in contrast to macrophages in normal skin, which produce these factors at lower levels than TAMS in the SCC microenvironment.

The macrophages of the SCC microenvironment have also been shown to be predominantly M2 macrophages, or alternatively activated macrophages. These macrophages are induced by IL-4, in contrast to M1 macrophages, or classically activated macrophages, which are induced by IFN-γ. A strong M1 macrophage response is thought to prevent tumor growth. In contrast, M2 macrophages have a lower antigen presenting capacity and have been positively correlated with tumor genesis and progression through inflammation. Recent studies have shown SCC- associated macrophages to be heterogeneously activated, with some expressing M1 markers, some expressing M2 markers and some expressing both M1 and M2 markers simultaneously [14]. This heterogeneous activation of TAMS in SCC gives rise to a potential therapy in driving TAM activation to the M1 anti-cancer phenotype.

TAMS have been shown to play a role in lymphangiogenesis, with the expression of vascular endothelial growth factor-C (VEGF-C) [23]. VEGF-C, a critical lymphangiogensis mediator, promotes increased lymph vessel density and has

been correlated with increased risk of metastasis in squamous cell carcinomas of the oral cavity and melanoma [24, 25]. The increased lymph vessel density spurred by VEGF-C is an important factor in cancer's development and spread.

With production of high levels of MMPs, expression of lymphangiogenic mediator VEGF-C and M2 characteristics, TAMS in SCC are failing to prevent tumor creation and progression and are rather promoting its survival and advancement. The overall behavior and subtype of TAMS in SCC show the immunosuppressive potential of immune cells when influenced by the tumor environment.

Dendritic Cells and SCC

Dendritic cells (DCs), the most potent antigen-presenting cell, exist in a variety of subtypes, and regulate the adaptive immune system [26, 27]. They are key players in cancer immune surveillance, with their ability to stimulate tumor-specific T-cell responses, along with having been shown to infiltrate various human tumors [28–31]. DCs are abundant in the skin immune system, existing mainly as epidermal Langerhans cells (LCs) and dermal myeloid DCs. LCs, with their epidermal localization, should be the first antigen presenting cell to encounter SCC tumor antigen, as SCC is a malignant proliferation of epidermal keratinocytes.

However, studies have shown that DCs from human cancers are often functionally compromised, with a decreased ability to induce IFN-γ and stimulate T-cells [32, 33]. Further studies have shown that the tumor microenvironment contains immunosuppressive cytokines which impair DC differentiation and function [26, 34].

With regards to DCs, SCC have been shown to have a relatively immunosuppressed microenvironment, with a lack of mature dendritic cells in comparison to normal skin (Fig. 42.2) [35, 36]. This is seen by the down-regulation of mature dendritic cell marker gene CD83 and decreased numbers of CD83 cells in SCC [6].

Additionally, SCC-associated mature myeloid dendritic cells (mDCs) have been shown to be functionally compromised and deficient in their ability to produce IFN-γ and stimulate T-cells, an important indication of the immunosuppressed microenvironment [37]. Even when cultured with mDC-maturing cytokines like IL1b, IL-6,TNF-α, and PGE2, SCC-associated mDCs remained impaired in their T–cell proliferation stimulation. This is despite their phenotypic maturity that is comparable to the mDCs of normal skin. This is thought to be due to the fact that the SCC cytokine milieu has been shown to be composed of immunosuppressive cytokines that suppress myeloid DCs, such as VEGF-A, TGF-β, IL-10, and IL-6 [37].

Langerhans cells (LCs) from SCC seem to be more capable of immune response than their dermal counterparts. LCs from SCC, in contrast to mDCs, have been shown to elicit a type 1 immune response when activated. Moreover, LCs from SCC have been shown to be more powerful stimulators of CD4 and CD8 T cell proliferation than those from normal skin and elicit a more powerful type 1 T-cell response. They also express higher levels of surface markers CD40, CD80, CD83, and CD86 than LCs from normal skin, making them more mature and is an important factor in immune response induction [38].

However, SCC-derived LCs still may have some limitations based on their gene profile. They show a mixed gene profile of upregulated immune activation genes, such as STAT4, IL15, and CD80 as well as upregulated immune tolerance genes, such as CD200 and receptor activator of NF-KB [38]. This mixed activation and tolerance profile is indicative of the tumor environment's effect on the LCs and more is still to be learned about how this impacts their behavior.

Basal Cell Carcinoma

Basal cell carcinoma (BCC) is the most common human malignancy, with a higher prevalence than all other malignant tumors combined. BCC is a malignant proliferation of keratinocytes from the basal layer of the epidermis. Sun exposure is the most important risk factor for BCC, but other risk factors include age and fair skin. BCC is slow-growing and highly curable, but can be extremely disfiguring if allowed to progress without intervention. BCC has a number of clinical presentations, spanning cystic, ulcerated, nodular, superficial, sclerosing, pigmented, and keratotic variants.

Cytokine and Chemokines in BCC

In BCC, a number of cytokines and chemokines are associated with its avoidance of immunosurveillance and subsequent development. Of the proinflammatory cytokines, IL-6, IL-8, IL-17, IL-22, and CXCL12 have been linked to BCC tumor progression. IL-6 has been shown to increase anti-apoptotic activity within BCC cell lines [39] and promote angiogenesis through the PI3k/Akt pathway, as well as through increasing the expression of the pro-angiogenic cytokine IL-8 [40, 41]. CXCL12 has also been shown to promote angiogenesis by binding to the CXCR4 receptor, which is expressed to a higher degree in more aggressive forms of BCC [42]. CXCL12 also upregulates the activity of matrix metalloprotease 13 (MMP-13), allowing for BCC invasion [43].

IL-17 and 22 have also been shown to increase proliferation and migration of BCC in vitro and tumor progression in vivo, through both their intrinsic signaling pathways and the induction of IL-6 and 8 production [44]. IL-10, an immunosuppressive cytokine, is upregulated in BCC and may

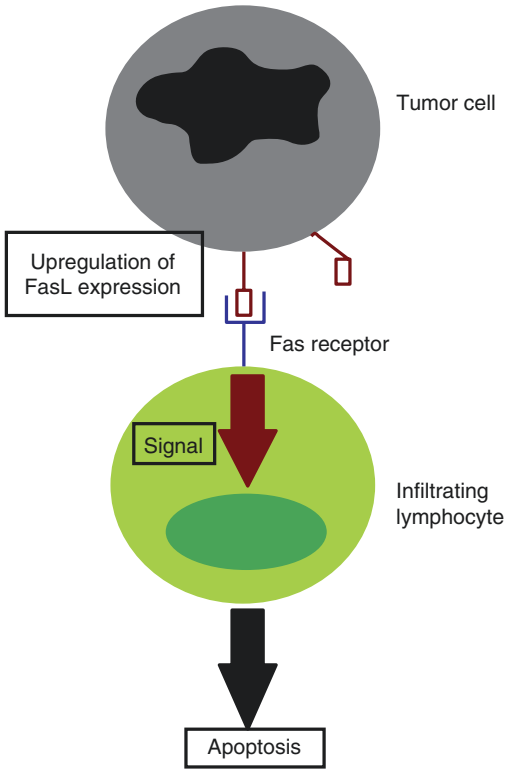

Fig. 42.3 BCC immune evasion through FasL. To evade immune detection, BCC cells upregulate expression of Fas ligand, which binds to the Fas receptor on the infiltrating lymphocyte. This binding inducing a signaling cascade within the lymphocyte, resulting in apoptosis

contribute to the immunosuppressed microenvironment of the tumor [45]. Its presence has been correlated with lack of HLA-DR, ICAM1, CD40, and CD80 expression, surface markers that aid in immune detection, as well as being correlated with immune cell maturity [46].

IFN-γ is a cytokine that has been shown to stimulate immune responses against cancer. In concordance with a permissively immunosuppressed microenvironment, BCC has decreased expression of IFN-γ receptor, which may play a part in the lack of cell-mediated immune response to BCC [47]. Conversely and logically, IFN-γ is elevated in actively regressing BCC [48]. Interestingly, IL-23, a cytokine which induces IFN-γ production as well as inducing antitumor effects in vitro, has also been shown to be elevated in BCC [49].

Fas ligand (FasL) is an apoptosis-inducing factor that by binding to its receptor on the cell surface, begins the apoptotic cascade of signaling within the cell. It is a member of the tumor necrosis factor family of receptor-ligand binding. When FasL is expressed by cancer cells, it induces the apoptosis of infiltrating lymphocytes, allowing the cancer to evade immune surveillance (Fig. 42.3). Some studies have shown BCC to express FasL, while others have had the opposite results, making the expression of FasL on the part of BCC still debatable [50–52].

In general, BCC is associated with a Th2 dominant microenvironment, which is the immune response correlated with immune tolerance. It is capable of significantly inhibiting the Th1 anti-tumor immune response. The Th2 environment is shown with increased expression of IL-4, IL-10, and CCL22, a chemokine responsible for regulatory T cell chemotaxis. However, the BCC microenvironment has also been shown to have an increased expression of interferon-associated genes and IL-23 expression, favoring a Th1 microenvironment [49]. This conflicting microenvironment, shown by the immunostimulatory and immunsuppressive cytokines in the BCC tumor milieu, is consistent with a dynamic state within the immune microenvironment.

Immune Cells and BCC

Dendritic cells, as mentioned earlier, are key in cancer immune surveillance and often have altered behavior in the unique microenvironment of the tumor. In the skin, they exist mainly as epidermal Langerhans cells (LCs) and dermal myeloid DCs. The presence and density of DCs in BCC is controversial, as studies have shown conflicting results. Some studies have shown a decrease and even absence of mature LCs, particularly in tumors of the face, and immature myeloid DCs were found to be present [49, 53], similar to the dendritic cell profile seen in SCC. This decrease in LC density in BCC is linked to increased aggressive behavior on the part of the tumor [54]. Additionally, in BCC cells, the depletion of macrophages and LCs resulted in enhanced tumor progression [55].

Other studies have shown an increased density of LCs within the BCC lesion, as well as in adjacent epithelium [56, 57]. An increase LC density within the BCC lesion is particularly associated with smaller tumor size and tumor location to the face [58]. One explanation for the contradiction in presence or absence of DCs in BCC that has been suggested is that the density of DCs in BCC changes over time, with an initial reduction allowing initiation and subsequent host response increasing DC density [59]. This is also consistent with the dynamic microenvironment suggested by the mixed cytokine profile of BCC.

Regulatory T cells (Tregs) are immune suppressive T cells, important in self-tolerance and immune homeostasis. Created in the thymus, they normally comprise 5–10% of the CD4 T cells in the periphery. They can also be induced in the periphery from naïve T cells [60]. Both induced and natural Tregs express the transcription factor forkhead box P3 (FOXP3), an important controller of suppressor protein expression and used to identify Tregs [61]. These cells have been found to surround BCC, which is consistent with the increased expression of the chemokine CCL22 (Fig. 42.4). This surrounding of BCC by Tregs can contribute to the

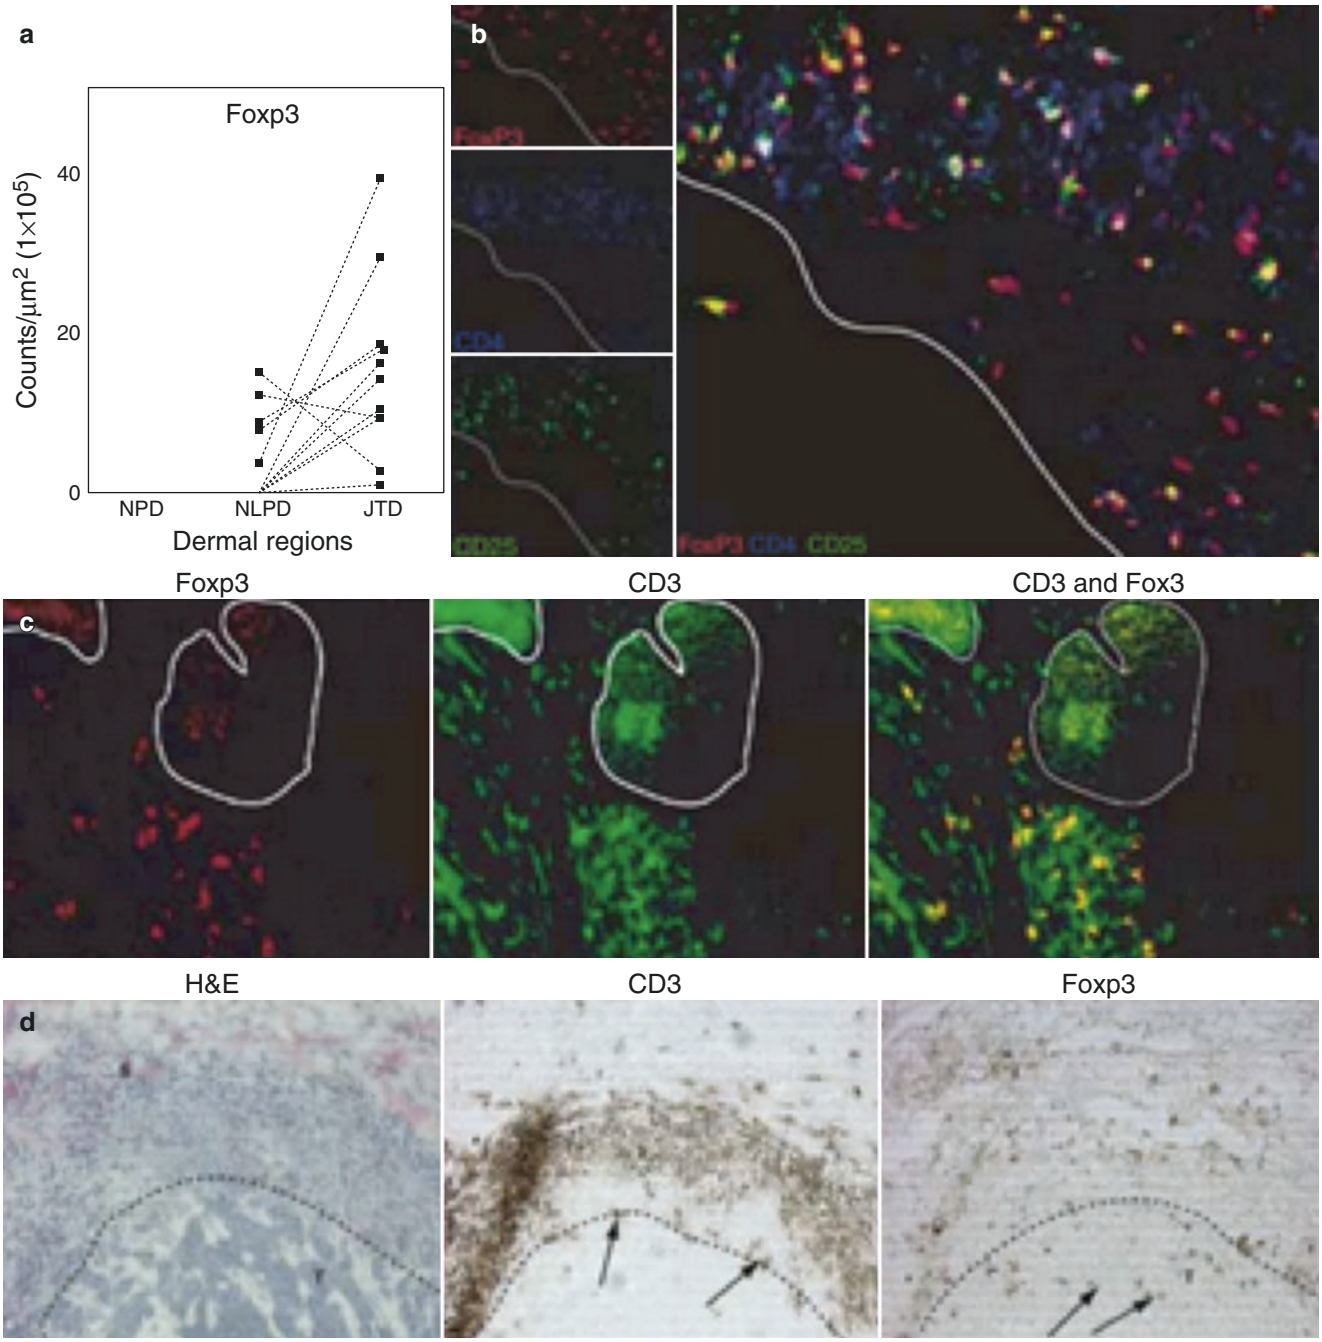

Fig. 42.4 BCC and regulatory T cells. (**a**) FoxP3+ cells were present in the "pseudocapsule" of inflammatory cells surrounding BCC. (**b**) Double label immunofluorescence confirmed that FoxP3+ cells expressed CD3. (**c**) Triple label immunofluorescence showing CD4+CD25+Foxp3+ cells associated with BCC. (**d**) Cell counts show increased numbers of Foxp3+ cells in juxtatumoral dermis (*JTD*) *versus* non-lesional papillary dermis (*NLPD*) *versus* normal papillary dermis (*NPD*)

immune evasion of the tumor, possibly through the impaired maturation of DCs [49].

Mast cells are also thought to contribute to the immunosuppressed microenvironment of BCC. They have been shown to accumulate at the periphery of BCC, especially in aggressive BCC tumors [62, 63]. Additionally, they participate in matrix degradation through the release of proteases, which allow tumor spread and contribute to tumor angiogenesis as a source of VEGF [64, 65], similar to the TAMS of SCC.

Imiquimod

With all the cytokines and immune cells contributing to an immunosuppressed BCC microenvironment,

immunomodulatory therapy options were a logical next step to explore. Imiquimod, one of the most successful therapies, is a topical treatment for BCC that has been shown to induce apoptosis in BCC [66]. It is an immune modifier and, more specifically, a Toll-like-receptor-7 (TLR-7) agonist, which induces multiple cytokines, stimulating an innate and adaptive cell-mediated immune response [67].

Imiquimod treatment results in various immune cells invading in stages. The tumor is initially infiltrated by CD4 T cells, followed by a massive intratumoral and peritumoral infiltration of macrophages, as well as activated DCs [68]. The plasmacytoid DCs are recruited by imiquimod's stimulation of Th1 cytokines, including IL-12. Imiquimod treatment efficacy has been linked to pretreatment DC density in the tumor, with a greater efficiency being shown with a higher density of pretreatment DCs [69]. Imiquimod also induces IFN-α, which in turn induces cell surface expression of FasR on the tumor cells, causing apoptosis of the tumor cells through the CD95 receptor ligand interaction [70–72].

Immunosuppression and Transplant-Associated NMSC

As evidenced by the previous points, the immune system plays a crucial role in the development and progression of non-melanoma skin cancer (NMSC). The most important risk factor for non-melanoma skin cancers is UV radiation. In addition to their mutagen properties, UVA and UVB have been shown to be immunosuppressive in humans. Studies have shown that UVA irradiation suppresses memory immunity to the seven antigens in the delayed-type hypersensitivity test Merieux [73, 74]. Additionally, irradiation with half the UVA in minimal erythema dose (MED), the amount of sunlight necessary to cause a sunburn, suppressed recall immunity to nickel [75]. In animal studies, lymphocytes from UV irradiated mice were unable to prevent malignant formation on UV-irradiated skin grafts in unirradiated mice [76]. Transplanted tumor cell lines, including SCC, which would be immunologically rejected in immunologically competent mice, were able to grow in UV immunosuppressed mice.

Another example of immunosuppression leading to increased risk of NMSC, as well as more aggressive behavior by the NMSC, is the occurrence of these cancers in patients with HIV infection. Immunosuppressed HIV-positive patients can develop rapidly growing cutaneous SCCs at a young age, with an increased risk of recurrence and metastasis [77].

The most obvious and important evidence linking immunosuppression and NMSC is seen in immunosuppressed

Fig. 42.5 Transplant-associated NMSC. Transplant recipient on long term immune suppression with multiple agents including calcineurin inhibitors presenting with multiple SCCs

organ transplant recipients (OTR), with SCC incidence being 60 to 100 times greater in this population than in the age-matched immunocompetent population [78]. The OTR population also has a greater likelihood of multiple skin cancers at presentation (Fig. 42.5) [79].

Furthermore, SCC in OTR is more aggressive, with a higher probability of recurrence and metastasis [80]. The risk of SCC in OTR seems to be directly proportional to the level of immunosuppression, with lower numbers of CD4 cells found in OTRs with NMSC versus OTRs without NMSC [81, 82].

This altered incidence and behavior of SCC in immunosuppressed patients can be attributed to the altered immune microenvironment. With regards to the modified microenvironment, transplant associated SCC (TSCC) has increased populations of immune cells that are immunosuppressive and produce pro-tumoral cytokines, as well as decreased populations of immune cells that initiate a Th1 (cell–mediated immunity) antitumor immune response [83].

The immunosuppressed TSCC immune microenvironment is altered in its T-cell populations and ratios. More specifically, TSCC has been shown to have increased IL-22-producing CD8+ cytotoxic T cells compared to immune competent SCC, as well as increased expression of IL22 receptors [84]. IL-22 is a pro-inflammatory cytokine typically involved in wound healing, which causes activation of genes involved in cell cycle progression and the prevention of apoptosis [85]. IL-22 has been shown to have pro-tumoral activity in multiple cancers. IL-22 has been shown to drive SCC proliferation in culture in a dose-dependent manner, most dramatically under starvation conditions [84]. This is in concert with the idea that IL-22 may drive SCC proliferation within the tumor,

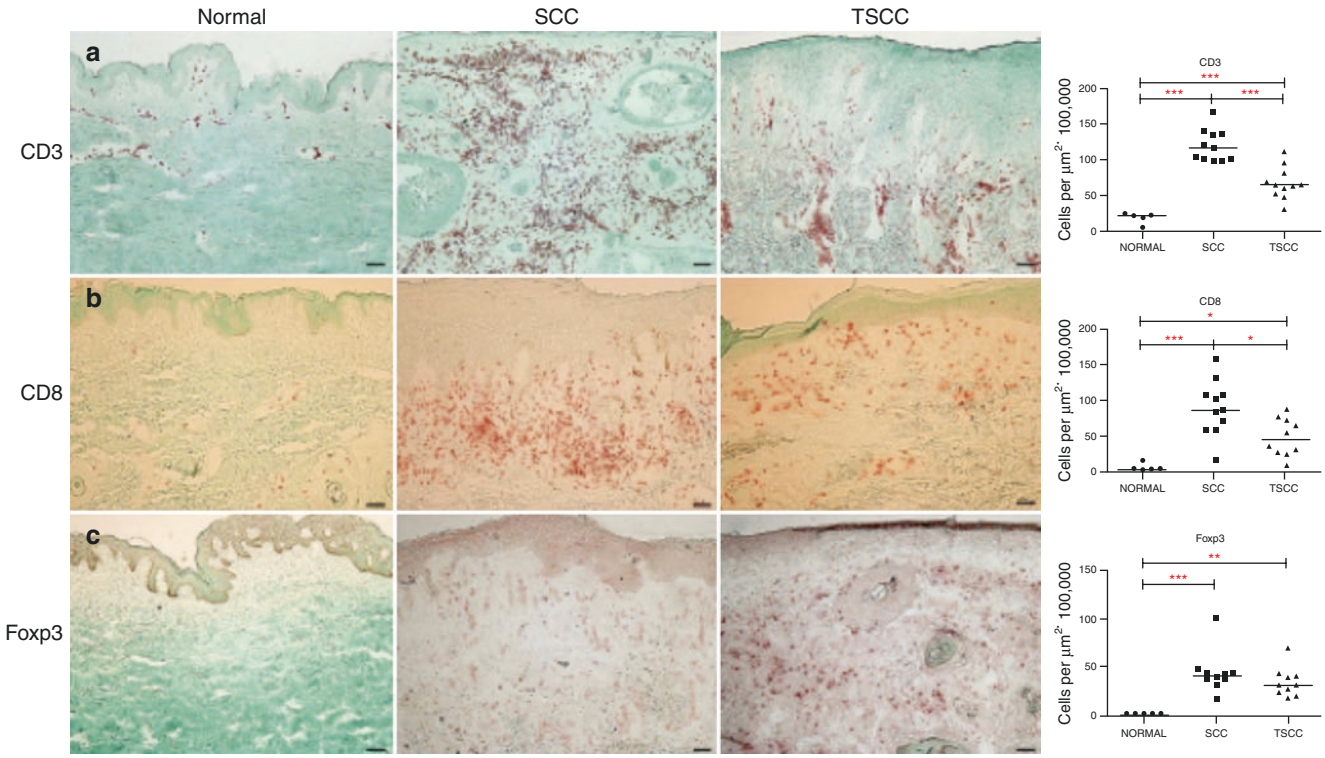

Fig. 42.6 T cell populations in SCC and TSCC. Immunohistochemical staining of normal skin, SCC and TSCC for T cell markers showing the increased amounts of CD3(**a**), CD8(**b**) and Foxp3(**c**) T cells in SCC and TSCC as compared to normal skin. Additionally, the ratio of Foxp3+ Tregs to cytotoxic CD8 T cells was increased in TSCC as compared to SCC, showing a tumor permissive environment in TSCC

where there are high metabolic demands and diminished enrichment.

Additionally, the CD8+ IFN-γ producing T cells in TSCC are decreased compared to SCC, which is associated with aggressive tumor behavior and increased metastasis [86]. TSCC also has an increased proportion of regulatory T cells (Tregs), which has been correlated with a poor prognosis in other carcinomas, such as breast and gastric (Fig. 42.6) [87, 88]. Tregs are important in preventing autoimmunity, but may suppress beneficial antitumor activity and aid in immune evasion [88–90].

TSCC has also been shown to have decreased CD4+ helper T (Th) cells infiltrating the tumor and reduced mRNA for IL17A. IL17A is a Th17-specific cytokine that is involved in inflammation and the recruitment of the innate immune system [91, 92]. The decreased IL17A favors graft tolerance but may weaken the host's anti-tumor response against the TSCC [93–96].

The skin adjacent to TSCC in OTRs has been shown to be Th2 immune response weighted, with decreased IFN-γ levels [83]. The Th2 gene expression is correlated with transplant tolerance and long-term allograft survival [97]. However, as mentioned earlier, the Th2 response is capable of significantly inhibiting the Th1 response, which is the anti-tumor immune response. This allows for the increased aggressiveness and recurrence rates of SCC in OTRs [83].

These changes in the immune microenvironment suggest a compromised inflammatory response in the SCC of OTRs. This alters the behavior and prognosis of TSCC but is a necessary component of immunosuppression for graft tolerance. Though a minimization of immunosuppression in heart and kidney transplant recipients showed reduction in the development of new SCC at 5 years [98], this reduction is not always feasible. A change in immunosuppression regimen should be considered, with calcineurin inhibitors being linked to higher incidences of cutaneous carcinomas, and sirolimus or everolimus being a better choice with respect to cutaneous tumorigenesis [99]. Lastly, the current knowledge of the immune microenvironment of TSCC opens new avenues of study, with cytokines like IL-22 being possible targets in future TSCC prevention and treatment.

Melanoma

Melanoma incidence rates have been increasing over that last three decades, and greater than 75,000 new cases are projected to be diagnosed in 2014, with over 9500 deaths estimated to occur. Although melanoma is only 4 % of all skin cancers, it accounts for greater that 80 % of skin cancer deaths. About a quarter of melanoma patients will experience recurrence and advanced stage disease [2].

The Immunogenicity of Melanoma

Melanoma is considered an extremely immunogenic tumor, with the capability of triggering host immunologic response. The immunogenicity is seen in the immune cell infiltrates that are often seen in melanoma tumors, as well as the relatively high rate of spontaneous regression with concurrent vitiligo. Many melanoma-specific antigens have been identified in triggering a T-cell immune response. Additionally, a number of immune therapies, such as IFN-α and IL-2, have been shown to be effective in patients, as discussed in the chapter 51 [100, 101].

Despite the established immunogenicity of the tumor, there are a number of immune suppressive mechanisms demonstrated to occur in melanoma, such as impaired antigen-presenting cell maturation, T cell anergy, the induction and recruitment of Tregs, and myeloid-derived suppressor cells [100, 102]. Thus, boosting or stimulating an immune response against melanoma has been and is still a promising avenue for therapy, and its exploration has resulted in some success with regards to disease-free and overall survival [103].

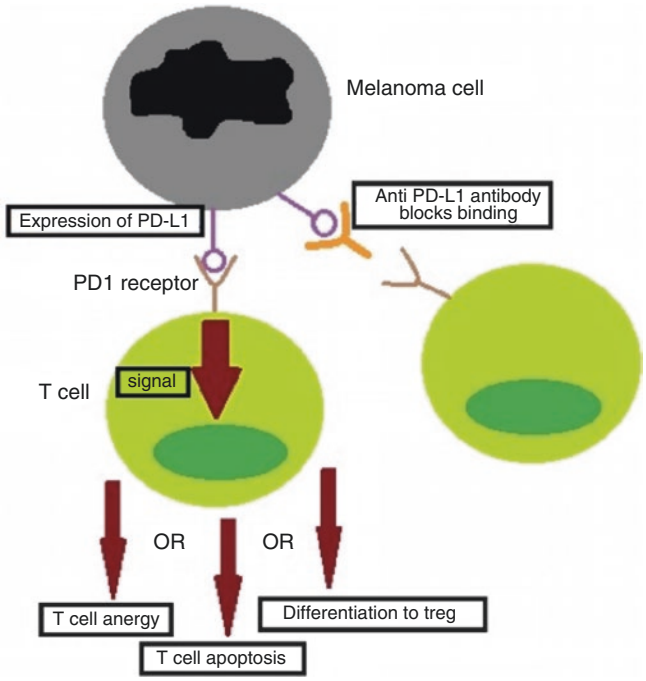

Fig. 42.7 Melanoma immune evasion through PD-L1. One method of immune evasion exhibited by melanoma is the expression of PD-L1 on its surface, which binds to the PD1 receptor on the surface of T cells. The binding of PD-L1 to its receptor causes intracellular signaling, leading to several different immunoinhibitory outcomes: T-cell anergy, apoptosis or differentiation of the T cell into a regulatory T cell (Treg). One of the immune therapies being explored is an anti-PD-L1 antibody, such as nivolumab, which blocks the PD-L1 on the melanoma cells from binding and inhibiting T cells

BRAF

In approximately half of human melanomas, activating mutations in the protein kinase BRAF allow the tumor cells to survive and proliferate [2]. BRAF is a proto-oncogene that is part of the RAF kinase family of growth signal transduction. This has been shown to be through the MEK/ERK pathway, which is important in cell division and differentiation. The most common mutation is the V600E BRAF, where a valine at position 600 is replaced by a glutamic acid. This mutated BRAF also has been linked to a deactivated AMPK, or AMP activated protein kinase, which inhibits cell growth in low energy states [104]. With AMPK deactivated, the melanoma cells can then grow despite lack of nutrients.

T Cell Anergy

Melanoma has multiple mechanisms for inhibiting the activation, proliferation and effector status of T cells. This primarily includes stimulating receptors on T cells, including those for PD-L1 and the B7-H4, both members of the same family of co-stimulatory molecules [101].

PD1 is an immunoinhibitory receptor on T cells that plays a crucial role in melanoma's immune escape. The PD1 ligand (PD-L1 or B7H1) is a member of the B family of costimulatory molecules that provides either an inhibitory or stimulatory secondary signal to T cells primarily binding HLA molecules on tumor cells. More specifically, the B7 family has been shown to control the effector phase of T-cell responses [105]. Specific tumors, such as prostate and renal cell carcinoma, have been shown to express B7 co-stimulatory molecules, which are involved in their escape from immunosurveillance [106].

PD-L1 has been found to be expressed by melanoma tumor cells. When the PD-L1 on the melanoma cell binds to the PD1 receptor on T cells, it causes an inhibition of T cell proliferation, survival and effector functions, such as cytotoxicity and cytokine release. It also induces apoptosis of tumor-specific T cells and promotes differentiation of CD4 T cells into regulatory T cells. Lastly, it increases the resistance of tumor cells to cytotoxic T cell attack [105]. Increased PD-L1 expression by melanoma is negatively correlated with survival (Fig. 42.7) [107].

This pathway is therefore an important therapeutic target, with anti-PD-L1 antibodies, such as nivolumab, tested as immunotherapeutic agents, either alone or in combination with other immune therapies. These have shown some success, but await further testing and demonstration of clinical effectiveness.

Another member of the B family of co-stimulatory molecules, B7-H4, has also been indicated in immune evasion of melanoma. Melanoma tumor cells have been found to express B7-H4, and its presence was shown to also have an inhibitory effect on T-cell cytokine production, in particular IFN-γ, TNF-α and IL-2 [101]. These cytokines are all integral to the T-cell mediated anti-tumor response. As mentioned above, high levels of PD-L1, or B7-H1, have been shown to correlate with reduced patient survival in melanoma. B7-H4 has also been associated with poor patient outcomes, with lower expression levels correlated with better survival [107].

Regulatory T Cells and Melanoma

Tregs, as mentioned earlier, are a dominant mechanism of tumor immune escape. Tregs are overrepresented in the peripheral blood of patients with melanoma and are found in the tumor microenvironment and affected lymph nodes as well [108]. The percent of Tregs infiltrating the melanoma lesions has been shown by some studies to negatively correlate with survival [109]. An even better predictor of survival is the ratio of CD8 T cells to Tregs in the tumor microenvironment [110].

Tregs are thought to accumulate in the melanoma tumor microenvironment through a number of mechanisms. As mentioned earlier, Tregs are both being induced by PD-L1 expressing melanomas and selectively surviving, as melanomas expressing PD-L1 are causing apoptosis in effector T cells. Secondly, chemokine secretion and integrin ligand expression of the melanoma tumor cells attracts Tregs from the periphery. Thirdly, immunosuppressive cytokines locally secreted by melanoma, such as TGF-β and IL-10, can induce and expand Treg populations [100].

Tregs' immunosuppressive capabilities are enhanced through molecular mechanisms, such as melanoma's expression of indoleamine 2,3 dioxygenase (IDO), IDO is an immunomodulatory enzyme which allows tumor cell immune escape through the depletion of tryptophan [111].

As Tregs are clearly an important part of melanoma's immune microenvironment and its ability to progress despite melanoma's immunogenicity, the removal or suppression of Tregs would seem to be a target ripe for therapeutic intervention. Despite many promising studies, clinical efficacy has not yet lived up to its potential, with agents based on IL-2 suppression (a crucial cytokine for Treg activation and proliferation) and FOXP3 vaccination not consistently showing improvement. Other emerging therapies that modulate Tregs, such as CTLA-4 blocking agents (CTLA-4 serves as an inhibitory molecule constitutively expressed by Tregs) and PD-1 blocking agents, have shown some success and need to be explored further [100].

Other Immunomodulatory Mechanisms of Melanoma

Some of the most important cells in melanoma immune modulation are myeloid-derived suppressor cells (MDSCs). As mentioned earlier, these cells are potent suppressors of T-cell mediated responses and contribute to immunosuppression in SCC. MDSCs contribute to melanoma tumor immune tolerance by releasing adenosine, an important immune regulator that is known to hamper the adaptive immune response [112, 113]. The adenosine receptor subtype A2a inhibits T-cell functions. Additionally, the A2b receptor subtype, activated by high adenosine levels in the hypoxic tumor microenvironment, has been shown to promote the expansion of MDSCs and accumulation in melanoma tissue, leading to an immune suppression cycle. MDSCs are also attracted by other inflammatory mediators produced during tumor progression [114].

Another common immune evasion mechanism is the downregulation or alteration of the HLA class I molecule necessary for antigen presentation, immune recognition, and anti-tumor response [115, 116]. A mechanism of HLA molecule expression downregulation noted in metastatic melanoma is through the loss of beta2-microglobulin (B2m), an important component of the HLA molecule. The B2m deficiency is mediated by a mutation of one copy of the B2m gene, followed by the loss of the other copy, i.e. loss of heterozygosity. The decrease in B2m and subsequent decrease in HLA class 1 molecule expression is correlated with decreased CD8 T cell tumor infiltration [117]. This loss may be an early event in tumor progression, leading to melanoma cells immune evasion of T cells and eventual metastasis [118].

Immune Therapy

Though melanoma is extremely immunogenic, in cases where it persists and even metastasizes, it employs multiple methods of immune evasion. Therefore, immune modifiers are important therapeutic avenues of exploration. IL-15 is a cytokine that stimulates innate and adaptive immunity, making it a logical therapeutic option to be explored in melanoma. It shares a receptor with IL-2, a similarly immunostimulatory cytokine, and in studies both IL-15 and IL-2 augment NK cell cytotoxic activity and increase transcription of perforin in vitro [119]. In trials, IL-15 delivered to melanoma resulted in tumor regression and increased long term survival, as well as resulting in an influx of NK and memory CD8 T cells [120, 121].

Diphencyprone (DPCP) is a topical immunotherapeutic agent that is currently in clinical trials as a therapy for

melanoma. It has demonstrated melanoma regression with treatment in early studies. Melanoma's regression with DPCP treatment is thought to be due to TH17 lymphocytes, the immune modulator subset of T helper cells, possibly through TLR4 signaling [122].

Many other immune therapies for melanoma have been and are currently being explored, including, as mentioned earlier, vaccines to certain cell markers, immunostimulatory cytokines and modulations of populations of immune cells present in melanoma's immune microenvironment. All of this is discussed further in Chapter 51.

Responsiveness to Immune Therapy

The presence and distribution of tumor-infiltrating lymphocytes (TILs) may be prognostically useful in melanoma. Their quantity has been qualified as absent, brisk, or non-brisk with a brisk grading in some studies predicting better disease-free and overall survival outcomes, independent of sex, age, and tumor stage. This has been contradicted by other studies showing the presence of TILs promoting tumor outgrowth and metastasis [123–125].

These differences in outcome can be explained by a difference in the cohort of patients examined, and more importantly, a lack of differentiation between different phenotypes. With CD4 and CD8 T cells infiltrating, the distinctions are crucial, as CD8 T cells can be inactivated and anergic, and CD4 T cells are a heterogeneous group and can be composed of Th1, Th2 or Tregs [123].

The genetic expression profile of melanoma is also a good predictor of its responsiveness to immune therapy. Melanomas with an upregulation of immune-related genes have been shown to have a favorable clinical response. The specific immune genes upregulated are the IFN-stimulated genes, the CXCR5/CCR5 ligands, the chemokine genes and the genes associated with immune effector functions. Besides a favorable response to immune therapy, the gene expression profile of immune activation was correlated with a good prognosis in melanoma patients [126].

Conclusion

Cutaneous malignancies are among the most common human cancers and compose a very significant health burden. The interaction between the immune microenvironment and the tumor is crucial in determining the tumor's ability to establish itself, grow and metastasize. The interplay between the tumor cells and the immune system has demonstrated the different mechanisms of immune evasion and suppression employed by both NMSCs and melanoma. These include a modulation of the cancer gene profile, such as the downregulation of stimulatory genes key in tumor immunity. Additionally, the mechanisms involve changing which populations of immune cells are present in the tumor microenvironment, such as having fewer NK cells and more Tregs present. Lastly, the cytokine profile surrounding these cancers is altered, enhancing tolerance, such as the switch to a TH2 cytokine profile. The understanding of the immune microenvironment of cutaneous malignancies is crucial, as it affords many targets for therapeutic options. There is still much more to explore and understand about the immune microenvironment of each cutaneous malignancy and as more is discovered, there are more opportunities to efficiently treat and cure these cancers.

Questions

1. What effect do each cutaneous form of dendritic cells (DCs) have on the immune microenvironment of SCC?
   A. DC are unable to stimulate Th1 lymphocytes to produce Interferon-gamma
   B. All DC subsets hyper-activated
   C. Langerhans cells isolated from squamous cell carcinomas are more impaired than dermal DC from the same tumor
   D. DC derived from tumors respond normally to maturational signals

Correct answer: (A) DC derived from tumors are unable to activate Th1 lymphocytes, a key cell type in tumor surveillance

2. What statement best describes the role of Tregs in both BCC's and melanoma's tumor milieu?
   A. Tregs directly stimulate tumor growth by secreting cytokines and prostaglandins
   B. Tregs render tumor cells resistant to cell death by causing them to downregulate FAS
   C. Tregs impair DC maturation, promoting tumor tolerance by the immune system
   D. Tregs increase tumor cell mobility, by destroying extra cellular matrix

Correct answer: (C) Tregs impair the maturation of DC

3. Which statements best describe melanoma's immune evasion mechanisms?
   A. Impaired antigen-presenting cell maturation
   B. T cell anergy
   C. Induction and recruitment of Tregs
   D. Induction of myeloid-derived suppressor cells
   E. All of the above
   F. None of the above

Correct answer: (E) All of the above mechanisms are active in melanoma immune evasion

4. What T-cell receptor(s) plays an important role in melanoma's immune evasion (more than one response may be correct)?
   A. CD28
   B. CD40 ligand
   C. Chemokine receptors
   D. Adenosine receptor subtype A2a
   E. PD-1
   F. CTLA-4

Correct answers: (D, E, F) Adenosine receptors, PD-1 and CTLA-4 are all inhibitory receptors that melanomas engage that promotes immune evasion from T cell responses

Biologic Therapies for Psoriasis

43

Lauren Guggina and Kenneth B. Gordon

Abstract

It is possible to suggest that the past two decades have led to greater advances in the treatment of extensive psoriasis than almost any other disease. The number of treatments available has grown tremendously and our treatment goals have changed radically. While at the turn of the century it was thought that complete clearance of psoriasis in patients who had extensive disease was not feasible in almost any patient, we now have medications that can attain complete clearance in up to 40 % of patients. With achievement of higher levels of response, a new understanding of the benefit of these responses to patients has identified a need for greater responses.

The development of targeted biologic immunotherapy for psoriasis has historically relied on the understanding of the pathophysiology of disease. However, the targeted nature of these medications, in concert with fortuitous clinical observation, has furthered the understanding of the pathological mechanisms in psoriasis. In turn, new insight has led to even more effective treatments. Thus, the use and study of biologics improves disease treatment in two ways. Their targeted nature can promote individual health by helping to treat the patient's disease while their study leads to global benefit by directing the creation of newer treatments. In this chapter, we will examine how biologics have changed our understanding of psoriasis and has led to the development of a multitude of new and exciting treatments.

Pre-biologic Understanding of Psoriasis and the Early Biologic Immunotherapies

Today, we take the concept of psoriasis being an immune mediated disease for granted. However, prior to the 1990s, this perspective was not universally held. Treatment with medications that impacted immune activity, like cyclosporin A, implied that immune mechanisms were potent targets for treatment. Immunohistochemical evaluation of tissue from psoriatic plaques for known cytokines and subpopulations of T cells along with human/mouse skin explant models led to a model of psoriasis pathophysiology that mimicked contact dermatitis. Psoriasis was considered to be a disease driven by CD4+ T cells with Th1 cytokines, including IFN-γ, inducing the changes in the skin. These T cells would be stimulated by antigen presenting cells using known pathways of stimulation through the T cell receptor and co-stimulation through the CD80 and 86/CD28 pathways. These cells would traffic in and out of the skin through specific interactions with the vasculature and keratinocytes.

Initial trials with targeted therapy were focused on interacting with these pathways, either by elimination of activated

CD4+ T-cells or interference with cell surface molecules governing co-stimulation and cell migration. Early studies with anti-CD4 monoclonal antibodies and denileukin diftitox demonstrated that reducing the number of activated T cells could, in fact, treat some patients [1, 2]. Likewise, blockade of co-stimulation the use of CTLA-4Ig, that interfered with CD28/CD80-86 interactions showed limited benefit for patients in very early clinical trials [3].

These observations resulted in the development of the first two biologic therapies approved for the treatment of psoriasis, alefacept and efalizumab. Alefacept was a fusion protein that was designed to block the co-stimulatory action of the CD2/LFA-3 interactions. In fact, it had the additional effect of eliminating T cells that expressed high levels of CD2, primarily previously activated CD4+ T cells [4]. According to the prevailing model of psoriasis at the time, this medication should have had significant efficacy. However, despite a proportion of patients having excellent long lasting improvement in disease, PASI 75 responses were only seen in 28–33 % of patients in the phase III trials [5, 6]. Despite being the first biologic therapy approved by the FDA for the treatment of psoriasis, due to this limited efficacy, alefacept was never adopted significantly by clinicians.

Efalizumab was the second biologic immunotherapy approved for psoriasis by the FDA. Efalizumab, too, was designed according to the CD4/Th1 model of psoriasis. This medication blocked CD11a, a sub-unit of LFA-1 that interacts with ICAM-1 on blood vessels, T cells, and keratinocytes to impact T cell activation and trafficking to the skin. While marginally more effective that alefacept, PASI 75 rates still were only 25–39 % [7–11]. Moreover, paradoxical psoriasis rebound was seen in patients who were withdrawn from the medication and even some who remained on treatment [12, 13]. Eventually, efalizumab was removed from the market due to cases of progressive multifocal leukencephalopathy (PML) [14]. However, the limited benefit of medications that targeted Th1 pathways demonstrated that new models of psoriasis were needed.

New Clinical Observations and a New Model for Psoriasis

Around the same time as alefacept and efalizumab were being developed, anti-tumor necrosis factor alpha (anti-TNF) therapies were being approved for Crohn's disease and rheumatoid arthritis. While TNF did not play a clear role in the early models of psoriasis pathophysiology, clinical observers were noting that treatment in patients treated for other conditions who had coincidental psoriasis were improving. This observation was made as early as 1996 in patients being treated in clinical trials of infliximab for Crohn's disease (Dafna Gordon, M.D., personal communication) and was reported in 2001 by Gottlieb and her co-workers [15]. Clinical trials with the anti-TNF agents, etanercept, infliximab, and adalimumab, discussed below, were significantly more successful than the anti-T cell agents and thus, demanded a re-thinking of the psoriasis model.

A number of observations helped to lead to a new understanding of psoriasis. Most information suggested a predominant role for innate immune responses in psoriasis. The role of cells and cytokines that play a critical role in local innate immune responses has become increasingly clear. Genetic analysis suggested a role for interleukin 23, a molecule that is produced by local mononuclear cells in response to tissue infection and injury [16, 17]. Similarly, Krueger and his associates identified that almost all the p40 protein in the skin was part of interleukin 23, not IL-12, as would be predicted by the Th1 model [18]. Likewise, high levels of IL-20 family cytokines along with IL-17, molecules that can induce keratinocyte changes seen in psoriasis, including more rapid proliferation and poor maturation, were present in high levels in psoriatic plaques [19, 20]. These findings were consistent with the observation that certain signal transduction pathways, including STAT-3 activation were a central finding in psoriatic keratinocytes [21, 22]. A number of experiments showed that all of these elements were necessary to see changes of psoriasis.

From these observations, and others, a new model for psoriasis has been developed that has governed our understanding of this disease and has potentially revolutionized therapy. As seen in Fig. 43.1, in patients who are genetically susceptible, some initiating step, local or systemic inflammation or injury, for example, initiates local, resident cells, including keratinocytes and mononuclear blood derived cells by cytokines like IFN-alpha. In turn, these cells producing innate activating factors, including TNF-α, lead to activation of specific dendritic cells, which, in turn, produce IL-23. IL-23 seems to be the critical switch that impacts local immune cells to produce the cytokines, including IL-17, that can have a direct impact on keratinocytes. At the moment, there is some controversy as to what cells are the primary producers of IL-17 in psoriasis. Specific T cells that produce IL-17, termed IL-17 T cells, presumably are central to IL-17 production in psoriasis [23]. However, immunofluorescence staining of IL-17 in psoriatic plaques has suggested that both neutrophils and mast cells may also be important in IL-17 release [24].

IL-17 is the direct connection between the immune system and keratinocytes. When bound to IL-17 receptor, expressed on keratinocytes, these skin cells begin to express anti-microbial peptides, secrete chemokines, and alter cell growth and differentiation in ways that are found in psoriasis [20, 25, 26]. Thus, a complete pathway for psoriasis, from initiating factors to keratinocyte alterations is evident in this

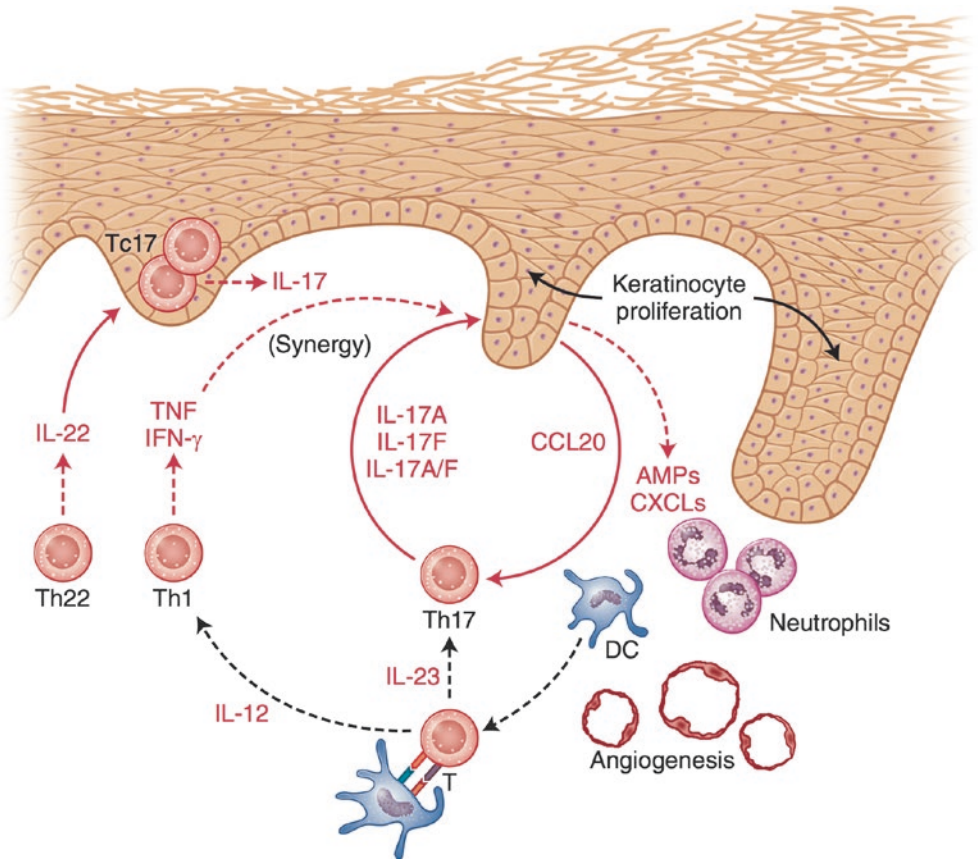

Fig. 43.1 Cytokine cascade resulting in clinical lesions of psoriasis. Interleukin 23 leads to production of IL-17 and IL-22 resulting in keratinocyte hyperproliferation and abnormal maturation. Additionally, the altered keratinocytes produce chemokines and other immune reactive proteins that promote increased inflammation, angiogenesis, and continued disease activity

model. However, it is critical to remember that any depiction of psoriasis immunopathogenesis as strictly linear is misleading. IL-17 and keratinocyte derived chemokines have important effects on the maintenance of the immune response by increasing cell migration into the skin [26–28]. Thus, the model can be visualized as having a feedback loop where psoriatic activation leads to perpetuation of the plaques.

The Psoriasis Model and Biologic Therapy

The model outlined above has significant implications for both older and newly designed biologic immunotherapy. In the schematized model in Fig. 43.2, it becomes clear that a number of places in the immune response could be excellent targets for treatment. These targets include the activation of IL-23 producing dendritic cells, the activation of Th17 cells by IL-23, and the induction of keratinocyte changes by IL-17. In fact, all of these breaks on the psoriasis pathways are in use for the treatment of psoriasis today. Anti-TNF agents have a significant role in inhibiting dendritic cell activation, ustekinumab binds and inactivates IL-12 and 23, while developing agents guselkumab and tildrikizumab block IL-23 alone, the newly approved secukinumab, ixekizumab and brodalumab block IL-17 interactions with keratinocytes. All these agents have a significant role in modern treatment of psoriasis and can lead to marked improvement in patients and better quality of life for those who suffer from psoriasis. These classes of biologic agents will be reviewed from the perspective of where they have the greatest impact on the immunopathogenesis of psoriasis.

Inhibiting Inflammation and Dendritic Cell Activation: The Anti-TNF Agents

One of the most important observations in the validation of the new psoriasis model was the understanding of how anti-TNF therapy could fit into this. As mentioned above, the efficacy of anti-TNF agents was identified prior to the elucidation of the current. Since these agents can be highly effective, it was critical to see how they may work. Krueger and his co-workers used gene expression signatures to investigate the earliest mechanisms by which the anti-TNF agent etanercept impacted local immunity by comparing Th1 expression signatures and Th17 signatures. They found that Th17 gene expression was inhibited earlier than Th1 responses and that the correlation of inhibition of Th17 genes to response was much greater than that of Th1 responses [29]. Moreover, by use of immunohistochemistry,

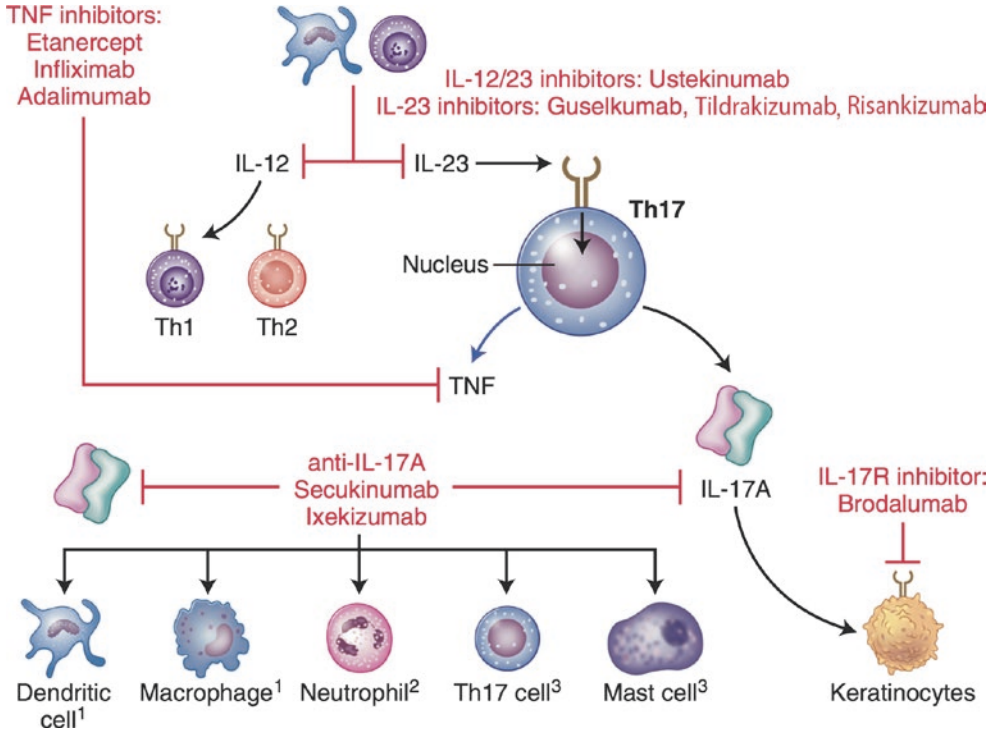

Fig. 43.2 Potential targets of immunotherapy for psoriasis including TNF-a, IL-17, and IL-23. Agents approved or in final stages of trials are listed with their targets

they identified that etanercept inhibited production of IL-23 and TNF by dendritic cells and proposed that this was the primary effect of anti-TNF agents [23].

Anti-TNF agents are, at the time of this writing, the most widely used family of biologic agents for psoriasis. There are three agents in this class that bind and deactivate their TNF target, etanercept, infliximab, and adalimumab that are presently approved for the treatment of psoriasis.

Etanercept

Etanercept is a fusion protein of the p55 receptor for TNF bound linked to a constant region, antibody backbone. It was the first anti-TNF agent approved for the treatment of psoriasis. Etanercept is dosed as a 50 mg subcutaneous injection given twice weekly for the first 3 months of treatment followed by weekly dosing. Etanecept is also approved for the treatment of psoriatic arthritis.

The primary endpoint of the pivotal phase III clinical trials with etanercept was after 12 weeks of therapy, when 49 % of subjects reached a PASI 75 at that time point [30]. Higher rates of response, including PASI 90, and complete clearance were not reported. At 6 months, with the continued 50 mg twice weekly schedule, the PASI 75 rate increased to 59 % [30]. However, with the indicated dosing schedule and dose reduction after 3 months, PASI 75 rates only reach 54 % [31]. Additional studies with 25 mg twice weekly resulted in only 51 % of patients reaching a PASI 75 [32]. Longer-term analysis has not been done in these clinical trials. Additional studies have shown that etanercept can be successful in treating scalp psoriasis [33].

Infliximab

Infliximab was the second medication in this class to be approved for psoriasis and is also approved for psoriatic arthritis. It is dosed as an IV infusion, usually over 2 h starting at a dose of 5 mg/kg given weeks 0, 2, 6 and then every 8 weeks. Infliximab is a chimeric, monoclonal antibody that maintains a primarily murine binding site.

Since its approval to very recently, infliximab has had the highest short term efficacy of any biologic immunotherapy. At the 10 week primary endpoint of the phase III clinical trials, infliximab had a PASI 75 of 80 % and a PASI 90 of 57 %, and complete clearance of 26 % [34]. However, due to a number of potential factors including a rapid decrease in blood levels due to the decrease in the frequency of dosing in maintenance therapy and/or immunogenicity of the medication, the clinical efficacy of infliximab decreases significantly over the first year. At 1 year, the efficacy decreases to only 61 % of patients achieving a PASI 75 from the original highs [34].

Adalimumab

Adalimumab was the most recent anti-TNF agent to be approved for the treatment of psoriasis. This medication is a human monoclonal antibody that is dosed as a 40 mg subcutaneous injection given as 80 mg week 1, 40 mg week 2, then 40 mg every other week. Like the other anti-TNF agents, it is approved for the treatment of psoriatic arthritis, as well.

The primary endpoint of the phase III clinical trials of adalimumab were 16 weeks. Inclusive in these trials was the Champion trial, the first biologic therapy comparator trial, comparing adalimumab with methotrexate. The PASI 75 in these trials was 79.6 % with a reported PASI 90 of 51.3 % and complete clearance of 16.7 %. In the Champion trial, adalimumab was markedly superior to methotrexate. Long term efficacy of adalimumab is, unfortunately, difficult to ascertain as the primary trials were done with a withdrawal and retreatment structure [35]. However, it is clear that there is some loss of effect of adalimumab over time [36]. Studies of adalimumab in palmar-plantar psoriasis have also shown benefit [37].

Anti-TNF Side Effects

While there are variances in safety outcomes between the anti-TNF agents, the general issues associated with them are present across the class. In understanding anti-TNF safety, it is critical to remember that this is the only class of psoriasis biologics that was initially developed for other indications, Crohn's disease and rheumatoid arthritis. Most of the reports of safety concerns with these medications stem from use in these other indications. An analysis by Burmester and colleagues showed that the rates of medication associated side effects for adalimumab were markedly lower for psoriasis in clinical trials than for other indications [38]. This finding may be due to a healthier clinical trial population, younger age, and/or the presence of other immune suppressive medication. Yet it makes comparison of the side effect profiles of anti-TNF agents with other agents approved only for psoriasis extremely difficult.

The primary risk associated with anti-TNF agents is infection. Anti-TNF agents have been associated with slight but increased risk of serious infections, opportunistic infections, and reactivation of tuberculosis and hepatitis B in the general populations studied. However, when psoriasis is studied exclusively, no increased risk of infection can be identified in short-term treatment when compared to placebo [39]. Nonetheless, it is likely that there is an infectious risk associated with anti-TNF agents for psoriasis, especially for non-serious infections [40]. Screening for latent tuberculosis should be done regularly and prior to starting patients should be screened for exposure to hepatitis B [41, 42].

Cancer risk of anti-TNF agents is more controversial. Concerns of an increased risk of lymphoma and certain solid tumors are common. No good information on these long-term risks exist in psoriasis patients treated with anti-TNF agents. However, in meta-analysis analysis of rheumatoid arthritis patients treated with TNF alpha inhibitors, lymphoma risk does not seem to be any higher in anti-TNF treated populations than in comparably severe patients treated with other modalities [43]. Likewise, the incidence of solid tumors as well as recurrence or cancer in patients who are treated with anti-TNF's does not seem to be increased [40]. In a recent prospective long term study of etanercept users, the rates of malignancies excluding NMSC and lymphoma were not higher than the rates of the general psoriasis population [44]. The possible exception to these findings are non-melanoma skin cancer and, possibly, melanoma, that seem to be a bit higher in anti-TNF treated patients [40].

Other risks associated with anti-TNF therapy, including worsening of demyelinating disease and congestive heart failure come from attempts to treat these conditions with this type of therapy [39, 41]. Anti-TNF agents did not seem to show benefit in these conditions and treatment seemed to worsen some patients. Thus, anti-TNF therapy should be avoided in patients who suffer from or are at high risk for these conditions.

Inhibiting Th17 Activation: Ustekinumab and the Anti-IL-23 Agents

Ustekinumab

The next step in the simplified sequential model of psoriasis pathogenesis is the activation of Th17 cells after stimulation with IL-23. Ustekinumab is a human monoclonal antibody directed against the p40 sub-unit protein shared by IL-12 and 23. Interestingly, it was initially postulated to be of use in psoriasis based on the older Th1 model through its impact on IL-12. Subsequently, the belief is that it is the impact on IL-23 that is most important [18, 45–47]. Ustekinumab has been shown to markedly down regulate gene expression in the Th17 pathway emphasizing its mechanism consistent with the sequential model [46].

Ustekinumab is given as either a 45 or 90 mg dose depending whether the patient is greater than or less than 100 kg. The primary endpoint of the initial phase III clinical trials with ustekinumab was PASI 75 at 12 weeks of therapy. Rates of response were around 67 % for those receiving 45 mg and 66–76 % for those receiving 90 mg dosing [48, 49]. In long-term extension trials, response was maintained with no evidence of significant safety signals [50]. One concern with blocking IL-12 was that this would induce immune deviation and increase the risk of infection. However, 5 year follow up

in clinical trials does not seem to lend credence to this theory with no increase in infection rates seen [51]. However, trials with another IL-12/23 inhibition, briakinumab suggested increased rates of infectious risk, skin cancers, and major adverse cardiac events suggesting that continued attention needs to be paid to safety outcomes [52, 53].

P19 Blockade: Inhibiting IL-23 Without IL-12

Despite the evidence suggesting the safety of ustekinumab, the data on briakinumab as well as theoretical concerns has led to the development of biologic medications that bind only to the p19 subunit of IL-23. This mechanism would leave IL-12 intact. Moreover, trials with these agents would answer a fundamental question, whether the IL-12/Th1 pathway that was the focus of the initial immunological models of psoriasis, has a therapeutic role at all in the treatment of this disease. At the time of this writing, phase II data on two medications, guselkumab and tildrakizumab, have been published. Both of these agents have high-level responses [54, 55]. In fact, in a comparator trial with adalimumab, guselkumab was more efficacious for both short and year-long therapy from a phase II study (Gordon, *NEJM*, in press). Peak efficacy was seen with PASI 75 scores at week 16 of 81 % compared to 71 % for those patients receiving adalimumab. Tildrikizumab also showed high level responses in phase II trials with PASI 75 results reaching 72 % (in press *British Journal Of Dermatology*). This high level efficacy continued through week 52. While safety is impossible to evaluate in small, phase II trials, it is difficult to imagine that the safety record will be inferior to that seen with ustekinumab. Thus, these trials validate the present model of psoriasis with a minimal to no role for the Th1 pathway and suggest more specific pathways for the treatment of psoriasis.

Inhibiting IL-17 Effector Function: Anti-IL-17 Monoclonal Antibodies

Upon identification of IL-17 as the critical connection between the immune system and the keratinocyte reaction in psoriasis, a number of biologic immunotherapies have been developed to inhibit this key cytokine. There are a number of different ways this IL-17 can be inhibited [56]. There are multiple isoforms of IL-17 found in psoriatic skin. There is upregulation of IL-17A and IL-17 F, which can form 2 sub-unit homodimers or form an A/F heterodimer, as well as IL-17C [25, 57]. Additionally, IL-17C is produced by keratinocytes and may have an autocrine function in the skin [58]. Interestingly, all of these isoforms bind to the IL-17 receptor A to have their effector function. Thus, it is possible to inhibit this system either by making a biologic molecule that would bind the cytokines themselves or more generally block the pathway by inhibiting binding to the receptor.

There are three new biologic medications that are designed to specifically inhibit IL-17. The first of these to be approved by regulatory authorities is secukinumab, a molecule that binds IL-17A specifically. Similarly, ixekizumab acts specifically on IL-17A not binding IL-17 F or IL-17C. In contrast, brodalumab blocks this pathway at the receptor level, binding and blocking activity of the IL-17RA receptor and inhibiting all three isoforms. Therefore, two theoretical questions arise. First, would blockade of the entire system through the receptor give higher levels of efficacy and second, is more specific blockade of IL-17A alone a safer strategy? These questions can only be answered by clinical data.

Phase III data on all of these drugs has recent become available. At the time of this writing, secukinumab has the most extensive available data set. In a recent publication of two phase III studies, this medication shows PASI 75 responses at week 12 of 77–82 % with 300 mg dosing and 67–72 % with 150 mg dosing [59]. In phase III trials, ixekizumab, shows PASI 75 results of 87–89 % and PASI 100 results of 35–41 % (*Lancet,* in press and presented at World Congress of Dermatology (WCD) 2015). Brodalumab has extremely high responses, as well, with PASI 75 responses of up to 85 % and PASI 100 of up to 42 % (presented at WCD 2015). What is fascinating is that the responses to all these medications is extraordinarily fast. Theoretically, this rapid response is related to the blockade of IL-17 itself which, along with inhibition of continued immune responses, stops the binding of the cytokine that directly impacts keratinocyte responses. Thus, as we are measuring the severity of psoriasis through clinical changes associated with keratinocyte reactions to inflammation, directly modifying this response could lead to greater improvement in disease, faster.

As secukinumab and ixekizumab has only recently been approved and brodalumab is not yet in general clinical use, it is impossible to definitively judge long-term safety. However, the clinical trials for all these medications have very large data sets and thinking of them collectively gives a sense of any safety issues of the class. By considering the role of IL-17 in health, the production of local responses to invading organisms, one would predict that these medications would increase the risk for local staphylococcal infections and candida infections. In fact, all three of these medications show some increase in very mild candida infections in the clinical trials population [59–61]. However, other infectious or other safety risks do not seem to be present. One additional completely unpredicted safety concern is the possibility of worsening established Crohn's disease. From a purely immunological point of view, blockade of IL-17 should

induce a great improvement in Crohn's. However, in clinical trials of patients with active Crohn's disease, a number of subjects worsened. At present, this difference between the very high level responses seen in psoriasis and the worsening of Crohn's remains a mystery though it has been ascribed to differences in the microbiome of the skin and the gut. Luckily, the effect on Crohn's seems to have little impact on patients with psoriasis though caution should be taken in patients who have both conditions.

One final safety concern has recently been identified with brodalumab among this class of medications, specifically. Though the data have not been fully analyzed, there have been a small number of completed suicides in the clinical trials of brodalumab. To date, there have been no completed suicides in either the secukinumab nor the ixekizumab clinical development programs, leading to a concern that this finding may be specific for blockade of IL-17 receptor rather than the cytokine IL-17A itself. While this remains speculation, the lack of events in both secukinumab and ixekizumab are comforting for the clinical use of these agents.

Conclusion

Psoriasis has a tremendous impact on patients who suffer from the condition and our society. Traditional treatment has been insufficient to ease the suffering associated with this disease. In the last two decades, however, the revolution of biological immunotherapy has completely changed how we think of psoriasis. From clinical observations and an understanding of pathophysiology, a new era of treatment has evolved. Rather than a disease that is possible to improve in some patients, we are approaching near clearance in a great majority of patients. This difference cannot be overstated in terms of the benefit it will provide for many years to come.

Questions and Answers

1. Which of the following drugs blocks the interleukin (IL) 17 receptor?
   A. adalimumab
   B. brodalumab
   C. guselkumab
   D. Ixekizumab
   E. Secukinumab

2. Which of the following drugs blocks both IL12 and IL23?
   A. brodalumab
   B. guselkumab
   C. risenkizumab
   D. tildrakizumab
   E. ustekinumab

3. Which isoform of interleukin (IL) 17 is blocked by ixekizumab?
   A. A
   B. B
   C. C
   D. D
   E. E

4. A surprising (from an immunological viewpoint) adverse event reported in some patients receiving anti-IL17 therapy, was worsening of which condition?
   A. Cardiac disease
   B. Crohn's disease
   C. diabetes
   D. Psoriasis
   E. Psoriatic arthritis

5. Which protein subunit is shared between IL12 and IL23?
   A. P12
   B. P19
   C. P23
   D. P35
   E. P40

Answer key

1. B
2. E
3. A
4. B
5. E

Therapy of Immunobullous Disorders

44

Kyle Amber and Michael Hertl

Abstract

Immunobullous disorders are chronic-relapsing diseases of the skin and mucous membranes with high morbidity and mortality which are linked to IgG autoantibodies that target adhesion molecules of the skin. In most instances, therapeutic approaches comprise the application of general immunosuppressive drugs. Treatment with high-dose systemic glucocorticoids and adjuvant immunosuppressive drugs is effective, but also bears the risk of considerable side-effects. In light of recent advances in the pathogenic understanding of immunobullous disorders, additional therapeutic targets including pro-inflammatory cytokines (TNF- α) and peripheral B cells have been identified. Herein we review the role of biologic inhibitors of these two processes.

Keywords

Introduction (Therapeutic Targets in Immunobullous Disorders)

Immunobullous disorders are chronic-relapsing diseases of the skin and mucous membranes with high morbidity and mortality [1, 2]. They are caused by a loss of intercellular adhesion of epidermal keratinocytes or dermal epidermal basement membrane, respectively, as a result of the binding of IgG or IgA autoantibodies against components of desmosomes, hemidesmosomes or components of the dermal-epidermal junction and dermal anchoring fibrils, respectively. Despite remarkable progress in understanding the immune pathogenesis of these disorders, the thorough characterization of their autoantigens and a general understanding of the immunological network which eventually leads to the formation of pathogenic autoantibodies is rather limited [3, 4].

In most instances, therapeutic approaches comprise the application of general immunosuppressive drugs [3, 4]. Treatment with high-dose systemic glucocorticoids and adjuvant immunosuppressive drugs is effective but also bears the risk of considerable side-effects. Due to their rarity, only few prospective controlled clinical trials are available in pemphigus and bullous pemphigoid (BP) which are limited by the low numbers of patients studied and the lack of statistically significant differences in many studies [5, 6]. A few studies compared different doses of prednisolone, i.v. corticosteroid pulses versus placebo, azathioprine versus mycophenolate mofetil, and the use of adjuvant treatment with methotrexate, cyclosporine, cyclosphosphamide, and high-dose intravenous immunoglobulins [7–9]. The combination of systemic corticosteroids (prednisolone, 1.0–1.5 mg/kg/d) and corticosteroid-sparing immunosuppressive drugs, mostly azathioprine and mycophenolate mofetil, is regarded as standard first-line therapy by most dermatologists. Derived from an advanced pathogenetic understanding, additional therapeutic procedures such as the depletion of peripheral B

cells with rituximab or the removal of pathogenic IgG autoantibodies by immunoadsorption has proved to be efficacious in some of these disorders, such as pemphigus, but have not yet been fully validated [10–12]. We here focus on two specific therapeutic approaches, i.e. the blockade of pro-inflammatory cytokines, i.e. tumor necrosis factor-alpha (TNF-α) and therapeutic depletion of autoaggressive B cells with the anti-CD20 monoclonal antibody, rituximab, which has shown major promise in achieving long-term remissions in pemphigus [13–15].

Blockers of Pro-inflammatory Cytokines

Tumor necrosis factor alpha (TNF-α) is a cytokine involved in systemic inflammation that primarily acts on NK-kB pathway and the MAPK pathways. TNF- α levels have been shown to be elevated in numerous autoimmune diseases, providing an avenue for treatment by decreasing these levels [16]. The finding that TNF- α levels are increased in the sera of pemphigus and pemphigoid patients [17, 18] has led to research in the area of TNF- α inhibition in immunobullous diseases. In pemphigus, TNF- α serum levels correlate with both the number of lesions as well as the IgG autoantibody titers [19, 20]. In patients with bullous pemphigoid, TNF- α serum levels are likewise elevated compared to healthy controls and correlate with the number of lesions [21, 22]. Studies of blister fluid in both PV and BP have demonstrated increased levels of TNF- α compared to serum [22–24].

Despite the clear increase of TNF- α in immunobullous disease, its functional role in the disease process is not entirely clear. In vitro studies have demonstrated that TNF- α increases the IgG autoantibody-mediated acantholysis of pemphigus vulgaris (PV). This was likewise demonstrated in a murine model [25, 26]. This increased acantholysis was demonstrated with TNF- α dependent increases in complement activation [25] which is a common finding histologically in PV patients. Yet, these data only demonstrate TNF- α's synergy with pathogenic IgG autoantibodies.

Initial reports of treatment with biologic TNF- α inhibitors appeared promising for the treatment of PV, pemphigus foliaceus (PF) and pemphigoid with success reported using infliximab [27–29], adalimumab [30] and etanercept [31–36]. Formal studies, though limited in size, have not been quite as promising. A randomized controlled trial of standard therapy with adjuvant etanercept failed to demonstrate any improved efficacy compared to standard therapy plus placebo in PV patients [37]. Likewise, a randomized study of pemphigus patients treated with infliximab with prednisone failed to demonstrate any clinical advantage over prednisone alone, though those patients treated with infliximab did IgG experience a significant decrease in anti-Dsg3 and anti-Dsg1 titers [38]. Oddly, studies using adjuvant sulfasalazine and pentoxifylline, a non-biologic and less specific TNF- α inhibitor, demonstrated improved patient outcomes compared to the standard therapy plus placebo group [39]. Likewise, in a randomized controlled trial of ocular cicatricial pemphigoid patients, adjuvant pentoxyfylline was associated with improved clinical and histopathologic outcomes [40]. The efficacy of non-biologic and less specific TNF- α inhibitors may suggest a therapeutic target that involves TNF- α, but does not solely deplete it.

While the efficacy of biologic anti-TNF- α appears limited, there have been additional reported cases of paradoxical development of immunobullous disease secondary to beginning anti-TNF- α biologic agents [41–44]. The paradoxical development of certain diseases following the initiation of TNF- α inhibitors has been well documented, with psoriasiform dermatoses, granulomatous eruptions, and uveitis being most frequently reported [45]. The paradoxical development of pemphigus may be explained by the observation that in one study, TNF- α negatively correlated with anti-desmoglein IgG autoantibodies in pemphigus patients in remission [46]. Thus, certain TNF- α levels may be required to keep the disease in check.

Rituximab in Pemphigus and the Pemphigoids

Rituximab is a chimeric monoclonal IgG that targets CD20, a glycosylated phosphoprotein expressed on the surface of all B-cells starting at the pro-B-cell phase. As B-cells mature, their expression of CD20 increases. Once B-cells mature into plasma cells, however, expression of CD20, as well as many other common B-cell surface antigens ceases. Rituximab therefore destroys B-cell progenitors, but not antibody secreting plasma cells or stem cells. Short-lived plasma cells are more dependent on CD20 memory B-cells for replenishment than long-lived plasma cells. Thus, rituximab has a greater effect on depletion of short-lived plasma cells. This can be demonstrated by the relative decrease in serum IgG autoantibodies to total immunoglobulin levels seen clinically, as IgG autoantibodies appear to be produced more frequently by short-lived plasma cells [47–49]. Likewise, IgG against common pathogens does not decrease following treatment with rituximab, indicating a failure to deplete long-lived plasma cells [47, 50]. Rituximab additionally exerts an effect on autoreactive T-cells in a less direct manner [51, 52].

The process of rituximab mediated B-cell depletion takes approximately 2–4 weeks, while B-cell repopulation occurs 5–6 months after infusion [14, 52–54]. With the destruction of the late pro-B-cells, new generations of immature B-cells replace the old, undergoing VDJ heavy chain arrangement and VJ light chain arrangement, which results in a novel antibody repertoire [53].

The loss of autoreactivity following treatment with rituximab is likely second to the changes in IgG reactivity against particular subdomains within Dsg3. Thus clinically, patients may maintain IgG antibodies against the ectodomain of Dsg3 despite treatment, yet these antibodies will not be pathogenic. As such, anti-Dsg1 IgG titers may be a more reliable marker of clinical status than anti-Dsg3 IgG [55].

Clinical Application

The efficacy of rituximab in the treatment of PV has been well documented through numerous large sized studies [13, 14, 56–60], with approximately 60–80 % of PV and PF patients experiencing complete remission [61–63]. Likewise, the use of rituximab in mucous membrane pemphigoid has additionally been well documented. Le Roux-Villet et al. demonstrated complete response in all affected sites in 68 % (17/25) of patients while Heelan et al. reported 75 % (6/8) patients to have a complete remission following a single cycle of rituximab [64, 65]. Fewer studies have been conducted in the other immunobullous disorders. In a review of 16 BP patients treated with rituximab, Shetty et al. demonstrated that 69 % of patients experienced complete remission, which remains comparable to that seen in PV and PF [66]. Likewise, numerous case reports have demonstrated successful clinical outcomes in patients with epidermolysis bullosa acquisita (EBA) treated with rituximab [67–75]. As EBA remains extremely rare with an estimated incidence of 0.2 per million per year [76], it is unlikely that larger studies will be possible. Despite the paucity of reported clinical outcomes in EBA patients treated with rituximab, efficacy appears comparable to that of other immunobullous disorders.

In contrast to the other immunobullous disorders, paraneoplastic pemphigus does not exhibit as consistent of a response to treatment, with most studies demonstrating only a marginal clinical improvement [77]. This is curious, as paraneoplastic pemphigus, like PF and PV, is an IgG mediated disease with numerous autoantibodies present. Additionally, paraneoplastic pemphigus most commonly occurs secondary to lymphoproliferative disorders, particularly non-Hodgkin lymphoma which is often responsive to rituximab on its own [77]. Thus, the effect of rituximab could be twofold by targeting the lymphoproliferative disease process while also leading to the destruction of B-cells before they develop into IgG autoantibody secreting plasma cells. Schadlow et al., however, presented a case that demonstrates that this may not be the case. They described a patient with long standing B-cell lymphoma who did not experience clinical improvement with rituximab [78]. It is thus possible that the length of time with the primary malignancy may affect the response to rituximab in paraneoplastic pemphigus. Nevertheless, paraneoplastic pemphigus is a complex disease that does not entirely follow the pathogenic steps seen in other immunobullous disorders.

Treatment Protocols

Standard treatment protocols for immunobullous disorders include the lymphoma protocol (375 mg/m^2 × 4 weeks) and the rheumatology protocol (1000 mg weekly × 2 weeks), with some less common protocols halving the dosage or duration of treatment. In one review by Zakka et al., patients treated with the lymphoma protocol demonstrated a slightly lower response rate with a higher mortality rate, yet a low rate of infection and relapse protocol than those patients receiving the rheumatology protocol [62]. Our analysis, however, demonstrated that patients responding to a single cycle of rituximab had a greater disease free period when treated with the lymphoma protocol rather than the rheumatology protocol. We additionally found the half rheumatology protocol (500 mg weekly × 2 weeks), to be the least efficacious of protocols, with a shorter time until relapse and fewer patients experiencing complete response [79]. Kanwal et al. likewise demonstrated this in a prospective blinded study comparing the full rheumatology protocol to the half rheumatology protocol [80]. Heelan et al. demonstrated success with a modified rheumatology protocol whereby patients receive 1 g on day 1 and 15, with 500 mg given at 6 month intervals when clinically necessary [60]. With this protocol, they achieved 89 % remission with or without adjuvant, and 28 % remission that did not necessitate adjuvant therapy. Nevertheless, treatment preferences vary widely between physicians and there still remains significant controversy regarding protocol selection [81].

Adjuvant therapies may additionally be used with these rituximab protocols, both during the initial cycle of rituximab and as maintenance. While more traditional immunosuppressants such as corticosteroids, azathioprine, mycophenolate and cyclophosphamide have been used, newer adjuvants such as immunoadsorption or IVIG have proven to be efficacious as well [13, 15].

Safety

The most common adverse reaction to rituximab is a mild transfusion reaction [82, 83], with more severe complications including cardiac toxicity and pulmonary toxicity [84, 85]. The most common associated adverse event remains infection. The risks of rituximab in the treatment of immunobullous disorders must, however, be compared to those associated with chronic steroid suppression and non-biologic

immunosuppressive medications. In a review of 153 pemphigus patients treated with rituximab, Feldman et al. demonstrated that only 7 % developed serious infections with 1.3 % fatalities [61]. Similarly, a large study of rituximab treatment for systemic lupus erythematosus (SLE) demonstrated a 9.5 % risk of serious infection [86]. However, in a large scale review of patients treated with rituximab for varying autoimmune disease, those with autoimmune blistering disease had a significantly greater mortality rate (10.4 % vs. 2.4 %) than those with other autoimmune diseases [84]. In contrast, an alternative study demonstrated the highest incidence of opportunistic infection in patients treated for SLE [87]. While the incidence of adverse events is reasonably a cause for concern, these values must be weighed against the risks of alternate therapies

Patients treated with corticosteroids demonstrated an 8 % incidence of mild to severe infections and patients treated with corticosteroids plus mycophenolate mofetil demonstrated a 21 % incidence of infection [88]. Interestingly, of the mucous membrane pemphigoid patients treated with rituximab, only those on concomitant immunosuppressants and high-dose corticosteroids experienced severe infectious complications [64]. As the classification of infection severity varies between individual studies, it remains challenging to truly compare the risks of infection in rituximab to traditional, non-biologic therapies.

Hepatitis B reactivation additionally remains a concern when starting a patient on rituximab. It is thus recommended to screen patients for hepatitis B before beginning therapy [89]. Chronic or high dosed systemic steroid therapy, however, also increases the risk of hepatitis B reactivation, though routine screening is not considered equally essential [90].

While IVIG has demonstrated efficacy in treating immunobullous disorders, it has also been suggested as a useful adjuvant to rituximab in decreasing the incidence of infections [13, 91]. While IVIG in theory repletes serum IgG at the time of B cell depletion, it is unclear how the two medications interact with each other, complement and the Fc receptor. Additionally, the use of IVIG in itself comes with certain risks ranging in severity from mild infusion reactions to aseptic meningitis [92].

Treatment Resistance

Resistance to rituximab can occur through the formation of anti-chimeric antibodies, as the murine sequences of the chimeric IgG_1 may contain immunogenic sequences. These anti-drug antibodies were more often observed in patients treated for autoimmune diseases rather than lymphoma. These anti-drug antibodies interfere with the ability of rituximab to bind to B-cells in vitro [93], leading to a decreased clinical response to treatment [94]. Additionally, these anti-drug antibodies are associated with the development of serum-like sickness and infusion reactions.

Fc receptor polymorphisms may additionally lead to treatment resistance by decreasing the affinity of receptor binding to IgG. For example, the FcγRIIIa polymorphism and FcγRIIa polymorphism are associated with a decreased response to rituximab in patients treated for lymphoma [95]. Similar findings were seen in SLE, where the FcγRIIIa polymorphism was predictive of decreased treatment efficacy, with a tenfold increase in rituximab serum level necessary to achieve comparable B-cell depletion. While these polymorphisms have known effects in other disease processes such as lymphoma and SLE, it is unclear what effect they have in immunobullous disorders. For example, while the spliced mRNA transcript of CD20 (D393-CD20) has been associated with treatment resistance in lymphoma patients, this transcript was not associated with treatment failure in patients with pemphigus [96].

The presence of central memory cells occupying the bone marrow compartment as well as long-lived B memory may lead to a decreased response to treatment, as these are not viable targets for rituximab [97]. This is consistent with our finding that an increase in the duration of disease was associated with a decrease in clinical response to treatment in patients with PV and PF treated with rituximab [79]. Lunardon et al. likewise found that patients treated with rituximab earlier in the course of the disease had better outcomes [58].

Relapse

Despite its immediate effectiveness in a majority of patients, rituximab does not necessarily appear to alter the long-term relapse rate [55]. In fact, in one large retrospective study of 92 pemphigus patients, 61 % of patients relapsed following a single cycle of the rheumatology protocol, with a mean duration of 15 months [60]. Interestingly, patients who required adjuvant immunosuppression experienced relapse sooner than those only receiving rituximab. We did not, however, find a correlation between adjuvants used and time to relapse [79]. Studies in mucous membrane pemphigoid have additionally demonstrated significant relapse rates necessitating further cycles in a fairly short period of time [65, 98].

Relapse rates may, however, be tied to the underlying genetic aberrations leading to clinical disease. For example, following multiple treatments with rituximab over an extended course of time, patients no longer express anti-Dsg3 B-cell response. Once this lineage of B-cells is successfully removed from the patient's immune repertoire, clinical disease ceases [99]. Likewise, there is an increase in the expression of the VH1-46 mutation in pemphigus patients, a

mutation of a gene involved in heavy chain VDJ recombination. This mutation leads to Dsg3 autoreactivity with few to no mutations necessary [100]. Thus in these patients, rituximab may not effectively prevent relapse, as new anti-Dsg-3 clones will simply reform following B-cell depletion.

Certain therapeutic options may exist to increase the length of time until relapse such as immunoadsorption [79] or minimal maintenance therapy. The use of intermittent rituximab following an initial cycle has proven controversial. Gregoriou et al. showed that purely prophylactic rituximab given 6 months following the initial rituximab cycle was ineffective in preventing relapse in pemphigus patients [101]. In cases of impending relapse however, Cianchini et al. demonstrated that repeated cycles of rituximab sufficiently mitigated clinical relapses without necessitating the use of concomitant immunosuppression [59].

Questions

1. What is the most common adverse reaction occurring with rituximab administration?
   A. Mild transfusion reactions

2. Does rituximab directly deplete plasma cells?
   A. No. It destroys pre-B-cells and mature B cells which eventually develop into plasma cells, but it has no direct effect on plasma cells or stem cells

3. What are the two most common dosing protocols for rituximab in the treatment of immunobullous disease?
   A. The lymphoma protocol (375 mg/m^2×4 weeks) and the rheumatology protocol (1000 mg weekly×2 weeks)

Topical Immune Response Modifiers: Adjuvants

45

Annemarie Uliasz and Mark G. Lebwohl

Abstract

Imiquimod and ingenol mebutate are topical treatments widely utilized for their anti-tumor effects on actinic keratosis (AK). In addition to their anti-tumor effects, both topical medications are reported to be effective as off-label alternatives to treat various viral, inflammatory, and malignant skin conditions.

Imiquimod is a topical immune modulator approved for the treatment of actinic keratoses, anogenital warts, and superficial basal cell carcinomas. Imiquimod exhibits anti-viral and anti-tumor effects by stimulating both the innate and adaptive immune responses via toll-like receptors (TLR). TLRs on antigen presenting cells induce the production of T-helper-1 cytokines leading to malignant cell death. The dosage, application, and duration depend on the condition being treated. The medication is largely well-tolerated, with application site reactions expected.

Ingenol mebutate is derived from the sap of the Euphorbia peplus plant. It has a dual mechanism of action comprised of initial rapid cell death followed by an acute inflammatory response. It is available as a topical gel and is administered over 2–3 days and has a favorable safety profile, making it an appealing alternative to other spot and field therapies.

Keywords

Imiquimod • Ingenol mebutate • Actinic keratosis • Toll-like receptors • Protein kinase C Field therapy

Key Points

- The topical immune response modifier imiquimod is a low molecular weight heterocycline imidazoquinoline amine
- Imiquimod stimulates both the innate and the acquired arms of the immune system via induction of T-helper-1 cytokines
- Imiquimod is Food and Drug Administration approved for the treatment of anogenital warts, as well as actinic keratoses and superficial basal cell carcinomas

Introduction

Imiquimod (Aldara™, 3M Pharmaceuticals; Zyclara™, Valeant), a low-molecular-weight heterocyclic imidazoquinoline amine, is a topical immune modulator that stimulates both the innate and the acquired arms of the immune system. Initially discovered when screening medications for anti-herpes virus activity [1], imiquimod is FDA-approved for the treatment of external anogenital warts, superficial basal cell carcinoma, and actinic keratoses. Various case reports and preliminary studies have also suggested imiquimod may be effective in the treatment of a wide range of other infectious, inflammatory, and malignant skin conditions.

Imiquimod offers a non-invasive and tissue-sparing alternative to treatments commonly used for warts or cutaneous tumors such as cryotherapy, electrocautery, surgical excision, laser ablation, trichloroacetic acid, and podofilox. For those individuals who are poor surgical candidates, refuse surgery, or whose anatomic site is not amenable, imiquimod is an effective option. As compared to destructive techniques, imiquimod offers an improved safety profile as local cytokine production decreases potential for systemic adverse events. Additionally, imiquimod is less damaging to tissue, resulting in a superior cosmetic outcome. This is especially desirable in the treatment of lesions situated in cosmetically sensitive sites including the face, as well as in patients in which healing from surgical sites is of particular concern. Furthermore, the ease of topical application allows patients to self-treat which may result in decreased cost and avoidance of multiple clinic visits.

Mechanism of Action

Imiquimod enhances the patient's immune response, stimulating both the innate immune response and the cellular arm of acquired immunity, with resultant anti-viral and anti-tumoral effects.

The innate immune response is stimulated via activation of antigen presenting cells (APCs) including monocytes, macrophages, and dendritic cells, and the subsequent release of cytokines and chemokines. Imiquimod produces an innate immune response via its action as a toll-like receptor (TLR) agonist. Toll-like receptors are a family of pattern recognition receptors found on the cell surface of APCs. Specifically, imiquimod binds to TLR-7 [2] and TLR-8 [3].

TLR-7 activation by imiquimod triggers a MyD88-dependent signaling cascade [2]. MyD88, a protein that associates with TLRs, acts to recruit protein kinases and transcription factors, resulting in activation of nuclear factor-kβ (NF-kβ). NF-kβ is a transcription factor that, upon activation, migrates to the nucleus and up-regulates the production of local pro-inflammatory cytokines, particularly interferon (IFN)-α, IFN-β, IFN-γ, tumor necrosis factor (TNF)-α, and interleukin-12 [4].

The IFN-α produced by APCs induces CD4+ T-cells to produce the IL-12β2 receptor. The binding of IL-12 to the IL-12β2 receptor induces the secretion of IFN-γ from naïve T cells, resulting in a Th1 immune response. Conversely, imiquimod suppresses a T helper cell type 2 (T_h2) immune response by inhibiting IL-4 and IL-5 [5].

Studies have described the effects of imiquimod on Langerhans cells, the major antigen presenting cells of the skin [6]. Imiquimod enhances the migration of Langerhans cells from the skin to regional lymph nodes, potentially enhancing viral and tumoral antigen presentation to naïve CD4+ T-cells. This results in differentiation of naïve T-cells into memory and activated T-cells. Upon return to the dermis, the activated T-cells produce the T_h1 cytokines IFN-α, IFN-γ, and TNF-α. These cytokines are responsible for imiquimod's anti-viral and anti-tumoral effects.

Additionally, imiquimod has been shown to produce apoptosis via circumnavigating mechanisms developed by malignant cells to resist apoptosis signals. One way imiquimod activates apoptosis is via activation of membrane-bound death receptors. For example, imiquimod induces Fas (CD95) receptor (FasR)-mediated apoptosis in basal cell carcinoma cells [7]. Fas, a member of the tumor necrosis receptor family, is a death receptor that mediates apoptosis via CD95 receptor-CD95 ligand (Fas-L) interaction. FasR expression is normally absent on BCC cells, allowing tumors to avoid apoptotic signaling. The IFN-α produced by imiquimod induces BCC cells to express FasR.

Another way in which imiquimod induces tumor-selective apoptosis is via the mitochondrial pathway of apoptosis. Imiquimod induces a Bcl-2-dependent translocation of cytochrome c from the mitochondria to the cytosol [8, 9]. This, in turn, leads to activation of caspase-9 and caspase-3 and a subsequent proteolytic cascade resulting in cell death.

Finally, it has been postulated that imiquimod may exert a therapeutic effect at distant sites located between the

application site and the regional lymph nodes via travel of immune cells through the lymphatics [10].

Dosage and Administration

Imiquimod, an off-white, fine crystalline solid, is chemically known as 1-(2-methylpropyl)-1*H*-imidazo[4,5-c]quinolin-4-amine ($C_{14}H_{16}N_4$). The molecular weight of imiquimod is 240.3. Each gram of cream contains 50.0 mg, 37.5 mg, or 25 mg of imiquimod in an off-white, oil-in-water vanishing base consisting of isostearic acid, cetyl alcohol, stearyl alcohol, white petrolatum, polysorbate 60, sorbitan monostearate, glycerin, xantham gum, purified water, benzyl alcohol, methylparaben, and propylparaben.

Imiquimod cream 5 % may be applied to an area of 25 cm^2 while the 3.75 % and 2.5 % formulations may be applied to a larger surface area, 200 cm^2. Imiquimod is supplied in individual 250 mg sachets as well as in pump bottles that dispense a similar amount. Although package inserts specify that a new sachet be opened for each application, one sachet may evenly cover an area of skin up to 386 cm^2 [11]. Imiquimod should be applied in a thin layer extending 1 cm beyond the affected area. Areas treated with imiquimod should not be occluded. Imiquimod should be left on the affected area for approximately 8 h. The frequency of application and duration of therapy depends on the condition being treated.

Safety

Imiquimod is contraindicated in those individuals with hypersensitivity to any of its ingredients. Additionally, it should not be applied in areas of dermatitis as it has been known to exacerbate inflammatory conditions such as pemphigus, psoriasis, and aphthous ulcers.

Despite case reports of imiquimod use during pregnancy without adverse effects on the fetus, at this time, there is insufficient data on the safety of imiquimod in pregnancy to make definitive conclusions [12]. Imiquimod is pregnancy category C. It is unknown if imiquimod is excreted in the breast milk of lactating women.

Application sight reactions (erythema, dryness, edema, crusting, weeping, erosion, ulceration, burning, pruritus, and pain) may occur after application of imiquimod cream. Local skin reactions, well-tolerated by most patients, are considered a normal and expected part of treatment with imiquimod, and are a good predictor of therapeutic efficacy. The intensity of these reactions tends to increase as dosing frequency increases, and rest periods may be required by some patients. Cool compresses, emollients, and topical antibacterials may provide symptomatic relief. Topical corticosteroids, however, should be avoided as they may blunt the therapeutic effect by impairing the immunologic reaction [13]. Systemic signs and symptoms such as malaise, nausea, myalgias, fever, and rigors may accompany local inflammatory reactions.

Approved Clinical Uses

External Genital Warts

Anogenital warts, or condyloma accuminata, are a clinical manifestation of a human papilloma virus (HPV) infection. The human papilloma virus, a non-enveloped double-stranded DNA virus, is classified into more than 100 types reflecting different oncogenic properties as well as tissue tropism. Anogenital warts are often difficult to eradicate, and most therapies involve lesional destruction. Although lesional destruction results in immediate elimination, these procedures are painful and recurrence is common, necessitating repeated treatment. Imiquimod, a non-destructive, patient-applied alternative, is unique in that it may be applied in the privacy of the patient's home, decreasing the number of office visits. More importantly, imiquimod reduces the viral load, thereby decreasing the rate of recurrence.

Imiquimod, in concentrations of 5 % and 3.75 %, is FDA-approved for the treatment of external anogenital warts in immunocompetent patients over the age of 12 years old. Imiquimod 5 % is applied once a day on alternating days three times per week until resolution of warts or for up to 16 weeks. Imiquimod 3.75 % is applied once a day until clearance or for up to 8 weeks. Frequency of application may be adjusted according to the local irritation experienced by patients [14]. Those experiencing minimal local irritation, may increase the efficacy by increasing the frequency of application, while those experiencing uncomfortable irritation may decrease the frequency of application.

In the treatment of warts, the efficacy of imiquimod appears to result from the reduction of HPV itself. In a randomized, controlled molecular study in which tissues were analyzed for HPV DNA and mRNA of several cytokines, both a local increase in interferon and a significant reduction in viral load were observed in skin biopsies taken from patients during and following imiquimod treatment [4]. The increased cell-mediated immunity provided by imiquimod results not only in control or reduction of HPV infection, but also long-term protection from recurrence and reinfection [4].

Several studies have demonstrated the safety and effectiveness of imiquimod 5 % cream for the treatment of external anogenital warts. Randomized, double-blind, placebo-controlled trials examining imiquimod 5 % used three times weekly for 16 weeks resulted in complete clearance in approximately 50 % of subjects [15, 16]. Females were noted to have significantly higher response rates. This

difference was attributed to the semi-occlusive effect of the foreskin as well as a higher degree of keratinization of penile skin compared to vulvar skin, the most common sites for genital warts in men and women.

Imiquimod 3.75 %, while demonstrating efficacy in the treatment of anogenital warts, offers an enhanced tolerability profile and shorter treatment course in comparison to imiquimod 5 %. The combined results from two randomized, placebo-controlled studies involving 534 women demonstrated that imiquimod 3.75 % cream applied once daily until clearance or for up to 8 weeks resulted in complete clearance of all warts in 36.6 % of subjects as compared to 28.3 % in imiquimod 2.5 % and 14.2 % in placebo at 16 weeks from baseline [17].

Actinic Keratoses

Actinic keratoses (AK) are precancerous skin lesions frequently occurring on sun-exposed areas of fair-skinned individuals, becoming more prevalent with advanced age. They are precursors to squamous cell carcinoma. Topical therapies are useful alternatives to cryotherapy and excisional surgery for treating areas of diffuse actinic keratoses. Furthermore, unlike surgical or ablative treatments, imiquimod possesses the unique capacity to uncover and treat sub-clinical lesions. Imiquimod, in concentrations of 5 %, 3.75 %, and 2.5 %, is FDA-approved for the treatment of facial and scalp actinic keratoses in immunocompetent adults. Imiquimod 5 % cream is FDA approved for twice weekly application for 16 weeks, but many variations from this schedule also have been shown to be effective. Imiquimod at concentrations of 3.75 % and 2.5 % is applied once daily for two 2 week treatment cycles separated by a 2 week no-treatment period.

Several clinical studies have been performed evaluating the safety and efficacy of imiquimod 5 % cream for the treatment of AKs. Persaud et al. initially reported the use of topical imiquimod 5 % cream for the treatment of actinic keratoses on the scalp of three individuals [18]. One subject was treated three times weekly for 4 weeks with nearly complete resolution of actinic keratoses accompanied by a marked inflammatory response. Two other subjects treated one half of their scalp with imiquimod, using the other half as comparison. After 8 weeks of two to three times weekly application with frequent rest periods to avoid inflammation, marked reductions in actinic keratoses were noted. These patients then continued to use imiquimod cream on both sides of the scalp two times per week for an additional 9 months. Treatment was well-tolerated and subsequent reduction in lesions was noted.

Persaud et al. conducted another study in which 22 subjects with at least six bilateral actinic keratoses applied imiquimod or placebo three times a week for 8 weeks [19]. If necessary, a 3 week rest period was allowed, followed by a subsequent reduction in dose frequency. Upon evaluation 8 weeks following treatment, average AK counts were significantly decreased in subjects treated with imiquimod compared to placebo-treated subjects. Of note, 53 % of the subjects required rest periods with 18 % of the subjects requiring two rest periods.

A meta-analysis including five placebo-controlled randomized studies was performed examining the treatment of actinic keratoses of the head and scalp with twice weekly imiquimod 5 % application for 12–16 weeks [20]. Complete clearance was observed in 50 % of subjects receiving imiquimod as compared to 5 % in the vehicle groups. Of note, twice weekly dosing versus three times weekly dosing was associated with less local skin reactions, less rest periods, and less subjects discontinuing treatment due to local skin reactions [21].

Trials have been performed to identify treatment regimens that optimize efficacy while reducing local skin reactions. Several studies have examined imiquimod used in a cyclical regimen for the treatment of actinic keratoses. An open-label pilot study by Salasche et al. examined imiquimod used in a cycle regimen for the treatment of actinic keratoses [22]. Discrete areas containing 5–20 AKs were selected for treatment. Twenty-five patients with 33 treatment areas participated. Imiquimod was applied to the entire treatment area three times a week for 4 weeks followed by a rest period of 4 weeks. If AKs in the treatment area were still present, this cycle was repeated up to three times. Of the 22 patients with 30 treatment areas that completed the study, total clearance of AKs was seen in 46 % of the treatment areas after the first cycle and in 82 % of the treatment areas after the second cycle. Four patients required rest periods prior to the scheduled 4-week rest period.

Several subsequent randomized, double-blind, placebo controlled studies have examined the safety and efficacy of this cyclical regimen which is currently approved for use in Europe [23–25]. Complete clearance rates ranged from 26.8 to 40.5 % after one 4-week treatment course, while a second course resulted in rates ranging from 53.9 to 68.9 %. One of the studies found that recurrence rates at a 1-year follow-up visit for imiquimod and placebo were 39 % and 57 % respectively [25].

Further exploration of the optimal dosing schedule lead to a study by Zeichner et al. which evaluated the safety and efficacy of once weekly imiquimod 5 % for 6 months (24 weeks) for the treatment of actinic keratoses on the face and scalp in 20 patients [26]. Although the treatment regimen was tolerable with minimal side effects and, in turn, enhanced compliance, the complete clearance rate was 6.7 %, significantly lower than currently approved treatment regimens.

Long-term efficacy of imiquimod 5 % has been evaluated in a study by Lee et al. [27]. One and a half years following the completion of four phase III studies in which patients applied imiquimod either two or three times weekly for 16

weeks, recurrence rates of approximately 25 % (twice weekly application) and 43 % (three times weekly application) were noted.

A long-term follow-up study by Stockfleth et al., in which the initial clearance rate of actinic keratoses treated with imiquimod 5 % three times weekly for 12 weeks was 84 %, demonstrated that 2 years later, the clearance rate was 80 % [28].

Seeking to enhance the tolerablilty and simplify the treatment regimen of imiquimod, two randomized, double-blind, placebo controlled studies involving 490 subjects with 9–10 AKs were conducted to evaluate the efficacy and safety of imiquimod 2.5 % and 3.75 % creams [29]. Subjects were randomized to receive either imiquimod (2.5 % or 3.75 %) or placebo applied daily to the entire face or balding scalp for two 3 week treatment courses, separated by one 3 week no-treatment interval. Complete and partial (greater than 75 % lesion reduction) rates were 5.5 % and 12.8 % (placebo), 25.0 % and 42.7 % (imiquimod 2.5 %), and 34.0 % and 53.7 % (imiquimod 3.75 %).

In a companion study (479 subjects) evaluating 2 week treatment cycles, complete and partial clearance (greater than 75 % lesion reduction) rates were 6.3 % and 22.6 % (placebo), 30.6 % and 48.1 % (imiquimod 2.5 %), and 35.6 % and 59.4 % (imiquimod 3.75 %) [30]. While these results were comparable to those reported in the previous study evaluating 3 week treatment courses, the 2 week treatment course regimen demonstrated enhanced tolerability with more than 90 % of subjects complying to their treatment regimens.

In contrast to other topical treatments for AKs, imiquimod has been shown to be more effective and produce a less severe local skin reaction than 5-fluorouracil (5-FU). A meta analysis comparing the efficacy of 5-FU and imiquimod in the treatment of actinic keratosis was performed involving ten studies [31]. Results demonstrated average efficacy rates of 52 % for 5-FU and 70 % for imiquimod.

Superficial Basal Cell Carcinoma

Arising from the basal layer of the epidermis, basal cell carcinoma (BCC) is the most common malignancy among Caucasians worldwide [32]. The three most common subtypes are nodular, superficial (sBCC), and morpheaform. Although metastases are rare, BCCs are locally invasive, aggressive, and destructive to the skin and surrounding structures. Treatment is predominantly surgical, consisting of excision, cryosurgery, curettage and electrodessication, and Mohs micrographic surgery. Although surgery offers a high cure rate, imiquimod is an effective alternative and should be considered in cases where patients are poor surgical candidates or cosmetic outcome is a concern.

Imiquimod 5 % is FDA-approved for the treatment of biopsy-confirmed superficial basal cell carcinoma in immunocompetent adults when surgical methods are less appropriate and when patients may be reliably monitored. Imiquimod 5 % is applied five times per week for 6 weeks. Studies have shown that occlusion does not yield a statistically significant effect on the efficacy of imiquimod [33].

Numerous trials evaluating the safety and efficacy of imiquimod 5 % cream for the treatment of sBCCs have been performed. A randomized, double-blind pilot study by Beutner et al. involving 35 patients demonstrated the safety and efficacy of imiquimod for the treatment of BCC [34]. The study examined five different treatment regimens, each lasting up to 16 weeks. Outcomes were evaluated clinically and histologically. Of the subjects receiving imiquimod, 83 % experienced complete clearing of their lesions. Complete resolution of nodular and superficial BCCs was seen in all subjects receiving twice daily, once daily, or three times weekly treatment with imiquimod. Of note, once-daily dosing was more effective than less frequent dosing. Resolution was seen in 60 % of those treated twice weekly, in 50 % of those treated once weekly, and in 9 % of those treated with placebo.

A phase II, open-label, randomized trial involving 99 patients reported a clinical and histological clearance rate of superficial basal cell carcinomas in 100 % in subjects treated with twice daily imiquimod for 6 weeks and 88 % in those treated with once daily imiquimod for 6 weeks [35]. Clearance rates for twice daily treatment three times per week and once daily three times per week treatment for a duration of 6 weeks were 73 % and 70 %, respectively. Although patients in a twice daily regimen arm achieved 100 % resolution, the local skin reactions were unacceptable.

Another phase II randomized, double-blind, vehicle-controlled study involving 128 subjects with sBCC examined longer treatment regimens [36]. Subjects received imiquimod or placebo in one of four dosing regimens lasting 12 weeks: twice daily, once daily, five times per week, or three times per week. Clearance rates of 87.1 % and 80.8 % were observed in those subjects who used imiquimod once daily and five times per week, respectively. Those who treated their tumors three times a week experienced 51.7 % clearance while those in the placebo group displayed a clearance rate of 18.8 %. Due to severe local skin reactions in those who used imiquimod twice daily, the safety profile of this regimen was not considered acceptable. Histological clearance rates for 12 weeks of treatment compared to the clearance rates seen following 6 weeks of treatment in previous studies proved to be similar, suggesting that an additional 6 weeks of treatment may be unnecessary.

Two phase III double-blinded, placebo-controlled studies involving 724 patients with primary superficial basal cell carcinoma were performed [37]. Subjects with one sBCC were treated with placebo or imiquimod 5 % cream once daily either five or seven times per week for 6 weeks. Upon evaluation 12 weeks post-treatment, 75 % of those using imiquimod five times weekly and 73 % of those using imiquimod seven times weekly subjects experienced both

histological and clinical clearance compared to 2–3 % of subjects treated with placebo. As the difference of clearance rates between the two imiquimod dosing regimens was not clinically significant, the authors recommended the five times per week dosing regimen.

A study by Marks et al., examined the safety and efficacy of imiquimod 5 % for the treatment of multiple sBCC's [38]. Sixty-seven adults (208 histologically confirmed tumors total) with 2–6 sBCCs each located on the neck, trunk, extremities were treated with imiquimod 5 % either five or seven times per week for 6 weeks. Histologic clearance was noted in 77 % of tumors with a lower rate of clearance observed in lesions located on the lower limbs as compared to the rest of the body.

A long-term open-label study evaluating the clinical recurrence of sBCC after treatment with imiquimod daily seven times per week for 6 weeks demonstrated an initial clearance rate of 94 % [39]. Five years following treatment, the estimated sustained clearance was 85.4 % [40].

In a similar long-term study performed in Europe, subjects used imiquimod once daily five times per week for 6 weeks for the treatment of sBCC. Initial clearance rates were reported to be 90 % at 12 weeks post-treatment. Five years following treatment, 86.9 % demonstrated an overall clearance success rate with histologic clearance in 81 % [41].

Imiquimod has also been found to be beneficial as an adjunct to the surgical removal of BCCs. Use of imiquimod 5 days per week for 2–6 weeks before Mohs excision of BCC has been reported to significantly reduce the size of the tumor, thereby resulting in a smaller cosmetic defect from the surgery [42].

Off Label Uses

Infectious Conditions

Molluscum Contagiosum

Molluscum contagiosum is a common cutaneous tumor caused by the double-stranded DNA pox virus. Although this infection is often self-limited in immunocompetent patients, patients commonly chose to treat this condition as lesions may be numerous. Current treatment modalities include cryotherapy, curettage, electrodessication, and application of trichloroacetic acid or cantharidin. Imiquimod's anti-viral and anti-tumoral properties may offer an effective alternative.

Several case reports have been published demonstrating eradication of molluscum contagiosum in both pediatric and adult populations [43]. In an open-label study involving 15 subjects, imiquimod 5 % cream was applied once daily five times per week for 16 weeks. Results demonstrated complete clearance in 80 % of the subjects [44]. Furthermore, there are reports of immunosuppressed individuals with molluscum contagiosum responding to imiquimod treatment [45]. Although several case reports and a small double-blind, randomized, vehicle-controlled pilot study [46] have suggested that imiquimod is effective in the treatment of molluscum contagiosum, two unpublished randomized, double-blind, vehicle-controlled trials involving 702 children (ages 2–12 years) in which imiquimod 5 % or vehicle was applied three times weekly for up to 16 weeks failed to demonstrate efficacy [47].

Herpes Simplex Virus 2

Genital herpes is a chronic sexually transmitted infection of the herpes simplex virus 2 (HSV-2). Imiquimod has been reported to be a successful alternative treatment in resistant cases.

A case of a 34 year old, HIV positive man with herpes simplex 2 virus infection resistant to acyclovir, famiciclovir, and valacyclovir has been reported in which imiquimod 5 % cream was used three times in 1 week [48]. Following imiquimod application, the lesions improved with no recurrence at 1 month post-treatment.

Martinez reported the case of a 37 year old, HIV positive man with a recurrent anogenital HSV-2 infection despite daily suppressive therapy with acyclovir or valacyclovir [49]. He was treated with imiquimod 5 % cream three times the first week and then two times the following week. Two weeks later, the skin lesions improved and HSV-2 detection by culture and PCR remained negative. Twelve months post-treatment, during which time the patient did not use suppressive therapy, no recurrence was observed.

In addition, there are case reports of successful treatment with imiquimod 5 % cream of HSV-2 resistant to both foscarnet and acyclovir [50].

In regard to recurrence rates of HSV-2, however, imiquimod has not demonstrated benefit in controlled studies. A double-blind, randomized, placebo-controlled trial examining the effect of imiquimod 5 % on recurrence rates of HSV-2 was performed [51]. Subjects with six or more HSV-2 outbreaks per year were randomized to apply placebo or imiquimod to the affected area once, twice, or three times weekly for 16 weeks for each recurrence. No significant difference in recurrence rates between placebo and imiquimod was found.

Cutaneous Warts

Common warts (caused by HPV types 2, 4, and 7) as well as flat warts (caused by HPV types 3 and 10) also appear to respond to imiquimod treatment. An open-label study using imiquimod 5 % cream once daily 5 days per week for up to 16 weeks for the treatment of common warts

resulted in complete clearance in 56 % of the subjects [44]. After approximately 9 weeks of treatment, wart size was found to be reduced greater than 50 %. At a 32-week follow-up evaluation, no recurrence of treated warts was observed.

An open-label trial evaluating the efficacy of imiquimod in the treatment of recalcitrant subungual and periungual warts has been conducted [52]. Salicylic acid was initially applied to the lesions to reduce hyperkeratosis and optimize imiquimod penetration. Imiquimod 5 % cream was then applied once per day five times per week for 16 weeks. Results showed that 80 % (12/15) of the subjects experienced complete resolution after an average of 3 weeks of treatment.

Another open-label study in which patients with recalcitrant plantar warts or periungual warts were treated with imiquimod 5 % cream daily under occlusion for 4 weeks resulted in complete clearance in 8/10 subjects [53].

Case reports have also detailed efficacy in the treatment of flat warts [54, 55]. A case report of a 21 year old, healthy woman with numerous flat warts of the forehead recalcitrant to topical retinoids, 5-fluorouracil, cryotherapy, and oral cimetidine documented subsequent complete clearance after 3 weeks of imiquimod 5 % cream applied three times a week [56].

Imiquimod has also proven beneficial in the treatment of recalcitrant warts in individuals with HIV [57–60].

Leishmaniasis

Leishmaniasis is a parasitic infection seen in developing countries. It is transmitted to humans through the bite of infected sandflies. Cutaneous leishmaniasis, the most common form of the disease, manifests as skin lesions at the infection site which may last for months to years. In animal studies, imiquimod was observed to stimulate leishmanicidal activity in macrophages [61].

Although not sufficiently effective as a monotherapy, imiquimod may offer benefit in the treatment of cutaneous leishmaniasis when used in conjunction with meglumine antimonate [62], and may provide enhanced cosmesis of the healing lesions [63].

Oncologic Conditions

Nodular Basal Cell Carcinoma

Compared to superficial basal cell carcinoma, nodular basal cell carcinoma tends to extend deeper into the dermis. Studies evaluating the efficacy of imiquimod on this subtype of basal cell carcinoma have shown varying results.

Two multi-center, randomized, dose response studies were performed evaluating four different dosing regimens for either 6 or 12 weeks [64]. Subjects in the 6 week open-label study were randomized to apply imiquimod either once or twice daily for 3 or 7 days per week. Those in the 12 week placebo-controlled study were randomized to apply imiquimod or vehicle once daily for 3, 5, or 7 days per week or twice daily for 7 days per week. Results demonstrated that dosing once daily 7 days per week resulted in the highest clearance rates: 71 % in the 6 week study and 76 % in the 12 week study. These results, although statistically significant do not approach the clearance rates seen in the treatment of superficial basal cell carcinoma. The difference may be attributable to the fact that nodular tumors tend to be denser and extend deeper into the dermis as compared to superficial tumors.

Another open-label study in which 15 subjects with nBCC were treated with imiquimod three times per week for 12 weeks yielded complete clearance in 100 % of the subjects [65].

A phase III, randomized, open label study involving 90 patients in which imiquimod 5 % was applied three times a week for 8 and 12 weeks showed only modest improvement in small nBCC's (<1 cm) with residual tumor present in more than one third (36 %) of treated lesions. There was no significant difference noted between the two treatment arms [66].

Although not as effective as the treatment of sBCC's, imiquimod may offer benefit in the treatment of nBCC when paired with other treatment modalities. A preliminary study in which imiquimod cream was used once daily for 1 month following curettage and electrodessication (C&D) of BCC resulted in a reduced frequency of residual tumor as well as an improved cosmetic outcome when compared to C&D alone [67]. Another study examined the use of imiquimod 5 % for 4 weeks prior to Mohs surgery for nBCC's located on the face [68]. The use of imiquimod significantly reduced the tumor size and subsequent surgical defect.

Basal Cell Nevus Syndrome

Basal cell nevus syndrome is an autosomal dominant disorder that, in addition to various systemic abnormalities, manifests with multiple BCCs. The successful treatment of both superficial and nodular basal cell carcinomas in the setting of basal cell nevus syndrome with imiquimod has been documented with nodular BCCs requiring more frequent dosing and a longer duration of treatment [69–74]. Imiquimod appears to offer an appealing alternative to multiple surgical excisions for people with BCNS.

Lentigo Maligna and Malignant Melanoma

Lentigo maligna is the in situ form of malignant melanoma. If left untreated, it may progress to invasive melanoma. Imiquimod may offer benefit in lentigo maligna or metastatic melanoma as an adjuvant therapy or when

surgery or radiotherapy is not a viable option. Numerous case reports and uncontrolled studies have detailed efficacy of imiquimod using various treatment regimens and with limited follow-up periods [75–90]. Close follow-up is warranted with multiple post-treatment biopsies given the possibility of recurrence or progression to invasive disease [91–94].

An open-label study involving 30 patients with lentigo maligna was conducted in which imiquimod was applied once daily for 3 months. One month following treatment, 93 % of subjects experienced complete histological and clinical clearance [95].

Another study examined the efficacy of imiquimod 5 % cream in the treatment of biopsy-proven lentigo maligna of the face in 12 subjects [96]. Imiquimod was applied three times a week for 6 weeks. If no inflammatory response occurred, the frequency of use was increased to daily application. Ten of the patients demonstrated histologic clearance with no relapse at a 6 month follow-up visit.

Cases of disseminated metastatic melanoma successfully treated with imiquimod 5 % cream have also been reported [97–105], and although the prognosis of metastatic melanoma is poor, imiquimod may offer benefit as an adjunctive or palliative treatment. A subject with history of melanoma involving the right knee presented with metastasis to the right lower leg [100]. After the metastases were treated with carbon dioxide laser ablation, new lesions appeared and were subsequently treated with imiquimod 5 % cream three times per week. Clinical and histological clearance was seen after 4 months, and no recurrence was observed after 15 months.

Xeroderma Pigmentosa

Xeroderma pigmentosa is an autosomal recessive disease characterized by defects in DNA repair. Exposure to sunlight results in a 1000-fold increase in the development of skin cancers. Several case reports have found benefit in the use of imiquimod for the treatment of active cutaneous neoplasms in these individuals while reducing the development of new lesions [106–110].

Squamous Cell Carcinoma In Situ and Invasive Squamous Cell Carcinoma

Several case reports have shown promise in the treatment of both in situ and invasive squamous cell carcinomas with imiquimod 5 % cream [111–119]. In the case of involvement of anatomic areas such as the genitalia that prove challenging for surgical treatment, imiquimod may offer an appealing alternative to surgery.

In a phase II, open-label study, imiquimod was applied once daily for 16 weeks for the treatment of Bowen's disease on the legs and shoulders of 15 subjects [120]. Sixteen weeks post-treatment, clearance rate of 93 % were observed.

A randomized, double-blind, placebo-controlled trial involving 31 subjects, revealed that those receiving imiquimod 5 % cream daily for 16 weeks resulted in 73 % resolution of cutaneous SCC in situ with no relapse during a 9 month follow-up period [121].

An open-label study examined the use of imiquimod 5 % cream used once daily five times per week for a maximum of 16 weeks in subjects who were unsuitable surgical candidates [122]. Following 8–12 weeks of treatment, complete clinical and histological resolution was observed in 4/5 Bowen's disease lesions and 5/7 invasive SCCs.

Although benefit has been observed, further studies are necessary to fully establish the efficacy and safety of imiquimod for the treatment of in situ and invasive squamous cell carcinoma.

Cutaneous T-Cell Lymphoma

Cutaneous T-cell lymphoma manifests as patches or plaques in early stages to tumors and erythroderma in advanced stages. Several case reports document successful treatment of limited patch and plaque stage mycosis fungoides with imiquimod 5 % cream [123–125].

A preliminary open-label pilot study involving six subjects was performed to evaluate the use of imiquimod in the treatment of patch and plaque stage mycosis fungoides when applied three times per week for 12 weeks [126]. Results demonstrated a histological and clinical response rate of 50 %.

Kaposi's Sarcoma

A case report describes resolution of HIV-related Kaposi's sarcoma following daily application of imiquimod 5 % cream for 4 months [127].

Imiquimod has also been examined in the treatment of classic or endemic Kaposi's sacroma in HIV-negative individuals [128]. A phase II, open-label trial evaluated the efficacy and safety of imiquimod 5 % cream applied under occlusion three times a week for 24 weeks in 17 subjects. Two subjects experienced complete resolution and six subjects had partial clearance [129].

Other Dermatologic Conditions

Keloids and Hypertrophic Scars

Keloids are hypertrophic scars that grow outside of the original borders of an injury. They represent an exaggerated, proliferative healing response. Current treatment includes intralesional corticosteroids, laser therapy, and cryosurgery.

Case series have found imiquimod 5 % cream to be effective in prevention of keloid recurrence on the earlobe when applied following surgical excision via tangential shave technique [130–132].

One pilot study demonstrated that 24 weeks following the application of postoperative imiquimod 5 % cream nightly for 8 weeks to 13 keloids excised surgically from the earlobes and back of 12 patients, none recurred at 24 weeks post-surgery [133].

Another study evaluated the use of imiquimod 5 % cream in the prevention of hypertrophic scarring following breast surgery [134]. In this double-blind, randomized, placebo-controlled trial involving 15 subjects, imiquimod was applied over the scar once every 3–4 days for 8 weeks. Twenty-four weeks after the surgery, the imiquimod treated scars were noted to have improved color and elevation when compared to placebo.

Subsequent studies, however, failed to demonstrate significant efficacy of imiquimod in prevention of recurrence of keloids on the trunk [135–137].

Porokeratosis of Mibelli

Porokeratosis of Mibelli is a disorder of epidermal keratinization with potential for malignant transformation. Imiquimod has been shown to be effective in the treatment of this condition in several case reports [138, 139].

A case of a 77 year old woman with porokeratosis of Mibelli involving the left shin has been reported [140]. Following application of imiquimod 5 % cream to the lesion once a day three times per week for 6 weeks, clinical resolution was observed at a 6 week post-treatment follow-up visit and no recurrence was seen at a 2-year follow-up visit.

In another case report, a 12 year-old girl with porokeratosis of Mibelli involving her left axilla was treated with imiquimod 5 % cream three times per week for 6 weeks [141]. Treatment was well-tolerated and no recurrence was observed 2 years following cessation of treatment.

Infantile Hemangioma

Infantile hemangiomas are benign vascular tumors that present within the first year of life and spontaneously regress over a period of years. Although the majority of these lesions resolve spontaneously, many leave residual fibro-fatty change, atrophy, or pigmentary alteration. Complications including ulceration, visceral involvement, or underlying structural impairment may occur in lesions of larger size or specific locations. Imiquimod has been found to offer benefit in the treatment of superficial infantile hemangiomas via increased tumor apoptosis and inhibition of vascular tumor enlargement [142].

Several case reports have illustrated success using imiquimod for uncomplicated infantile hemangiomas with resolution of lesions after 3–5 months [143–147].

A phase II open-label study evaluating imiquimod 5 % cream applied three to seven times per week for 16 weeks to non-ulcerated proliferating superficial or mixed infantile hemangiomas demonstrated that benefit was limited to superficial hemangiomas [148].

Imiquimod has been found to be well tolerated in the treatment of infantile hemangiomas with the majority of patients experiencing local skin reactions. Reports of fever have been documented in cases of imiquimod applied to ulcerated hemangiomas. Epistaxis was observed when imiquimod was used for a lesion located on the nasal side wall [147].

Granuloma Annulare

Granuloma annulare is a self-limited dermatosis manifesting as confluent papules in an annular configuration often involving the extremities. A case of a 12 year old girl with granuloma annulare involving the right foot has been reported [149]. After failing to respond to topical superpotent steroids, the lesion was treated with imiquimod 5 % cream nightly for 6 weeks. Following 6 weeks of treatment with imiquimod, the lesion had clinically resolved.

The successful use of imiquimod 5 % cream in the treatment of granuloma annulare was also documented by Badavanis et al. [150]. Four subjects were treated with imiquimod 5 % cream once daily from three to seven times per week for up to 12 weeks of treatment. One subject experienced relapse and was treated for an additional 6 weeks with subsequent resolution. All patients remained free of recurrence at 18-months post-treatment.

Conclusion

Imiquimod cream, an immune response modifier, offers a safe and effective alternative to ablative and surgical treatments for external genital warts, actinic keratoses, and superficial basal cell carcinomas. Although surgical excision may be more efficacious in the treatment of skin cancers, imiquimod may serve as a tissue-sparing, cosmetically appealing, and cost-effective option to those patients who are poor surgical candidates, who refuse surgery, or whose anatomical site is not amenable to surgery. As a stimulator of both innate and acquired immune responses with resultant anti-viral and anti-tumoral effects, imiquimod demonstrates potential in the treatment of several other virus-associated and oncological cutaneous conditions.

Key Points

- Ingenol mebutate is derived from the sap of the *Euphorbia peplus* plant.
- Ingenol mebutate has a unique dual mechanism of action inducing rapid and direct cell death within hours of application followed by an acute inflammatory response that eliminates residual tumor cells.
- Ingenol mebutate is Food and Drug Administration approved for the treatment of actinic keratoses

Ingenol Mebutate

Ingenol mebutate (Picato™, Leo Pharma), a macrocyclic diterpene ester, is the active constituent in the sap of *Euphorbia peplus*. Commonly known as radium weed, petty spurge, or milkweed, *E. peplus* has been used for centuries as a traditional remedy for cutaneous conditions including skin cancer [151–153].

Owing to a substantially shorter course of treatment (2–3 days) and duration of local cutaneous reaction, ingenol mebutate offers an appealing alternative to other topical agents used for the treatment of actinic keratoses.

Mechanism of Action

Ingenol mebutate has a dual mechanism of action. Ingenol mebutate first induces rapid and direct cell death within hours of application followed by an acute inflammatory response that eliminates residual tumor cells.

In vitro and in vivo studies on B16 mouse melanoma cells exposed to ingenol mebutate revealed disruption of the cell membrane, loss of mitochondrial membrane potential, and mitochondrial swelling resulting in rapid primary necrosis. As a result of the rapid destruction of tumor cells, a treatment duration of 2–3 days is sufficient. Unlike other anti-cancer agents, ingenol mebutate does not trigger apoptosis, and thus the development of apoptosis resistance in tumor cells is unlikely to compromise its activity [154].

Following the initial cell necrosis, an acute inflammatory response occurs [155]. Ingenol mebutate activates protein kinase c resulting in the release of pro-inflammatory cytokines (IL-1B, IL-8, TNF-alpha), the production of tumor-specific antibodies, an enhanced endothelial adhesion molecule expression, and a substantial infiltration of neutrophils which generate tumoricidal reactive oxygen intermediates [156–158]. The end-result is eradication of residual tumor cells via neutrophil mediated antibody dependent cellular cytotoxicity (ADCC). The elimination of residual tumor cells is thought to be essential in preventing relapse. Furthermore, the inflammatory response appears to confer a favorable cosmetic outcome via expedited healing and a rapid regeneration of the normal cutaneous architecture.

Dosage and Administration

Ingenol mebutate (chemical structure $C_{25}H_{34}O_6$) has been formulated as a topical gel. Each gram contains 150 or 500 mcg of ingenol mebutate in a base of isopropyl alcohol, hydroxyethyl cellulose, citric acid monohydrate, sodium citrate, benzyl alcohol, and purified water.

For the indication of actinic keratoses. The 0.015 % gel is applied once daily for three consecutive days (face or scalp) while the 0.05 % gel is applied once daily for two consecutive days (trunk or extremities) [159].

Safety

The most common side effects of ingenol mebutate were application-site reactions including erythema, scale, crusting, edema, vesiculation, erosions, ulceration, pruritus, pain, and irritation. Skin reactions typically occurred within 1 day of treatment initiation, peaking in intensity 1 week following application, and resolving within 2 weeks on the face/scalp and 4 weeks on the trunk/extremities.

Reports of periocular pain, edema, ptosis have been documented. Prompt hand washing after application and avoidance of contact with the eyes is recommended.

No evidence of skin sensitization, photoirritation, or photoallergic potential has been demonstrated [160].

Ingenol mebutate is pregnancy category C. It is unknown if ingenol mebutate is secreted in the breast milk of lactating women.

Approved Clinical Uses

Actinic Keratoses

The long history of community use of the sap of *Euphorbia peplus* for skin cancers without significant adverse effects prompted the initiation of a phase I/II study on the effect of E. peplus on non-melanoma skin cancer [161]. Participating subjects had one or more basal cell carcinomas or squamous cell carcinomas (in situ or invasive) that had failed previous treatments or were considered unsuitable for surgical intervention (due to size, location, multiplicity of lesions, or medical comorbidity). The sap of *E. peplus* was applied once daily for three consecutive days to a total of 48 skin cancer lesions amongst 36 patients. Histologic clearance at 1 month was 82 % (BCC), 94 % (SCCIS), and 75 % (SCC). At a 15

month follow-up, rates were 57 % (BCC), 75 % (SCCIS), and 50 % (SCC).

Several subsequent studies have demonstrated the safety and efficacy of ingenol gel for the treatment of actinic keratoses. A randomized, double blind, vehicle-controlled, parallel group phase II study by Siller et al. evaluated the safety and efficacy of two applications of various concentrations of ingenol mebutate gel (0.0025 %, 0.01 %, and 0.05 %) [162]. Fifty-eight subjects participated. Five AKs on each subject were selected to be treated by the investigators. Lesions were located on the face, scalp, chest, and arms. The treatment was found to be safe and well tolerated. The most common skin responses were dose-related erythema, flaking, scaling, xerosis, scabbing and crusting which resolved rapidly returning to baseline 1 month after treatment cessation. Efficacy was greatest for the 0.05 % gel, and by the end of the study on day 85, complete clinical clearance was achieved in 71 % of those who were treated with the 0.05 % gel. Clinical clearance of 4 out of 5 AK's was achieved in 67 % of those treated with the 0.05 % gel compared to 17 % of those who received the vehicle only. Histological clearance was observed in 42 % of treated lesions irrespective of the concentration of gel.

Another randomized, double blind, double dummy, vehicle-controlled phase II study by Anderson et al. involving 222 subjects evaluated the safety, tolerability, and efficacy of ingenol mebutate gel applied to non-facial actinic keratoses (0.025 % for 3 days and 0.05 % for 2 or 3 days) [163]. Subjects had 4–8 actinic keratoses within a 25 cm^2 area. Efficacy was dose dependent with 56.0–75.4 % of those receiving ingenol mebutate achieving the primary efficacy end point of partial clearance (≥75 % of baseline lesions cleared) at day 57 compared to 21.7 % for vehicle. Local skin reactions were experienced by up to 96 % of subjects in the active treatment arms with resolution noted 2–4 weeks later. No evidence of scarring or serious adverse events were observed.

The results of four randomized, double-blind, placebo-controlled phase III studies involving a total of 1005 subjects were combined to evaluate the safety and efficacy of ingenol mebutate 0.015 % (once daily for three consecutive days on the face and scalp) and 0.05 % (once daily for two consecutive days on the trunk and extremities) applied to a 25 cm^2 area [164]. Complete clearance at day 57 was higher in those treated with ingenol mebutate versus placebo: 42.2 % vs 3.7 % for lesions of the face and scalp, and 34.1 % vs 4.7 % for lesions on the trunk and extremities. Ingenol mebutate gel was well tolerated with local skin reactions peaking at day 4 (face/scalp) and between days 3 and 8 (trunk/extremities). Local skin reactions approached baseline for all groups receiving active medication by day 29. Minimal pigmentary changes and scarring were observed in subjects receiving the study medication. Of note, over 98 % of the patients assigned to the ingenol mebutate group applied the study medication on all days.

Those who had achieved complete clearance at day 57 were enrolled in a subsequent 12 month observational follow-up study evaluating subsequent recurrence [165]. Compared to baseline, the sustained clearance rate in the face/scalp group was 87.2 %. The sustained clearance rate in the trunk/extremity group was 86.8 %. The median time to recurrence was estimated to be 365 days (face/scalp) and 274 days (trunk/extremity).

The safety and efficacy of ingenol mebutate 0.015 % gel following cryosurgery for the treatment of actinic keratoses on the face and scalp was assessed in a randomized, double-blind, placebo-controlled phase III trial [166]. Subjects (n = 329) were randomized to receive either ingenol mebutate 0.015 % gel or vehicle 3 weeks after cryosurgery. Complete clearance rate was greater in those treated with ingenol mebutate compared to placebo (60/5 % vs 49.4 %).

Off Label Uses

Nonmelanoma Skin Cancers

A phase II study involving 60 patients with biopsy proven basal cell carcinomas was performed evaluating the safety of topical ingenol mebutate gel at three different concentrations (0.0025 %, 0.01 %, and 0.05 %) [167]. The gel was applied once daily for two (0.0025 %, 0.01 % gels) or three (0.05 % gel) consecutive days to a total of 60 BCCs. The safety profile was tolerable with local skin responses reported. Efficacy was dose-dependent with 5/8 patients (63 %) in the 0.05 % group achieving histologic clearance.

Recurrent Malignant Melanoma In Situ

A case report details the treatment of recurrent malignant melanoma in situ of a 91 year old woman [168]. The patient had initially presented with a nodular melanoma that was subsequently surgically excised. Recurrence was noted at a follow-up visit and histologically determined to be a malignant melanoma in situ. As the patient refused further surgical intervention, ingenol mebutate gel 0.015 % gel was applied once daily for three consecutive days. At a 1 month follow-up visit, the lesion was both clinically and histologically resolved.

Molluscum Contagiosum

The treatment of molluscum contagiosum with ingenol mebutate is described in a case report of a 4 year old girl with lesions on the abdomen and extremities [169]. She had failed prior treatment with imiquimod 1 % for 1 month and was subsequently treated with ingenol mebutate 0.015 % gel once daily

for three consecutive days. The patient noted a mild local skin reaction 3 days after initial application. Treatment was continued for an additional 3 days resulting in clearance of lesions with no signs of recurrence at a 1 month follow-up visit.

Conclusion

Ingenol mebutate is a valuable new option for the treatment of actinic keratoses. Its unique dual mechanism of action provides significant efficacy while a brief 2 or 3 day dosing regimen and highly favorable tolerability profile ensure considerable patient adherence.

Questions

1. Which of the following best describes the mechanism of action of imiquimod?
   A. blocks synthesis of the pyrimidine thymidine, which is a nucleoside required for DNA replication
   B. competitively inhibits and inactivates HSV-specified DNA polymerases preventing further viral DNA synthesis without affecting the normal cellular processes
   C. it produces an innate immune response via its action as a toll-like receptor (TLR) agonist
   D. Following an initial cell necrosis, protein kinase c is activated resulting in the release of pro-inflammatory cytokines, tumor-specific antibodies, an endothelial adhesion molecule expression, and a substantial infiltration of neutrophils which generate tumoricidal reactive oxygen intermediates

2. Which of the following statements is false?
   A. imiquimod has been shown to be more effective and produce a less severe local skin reaction than 5-fluorouracil (5-FU)
   B. imiquimod is FDA approved to treat molluscum contagiousum
   C. The most common side effect of ingenol mebutate are application-site reactions
   D. Imiquimod possesses the unique capacity to uncover and treat sub-clinical actinic kersatoses

3. Which of the following best describes the mechanism of action of ingenol mebutate?
   A. Following an initial cell necrosis, protein kinase c is activated resulting in the release of pro-inflammatory cytokines, tumor-specific antibodies, an endothelial adhesion molecule expression, and a substantial infiltration of neutrophils which generate tumoricidal reactive oxygen intermediates
   B. a MyD88-dependent signaling cascade2 acts to recruit protein kinases and transcription factors, resulting in activation of nuclear factor-kβ (NF-kβ) that, upon activation, migrates to the nucleus and up-regulates the production of local pro-inflammatory cytokines
   C. blocks synthesis of the pyrimidine thymidine, which is a nucleoside required for DNA replication
   D. choices A+B
   E. none of the above

Answers

1. C
2. B
3. A

Topical Immune Response Modifiers: Antiinflammatories

46

Thomas A. Luger, Ian McDonald, and Martin Steinhoff

Abstract

In recent years, major findings such as blockade of the calcineurin pathway in T lymphocytes led to the identification of novel targets for the treatment of inflammatory skin diseases. The first systemic specific calcineurin inhibitor (CI) for the treatment of inflammatory skin diseases was cyclosporin A (CsA), which demonstrated efficacy both in psoriasis and atopic dermatitis (AD). Because of its systemic adverse effects and the inability to generate a topical CsA compound, there still exists a need for better immunomodulatory agents. Later, the calcineurin inhibitor tacrolimus (FK506) was successfully approved as an efficient topical drug. Subsequently a second calcineurin inhibitor (pimecrolimus, ASM 981) was developed and approved for the topical treatment of atopic dermatitis. Both CIs have been shown to function as effective inhibitors of inflammatory responses in the skin. In addition to T cells, they appear to target other inflammatory cells including mast cells, eosinophils and basophils, blocking cytokine production and reducing associated pruritus. This chapter focuses on topical CIs and briefly discusses recent promising developments of topical antiinflammatory agents.

Keywords

Antiinflammatories • Topical calcineurin inhibitors • Tacrolimus • Pimecrolimus • CI • TH1 and TH2 cytokines • Pharmacokinetic Studies • Atopic-induced pruritus • Pruritus

Key Points

- New antiinflammatory therapies against atopic dermatitis and other inflammatory skin diseases have become available in recent years.
- Topical calcineurin inhibitors include tacrolimus and pimecrolimus.
- Topical calcineurin inhibitors exert a potent antiinflammatory activity with a low immunosuppressive potential and no induction of skin atrophy.

In recent years, major findings such as blockade of the calcineurin pathway in T lymphocytes led to the identification of novel targets for the treatment of inflammatory skin diseases. The first systemic specific calcineurin inhibitor (CI) for the treatment of inflammatory skin diseases was cyclosporin A (CsA), which demonstrated efficacy both in psoriasis and atopic dermatitis (AD). Because of its systemic adverse effects and the inability to generate a topical CsA compound, there still exists a need for better immunomodulatory agents. Later, the calcineurin inhibitor tacrolimus (FK506) was successfully approved as an efficient topical drug [1]. Subsequently a second calcineurin inhibitor (pimecrolimus, ASM 981) was developed and approved for the topical treatment of atopic dermatitis. Both CIs have been shown to function as effective inhibitors of inflammatory responses in the skin. In addition to T cells they appear to target other inflammatory cells including mast cells, eosinophils and basophils, blocking cytokine production and reducing associated pruritus [2, 125]. This chapter focuses on topical CIs and briefly discusses recent promising developments of topical antiinflammatory agents.

Besides CIs, glucocorticoids (GCs) are widely used topical antiinflammatory agents in dermatology. However in addition to their therapeutic benefits their adverse effects have also become apparent [13–17].The use of glucocorticosteroids is discussed in Chapter 48 and so this chapter focuses on the impact of CIs as antiinflammatory agents in dermatology.

Mechanism of Calcineurin Inhibition by Tacrolimus and Pimecrolimus

Tacrolimus and pimecrolimus are ascomycin macrolactam derivatives produced by bacteria. While tacrolimus is a product of *Streptomyces tsukubaensis*, pimecrolimus was generated from *Streptomyces hygroscopicus var. ascomycetus*. Both bind, albeit with different affinity, to a cytosolic immunophilin receptor, defined as FK-binding protein-12 (macrophilin-12) [9]. After binding, the macrophilin complex associated with either tacrolimus or pimecrolimus inhibits a calcium-dependent serine-threonine phosphatase, defined as calcineurin. Thereby, dephosphorylation and nuclear translocation of a cytosolic transcription factor, the nuclear factor of activated T-cell protein (NF-ATp) is inhibited [6, 18]. Therefore, both tacrolimus and pimecrolimus can be defined as CIs.

In Vitro Effects

Tacrolimus and pimecrolimus inhibit the production of TH1 and TH2 cytokines such as interleukin-2 (IL-2), IL-4, IL-8, tumor necrosis factor-α (TNF-α), and interferon-γ (IFN-γ) in vitro. The generation of granulocyte-macrophage colony-stimulating factor (GM-CSF) can also be blocked by these compounds. Pimecrolimus is also capable of supporting antiinflammatory effects on T-helper-2 (Th2) cells by downregulating IL-5 and IL-13 in $CD4^+$ as well as in $CD8^+$ T cells [19], diminishing the number of $CD1^+$ inflammatory dendritic cells from the epidermis [19, 20], and stimulating apoptosis in skin T cells but not in Langerhans cells [20]. In mast cells, pimecrolimus inhibits the release of mast cell mediators such as histamine [1, 18, 21]. In contrast to GC, the topical application of pimecrolimus does not affect the density of epidermal Langerhans cells [22], and does not alter the function of dendritic cells with respect to costimulatory molecule expression or T-cell proliferation [23]. In keratinocytes or endothelial cells, pimecrolimus does not affect cell adhesion molecule expression.

In contrast to pimecrolimus, tacrolimus modulates certain effects of inflammatory dendritic epidermal cells (IDECs) such as the expression of the high-affinity receptor for IgE (FcεRI) [21, 24, 25].

Tacrolimus also inhibits apoptosis of keratinocytes and T cells, thereby suppressing chemokine secretion by eosinophils and release of inflammatory mediators from mast cells [20]. In contrast to corticosteroids, neither tacrolimus nor pimecrolimus affects fibroblast functions such as collagen synthesis and therefore do not cause skin atrophy. In contrast to GC, pimecrolimus does not impair epidermal barrier function. This may explain why tachyphylaxis has not been observed upon treatment with topical CI.

In Vivo Effects

The in vivo antiinflammatory capacities of tacrolimus and pimecrolimus have been investigated in several animal models of contact dermatitis. Both compounds block the elicitation phase of contact dermatitis, thereby diminishing the inflammatory activity. The in vitro evidence of a significantly lower immunosuppressive potential of pimecrolimus

in comparison to tacrolimus has been supported by in vivo animal studies. Here, pimecrolimus, in contrast to tacrolimus, had no effect on the sensitization phase of allergic contact dermatitis and thus apparently does not impair the primary immune response. This has been further supported by a variety of other animal models of immune-mediated diseases. Using a localized rat model of graft-versus-host reaction, pimecrolimus was significantly less effective than tacrolimus. In another rat model of kidney transplantation, pimecrolimus again was less effective in preventing graft rejection when compared to tacrolimus or cyclosporin A. Moreover, upon investigation of the effect on T-helper-cell–assisted B-cell activation in rats, pimecrolimus turned out to be significantly weaker when compared to that of tacrolimus [24, 26, 27].

Pharmacokinetic Studies

The question of potential systemic exposure is one of major concern in the development of a novel compound for topical application. The intact skin barrier restricts the passage of substances greater than 500 Da. As a result the penetration and permeation of topical cacineurin inhibitors whose molecular weight is greater than this (tacrolimus 822 Da, pimecrolimus 810 Da) is impaired. In addition, their lipophilic properties showed higher affinity for skin and lower potential for systemic absorption compared with other agents [125]. The capacity of pimecrolimus to penetrate into and permeate through the skin was investigated in vitro using human cadaver skin. This was compared to corticosteroids and tacrolimus. Accordingly, the amount of pimecrolimus penetrating into the skin was similar to that of corticosteroids or tacrolimus. However, pimecrolimus was observed to permeate significantly less through skin in comparison to corticosteroids or tacrolimus [28]. Therefore, one may suggest that following the topical application of pimecrolimus, the risk of systemic exposure is low and the ultimate possibility of systemic side effects is most unlikely [27]. This has been supported by several pharmacokinetic studies, which proved that after topical use of pimecrolimus in patients with atopic dermatitis, serum concentrations were equally low regardless of the age, severity of disease, and body area treated. In 99 % of the samples tested, concentrations were below 2 ng/mL, which is far below the level of 10–15 ng/mL, which is required for a systemic antiinflammatory effect [29].In contrast to tacrolimus, serum concentrations of pimecrolimus in this range did not cause systemic adverse events as has been shown in several clinical trials [30, 31].

Although the metabolism of pimecrolimus in the skin has not yet been carefully investigated, it might be assumed that it is removed by desquamation. In contrast, serum tacrolimus levels were detected more frequently following topical application in patients with atopic dermatitis. However, usually these levels were low and transient because circulating tacrolimus was no longer detectable upon improvement of skin barrier function after short-term treatment [32]. The reason for the observed differences between tacrolimus and pimecrolimus, however, is not completely understood. One possible explanation may be the different structure, lipophilicity, as well as content of lipophilic groups of these compounds. Moreover, pimecrolimus in contrast to tacrolimus has a high affinity for epithelial structures such as the skin but a low affinity for lymphoid organs [27].

Pharmacokinetic long-term studies over 1 year have further demonstrated [33] that the blood concentrations of pimecrolimus cream were rather low; moreover, no accumulation was observed and only a minimal increase was detected with increasing body surface area (BSA) during treatment [33, 34].

These results suggest that pimecrolimus does not cause any detectable systemic effects during long-term studies [35, 36].

Clinical Studies on Efficacy and Safety of Calcineurin Inhibitors

Both CIs have been developed for the topical treatment of atopic dermatitis and are approved for this indication in many countries around the world. Tacrolimus can be obtained as 0.03 % and 0.1 % ointment (Protopic®), whereas pimecrolimus is available as a 1 % cream (Elidel®). While tacrolimus is approved for the treatment of moderate and severe atopic dermatitis in adults and children ≥2 years old, pimecrolimus cream (1 %) is available and approved for mild and moderate cases of atopic dermatitis in adults and children ≥2 years old. In some countries, pimecrolimus has been approved for the therapy of atopic dermatitis regardless of age and severity of the disease [37–39]. For both CIs, several clinical trials verified both compounds to be highly effective for the treatment of atopic dermatitis [9, 24, 40].

In January 2006 the US Food and Drug Administration (FDA) issued a boxed warning based on a theoretical risk of malignancy including lymphoma with topical CI use. In September 2010 the FDA released a review of TCI safety based on five peer reviewed studies. At that time they concluded that there may be a possibility of an association between tacrolimus and an increased risk of lymphoma. However epidemiological and clinical data since then have failed to demonstrate a causal link. Indeed in post marketing registries the observed number of malignancies and lymphomas has been very low and comparable or less than the number observed in the general population. In addition a number of published reviews have concluded that no conclusive proof has emerged to link TCI with malignancy in the 9 years since

the boxed warning [131–133]. Meanwhile, topical CIs have been established or reported as alternative therapeutic strategies for skin diseases other than atopic dermatitis. Both tacrolimus ointment and pimecrolimus cream have been documented as successful treatment modalities for rosacea, lichen planus, psoriasis, lichen sclerosus et atrophicans, lupus erythematosus, and many others (reviewed elsewhere [39]).

From an economic point of view, in the long run CIs have been shown to be cost-effective [41], although at the moment they are more expensive than glucocorticoids [42]. However, as already mentioned, one has to consider age (infants, children, elderly people with skin atrophy), localization (face, groin, inframammary area), and severity (large proportions of the skin), for in these cases CIs are superior and safer therapeutic modalities. Thus, a fair calculation between CIs and other drugs such as glucocorticoids (GCs) may be difficult [41, 43, 44]. More studies are needed to further calculate costs of GC versus CI therapy.

In the first clinical trial of adults with atopic dermatitis, tacrolimus ointment significantly reduced skin lesions and pruritus within 3 weeks of treatment [45]. Subsequently, randomized double-blind controlled studies further defined the efficacy, tolerability, and safety of tacrolimus [44, 46]. In adults, 0.1 % tacrolimus ointment was as effective as hydrocortisone butyrate 0.1 % ointment [44, 47]. In children (2–15 years), 0.03 % ointment was more effective as compared to 1 % hydrocortisone acetate ointment [48], and more effective than a mild topical glucocorticoid ointment [44]. Subsequently, tacrolimus was compared to various topical glucocorticoids. In a meta-analysis of 25 randomized controlled trials, tacrolimus 0.1 % ointment was superior to hydrocortisone acetate (1 %), hydrocortisone valerate, and hydrocortisone butyrate (0.1 %), whereas tacrolimus (0.03 %) ointment was as effective as hydrocortisone acetate (1 %), but less effective than hydrocortisone butyrate.

After these successful short-term studies revealing efficacy of topical tacrolimus, a multi-center, open-label, non-comparative trial was performed [49]. Within the first week of treatment, most of these patients experienced a significant amelioration of eczema and pruritus. Of note, an increasing improvement was observed until month 3 after treatment. After 12 months, an excellent improvement (≥90 %) or clearance of the symptoms was reported in 68.2 % of patients. An improvement (≥50 %) was noted in 90.9 % of the cases [50]. Laboratory parameters did not change significantly during the study period. A burning sensation (47 %) usually terminated after initiation of treatment, and burning or itching was only occasionally reported [50]. Importantly, no tachyphylaxis was observed in these patients. The excellent long-term efficacy of tacrolimus ointment for the treatment of atopic dermatitis in children as well as adults was verified in several clinical studies [51]. By measuring tacrolimus plasma levels in patients treated with tacrolimus ointment it was revealed that in 67.1 % of patients tacrolimus plasma levels remained below the level of detection. High levels were found only in 0.4 % (≥5 ng/mL) of patients [5]. In patients with Netherton syndrome, blood concentrations over 20 ng/ml could be detected [53]. Despite these rare cases, systemic exposure after topical application of tacrolimus is very low. In summary, there is no evidence for systemic accumulation resulting in adverse side effects following the long-term treatment with tacrolimus ointment [54].

The efficacy of pimecrolimus 1 % cream for the treatment of atopic dermatitis in adults, children, and infants was verified in several clinical trials [4, 24, 39, 55–58]. Importantly, no significant drug-related adverse events were observed in these studies when applied twice daily. In comparison to both corticosteroids and tacrolimus, the capacity of pimecrolimus to permeate through the skin was significantly lower, indicating a very low risk of systemic exposure following the topical application of pimecrolimus cream [27]. This is also supported by studies with patients suffering from Netherton syndrome [59, 60]. In one recent study by Yan et al., three patients with Netherton syndrome received twice daily application of pimecrolimus 1 % cream over 18 months. In addition to the significant clinical improvements noted, blood levels recorded ranged from 0.625 to 7.08 ng/ml, revealing levels much lower than expected or required to cause systemic immunosuppression. These results were seen even when pimecrolimus was applied to 50 % of the body surface area [130] Therefore, long-term studies indicate a very low potential of systemic toxicity, immunosuppression, and local or systemic infections for pimecrolimus 1 % cream [61–63].

In children (2–17 years) and infants (3–23 months) with mild, moderate, or even severe atopic dermatitis, several multicenter clinical trials have further demonstrated [64] that pimecrolimus 1 % cream is highly effective within 8 days for treating both the eczema and the pruritus. No side effects including viral or bacterial infections were reported [56, 65, 66]. Thus pimecrolimus 1 % cream is a safe and effective therapeutic option in children and infants with atopic dermatitis. Of note, significantly more patients in the pimecrolimus group were maintained without glucocorticoid therapy [65, 67]. Due to its efficiency and low profile of adverse events, it is recommended to begin a topical CI therapy at an early stage of atopic dermatitis and probably for other inflammatory skin diseases [40, 68]. Under these circumstances, when the disease develops during CI therapy, intermittent use of other antiinflammatory compounds such as GC will be beneficial [69]. Tacrolimus ointment and pimecrolimus cream may even have a prophylactic effect when used intermittently after an episode of atopic dermatitis when patients still suffer from pruritus (every second to third day). In two clinical trials the efficiency of pimecrolimus was compared to that of glucocorticoids. In a short-term study pimecrolimus was less effective after 3 weeks than betamethasone valerate,

although the maximal efficacy of pimecrolimus was not studied in detail. Moreover, in a long-term, double-blind, randomized multicenter clinical trial, the efficacy of pimecrolimus was compared to that of triamcinolone-acetonide 1 % cream or 1 % hydrocortisone. Although a significant improvement was observed in both groups, less severe side effects were observed in the pimecrolimus group [70–73].

When comparing the effect of topical CIs with topical GC on the epidermal barrier it has been shown that both tacrolimus and pimecrolimus result in a significant increase in the number of lipid lamellae in the intracellular space. This increase is greater than that observed in the GC treated group. As the synthesis and storage of lipids in the lamellar bodies is essential for an effective barrier, this highlights an important therapeutic effect that TCIs have on repairing the epidermis and in reducing epidermal water loss [125, 126]. This may suggest a superior effect of TCIs in repairing skin barrier architecture, preventing penetration of allergens and subsequent relapse.

Effects of Calcineurin Inhibitors on Innate Immunity and Host Defense

The safety and tolerability of tacrolimus ointment has been demonstrated in children and adults with atopic dermatitis. The most common local adverse event was a sensation of burning (in 29.9 % of children and 46.8 % of adults). Transient itching was noted in some children (23.1 %) and adults (25.8 %), which was most likely due not to infection but to neuronal activation [74]. The local adverse events were only noted during the first few days of treatment and were mild to moderate [51]. Concerning side effects on skin appendages, the risk of developing folliculitis or acne was increased in a few young adults [50].

An increased rate of bacterial skin infections could not be observed [50], and a decreased colonization with *Staphylococcus aureus* in the eczematous skin lesions was observed [75], which may be due to a normalization of cutaneous innate immunity after restoration of skin integrity. Atopic dermatitis patients exert an impaired capacity to produce antimicrobial peptides such as defensins and cathelicidins [76–82]. This effect may be due to a predominant TH2 immune response in atopic individuals. Moreover, IL-4 and IL-13, which are increased in atopic dermatitis, inhibit the production of antimicrobial peptides [82].

A slight, nonstatistically significant, increase of local viral infections such as herpes simplex was reported [11]. However, none of these cases caused a therapeutic problem [83]. The idea that pimecrolimus exerts long-term preventive effects in atopic dermatitis was verified by studies showing no relation between pimecrolimus treatment and the occurrence of eczema herpeticum [84, 85]. Moreover, clinical investigations verified that pimecrolimus 1 % cream was not associated with a significantly increased risk of the development of fungal, bacterial, or viral skin infections [61–63].

The effect of pimecrolimus on innate immunity in patients with AD was investigated in a double-blind, randomized, vehicle-controlled study which looked at its effect on IL-13 and antimicrobial peptides (AMPs) cathelicidin and human β defensin (HBD)-3. After 3 weeks of application a statistically significant reduction in IL-13 (which plays a pivotal role in the development of AD lesions) was observed when compared with the vehicle-treated group. In addition there was no significant reduction in catelicidin expression observed. While there was no increase in AMPs overall, its use was not associated with further suppression of the innate immune response [127]. This is in contrast to topical corticosteroids which have a more pronounced inhibition of AMP protein and mRNA levels suggesting a greater suppression of the innate immune system [126].

By using recall antigen tests, no impaired cellular immune response was observed in the skin even after long-term application of tacrolimus 0.1 % ointment [50]. Thus, tacrolimus-associated infections may not be regarded as a major risk factor in atopic dermatitis. Moreover, there is no evidence that the capacity to respond to vaccination with an appropriate antibody production is affected after topical pimecrolimus therapy. It does not alter the migratory capacity of antigen-presenting dendritic cells and does not impair the primary immune response. Despite these studies and reports, cessation of topical application with CI is recommended until total clearance of a viral infection. Surprisingly, the incidence of bacterial infections was found to be decreased during the application of pimecrolimus or tacrolimus. This was most likely due to a normalization of innate defense mechanisms [82].

Effects of Calcineurin Inhibitors on Pruritus

Calcineurin inhibitors play an important role in the treatment of atopic-induced pruritus [86]. Of note, a significant improvement of pruritus was observed within a few days of treatment using pimecrolimus cream [63], which has a beneficial effect on the quality of life in patients with atopic dermatitis [62]. Within 1 week of treatment pruritus was significantly decreased in these patients [87]. Thus, pimecrolimus 1 % cream is effective for the treatment of mild, moderate, and severe atopic dermatitis in adults as well as children and infants. In randomized multicenter, double-blind studies it was further demonstrated that significantly fewer infants treated with pimecrolimus developed severe flares as compared to controls [61, 63].

Itchy lesions that are often resistant to therapy, such as on the face and neck, also responded well to pimecrolimus

therapy [65]. The same adverse events were also observed with tacrolimus in patients with atopic dermatitis, namely burning and a feeling of warmth. These sensations were regarded as mild and transient, lasting only 1–3 days [61–63]. This seems to be dependent on a transient release of preformed neuromediators such as substance P (SP) and calcitonin gene–related peptide (CGRP) from primary afferent nerve endings [74, 86, 88]. Siepmann et al. also demonstrated a significant improvement of pruritus in patients with prurigo nodularis (PN) when treated with topical pimecrolimus, including those patients with PN who did not have an atopic background. This randomized doubleblind phase II trial, demonstrated antipruritic effects within 10 days of starting treatment. It also demonstrated improvement of the prurigo nodules and dermatological quality of life [128].

Effects of Calcineurin Inhibitors on Atrophy

The effect of tacrolimus on fibroblast collagen formation was also determined in a double-blind study. Tacrolimus (0.03 % and 0.1 %), betamethasone valerate, and a vehicle control were compared after 1 week of application for skin thickness and procollagen peptide concentration in suction blister fluids. In contrast to betamethasone valerate, tacrolimus had no effect on procollagen propeptide production and caused no reduction of skin thickness [89]. Thus, the absence of skin atrophy is a major advantage in the treatment with CI [1, 7]. In summary, it is well documented that pimecrolimus does not affect collagen synthesis and therefore does not cause skin atrophy in mice or humans [90].

Risk of Pimecrolimus by Ultraviolet Exposure and in Skin Cancer

The use of systemic immunosuppressants such as cyclosporin A is well known to be associated with an increased risk for the development of ultraviolet (UV)-induced skin cancer such as basal cell carcinoma and squamous cell carcinoma, as well as of the development of actinic keratosis [91, 92]. The long-term experience with topical corticosteroids indicates that they might not be applicable for local treatment with immunomodulators. Therefore, it was necessary to analyze the incidence of developing skin cancer after treatment with tacrolimus. The incidence of skin cancer following the use of tacrolimus ointment has remained very low [93].

In contrast, it is well documented from animal studies that tacrolimus inhibits the development of phorbol ester-(TPA)-induced skin tumors [94].Tacrolimus also suppresses transforming growth factor-β1 receptor (TGFβ1R) activation [95], and prevents keratinocyte apoptosis [96]. Importantly, various animal studies have demonstrated that the topical application of pimecrolimus cream and additional UV-irradiation were not associated with an increased incidence of epidermal or melanocytic skin tumors [10]. Moreover, topical treatment with tacrolimus and pimecrolimus prevents the UV-mediated formation of dimethylthymidine dimers, suggesting a protective effect of these compounds against UV exposure [97]. However, future controlled studies are required to further elucidate the role of CI in UV-mediated skin damage. Meanwhile, a preventive strategy using appropriate sunscreens with topical CI treatment is recommended [10, 11, 98]. The question of tumor formation following long-term treatment with topical tacrolimus cannot be definitively answered at present. A recently published literature review looking at the extent to which topical CI use is associated with melanoma and non melanoma skin cancers found no evidence to date to support such an association. However limitations of the studies have meant that existing data to date is inadequate to give conclusive recommendations [129].Therefore, concomitant UV therapy should be avoided and the patients should be instructed to use UV-protective measures [10, 99].

Comparison of Topical Calcineurin Inhibitors

In a multicenter, randomized study, it was shown that tacrolimus 1 % ointment was more effective than pimecrolimus 1 % cream in adults and children with moderate/severe atopic dermatitis (AD) and at week 1 with mild AD. Tacrolimus was also superior with respect to itch scores and onset of action while no differences were observed concerning adverse side effects [100]. In summary, the first clinical trials already provided evidence for tacrolimus and pimecrolimus as safe and effective topical compounds for the treatment of AD in adults and children, with improvement both in pruritus as well as eczematous lesions [46]. A recent clinical investigator-blinded trial compared pimecrolimus 1 % cream and tacrolimus 0.03 % ointment in children. The efficacy of pimecrolimus 1 % cream was comparable to that of tacrolimus 0.03 % ointment. Pimecrolimus cream was better tolerated, and lesions in the face and neck healed faster after treatment with pimecrolimus cream [101–103]. However, one has to consider that the vehicle of tacrolimus and pimecrolimus is different: while tacrolimus is approved as an ointment, pimecrolimus is a cream. Therefore, patients with dry skin show a better tolerability of the ointment (tacrolimus), while the cream is predominantly preferred by patients with acute, erosive lesions.

Future Topical Anti Inflammatory Treatments

As a result of ongoing, successful research, exploring the pathophysiology of atopic dermatitis and its inflammatory pathways, potential therapeutic targets have been identified. This has resulted in the development of some novel topical anti inflammatory agents, many of which are currently in clinical trials.

Phosphodiesterase inhibitors (PDEs) inhibit the degradation of cyclic adenosine monophosphate (cAMP) and have emerged as potential topical treatments for AD. Blocking PDE4 reduces TNF-α gene expression in macrophages and dendritic cells and also reduces T cell proliferation and production of proinflammatory cytokines IL-2, IL-4 and IL5. They also enhance the expression of IL-10 [135]. The topical application of E6005, a novel PDE4 inhibitor has been demonstrated to have significant antipruritic activity in mice with chronic atopic dermatitis [136]. As a result a phase 1 study looking at the therapeutic action of a topical PDE4 inhibitor is currently underway in patients with atopic dermatitis.

NF-kB decoy is a double-stranded deoxyribonucleic acid (DNA) oligodeoxynucleotide that mimics the NF-kB binding sequence on chromosomal DNA, thereby inhibiting the production of the inflammatory response triggered by NF-kB. The efficacy of topical NF-kB decoy in AD has been demonstrated in a number of mouse models [136, 137]. It reduces the expression of inflammatory cytokines such as IL-1β, TNF-α, ICAM-1 and macrophage inflammatory protein 2-α precurser, thereby reducing inflammation and restoring skin barrier function [137]. A phase 2 study was subsequently performed to evaluate the safety and tolerability of twice daily application of NF-kB decoy to adults and results are pending.

WBI-1001 is a novel synthetic compound demonstrating nonsteroidal antiinflammatory activity. It was originally derived from metabolites of a unique group of bacterial symbionts of entomopathogenic nematodes. It has been shown to inhibit proinflammatory cytokines including IL-2, IL-13, IL-17A and TNF-α [140]. Bissonnette et al., in a 12 week, multicenter, randomized, placebo-controlled double-blind trial demonstrated that topical WBI-1001 at concentrations of 0.5 % and 1.0 % was an efficacious and safe topical treatment for patients with mild to severe AD. However the study did not match the effectiveness to an active comparator and so further studies are required [141].

Mapracorat is a selective glucocorticoid receptor agonist (SERGA) which is currently in two phase 2 clinical trials evaluating its safety and efficacy in patients with AD. It is a highly selective glucocorticoid receptor ligand with immunomodulatory and antiinflammatory effects but with a more favourable side effect profile than topical GCs [139]. Its effect has been demonstrated at a cell signalling level by the inhibition of p38 mitogen-activated protein kinase (MAPK), C-Jun N-terminal kinase (c-JNK), activator protein 1 (AP-1) and NK-kB transcriptional activity.

Conclusion

Topical CIs have established a broad, effective, and safe treatment modality for mild to severe subtypes of atopic dermatitis and other inflammatory skin diseases. During the usage of topical tacrolimus or pimecrolimus, respectively, adverse side effects are rare. Topical CIs are the first antiinflammatory compounds that are suitable for effective, long-term treatment of inflammatory skin diseases. Moreover, they also may be used as an early local therapy when the first signs of itching and eczema appear. Perhaps early and effective local therapy using these novel compounds in infants and children may even have a preventive effect [5, 11]. Therefore, early therapeutic intervention is recommended when lesions or pruritus occur. However, clinical studies are still required to investigate the course of the chronic skin disease treated with CIs with respect to the frequency and severity of the skin lesion. There is evidence that the quality of life in these patients and their relatives has significantly improved [5, 11].

The availability of tacrolimus ointment and pimecrolimus cream as two different formulations is useful because the different vehicle formulations vary regarding skin dryness, patient age, and severity of the disease. Because of its profile and vehicle, pimecrolimus 1 % cream can be recommended in infants and children [27, 104].

Thus far, successful treatment with topical CI has been described in atopic dermatitis [7, 10, 68, 69, 72, 105, 106], seborrheic eczema [107], steroid-induced perioral dermatitis, steroid-induced rosacea [108], erythrotelangiectatic as well as papulopustular and edematous rosacea [109], perianal dermatitis, chronic actinic dermatitis [110], disseminated granuloma annulare [111, 112], lichen planus [113], hand eczema, mucous lesions of lichen planus [114], lichen sclerosus et atrophicans, pyoderma gangrenosum, lupus erythematosus, dermatomyositis, bullous autoimmune diseases, lichen amyloidosus, lichen aureus, chronic actinic dermatitis [5, 11, 104, 111, 115–118], chronic graft-versus-host disease [119, 120], asteatotic eczema [121], and vitiligo [122], although UV light may be additionally mandatory [123, 124]. In contrast, treatment of alopecia areata in humans with CI was not effective [123].

The introduction of topical CI as antiinflammatory agents to combat inflammatory skin diseases has already changed our position about the optimal treatment of inflammatory and autoimmune skin diseases. However, the future position of topical CI for the treatment of atopic dermatitis and other inflammatory skin diseases depends on further well-controlled clinical trials.

In the last few years, a huge improvement has been observed for the development of new anti-inflammatory therapies against atopic dermatitis and other inflammatory skin diseases by immunomodulatory agents. Topical CIs such as tacrolimus or pimecrolimus exert a potent antiinflammatory activity with a low immunosuppressive potential. In many controlled clinical trials, tacrolimus ointment as well as pimecrolimus cream have been shown to be highly effective and safe. They are also well tolerated and do not induce skin atrophy in long-term studies. One of the major adverse events observed with CIs is a transient sensation of burning, which ceases within days. UV-protective modalities are recommended during the treatment with topical CI, although side effects such as skin cancer and systemic immunosuppression have not been observed as of yet in controlled clinical studies. In addition to atopic dermatitis topical CI are effective agents for the treatment of many inflammatory skin diseases including perioral dermatitis, seborrheic eczema, and lichen sclerosus et atrophicus. Future studies will have to determine whether early and perhaps prophylactic application of topical CI may prolong or prevent the onset of inflammatory responses in various skin diseases. In recent years, our knowledge about potent topical GCs with fewer side effects has also greatly improved. Long-term studies revealed a low potential of topical GC to induce atrophy as compared to classic GC. Thus, modern topical therapies with topical CI and GC have established an improvement for the treatment of atopic dermatitis. However, other novel specific antiinflammatory therapies are still needed for rapid and safe long-term treatments for atopic dermatitis and other inflammatory or autoimmune skin diseases. It is possible that the new agents discussed within this chapter may some day become part of the treatment algorithm for various inflammatory dermatoses.

Questions

1. **The following statements describe the actions of calcineurin inhibitors except for?**
   A. Calcineurin inhibitors inhibit the effect of T1 and T2 cytokines in addition to the generation of granulocyte-macrophage colony-stimulating factor
   B. In contrast to topical glucocorticosteroids, the use of Calcineurin inhibitors is not associated with tachyphylaxis
   C. Calcineurin inhibitors have a direct affect on fibroblast function including collagen synthesis resulting in skin atrophy
   D. Unlike glucocorticoids pimecrolimus does not affect the density of epidermal Langerhans cells or affect the keratinocyte or endothelial cell expression of cell adhesion molecules

2. **Regarding systemic absorption of calcineurin inhibitors which of the following is NOT true?**
   A. Penetration and permeation of CIs is limited by their molecular weight
   B. In vitro and pharmacokinetic studies demonstrate that topical application of pimecrolimus results in significant risk of systemic exposure and side effects
   C. Their lipophilic properties show higher affinity for skin and less potential for systemic absorption compared with other agents
   D. The concentration of CIs required for a systemic anti-inflammatory affect is 10–15 ng/ml

3. **Local adverse affects to TCIs include all of the following except?**
   A. Stinging sensation
   B. Burning sensation
   C. Transient itching
   D. Increased risk of bacterial skin infections
   E. Onset in the first few days of treatment

4. **Which of the following is NOT true regarding the effect of TCIs on itch?**
   A. They are effective in significantly reducing atopic dermatitis associated pruritus within 1 week
   B. They are effective in treating pruritus associated with nodular prurigo
   C. Tacrolimus has shown superior efficacy over pimecrolimus with regard to itch scores and onset of action
   D. Itchy lesions that are often treatment resistant on the face and neck have been shown to respond well to pimecrolimus
   E. While they have effective antipruritic effects in nodular prurigo they have no effect on the prurigo nodules

5. **Which of the following statements regarding the safety of TCIs is NOT true?**
   A. The FDA issued a black box warning regarding a theoretical risk of malignancy including lymphoma with topical CI use in 2006
   B. There has been no conclusive proof to date to link TCI with malignancy
   C. Patients should be advised to use UV-protective measures while using TCIs
   D. Concomitant UV therapy should be avoided
   E. Animal studies have demonstrated an increased incidence of epidermal and melanocytic skin tumors when topical application of Pimecrolimus was combined with UV-irradiation

6. **Which of the following statements is true regarding TCIs?**
   A. Pimecrolimus is available as a 1 % ointment
   B. Both tacrolimus and pimecrolimus have no effect on rosacea, lichen planus, psoriasis or lichen sclerosis et atrophicans
   C. Tacrolimus has demonstrated superior and comparable efficacy to topical GCs in the treatment of atopic dermatitis
   D. Tacrolimus is approved for the treatment of moderate and severe atopic dermatitis in adults only
   E. Treatment should be stopped once symptomatic control has been achieved

Traditional Immune-Modulating Drugs

47

Stephen E. Wolverton and Mouhammad Aouthmany

Abstract

The subject of traditional immune modulating drugs is potentially vast. However, only a small number of these drugs are commonly used by dermatologists. This chapter addresses the key mechanisms of how the majority of inflammatory skin diseases are treated, and discusses six systemic drugs from four drugs groups: (1) calcineurin inhibitors: cyclosporine; (2) antimetabolites/purine analogues: azathioprine and mycophenolate mofetil; (3) antimetabolites/folate antagonists: methotrexate and dapsone; (4) alkylating agents: cyclophosphamide; and (5) lysosomotropic agents: hydroxychloroquine. This classification scheme is a reasonable way to categorize the drugs, although it should be noted that several of these drugs have additional mechanisms of action that differ from the above categories. Furthermore, it is not realistic to discuss all available immune-modulating drugs; several notable drug groups not covered in this chapter include retinoids and interferons.

Keywords

Immune-Modulating Drugs • Calcineurin inhibitors • Antimetabolites • Alkylating agents • Systemic calcineurin • Cyclosporine • Alkylating agent • Cyclophosphamide • Psoriasis • Atopic dermatitis • Azathioprine Mechanisms • Methotrexate

Key Points

- Traditional immune modulating drugs include calcineurin inhibitors, antimetabolites, and alkylating agents.
- Antimetabolites include purine analogues (e.g., azathioprine and mycophenolate mofetil), and folate antagonists (e.g., methotrexate and dapsone).
- The most widely used systemic calcineurin inhibitor is cyclosporine.
- The most commonly used alkylating agent is cyclophosphamide.

The subject of traditional immune modulating drugs is potentially vast. However, only a small number of these drugs are commonly used by dermatologists. This chapter addresses the key mechanisms of how the majority of inflammatory skin diseases are treated, and discusses six systemic drugs from four drugs groups: (1) calcineurin inhibitors: cyclosporine; (2) antimetabolites/purine analogues: azathioprine and mycophenolate mofetil; (3) antimetabolites/folate antagonists: methotrexate and dapsone; (4) alkylating agents: cyclophosphamide; and (5) lysosomotropic agents: hydroxychloroquine (Table 47.1). This classification scheme is a reasonable way to categorize the drugs, although it should be noted that several of these drugs have additional mechanisms of action that differ from the above categories. Furthermore, it is not realistic to discuss all available immune-modulating drugs; several notable drug groups not covered in this chapter include retinoids and interferons.

The emphasis here is on the primary mechanisms of action, particularly as these mechanisms relate to common indications, significant adverse effects, and drug interactions. The discussion of these indications, adverse effects, and drug interactions is brief, emphasizing those with the greatest clinical relevance for the practicing dermatologist. Chapters and reviews that provide greater detail of potential interest are cited.

The drugs above can be divided into two broad groups: immunosuppressive and anti-inflammatory. But many drugs overlap the categories; methotrexate, for example, has both immunosuppressive and anti-inflammatory mechanisms. Thus, considering the drugs discussed as "immune modulating" in a broad sense is a very reasonable approach.

Cyclosporine

Mechanisms of Action [1]

The most established role of cyclosporine (CsA) in psoriasis and other immune-mediated dermatoses is its effect on T lymphocytes [2]. Calcineurin is a calcium- and calmodulin-dependent enzyme that is of central importance to the T-cell amplification of the immune response, in particular inducing increased levels of interleukin-2 (IL-2) (Fig. 47.1). Cyclosporine inhibits calcineurin, which leads to reduced activity of the transcription factor, nuclear factor of activated T cells 1 (NFAT-1) [3]. This transcription factor is important in regulating transcription of a number of cytokine genes, the most significant being IL-2. Because IL-2 causes the proliferation of activated helper T cells (CD4) and cytotoxic T cells (CD8), impaired IL-2 production leads to a decline in the number of activated CD4 and CD8 cells in the epidermis and dermis.

In addition, CsA inhibits the production of interferon-γ, which in turn downregulates intercellular adhesion molecule 1 (ICAM-1) production. ICAM-1 is expressed on the surface of various cells such as keratinocytes and dermal capillary endothelium, playing an important role in the immune process by affecting trafficking of various inflammatory cells. Finally it is important to note that cyclosporine is both a cytochrome P-450 (CYP) 3A4 substrate and inhibitor, explaining many of the numerous potential drug interactions involving cyclosporine.

Table 47.1 Traditional immune-modulating drugs

Category	Drug name	Specific enzyme(s) inhibited
Calcineurin	Cyclosporine	Calcineurin inhibitors
Antimetabolites/purine analogues	Azathioprine	None
	Mycophenolate mofetil	Inosine monophosphate dehydrogenase
Antimetabolites/folate antagonists	Methotrexate	Dihydrofolate reductase, Thymidylate synthetase
	Dapsone	Dihydropteroate synthetase, Myeloperoxidase
Alkylating agents	Cyclophosphamide	None
Antimalarials	Hydroxychloroquine	None

Clinical Applications of Cyclosporine Mechanisms [1]

Common Indications

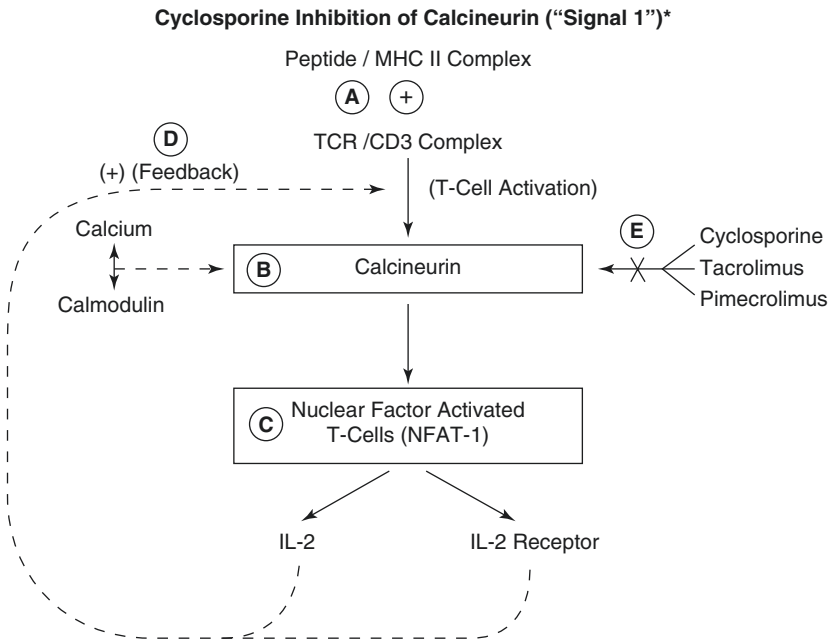
1. Psoriasis, atopic dermatitis, refractory urticaria; T-cell inhibition through cyclosporine inhibition of calcineurin and resultant reduced NFAT-1 production.
2. Pyoderma gangrenosum, immunobullous dermatoses (pemphigus and pemphigoid), autoimmune connective tissue diseases (dermatomyositis), and many others; additional dermatoses in which the T cell has a key role in the pathogenesis.

Significant Adverse Effects

1. Renal disease and resultant hypertension; kidney has relatively high levels of calcineurin.
2. Neurologic adverse effects (such as tremors, headache, paresthesias); various neurologic cell types likewise with relatively high levels of calcineurin.

Drug Interactions

1. Macrolides (erythromycin > clarithromycin), azole antifungals (ketoconazole > itraconazole); cyclosporine toxicity due to these CYP3A4 inhibitors.
2. Rifampin (and other "enzyme inducers"); loss of cyclosporine efficacy due to CYP3A4 inducers.
3. Statins such as simvastatin, atorvastatin, lovastatin > rosuvastatin, fluvastatin. CYP3A4 inhibition increasing the risk of rhabdomyolysis from these statins. Pravastatin has no CYP metabolism and is the best choice to use with cyclosporine.
4. Numerous other CYP-based drug interactions (see pertinent table in Lee and Koo [1]).



* This calcineurin/"signal 1" system creates a highly efficient immunologic responce to various antigenic (or superantigen) stimuli.

A The peptide/MHC II complex on the antigen presenting cell interacts with the T-cell receptor (TCR)/CD3 complex and results in T-cell activation; ↑calcineurin activity is one result of this T-cell activation.

B With calcium as a cofactor, and through interaction with the calcium binding protein calmodulin, calcineurin ↑ activity of the transcription factor NFAT-1.

C NFAT-1 ↑ formation of both the cytokine IL-2 and the IL-2 receptor.

D Through subsequent binding of IL-2 to IL-2 receptor, the T-cell activation is further amplified.

E **Cyclosporine** (as well as **tacrolimus** and **pimecrolimus**) inhibits the key enzyme, calcineurin, in this system with ↓ IL-2 and ↓ IL-2 receptor production, with the net effect of inhibiting "signal 1".

Fig. 47.1 Cyclosporine inhibition of calcineurin*. *IL* interleukin, *MHC* major histocompatibility complex

Azathioprine

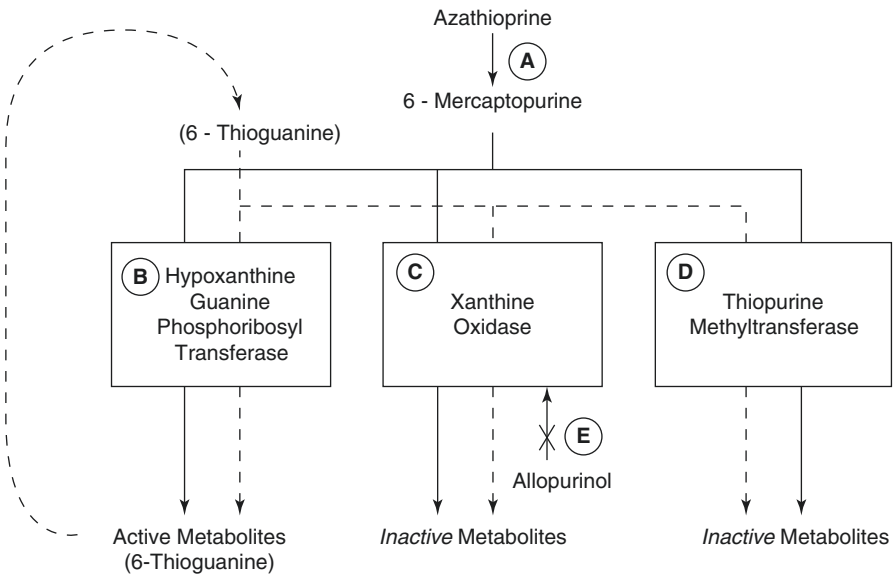
Mechanisms of Action [4]

Azathioprine's active metabolites are 6-thioguanine (6-TG) monophosphate and other 6-TG metabolites; these metabolites are structurally very similar to the endogenous purines adenine and guanine. This structural similarity to the endogenous purines allows these 6-TG metabolites to be incorporated into DNA and RNA, inhibiting purine metabolism and cell division [5, 6]. T-cell–mediated function is depressed, and antibody production is diminished in the B cell [7]. Azathioprine also decreases the number of Langerhans cells (and the ability to present antigens) and other antigen-presenting cells in the skin [8].

Azathioprine is a prodrug which is rapidly converted to 6-mercaptopurine (6-MP) upon absorption. There are three metabolic pathways which subsequently metabolize 6-MP: (1) hypoxanthine- guanine phosphoribosyltransferase (HGPRT), which leads to formation of the active 6-TG metabolites; (2) thiopurine methyltransferase (TPMT), which leads to inactive metabolites; and (3) xanthine oxidase (XO), which also leads to inactive metabolites (Fig. 47.2).

The degradative pathways TPMT and XO may indirectly alter the levels of 6-TG metabolites in different ways. The TPMT activity is reduced or absent in certain patients with a genetic polymorphism, while XO can be inhibited by drug interactions with azathioprine involving allopurinol and febuxostat [9, 10]. The net effect of these clinical scenarios is the risk of significant myelosuppression due to increased 6-TG metabolites. In contrast, patients with high levels of TPMT have relatively low levels of the active 6-TG metabolites and may be therapeutically underdosed with azathioprine [11, 12].

It is important to note that significant variation of TPMT activity is present when comparing different ethnic



A **Azathioprine** is initially converted to active form **6-mercaptopurine** (6-MP).

B Hypoxanthine guanine phosphoribosyl transferase (HGPRT) converts 6-MP to active metabolites **(6-thioguanine)**.

C Xanthine oxidase converts 6-MP to *inactive* metabolites.

D TPMT converts 6-MP to *inactive* metabolites (with genetic TPMT deficiency, shunting 6-MP to the HGPRT pathway occurs, with ↑↑ 6-thioguanine metabolites and subsequent *toxicity*; with genetically high TPMT levels, the result is ↓ 6-thioguanine metabolites, with *loss* of *efficacy*.

E **Allopurinol** inhibits xanthine oxidase, shunting 6-MP to HGPRT pathway, with ↑ toxicity.

Fig. 47.2 Azathioprine metabolic pathways

groups. Genetic testing (genotype) for TPMT is readily available, and can generally at least verify that the patient is a homozygote for high activity (TPMT 1*/1*) or a heterozygote for high activity (TPMT 1*/other allele). Functional assays of thiopurine methyltransferase red blood cell (RBC) activity are also available and widely utilized [11].

Clinical Applications of Azathioprine Mechanisms [4]

Common Indications

1. Pemphigus and pemphigoid spectrums; azathioprine inhibition of antibody production.
2. Cutaneous vasculitis (refractory), pyoderma gangrenosum, severe atopic dermatitis, chronic actinic dermatitis, sarcoidosis; inhibition of T-cell function.

Significant Adverse Effects

1. Carcinogenicity including non-Hodgkin's B- cell lymphomas (this does not appear to be a significant risk with dermatologic conditions with immunologic etiologies; no doubt is a risk with organ transplantation patients), due to altered immune surveillance resulting from azathioprine immunosuppressive properties.
2. Myelosuppression, especially with genetically decreased TPMT levels, shunting 6-MP increasingly to HGPRT pathway, resulting in increased 6-TG metabolites.
3. Opportunistic infections (theoretically; in reality opportunistic infections are very uncommon with azathioprine use for dermatologic indications), due to altered immune surveillance resulting from T-cell and B-cell effects of azathioprine.
4. Gastrointestinal (GI) adverse effects, such as rapidly dividing cells given that azathioprine a cell-cycle–specific antimetabolite.

Drug Interactions

Allopurinol; XO inhibition by allopurinol shunts increased amounts of 6-MP through the HGPRT pathway, leading to increased 6-TG metabolites.

Mycophenolate Mofetil

Mechanisms of Action [13]

Mycophenolate mofetil is rapidly converted to mycophenolic acid (MPA). On systemic absorption, MPA is inactivated by glucuronidation in the liver, and subsequently converted back to its active form by β-glucuronidase within the epidermis and gastrointestinal tract.

Mycophenolic acid has a key role in immune-mediated skin diseases by inhibiting de novo purine synthesis. It is a noncompetitive inhibitor of inosine monophosphate dehydrogenase (Fig. 47.3). Cells relying on de novo purine synthesis, rather than the purine salvage pathway, are preferentially affected. Therefore, the proliferative responses of T lymphocytes and B lymphocytes, which lack the purine salvage pathway, are blocked [14, 15]. Virtually all other cell lines in the body can utilize the purine salvage pathway, which lessens the inhibitory effects of this drug on nonimmunologic cells. Mycophenolic acid also leads to decreased levels of immunoglobulins and decreased delayed-type hypersensitivity responses [16].

Clinical Applications of Mycophenolate Mofetil Mechanisms [13]

Common Indications

1. Pyoderma gangrenosum, psoriasis; relatively selective T-cell inhibition by mycophenolate mofetil.
2. Immunobullous dermatoses (including cicatricial pemphigoid, pemphigus vulgaris, others); relatively selective B-cell inhibition by this drug.

Significant Adverse Effects

1. Gastrointestinal adverse effects; antimetabolite, cell-cycle specific effects on rapidly dividing cells theoretically; however, these cells in the GI tract largely have salvage pathway for purine metabolism.
2. Relatively small number of serious adverse effects; probably the result of the selectivity for the mechanism, with effects primarily on T- and B-lymphocyte subsets.

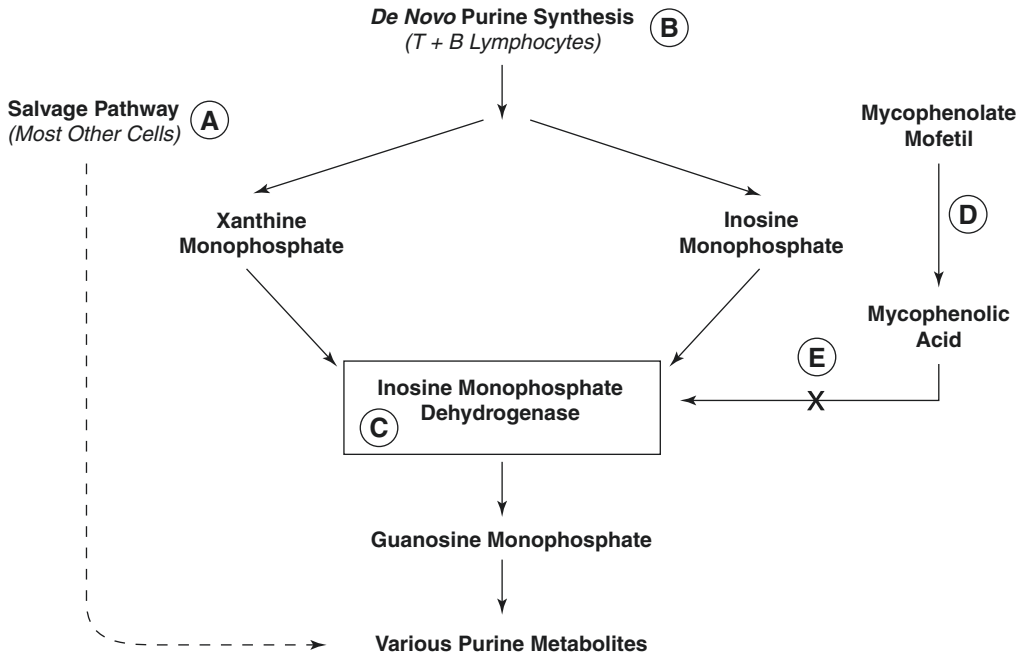
Drug Interactions

Azathioprine, methotrexate, tumor necrosis factor (TNF) inhibitors; pharmacodynamic interaction with potential for increased myelosuppression or opportunistic infections.

Methotrexate

Mechanisms of Action [17]

Methotrexate competitively and reversibly binds to dihydrofolate reductase, which prevents the conversion of dihydrofolate to tetrahydrofolate (Fig. 47.4). Tetrahydrofolate is a necessary cofactor in the synthesis of thymidylate and purine nucleotides needed for DNA and



A Most nucleated cells in the body are able to produce various purine metabolites via the "salvage pathway" (not shown in detail).

B "De novo" purine synthesis is the major route of purine synthesis for T-lymphocytes and B-lymphocytes.

C Inosine monophosphate dehydrogenase converts two different substrates – xanthine monophosphate and inosine monophosphate – into guanosine monophosphate.

D **Mycophenolate mofetil** is a prodrug which first must be converted to the active drug form mycophenolic acid.

E **Mycophenolic acid** inhibits inosine monophosphate dehydrogenase, thus depriving the T- and B-lymphocytes of purine metabolites necessary for growth and replication; the net result is a relatively selective immunosuppression.

Fig. 47.3 Mycophenolate mofetil inhibition of de novo purine synthesis

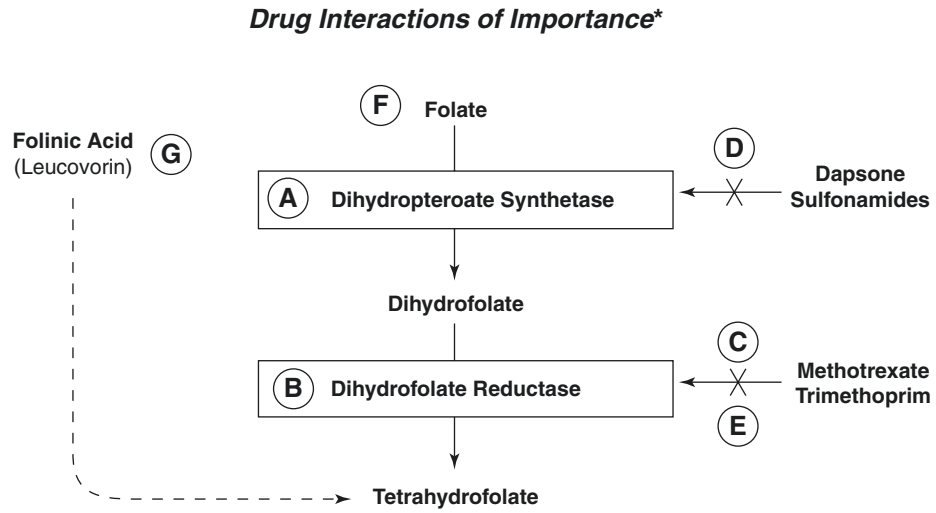
RNA synthesis. A partially reversible, competitive inhibition of thymidylate synthetase also occurs within 24 h after administration of methotrexate. Methotrexate is an antimetabolite specific for the S phase (synthesis, including DNA synthesis) of cell division, with the greatest impact on rapidly dividing cells. Cells of the GI tract and various hematologic cells are rapidly dividing groups of cells that are particularly sensitive to methotrexate inhibition of cell division.

Immunosuppression probably occurs because of inhibition of DNA synthesis in immunologically competent cells. The drug can suppress primary and secondary antibody responses as well [18, 19]. There is no significant effect on delayed-type hypersensitivity. An additional effect of MTX is to block migration of activated T cells into various tissues through alteration of various adhesion molecules [20]. The drug's anti-inflammatory effects are likely predominantly mediated by local increases in adenosine concentration, which has inherent anti-inflammatory properties. This increased adenosine production is the result of complex interactions with aminoimidazole carboxamide ribonucleotide (AICAR) transformylase and ecto-5′-nucleotidase [21].

Clinical Applications of Methotrexate Mechanisms [17]

Common Indications

1. Psoriasis, related to methotrexate T-cell inhibitory effects.
2. Atopic dermatitis; perhaps T-cell and anti-inflammatory effects as well, at least in part due to locally increased adenosine levels.
3. Bullous dermatoses (pemphigus and pemphigoid spectrums), autoimmune connective tissue diseases



* In general, this metabolic pathway is more important to the adverse effects of methotrexate (including drug interactions) than it is for drug efficacy. The fully reduced tetrahydrofolate is important for subsequent pyrimidine nucleotide synthesis.

A Folate (folic acid) is initially reduced to dihydrofolate by dihydropteroate synthetase.

B Dihydrofolate if further reduced to tetrahydrofolate by dihydrofolate reductase.

C **Methotrexate** inhibits this pathway through competitive inhibition of dihydrofolate reductase (DHFR).

D **Dapsone** and various **sulfonamides** inhibit dihydropteroate synthetase, and thus, can amplify the inhibition of DHFR by methotrexate.

E **Trimethoprim** (including fixed combinations with sulfamethoxazole) also inhibits DHFR, and thus can amplify the inhibition of this pathway by methotrexate.

F **Folic acid** given in therapeutic doses essentially competes with methotrexate for DHFR, reducing the adverse effects of methotrexate by ↑ tetrahydrofolate production.

G **Folinic acid**, in a sense does an "end run" around the methotrexate inhibition of folate, serving as a fully reduced substrate for pyrimidine synthesis.

Fig. 47.4 Methotrexate and folate metabolism

(dermatomyositis, morphea), sarcoidosis; methotrexate has a backup role as steroid-sparing agent due to the drug's immunosuppressive effects.

Significant Adverse Effects

1. Hepatotoxicity; nonimmunologic etiology in the great majority of cases, with methotrexate inducing fatty liver changes (risk further increases with conditions that induce fatty liver such as obesity, diabetes mellitus, excess alcohol).
2. Carcinogenicity; theoretically related to methotrexate immunosuppressive properties (this risk is primarily an issue in rheumatoid arthritis patients; minimal risk if any in psoriasis patients).
3. Gastrointestinal adverse effects such as nausea, related to cell-cycle specific properties as an antimetabolite; this risk is largely reduced by folic acid (folate) supplementation as a competitive antagonist of dihydrofolate reductase (DHFR).
4. Cytopenias such as pancytopenia, agranulocytosis, related to cell-cycle specific properties as an antimetabolite; also largely reduced risk by folic acid (folate) supplementation.

Drug Interactions

1. Trimethoprim, like methotrexate, is a DHFR inhibitor, thus amplifying the effect on this important folate metabolism enzyme.
2. Sulfonamides, dapsone (a sulfone); these drugs are dihydropteroate synthetase inhibitors, magnifying the folate pathway effects of the DHFR inhibitor methotrexate.

3. Alcohol and systemic retinoids, the pharmacodynamic effect being drugs with a risk of liver toxicity as well.

Dapsone

Mechanisms of Action [22]

The antimicrobial activity of dapsone in the treatment of leprosy is the result of inhibition of the folate metabolic pathway, specifically by the inhibition of dihydropteroate synthetase (Fig. 47.4) [23].

In contrast, dapsone inhibits the myeloperoxidase-peroxide-halide–mediated cytotoxic system as a central component of neutrophil respiratory burst (Fig. 47.5). This inhibition likely plays a key role in controlling the degree of neutrophil-induced destruction in cutaneous lesions [24]. The lack of neutrophils in the skin of patients being treated with dapsone suggests that this drug may also affect the chemotaxis of neutrophils. Dapsone inhibits chemotaxis to the chemoattractant N-formyl-methionyl-leucyl-phenylalanine (F-met-leu-phe) [25]. The net result of these two effects on neutrophils is the decreased presence of neutrophils (inhibition of chemotaxis) and decreased destructive capacity of neutrophils (inhibition of myeloperoxidase and the resultant respiratory burst) in a wide variety of dermatologic conditions.

The enzyme inhibited by dapsone, myeloperoxidase, is also present in eosinophils and monocytes, with a probable role in respiratory burst-mediated microbial destruction in these cells as well.

Clinical Applications of Dapsone Mechanisms [22]

Common Indications

1. Dermatitis herpetiformis and related conditions such as linear immunoglobulin A (IgA) bullous dermatosis; dapsone effects on neutrophil chemotaxis and respiratory burst mechanism due to myeloperoxidase inhibition.
2. Bullous lupus erythematosus, pyoderma gangrenosum, pemphigoid (bullous, cicatricial), urticarial vasculitis, aphthous stomatitis; also dermatoses with a central role of neutrophils in the disease process; chemotaxis and respiratory burst effects of dapsone.
3. Eosinophilic cellulitis, granuloma faciale; dermatoses with a central role of eosinophils; dapsone myeloperoxidase inhibition relevant in eosinophils as well.
4. Granuloma annulare, granulomatous rosacea; dermatoses with a central role of monocytes and granuloma formation; dapsone myeloperoxidase inhibition relevant in monocytes as well.
5. Infectious diseases such as leprosy, malaria; largely due to dihydropteroate synthetase inhibition.

Significant Adverse Effects

1. Agranulocytosis, mechanism uncertain; however, selectivity for neutrophils (over platelets, red blood cells [RBCs]) likely due at least in part to neutrophil myeloperoxidase inhibition.
2. Hemolysis, not immunologically mediated; instead is related to dapsone-induced RBC oxidative stress.
3. Dapsone hypersensitivity syndrome, immunologically mediated, but not directly related to the two primary enzymes dapsone inhibits (myeloperoxidase and dihydropteroate synthetase).

Drug Interactions

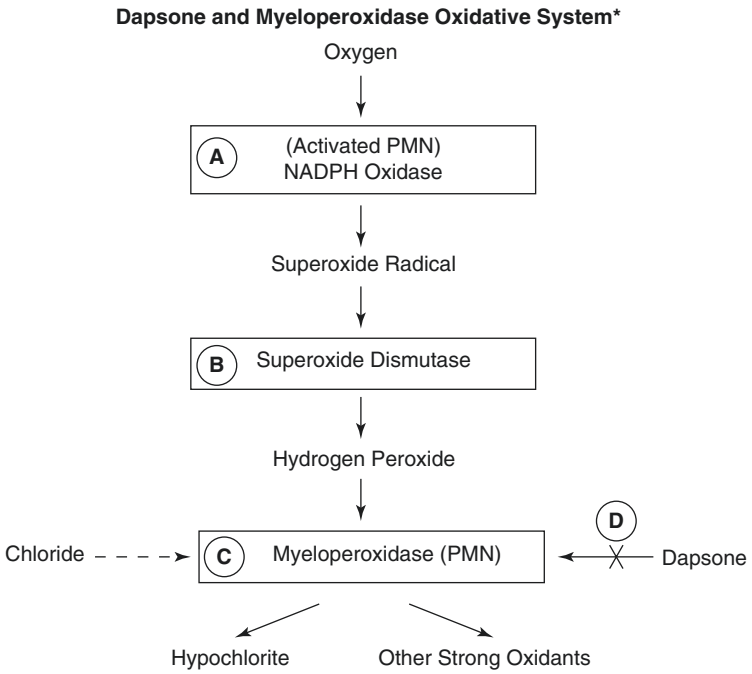
1. Trimethoprim, methotrexate; inhibition of dihydrofolate reductase, thus amplifying folate metabolism inhibition at two different steps (given dapsone dihydropteroate synthetase inhibition).
2. Sulfonamides; inhibition of dihydropteroate synthetase, theoretically amplifying the effects of dapsone on this enzyme.

Cyclophosphamide

Mechanisms of Action [13]

Systemic cytotoxic agents from the alkylating agents group include cyclophosphamide and chlorambucil. This section discusses the more potent immunosuppressive agent cyclophosphamide. In contrast with the antimetabolites previously discussed, cyclophosphamide is cell-cycle nonspecific. Thus, all cell types can be susceptible to the benefits and adverse effects of this drug. Alkylating agents alter the chemical properties and structure of DNA, regardless of timing in the cell cycle. The highly reactive ethyleneimine intermediate for cyclophosphamide is formed and covalently binds with various nucleophilic centers within DNA. Through their effect on protein synthesis, the alkylating drugs interfere with the production of cytokines, growth factors, adhesion molecules, and other substances required for cell growth and differentiation. As a result, these drugs are often mutagenic [26].

Cyclophosphamide depresses B-cell function more than T-cell function. The effect on T-cell activity is variable, with greater activity when the drug is given before antigen



* This enzyme system is present in neutrophils (PMN), eosinophils, and monocytes as a mechanism of microbial destruction through its oxidative properties.

A Oxygen is metabolized to the superoxide radical by the enzyme NADPH oxidase, which is produced by activated PMN.

B Subsequently, superoxide dismutase converts the superoxide radical to hydrogen peroxide.

C With hydrogen peroxide and chloride ions as substrates, myeloperoxidase produces hypochlorite and other strong oxidants leading to microbial destruction; however, in many neutrophilic dermatoses this system may damage various normal tissues.

D Through inhibition of myeloperoxidase, **dapsone** reduces the oxidative damage to normal tissues in various neutrophilic dermatoses, as well as dermatoses in which eosinophils and monocytes (granulomatous dermatoses) play a pathogenic role.

Fig. 47.5 Dapsone and myeloperoxidase oxidative system*. *NADPH* reduced nicotinamide adenine dinucleotide phosphate, *PMN* polymorphonuclear lymphocytes

presentation. In addition, suppressor T cells (CD8) appear to be significantly more affected than helper T cells (CD4) [27].

Three broad primary effects result from alkylation: (1) DNA may cross-link with another nucleophilic residue, (2) there is an abnormal base pairing with thymine, and (3) depurination may occur with resultant chain scission by several different mechanisms. If these mutations overwhelm the DNA repair system, the result is either cell death or mutagenesis and carcinogenesis [27, 28].

Hemorrhagic cystitis and resultant increased risk of bladder carcinoma due to cyclophosphamide are believed to be largely due to local increased concentrations of acrolein metabolites of cyclophosphamide [29].

Clinical Applications of Cyclophosphamide Drug Mechanisms [13]

Common Indications

1. Cicatricial pemphigoid (sight-threatening), severe pemphigus vulgaris; of all the drugs discussed in this chapter, cyclophosphamide is probably the most potent immunosuppressant and thus can be a definitive treatment of the most serious dermatoses.
2. Systemic vasculitis syndromes (such as Wegener's granulomatosis); similar reasoning as above, although these vasculitis subsets are seldom managed by dermatologists alone.

Significant Adverse Effects

1. Myelogenous leukemias; not an issue with other immunosuppressive agents; probably an issue with cyclophosphamide and other alkylating agents due to the structural alterations of DNA.
2. Bladder carcinoma (typically preceded by hemorrhagic cystitis), due largely to the acrolein metabolites of cyclophosphamide.
3. Myelosuppression; cyclophosphamide is a cell- cycle nonspecific drug, yet still has its greatest effect on rapidly dividing cells.

Drug Interactions

Chlorambucil, methotrexate, azathioprine-induced myelosuppression; pharmacodynamic effect with negatively synergistic impact on myelogenous cell precursors.

Hydroxychloroquine

Mechanisms of Action

The systemic antimalarial agents used in dermatology include hydroxychloroquine, chloroquine, and quinacrine. Although the exact mechanism of action is not fully understood, it is postulated that antimalarial agents are lysosomotropic agents that act on a wide range of pathways which provide an immunomodulatory, anti-inflammatory, anti-proliferative and photo-protective effects [30, 31].

Immunomodulatory effects occurs due to the accumulation of antimalarials in lysosomes and endosomes, increasing the pH and thereby disrupting proper endosomal maturation. This results in disruption of Toll-like receptor interactions and can lead to a decrease in the ability of antigen presenting cells in processing and expressing major histocompatibility complexes. Additionally, this disruption of endosomal maturation can lead to a decrease in release of interleukin 2 from CD4+ T-cells, reducing lymphocyte responsiveness and proliferation. Furthermore, the reduction of proper release of cytokines from these lysosomes would lead to an impaired chemotaxis of various inflammatory cells. Finally, antimalarials protect against ultraviolet induced damage on cells through effects of prostaglandin metabolism and inhibition of superoxide production or possibly by enhancing UVB-induced factors involved to protect against UV damage. This would result in a decrease in inflammation within the keratinocytes and possible release of self-antigens as a result of apoptosis that can be induced by UV radiation.

Clinical Applications of Hydroxychloroquine Drug Mechanisms [30]

Common Indications

1. Lupus erythematosus and other photosensitive dermatosis such as porphyria cutanea tarda, polymorphous light eruption, solar urticaria and dermatomyositis (including sine myositis); antimalarials effects on enhancing UVB-induced factors and inhibition of superoxide production;
2. Granulomatous dermatoses which includes cutaneous sarcoidosis and generalized granuloma annulare;
3. Panniculitis such as chronic erythema nodosum and lupus panniculitis;
4. Oral lichen planus.

Significant Adverse Effects

1. Ocular adverse effects include corneal deposition, loss of accommodation and premaculopathy which are all reversible. True retinopathy is also possible with prolonged use and is irreversible.
2. Hematological: rarely agranulocytosis or pancytopenia. Hemolysis in patients with G6PD deficiency.

Drug Interactions

1. Most significant is between antimalarials as usage of both would have an additive effect on causing retinopathy.
2. Antimalarials have been known to increase digoxin levels.
3. There may be an increased risk of hemolysis with the concurrent use of other agents such as dapsone in individuals with reduced G6PD activity (this effect is much greater with 8-aminoinolines such as primaquine).

Conclusion

Most traditional immune-modulating drugs used by dermatologists fall into four groups: calcineurin inhibitors, antimetabolites/purine analogues, antimetabolites/folate antagonists, and alkylating agents. The systemic calcineurin inhibitor most commonly used by dermatologists is cyclosporine. Purine analogues are represented by azathioprine and mycophenolate mofetil. Methotrexate and dapsone are commonly used folate antagonists. Alkylating agents are represented by cyclophosphamide. Although the antimalarial mechanisms are hardest to define, the lysosomotropic effects may explain much of the efficacy of the 4-aminoquinolines such as hydroxychloroquine. All of these drugs have uses in dermatology, but they also have significant adverse effects and the potential for drug interactions.

Questions and Answers

1. Which of the following statements is false?
   A. Calcineurin is a calcium-dependent enzyme
   B. Calcineurin is a calmodulin-dependent enzyme
   C. Cyclosporine inhibits calcineurin
   D. Cyclosporine stimulates production of interferon gamma

2. Which of the following statements is true?
   A. One of azathioprine's active metabolites is 6-thioguanine (6-TG) monophosphate
   B. Azathioprine increases the number of Langerhans cells
   C. 6-mercaptopurine is metabolized by hypoxanthine-guanine phosphoribosyltransferase (HGPRT) leading to formation of the inactive 6-thioguanine metabolites
   D. 6-mercaptopurine is metabolized by thiopurine methyltransferase (TPMT) leading to active 6-thioguanine metabolites

3. Which of the following statements is true regarding mycophenolate mofetil?
   A. It is a competitive inhibitor of inosine monophosphate dehydrogenase
   B. It is activated by glucuronidation in the liver
   C. It is rapidly converted to mycophenolic acid (MPA)
   D. Cells relying on the purine salvage pathway, are preferentially affected by mycophenolic acid

Topical Corticosteroids

48

Ulrich R. Hengge

Abstract

Since Marion Sulzberger introduced glucocorticosteroids (GCSs) in 1951, they have revolutionized clinical medicine. This chapter provides an updated overview of their mode of action, their use in dermatology, and their adverse-effect profile. While systemic GCSs have a long list of indications, topical corticosteroids represent the mainstay for treating inflammatory diseases of the skin. Adverse effects depend on the dose, the duration of treatment, and the preexisting medical conditions. For topical application, the nature of the drug, the vehicle, and the site of application determine the side-effect profile. The most frequent cutaneous adverse effects include atrophy, striae, rosacea, perioral dermatitis, acne, and purpura. With lower frequency, hypertrichosis, pigmentation changes, delayed wound healing, and skin infections as well as contact sensitization are observed. Important systemic adverse effects include musculoskeletal, ophthalmologic, nervous system, metabolic, and cardiovascular manifestations. The main characteristics of GCSs are potent anti-inflammatory, antiproliferative, and immunosuppressive effects, which give them a long list of potential indications in medicine. In particular, GCSs are extremely effective in the treatment of many autoimmune and inflammatory diseases.

Keywords

Topical Corticosteroids • Glucocorticosteroids • GCSs • Hypothalamicpituitary-adrenal (HPA) • Corticotropin-releasing hormone (CRH) • Adrenocorticotropic hormone (ACTH) • Musculoskeletal Osteoporosis • Osteonecrosis • Axis Suppression • Skin • Skin disease

Key Points

- Glucocorticosteroids (GCSs) have anti-inflammatory, antiproliferative, and immunosuppressive effects.
- Glucocorticosteroids exert their effects by binding to glucocorticoid receptors (GR) and by modification of transcription of corticosteroid-responsive genes.
- Glucocorticosteroids induce neutrophilia, lymphopenia, eosinopenia, and monocytopenia as well as reduce access of inflammatory cells at the site of active infection.
- To improve the benefit-risk ratio of GCSs, new interventions have been developed, including liposomal GCS, GR agonists, and nitroso-glucocorticoids.
- Drugs that induce the hepatic cytochrome P-450 system accelerate the clearance of GCSs, while other drugs inhibit this system.
- The side effects of GCSs are strictly dose dependent.
- The vehicle in which the topical steroid is formulated influences the absorption and potency of the drug.

Since Marion Sulzberger introduced glucocorticosteroids (GCSs) in 1951, they have revolutionized clinical medicine [1]. This chapter provides an updated overview of their mode of action, their use in dermatology, and their adverse-effect profile. While systemic GCSs have a long list of indications, topical corticosteroids represent the mainstay for treating inflammatory diseases of the skin. Adverse effects depend on the dose, the duration of treatment, and the preexisting medical conditions. For topical application, the nature of the drug, the vehicle, and the site of application determine the side-effect profile. The most frequent cutaneous adverse effects include atrophy, striae, rosacea, perioral dermatitis, acne, and purpura. With lower frequency, hypertrichosis, pigmentation changes, delayed wound healing, and skin infections as well as contact sensitization are observed. Important systemic adverse effects include musculoskeletal, ophthalmologic, nervous system, metabolic, and cardiovascular manifestations. The main characteristics of GCSs are potent antiinflammatory, antiproliferative, and immunosuppressive effects, which give them a long list of potential indications in medicine. In particular, GCSs are extremely effective in the treatment of many autoimmune and inflammatory diseases.

Synthesis of Glucocorticosteroids

Glucocorticosteroids are produced in the adrenal cortex, which secretes cortisol as well as the weak androgens androstenedione and dehydroepiandrosterone. Normally, cortisol secretion is regulated by hormonal interactions within the hypothalamic pituitary-adrenal (HPA) axis upon pulse secretion of the hypothalamic corticotropin-releasing hormone (CRH). This prompts the secretion of adrenocorticotropic hormone (ACTH) from the anterior pituitary, which then causes the secretion of cortisol from the adrenal cortex at a daily dose of 20 mg; however, cortisol output may increase by ten times upon stress.

Pharmacology

The family of steroids, including GCSs, is based on the four-ring structure of cholesterol, with 3-hexane rings and one pentane ring (Fig. 48.1) [2].

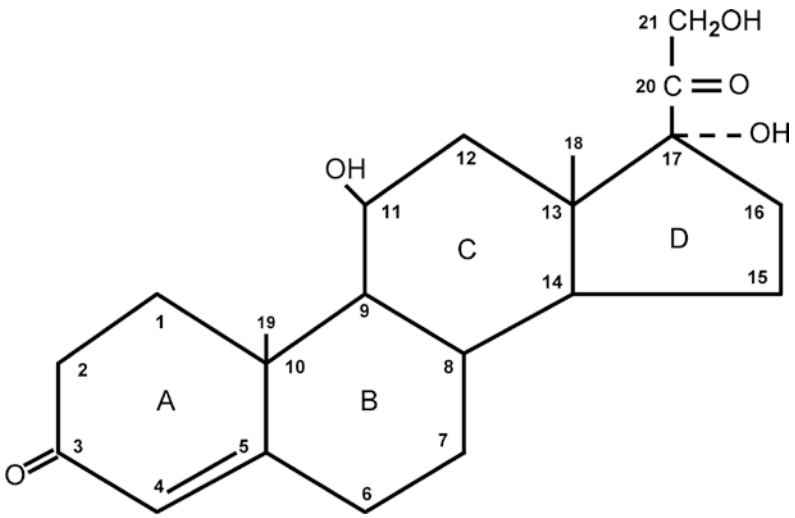

Fig. 48.1 Chemical structure of cortisol. Note the four-ring structure and the hydroxyl group at position 11

Modifications of the basic GCS structure result in agents with variant potency, mineralocorticoid activity, metabolism, and duration of action (Table 48.1). Important for the therapy of patients with hepatic insufficiency is the fact that the ketone group at the 11 position of cortisone must undergo hepatic conversion to a hydroxyl group to produce the active agent hydrocortisone (cortisol). Likewise, prednisone must undergo the same activation by 11-hydroxylation to become the active prednisolone. Therefore, for patients with liver problems, the use of prednisolone is recommended instead of prednisone. Glucocorticosteroids are absorbed in the jejunum with peak plasma levels occurring within one hour. Of note, administration with food does not decrease peak plasma concentrations but may delay its absorption.

Molecular Mechanism of Action

Glucocorticosteroids exert their effect by binding to glucocorticoid receptors (GRs) and by modification of transcription of corticosteroid-responsive genes. Free GCSs readily diffuse through the plasma membrane to bind to GRs in the cytoplasm, which leads to release of the heat-shock protein (hsp) 90. Upon release of hsp90, two nuclear localization signals are exposed, which allow the nuclear accumulation of the GR complex.

The GR forms a dimer that binds to glucocorticoid response elements within the promoter region of steroid-responsive genes. From this interaction, transrepression or transactivation of regulatory proteins may occur. It has become increasingly clear that many adverse effects of GCS are predominantly caused by transactivation (e.g., diabetes and glaucoma, osteoporosis, skin atrophy, growth retardation, and Cushing syndrome) [3]. By contrast, anti-inflammatory effects are mostly mediated by transrepression of proinflammatory cytokines or cyclooxygenase-2 (COX-2) [3, 4].

The discovery that activation and repression of the GR are genetically separable has fueled intense research on more selective receptor ligands [5]. The precise confirmation that the receptor assumes after ligand binding is determined by the structure of the given binding partner. Upon binding, structural alterations occur that allow interactions of the DNA-binding surface with specific glucocorticoid response elements such as the formation of homodimers and the binding of different co-activators and co-repressors at the ligand-binding domain that induce either activation or repression of gene transcription [6]. In particular, transcriptional repression activity is sensitive to the glucocorticoid-mediated anti-inflammatory and antiproliferative effects [7]. Several mechanisms of transcriptional repression such as interactions of the GR with DNA or with nonreceptor protein– protein complexes have been described [6]. Recently, a number of more selective GR ligands have been discovered; they are called selective GR agonists (SEGRAs) or dissociating GCSs [6]. The SEGRAs predominantly induce the desired transrepression effects, whereas transactivation properties are significantly reduced [3]. While some of these compounds have an encouraging side-effect profile, equivalent anti-inflammatory efficacy as compared with prednisone and dexamethasone still has to be demonstrated for compounds such as deflazacort [8].

Effects on Inflammatory Cells

Glucocorticosteroids induce neutrophilia, lymphopenia, eosinopenia, and monocytopenia. They also reduce access of inflammatory cells at the sites of active inflammation. However, important neutrophil functions such as phagocytosis and bactericidal activity remain largely unaffected by pharmacologic doses of GCSs. Transient lymphopenia occurs through redistribution of T lymphocytes to other lymphoid compartments, possibly through a change in adhesion molecule expression.

Table 48.1 Glucocorticosteroid agents

Compound	Equivalent glucocortico steroid dose (mg)	Mineralocorticoid potency (relative)	Duration of activity (h)
Short acting			
Cortisone	25	2 +	8–12
Hydrocortisone	20	2 +	8–12
Intermediate acting			
Prednisone	5	1 +	24–36
Prednisolone	5	1 +	24–36
Methylprednisolone	4	0	24–36
Triamcinolone	4	0	24–36
Long acting			
Dexamethasone	0.60	0	36–54
Betamethasone	0.75	0	36–54

Table 48.2 Major indications for systemic GCS use in dermatology

Inflammatory dermatoses and allergies
Contact dermatitis (various)
Atopic dermatitis
Photodermatitis
Exfoliative dermatitis
Erythrodermas
Urticaria
Erythema exudativum multiforme
Stevens-Johnson syndrome
Erythema nodosum
Sweet syndrome
Bullous dermatoses
Pemphigus (all forms)
Bullous pemphigoid
Cicatricial pemphigoid
Linear immunoglobulin A bullous dermatosis
Epidermolysis bullosa acquisita
Herpes gestationis
Erythema multiforme (major/minor)
Toxic epidermal necrosis
Vasculitis
Cutaneous (various types)
Systemic (various types)
Collagen vascular diseases
Lupus erythematosus (all subsets)
Dermatomyositis
Systemic sclerosis
Mixed connective tissue disease syndrome
Eosinophilic fasciitis
Relapsing polychondritis
Neutrophilic dermatoses
Pyoderma gangrenosum
Acute febrile neutrophilic dermatosis
Behçet's disease
Miscellaneous dermatoses
Sarcoidosis Lichen
Planus Polyarteriitis
Nodosa Panniculitis
Urticaria/angioedema
Arthropod bites/stings
Hemangiomas

Potential Indications and Contraindications

The list of potential indications for use of GCS in dermatology is long (Table 48.2). Primary indications are severe forms of eczema and autoimmune diseases, including bullous and collagen vascular diseases. In addition, GCSs are extremely useful drugs in the treatment of graft-versus-host disease [9].

Moreover, a number of cancers such as certain lymphomas and leukemias (e.g., multiple myeloma) respond well to combination therapy that includes GCSs. In these diseases, cancer cells are killed through GCS-mediated induction of apoptosis.

Contraindications include herpesvirus keratitis, active viral infections, invasive mycosis, and allergy to GCSs as well as administration following vaccination. Relative contraindications include hypertension, cardiac insufficiency,

peptic ulcers, psychosis, tuberculosis, diabetes, osteoporosis, glaucoma, cataracts, and pregnancy.

Dosing and Administration

Dermatologists most often prescribe GCSs for short periods of time to treat acute dermatoses such as contact dermatitis or different kinds of disorders. The therapeutic principle is to start at a high dose and to reduce the dose upon effect to maintenance dosing below the Cushing equivalent. Many corticoid-sensitive conditions are treated by oral burst therapy followed by a 2- to 3-week tapering course with a drug of intermediate duration of action such as prednisone; typically initial doses are in the range of 40–60 mg per day. From a pharmacoeconomic standpoint, GCSs have a very high cost effectiveness ratio; however, this is hampered by the costs of management of side effects. For example, prednisone is convenient as it is inexpensive and available in many dosages. The drug is usually given as a single dose in the morning rather than dosing being divided over the course of the day in order to minimize HPA axis suppression.

Severe and life-threatening dermatoses such as pemphigus vulgaris or severe drug reaction require higher doses of GCSs to suppress and control the disease. Especially for high-dose treatment, the doses can be separated by 4 to 6 hours to achieve better early control. The next step is to consolidate the drug to a single morning dose, prior to tapering. Alternatively, every-other-day administration may also be used as it has been shown to minimize suppression of the HPA axis. The addition of a steroid-sparing agent (e.g., mycophenolate mofetil or azathioprine) is often necessary for long-term GCS treatment such as for pemphigus vulgaris prior to tapering. Typical tapering is accomplished by 20-mg steps when the initial dose was more than 60 mg per day. Smaller tapers are used for lower initial doses until the physiologic dose range of 7.5 mg per day of prednisone is reached.

Intravenous pulse therapy is used for lifethreatening dermatoses using methylprednisolone in doses of 0.5–1 g per day for 5 days with a subsequent change to oral therapy. Cardiac conditions due to acute electrolyte shifts and arrhythmias are the most significant complications of a high-dose regimen. Due to the mineralocorticoid activity, potassium substitution may also be necessary.

To minimize corticosteroid side effects associated with GCS use, local application (e.g., inhalation) or fine-tuned dosing regimens have been developed to improve the benefit-risk ratio. One additional progress report includes the development of liposomal GCSs, which selectively accumulate at the site of inflammation [10]. Another current approach to optimize therapy with conventional GCS is to change the timing of glucocorticoid delivery (timed-release capsules) and the combination with 11β-hydroxysteroid dehydrogenase that increases the level and action of endogenous GCSs. For an additional improvement, new drugs such as selective GR agonists or nitroso-glucocorticoids (nitrosteroids) are in development. The nitrosteroids are characterized by an aliphatic or aromatic molecule, which links a conventional GCS derivative with nitric oxide (NO). Representatives of this class are NO-prednisolone and NO-hydrocortisone, which slowly release NO, exerting antiinflammatory effects [11]. The NO effect is synergistic to the effect of prednisolone, leading to an up to tenfold more potent antiinflammatory response than those of prednisolone alone [12].

Modes of Application

Glucocorticosteroids can be applied as topical and systemic treatment, but may also be administered locally to the nasal mucosa or be inhaled for the treatment of asthma. Recent studies suggest that inhaled steroids may also exhibit comparable side effects, including growth retardation in children [13] and reduction of bone markers in adolescents [14].

Local injections of triamcinolone are frequently being used to treat keloids. In addition, intraarticular injection represents a local application against rheumatic diseases.

Drug Interactions

As several drugs, such as rifampin, phenytoin, and phenobarbital, induce the hepatic cytochrome P-450 system, the clearance of GCSs may be accelerated in patients taking these medications. Dose-lowering adjustments may be necessary with enzyme inhibitors such as ketoconazole. Estrogens also potentiate the effect of GCS, because the two agents are metabolized similarly and have similar protein-binding characteristics [15].

The dose of GCS needs to be adjusted in patients with chronic active hepatitis and reduced renal function [16]. Conversely, in patients with hyperthyroidism, the biologic effect of prednisolone is reduced and may require higher doses.

Side Effects

The side effects of GCS are strictly dose-dependent. In addition, some side effects are known to depend on age and sex. In general, the side effects of GCS therapy show different degrees of severity. Table 48.3 contains a list of relevant side effects of GCS.

Table 48.3 Important side effects of glucocorticosteroid therapy

Musculoskeletal effects
Osteoporosis
Osteonecrosis
Growth retardation
Myopathy

Nausea and vomiting
Peptic ulcer disease
Cutaneous effects
Striae, purpura, telangiectasias, and atrophy
Cushing syndrome
Impaired wound healing
Hypothalamic-pituitary-adrenal axis suppression

Musculoskeletal

Osteoporosis

Osteoporosis is the most prevalent of the extremely important and severe musculoskeletal effects of long-term GCS therapy, but can be reduced or prevented with early physician intervention. Osteoporosis develops in 30–50 % of patients treated with long-term GCS therapy [17]. The typical patients suffer from chronic diseases such as rheumatoid arthritis, chronic destructive pulmonary disease, and asthma, or have had an organ transplantation. Postmenopausal women are especially at a significantly increased risk of fractures [18].

Importantly, the rate of bone loss is highest in the first 6 months of therapy; thereafter, the rate of bone loss is diminished. Upon discontinuation of steroid therapy, patients partly regain bone tissue. Glucocorticosteroid-induced bone loss affects trabecular bone and the cortical rim of vertebrae to a significantly higher degree than cortical bones ("long bones"). This is due to the much higher metabolic turnover rate of trabecular bone. Glucocorticosteroids cause this side effect by reducing intestinal absorption and renal tubular resorption of calcium. The reduced calcium serum concentration causes increased parathormone release that further promotes bone loss (secondary hyperparathyroidism). In addition, GCS can induce decreased gonadal function in both sexes. The most sensitive technique to diagnose osteoporosis is dual-energy x-ray absorptiometry (DEXA) [19].

Bone density studies should be performed every 12 months in patients with long-term corticosteroid therapy. Besides the use of bisphosphonates (alendronate and risedronate) as effective drugs preventing and treating GCS-induced osteoporosis [20], progress in treating GCS-associated side effects has been limited. There are additional data to support the effectiveness of calcium and vitamin D supplementation in preserving bone mass in patients receiving long-term GCS therapy [21].

Osteonecrosis

Osteonecrosis (aseptic necrosis) can also result from GCS therapy. It most commonly occurs on the proximal femur or the humeral head. In contrast to osteoporosis, osteonecrosis more frequently affects active patients and is particularly common in men [22, 23].

Growth Retardation

Growth suppression from GCS usually occurs with systemic therapy and may only occasionally be a consequence of extensive treatment with topical or inhaled potent GCS. When GCSs are given under the age of 2 or at puberty [24], the risk of growth retardation is especially significant. The studied patients were significantly shorter in height, had a significantly greater body mass index, and a higher prevalence of obesity than did the controls [24]. On average, they had received 23 grams of GCS for the treatment of nephrotic syndrome. The causes are multifaceted: interference with nitrogen and mineral retention, bone formation, inhibition of mitosis, and collagen synthesis [25]. Treatment of GCS-mediated growth inhibition with growth hormone shows some promise [26].

Myopathy

There are two forms of myopathy induced by GCS. One form is an acute myopathy seen almost exclusively in patients treated with high-dose intravenous GCS for status asthmaticus. The second form of myopathy is relevant to dermatology and is characterized by progressive symmetric proximal muscle weakness, which is usually painless and begins on the lower extremities after several months of therapy [27]. While the particular mechanism of GCS's effect on muscle mass has not been determined, hypogonadism (e.g., estrogen and testosterone) is likely to be involved, as it is present in many GCS patients. Diagnosis of GCS myopathy may be difficult in some patients, as muscle biopsies usually show nonspecific findings, and electromyographic studies are usually normal in this condition.

Ophthalmologic Effects

Cataract formation upon extended periods of GCS treatment has been described [28]. To detect initial changes, routine eye examinations twice yearly are recommended for all patients treated with longterm systemic GCS.

Open-angle glaucoma may also occur upon GCS treatment, especially in patients with a history of rheumatoid arthritis, type 1 diabetes, or a positive family history for glaucoma [29]. The detection of elevated intraocular pressure is important, as this condition is usually reversible within 1–4 weeks, when detected early.

Nervous System Effects

Affective disorders (anxiety, insomnia, euphoria, and emotional lability) are more frequent than confusional or psychotic states. The onset of symptoms is usually within 1 or 2 weeks after starting therapy, especially in patients with a prior history of psychiatric diseases [27]. Importantly, patients with systemic lupus erythematosus, who may suffer from lupus and encephalopathy may be difficult to differentiate from patients with steroid-induced psychosis. Discontinuation of GCS is usually the treatment of choice, rather than starting neuroleptic or antidepressive therapy.

Pseudotumor cerebri, presenting with headache, nausea, vomiting, and papillary edema, is a rare complication of long-term GCS administration and occurs predominantly in boys. It usually occurs when steroids are rapidly tapered or stopped [27].

Metabolic Effects

The manifestation of hyperglycemia and secondary diabetes is a typical complication of GCS therapy [30]. Relative insulin resistance is produced by decreasing the insulin affinity of cellular receptors and possibly by diminishing postreceptor effects of insulin [31, 32]. In addition, GCSs effect insulin-mediated increases in blood flow to muscles and increases in glucose output by increasing the rate-limiting enzyme of gluconeogenesis (i.e., phosphoenolpyruvate carboxy kinase). Therefore, following patients' regular blood glucose levels during continued GCS therapy is important [33]. If needed, insulin is the therapy of choice, as oral antidiabetics often take weeks before the onset of effects.

Hyperlipidemia may be worsened by GCS, especially in patients with diabetes mellitus, obesity, hypothyroidism, or family history of lipid disorders.

Weight gain may occur as a consequence of increased appetite and fluid retention with GCS therapy. Facial, supraclavicular, and posterior cervical fat depots are particularly sensitive to GCS, resulting in the moon face and buffalo humps that are characteristic of long-term GCS treatment. These symptoms severely impact on patients' well-being by negatively affecting their appearance and by predisposing them to obesity-related health issues.

Cardiovascular Effects

Excess GCSs can lead to increased blood pressure as they affect several points of blood pressure regulation. Hypertension may develop as a consequence of the mineralocorticoid activity of exogenous GCS. Usually, the kidney

is protected from the effects of excess cortisol through the oxidizing effect of 11β-hydroxysteroid dehydrogenase-2, a tissue-specific enzyme capable of converting cortisol to cortisone. However, aldosterone as well as synthetic steroids with modifications and different positions are not susceptible to this activity and exert a major effect directly on the kidney through both mineralocorticoid receptors and GR, leading to transepithelial sodium transport and sodium reabsorption in the proximal tubule [34]. A similar mode of action may be present in brain, where the 11β-hydroxysteroid dehydrogenase-2 is expressed along with mineralocorticoid receptors in selected areas that are involved in central regulation of salt, water balance, and blood pressure [35].

These processes trigger intravascular and extracellular volume expansion. In addition, a decrease in vasodilatory prostaglandins and prostacyclins has been detected upon GCS therapy [36], which contributes to hypertension.

Infection

Patients on GCS therapy are at an increased risk for infections, including bacterial, fungal, viral, and protozoal infectious agents. Making the diagnosis is sometimes difficult, as fever and many other signs of inflammation may be masked. Although neutrophilia is induced by GCS, the presence of greater than 6 % band forms suggests a coexistent infection [37]. Opportunistic infections such as *Pneumocystis jirovecii* and *Toxoplasma gondii* may occur in patients on chronic GCS therapy who are not HIV-positive. In addition, reactivation of tuberculosis remains a concern in this patient population [38]. Concomitant isoniazid has been advocated in patients with a positive tuberculin skin test undergoing long-term GCS therapy.

Inhibition of Wound Repair

The inhibition of wound repair results from inhibiting the natural and critical process of inflammation as part of the normal wound-healing process to remove debris and bacteria [39]. Moreover, GCSs inhibit collagen synthesis and collagen cross-linking, and thereby affect structural components of a healing wound [40].

Obstetric and Gynecologic Effects

Clinical experience in several trials has shown minimal adverse effects in pregnant and lactating women during GCS therapy [41, 42]. The American Academy of Pediatrics has determined prednisone to be compatible with breast-feeding, even though there is an excretion in breast milk [43].

Despite the fact that systemic GCS can cross the placenta to various degrees, there is no proof of the detrimental effect on the developing human brain or on vascular disease such as hypertension and atherosclerosis [44, 45]. However, pregnant or lactating women should be monitored for complications such as osteoporosis and glucose intolerance (gestational diabetes).

Gastrointestinal Effects

Nausea and vomiting may occur with oral GCS therapy. These side effects can be minimized if the GCS is taken with food. The association of GCS therapy and peptic ulcer disease remains controversial [46]. In particular, the simultaneous intake of GCSs with nonsteroidal anti-inflammatory drugs as well as smoking and alcohol use have to be considered. Concurrent therapy with proton pump blockers is advised in patients with a history of peptic ulcer disease.

Cutaneous Effects

Cutaneous side effects consist of atrophy of the dermis and subcutaneous tissue, striae, rarefaction of elastic tissue (frequently causing corticoid purpura and steroid acne), telangiectasias, and hirsutism. These and other cutaneous side effects are discussed in the section on topical GCS below.

Hypothalamic-Pituitary-Adrenal

Axis Suppression

The onset of HPA axis suppression is usually evident within 5 days of high-dose prednisolone therapy, suppressing ACTH and cortisol secretion. With longer treatment duration, clinically important adrenal suppression becomes a concern. Full recovery of adrenals may require up to 1 year in certain cases [38]. In addition, patients with chronic adrenal suppression, including HIV patients, may need GCS supplementation in critical conditions such as perioperative stress or sepsis.

A more common clinical problem than adrenal crisis is the steroid withdrawal syndrome. Patients' symptoms generally include arthralgias, mood swings, headache, lethargy, nausea, and vomiting, and are most frequently noted on rapidly tapering of GCS after extended periods of treatment [47].

Topical Corticosteroids

Topical corticosteroids (TCSs) have a particular adverse-effect profile, primarily directed at the treated skin area, that occurs regularly with prolonged treatment. The severity

Table 48.4 Potency of selected topical corticosteroid preparations

Class 1 (superpotent)	Betamethasone dipropionate ointment, cream 0.05 % (Diprolene, Diprosone)
	Clobetasol propionate ointment, cream 0.05 % (Temovate, Dermoxin)
	Diflorasone diacetate ointment 0.05 % (Florone, Psorcon)
	Halobetasol propionate ointment, cream 0.05 % (Ultravate)
Class 2 (potent)	Amcinonide ointment 0.1 % (Cyclocort)
	Desoximetasone ointment, cream, gel 0.25 % (Topicort, Ibaril)
	Diflorasone diacetate ointment 0.05 % (Florone, Maxiflor)

depends on the potency of the drug, the vehicle, and the location of its application (Table 48.4). The most frequent adverse effects include atrophy, striae, rosacea, perioral dermatitis, acne, and purpura (Table 48.5). With lower frequency, hypertrichosis, pigmentation changes, delayed wound healing, and exacerbation of skin infections are observed. Of particular

interest is the rate of contact sensitization against corticosteroids, which is considerably higher than generally believed. Systemic reactions following topical application such as hyperglycemia, glaucoma, and adrenal insufficiency have also been reported, especially in children.

Selection and Characteristics of Topical Glucocorticosteroids

Low- to medium-potency agents are generally used for treating thin, acute, inflammatory skin lesions (e.g., face, intertriginous areas), whereas highly or superpotent agents are often required for treating chronic, hyperkeratotic, or lichenified lesions (e.g., palms and soles) (Table 48.4). Most preparations are applied once or twice daily. More frequent application may be necessary on the palms or soles due to the thick stratum corneum. Every-other-day or weekend-only application may be effective for treating several chronic conditions. Low-potency agents are preferentially used in infants and the elderly. Infants have a high body surface to weight ratio; elderly patients have thin, fragile skin.

The vehicle in which the topical corticosteroid is formulated influences the absorption and potency of the drug [48]. Ointment bases enhance penetration of the drug by their occlusive effect and increase the hydration of the stratum corneum. Creams are preferred for acute and subacute dermatoses; they may be used on moist skin or intertriginous areas.

Marked regional variation in the extent of transcutaneous penetration has been documented [49]. While absorption on the forearm (1 %) is poor, the scalp absorbs around 4 % and the scrotum up to 35 % of applied drug. Consequently, the groin, axillae, neck, and face are more likely to develop local side effects [50, 51]. The reasons for this difference in absorption are due to the thickness of the stratum corneum and its lipid composition [49]. For these reasons, the skin of delicate sites such as the eyelids is much more likely to develop side effects of TCS therapy.

Pharmacologic Characteristics of Topical Glucocorticosteroids

Chemical substitution at certain key positions is able to modify the potency of GCS (see Tables 48.1 and 48.4). For example, halogenation at the 9-α position enhances the potency by improving activity within the target cell and decreasing breakdown into inactive metabolites [52]. Along the same lines, masking or removing the hydrophilic 17-dihydroxyacetone side chain or the 16-α- hydroxy group increases the molecule's lipophilicity, thus enhancing penetration through the stratum corneum [52].

The strength of TCS has been classified according to the vasoconstrictor assay, which is based on the extent to which the compound induces cutaneous vasoconstriction ("blanching effect") in normal human subjects (Table 48.4) [53]. The vasoconstriction test has been established in 1962 as a rough estimate of the efficacy of TCS [54, 55].

It represents a nonspecific and simple in vivo test, since the phenomenon of vasoconstriction is not linked to the

Fig. 48.2 Thickened lichenified skin, severe epidermal atrophy, and erythema following inappropriate use of high-potency corticosteroids on the face and eyelids. Telangiectasias were also present

receptor-mediated activity of steroids. However, the exact cause of this vasoconstriction remains unknown [56]. Alternatively, the ultraviolet (UV) erythema test measures the inhibitory effects of TCS on an experimentally elicited erythema [57]. The atrophy test is an important addition to the antiinflammatory tests, since it can be used to determine those TCSs that have only a slight antiproliferative effect (atrophogenic potential). Using the Duhring chamber, the corticosteroid to be tested is applied to the same skin area for 3 weeks under occlusion [58]. At this point, the resulting atrophy and the extent of telangiectasias are evaluated by a defined score.

Under normal conditions, up to 99 % of TCSs applied to human skin are removed by rubbing, washing off, and exfoliation, and only about 1 % is therapeutically active [59]. However, only this 1 % of percutaneously absorbed TCSs can exert systemic adverse effects, while cutaneous adverse effects may also result from the transient presence of TCSs [60].

Adverse Effects of Topical Glucocorticosteroids

A number of possible adverse effects of TCSs have been reported (see Table 48.5). Principally, systemic GCS can cause the same cutaneous manifestation as TCS.

Atrophy

All TCSs have been shown to cause skin atrophy, albeit to a variable degree [61, 62]. Signs of atrophy include telangiectasias (an abnormal dilatation of capillary vessels and arterioles), increased transparency and shininess of the skin, as well as the appearance of striae [50, 63]. The factors that influence the degree of skin atrophy include age, body site, potency of TCS, and the presence of occlusion. Atrophy has now been recognized as the most common adverse effect of topical corticosteroid therapy (Fig. 48.2) [64]. Topical application of corticosteroids can cause atrophy, not only because of the suppressive action on cell proliferation, but also due to inhibition of collagen synthesis [65]. In addition to epidermal and dermal thinning, corticosteroids stimulate human dermal microvascular endothelial cells, leading to the occurrence of telangiectasias [66].

Fig. 48.3 Striae distensae rubrae as a sign of topical corticosteroid (TCS) abuse from treating eczema on the left axilla in a nonobese 27-year-old man

Striae

Striae (rubrae distensae) are visible linear scars that form in areas of dermal damage, presumably upon mechanical stress (Fig. 48.3) [67]. They develop as an initial inflammation and edema in the dermis, followed by the deposition of dermal collagen along the lines of mechanical stress.

Steroid Rosacea

Facial dermatoses are usually steroid-sensitive and do not require potent formulations. The classical history of steroid

Fig. 48.4 Long-term inadvertent use of TCS for treatment of perioral and cheek dermatitis. Note the prominent telangiectasias

rosacea begins in a middle-aged woman with intermittent papules and pustules that are initially controlled by steroids of low potency (Fig. 48.4). Subsequently, the lesions reappear, leading to tachyphylaxis and steroid addiction [68].

Acne

Topical steroids can rapidly induce acneiform eruptions [69–71]. These studies attributed the acnegenic effect to the degradation of the follicular epithelium, resulting in extrusion of the follicular content (Fig. 48.5).

Perioral Dermatitis

Steroid-induced perioral dermatitis was described as a facial eruption in females that was composed of follicular papules and pustules on an erythematous background beginning in a perioral distribution with prominent sparing of the skin adjacent to the vermilion border [72].

Steroid Addiction and Tachyphylaxis

Corticosteroid addiction has been described as an ongoing inadvertent use of potent topical corticosteroids used mostly for inflammatory diseases of the face [68].

Tachyphylaxis is characterized by decreasing effects of corticosteroids upon continued treatment as revealed by the vasoconstrictor and proliferation inhibition assays. Due to the tissue becoming less sensitive (tachyphylaxis), more potent preparations are frequently being used to achieve comparable effects [73], yielding more severe side effects.

Fig. 48.5 Steroid acne in the face characterized by pustules, erythema, and several open and closed comedones on the forehead. Note the free margins around the vermilion border

Hypertrichosis

Steroids promote the growth of vellus hair by an unknown mechanism [74]. Variable degrees of hypertrichosis remain a more common manifestation of systemic corticosteroid use. The darker hair may persist for months after withdrawal of steroids.

Hypopigmentation

Decreased pigmentation after topical use is quite common, though frequently unnoticed. Americans of sub-Saharan African lineage are particularly affected. Most likely, steroids interfere with the synthesis of melanin, leading to patchy areas of hypopigmentation. The lesions are generally reversible upon discontinuation of steroid therapy.

Purpura and Stellate Pseudoscars

Purpura occurs due to severe dermal atrophy and loss of intercellular substance, and blood vessels lose their support and rupture. The resulting fragility of dermal tissue leads to hypopigmented, depressed scars [75]. These stellate pseudoscars develop most frequently over the extremities mostly on severely atrophic, telangiectatic purpuric skin (see Fig. 48.2).

Fig. 48.6 Tinea incognito of the leg. This patient was treated with corticosteroids masking the diagnosis of tinea

Aggravation of Cutaneous Infections

Mucocutaneous (e.g., skin, nails, mucous membranes) fungal infections are common during treatment with corticosteroids and often occur early in therapy [76, 77]. The incidence of skin infections varies, but is probably between 16 and 43 % [76]. Infections include tinea versicolor, onychomycosis due to *Trichophyton* and *Candida* species, and dermatophytosis (Fig. 48.6) [76]. The term *tinea incognito* serves to describe dermatophyte infections that became unrecognizable because of suppression of inflammation and fungal proliferation [78].

Granuloma gluteale is a persistent reddish-purple, granulomatous papulonodular eruption occurring on the buttocks, thighs, or inguinal folds in children. It is a well-known consequence of diaper dermatitis that is being treated with corticosteroids [79].

Delayed Wound Healing

The effects of TCS and systemic GCS on wound healing include keratinocytes (epidermal atrophy, delayed reepithelization), fibroblasts (reduced collagen and ground substance resulting in dermal atrophy and striae), vascular connective tissue support (telangiectasias, purpura, easy bruising), and impaired angiogenesis (delayed granulation tissue formation) [38].

Contact Sensitization

Several multicenter studies have been performed addressing contact hypersensitivity to TCS, yielding a prevalence of 0.2–6 % [80–83]. It seems that nonfluorinated corticosteroids (e.g., hydrocortisone, hydrocortisone-17-butyrate, and budesonide) result in a higher prevalence of corticosteroid allergy in comparison with fluorinated compounds [84].

Systemic Adverse Effects with Topical Administration

Systemic adverse effects from TCS are relatively infrequent, but may occur. In particular, glaucoma following the use of TCS around the eye has been recognized as a rare but serious problem [85, 86]. This is not surprising, if one considers that the penetration of TCS is up to 300 times greater through the eyelid than on other body sites [49]. Topical corticosteroid and systemic GCS therapy have been associated with cataract formation, but systemic GCSs are most often responsible for this complication [87]. In addition, short-term enhancement of plasma cortisol levels has been detected upon topical application of hydrocortisone [88]. All effective TCSs possess the potential to suppress the HPA axis [89].

Increasing steroid penetration has been shown to increase the potential for HPA suppression especially in children with atopic dermatitis [90–92]. The advent of superpotent derivatives such as clobetasol propionate, betamethasone dipropionate, and diflorasone diacetate have an increased ability to suppress adrenal function. As little as 2 grams per day of clobetasol propionate 0.05 % cream can cause a decreased morning cortisol after only a few days [93, 94]. A recent open-label trial has addressed the potential suppression of the HPA axis using 0.1 % fluocinonide cream in pediatric patients with atopic dermatitis with regard to adrenal suppression [95].

In this multicenter, multidosing, open-label trial, 0.1 % fluocinonide cream was applied to patients in four different age cohorts, from 3 months to 18 years of age, who suffered from moderate to severe atopic dermatitis in excess of 20 % body surface area involvement. No suppression of the HPA axis was observed in any patient treated once daily or in patients younger than 6 years of age. One of 15 (7 %) and two of 16 (13 %) patients from 3 months to 2 years and 2–6 years, respectively, developed HPA axis suppression when receiving twice daily 0.1 % fluocinonide treatment to more than 20 % of body surface area [95].

With the majority of patients with HPA suppression demonstrating exclusive laboratory test abnormalities, several cases of severely impaired stress responses have been reported, especially in children following treatment with high potency TCS [96–98]. Recovery from steroid-induced adrenal insufficiency is time-dependent and occurs spontaneously. The administration of TCS has also led to iatrogenic Cushing's syndrome [99, 100]. In addition, there is a possibility of retarded growth in children exposed to long-term potent and superpotent topical TCS formulations [96]. For prevention, it has been suggested that less than 50 grams per week of potent corticosteroids should be used [101].

Table 48.6 Optimal use of topical glucocorticosteroids

1. Appropriately potent compound to achieve disease control
2. Continuation with a less potent preparation after sufficient response
3. Reduction of frequency of application
4. Continuation of daily application with the weakest effective preparation
5. "Tapering off" treatment upon complete healing
6. Particular care in treating children and the elderly, in particular at certain locations (e.g., scrotum, face and flexures, and around the eyes)

Prevention of Adverse Effects

Guidelines regarding the use of TCS and suggestions were provided to prevent their misuse [62, 102, 103].

Possible measures to prevent side effects include the use of lower potency steroids, the application only in the morning, and alternate-day treatment (reducing tachyphylaxis and avoidance of occlusion) (Table 48.6) [104].

Conclusion

Glucocorticosteroids have anti-inflammatory, antiproliferative, and immunosuppressive effects. These effects are exerted by GCS binding to glucocorticoid receptors (GRs) and by modification of transcription of corticosteroid-responsive genes. Neutrophilia, lymphopenia, and eosinopenia are induced by GCSs, which also reduce access of inflammatory cells at the site of active infection. To improve the benefit-risk ratio of GCSs, new interventions have been developed, such as liposomal GCSs, GR agonists, and nitroso-glucocorticosteroids. Some drugs inhibit the P-450 system, reducing clearance of GCSs, while other drugs induce the system, accelerating clearance. The side effects of GCSs are strictly dose-dependent, but the vehicle in which topical steroids are formulated influence the absorption and potency of the drug.

Questions

1. Which of the following drugs inhibit the hepatic cytochrome P-450 system, requiring dose-lowering adjustments in glucocorticosteroids?
   (a) Rifampin
   (b) Ketoconazole*
   (c) Phenytoin
   (d) Phenobarbital

2. Which of the following modifications of glucocorticosteroids enhances the potency by improving activity within the target cell and decreasing breakdown into inactive metabolites?
   (a) Removing the 17-dihydroxyacetone side chain
   (b) Removing the 16-alpha hydroxyl group
   (c) Halogenation at the 9-alpha position*
   (d) Halogenation at the 16-alpha position

3. Glucocorticosteroids can induce acneiform eruptions by which mechanism?
   (a) Increased growth of *P. acnes*
   (b) Degradation of the follicular epithelium*
   (c) Inhibition of collagen synthesis
   (d) Inhibition of elastin synthesis

Answers

1. b
2. c
3. b

* indicates the correct answers to the questions

Abstract

Vaccines are one of the leading tools used for maintenance of public health, and have made a tremendous contribution to the goal of reducing the incidence of numerous diseases since their inception. The prevention of diseases such as smallpox, polio, measles, and hepatitis B have had an enormous impact on world health over the last century. Research has led to the development of different types of vaccines, including live-attenuated, inactivated, conjugate, and recombinant vaccines. Herpes zoster and diseases caused by human papillomavirus represent important dermatologic conditions which have been the target of vaccines. Recent advances in the development of new vaccines for HIV, herpes simplex, and certain malignancies represent the next horizon for disease prevention and treatment with vaccines. Despite the challenges among implementing vaccination programs and public education regarding immunization, the available data from approximately 200 years of research shows that manipulation of the immune system with vaccines has been of great benefit.

Key Points

- Vaccination is ranked as the greatest public health achievement in the last century.
- Universal childhood immunization in the United States has led to a significant decrease in the incidence of several diseases.
- Vaccines may cause adverse reactions but most are mild and well tolerated.
- Many more vaccines are currently in development, and continuing vaccine research provides a promising outlook for prevention of more diseases in the near future
- The future of vaccines includes live-agent vaccines as vectors of other antigens, sequential immunization, immunization with DNA, and therapeutic vaccines.

Four criteria are needed for the success of a vaccine-based eradication program: (1) the infection must be limited to humans (no animal reservoir); (2) with viral infections there must be only one or a few strains of the virus, and these strains must have constant antigenic properties; (3) the virus must not persist in the infected host; and (4) the vaccine should be effective [1]. Vaccination as the route to prevention is the best option for controlling the spread of infectious diseases. Immunization can prevent or modify the severity of illness in the individual and interrupt or reduce the transmission of the pathogens to other susceptible people. Through these mechanisms, vaccines against smallpox, polio, measles, and hepatitis B have had an enormous impact on world health over the last 50 years. Vaccination is ranked as the greatest public health achievement in the last century, contributing the most to decreased global morbidity and mortality [2, 3].

There is a still great need for vaccines for many organisms since an inadequate number of antimicrobial drugs are available for the multiple microbes that exist. There are many reasons why it is difficult to produce the many necessary vaccines, including that all microorganisms deploy evasion methods that interfere with effective immune responses; further, for many organisms, it is still unclear which immune responses provide effective protection, particularly in developing vaccines against agents that cause persistent or chronic infections. Such infections, which notably include the human immunodeficiency virus (HIV), are subject to significant antigenic variation. Most current vaccines are directed against acute infections, when a sublethal dose of the agent is controlled and rapidly cleared by the immune system (Table 49.1).

Control of Infection

Extracellular Infection

Cytokines secreted by $CD4^+$ T-helper-1 (Th1) T cells aid in activating phagocytic cells such as macrophages and thus help in the destruction of the foreign agent in this fashion or complexed with an antibody.

Intracellular Infection

With intracellular infections with viruses, cytotoxic T lymphocytes (CTLs) play a dominant role in controlling and clearing the infection. In addition to its active role in killing infected cells, cytotoxic T cells secrete potent cytokines with antiviral and macrophage-activating capabilities, such as interferon-γ (IFN-γ) and tumor necrosis factor-α (TNF-α) [1]. With intracellular bacterial infections, the immune response is not as straightforward. Both $CD4^+$ Th1 and $CD8^+$ T cells have an important role in reducing, controlling, and clearing the infection [4–7].

Regional Immunity

The mucosal surfaces of the human body are far greater in area in comparison to the skin and are well endowed with draining lymphoid tissues, with the exception of the vagina. The main routes of infection are the gut, the rectum, the genitourinary tract, the respiratory tract, and the eye. There is a common mucosal system, so that immunization at one site can result in protection at that and other mucosal areas. For instance, the adenovirus vaccine is administered orally but offers protection against a respiratory infection [8]. In addition, since the female genital tract is devoid of lymph tissue, systemic immunization is necessary to confer protection. Specifically, immunization through the respiratory tract was shown to be superior to other routes in inducing protection in the female genital tract [7, 9–11].

The formation and secretion of secretory immunoglobulin A (sIgA), is the first line of defense in the mucosal immune system; sIgA binds to antigens and their toxins and subsequently aids in prevention of attachment and penetration of the mucosal surface. Cytotoxic T cells have also been shown in the cytobrush specimens from the cervix of HIV-infected women [12]. Thus, protection in mucosal immunity is likely mediated through humoral and cell-mediated mechanisms.

Immunologic Memory

Most organisms are detected and destroyed within hours by defense mechanisms that are not antigen-specific and do not require any prolonged period of induction. This illustrates the mechanism of innate immunity. Only when a pathogen or antigen is able to break this early line of defense will an adaptive immune response ensue, including the production of antigen-specific effector cells, secretion of antibodies by B cells, direct cytotoxic activity (CTLs), or via the secretion of immunologic mediators and effector molecules such as cytokines and chemokines. Most of the effector cells will die within 10–14 days after infection, but some cells survive as highly reactive plasma cells (B cells) or memory cells (B and T cells) to combat subsequent infection. The goal in preventative vaccination is to stimulate the adaptive response in the body with formation of long-lasting antibodies against a specific pathogen and induction of memory cells. The mechanism of how it should be achieved through immunization is less certain, but significant information has been elucidated about immunologic memory thus far [13–15].

B-Cell Memory

A memory B-cell is one that has undergone immunoglobulin isotype switching and somatic hypermutation [16]. This differentiation process starts late in the primary immune response and takes place in the germinal centers of lymph nodes. Upon reencountering the same pathogen (or antigen in a booster vaccine), the memory cells start dividing at a high rate and differentiate into antibody-secreting plasma cells. Further, memory cells produce antibody of higher average affinity than unprimed B cells; the affinity of that antibody persists to increase during the ongoing secondary and subsequent antibody responses.

T-Cell Memory

After immunization, the number of T cells reactive to a given antigen increases markedly as the majority become effector T cells; then the number falls back to continue at a level significantly (100- to 1000-fold) above the initial frequency. These cells carry cell-surface proteins more characteristic of effector cells than of naive T cells. Both $CD4^+$ and $CD8^+$ T cells can differentiate into two types of memory cells. One type is called effector memory cells because they can quickly mature into effector T cells and secrete large amounts of cytokines such as IFN-γ, interleukin-4 (IL-4), and IL-5 early after re-stimulation. They probably develop from effector T cells and are relatively short-lived [17]. The other type is called central memory cells, and they are long-lived in the absence of antigen and are able to deal with systemic pathogenic infections. Recently, a new type of T cell, the T memory stem cell, has been recognized in the $CD8^+$ which has the ability to reproduce itself as well as give rise to effector memory and central memory cells. These cells have been shown to play a significant role in immune homeostasis and have been a target in recent therapies targeting intracellular pathogens and cancer [18].

Routes of Vaccination

Most vaccines are currently given by injection, which has two main disadvantages. The first is that injections are painful and expensive, requiring needles, syringes, and a trained injector. Mass vaccination can be arduous through this route. The disadvantage from an immunologic standpoint is that the injection may not be the most effective way of stimulating an appropriate immune response since it is not imitating the route of the majority of the pathogens.

Although the presentation of soluble protein antigens by the oral route often results in tolerance, which is necessary with the large load of food-borne and airborne antigens presented to the gut and respiratory tract, many pathogens that cause significant morbidity and mortality across the world infect mucosal surfaces or enter the body through mucous surfaces. For this reason, several vaccines targeting the mucosal immune response have been and are currently being studied. For instance, there is the Sabin trivalent oral poliovirus vaccine (OPV). Unfortunately due to one case of paralysis, the Centers for Disease Control (CDC) and the American Academy of Pediatrics have recommended that only inactivated polio vaccine (IPV) be used after January 1, 2000 [19]. Oral polio vaccines are still being used in

areas outside the United States where polio is endemic [20]. In addition, a safe and effective intranasal influenza vaccine has been available for several years. Buccal, sublingual, vaginal, and eye mucosa methods of vaccination have recently been studied in preclinical investigations and have shown promising results [21, 22].

Due to the significant advances in the technology of immunization, other routes of delivery are being considered. For instance, viral and bacterial antigens have been produced in transgenic plants [23, 24]. Plant-based vaccines offer a means to deliver large quantities of a designated antigen in an encapsulated form. This encapsulation appears to protect against rapid and complete degradation of orally administered recombinant proteins. Thus, there is the potential for antigen to be gradually released into the gastrointestinal tract as host tissue is digested. This should theoretically permit an increased proportion of orally administered antigens to reach the effector sites, such as Peyer's patches lining the gastrointestinal tract [25]. A few human vaccine candidates have entered or completed phase I clinical trials. These include diarrheal vaccine candidates targeting enterotoxigenic *Escherichia coli* [26, 27] and Norwalk virus [28] and candidates against hepatitis B, rabies, smallpox, RSV, diphtheria, influenza, and anthrax [29–31].

Another route being considered is epicutaneous immunization. In the past few years, it has been elucidated that application of antigen onto bare skin induces potent systemic and mucosal immunity in an antigen-specific manner via Langerhans and dendritic cells [32–34]. Coadministration of nonspecific adjuvants, such as cholera toxin, is necessary to induce good immune responses. It has recently been demonstrated that a natural adjuvant effect can be achieved by disrupting the stratum corneum prior to topical antigen application; this act stimulates the Langerhans cells [32]. Epicutaneous immunization also generates active antigen-specific immunity in the gut and particularly augments Th2 responses subsequent to oral antigen [35] and inhalation of antigen [36]. The search for methods of vaccine delivery not requiring a needle and syringe has been influenced by concerns of pandemic disease, bioterrorism, and disease eradication campaigns [37]. Early testing of skin-patch tests is beginning, and past data with epicutaneous influenza vaccine showed that the vaccine was well tolerated by human volunteers [38].

Vaccine Development

Live-Attenuated Vaccines

Viruses

Live-attenuated viral vaccines are composed of viruses that are traditionally grown in cultured cells. Viruses are typically selected for preferential growth in nonhuman cells, and, in the course of selection, become less capable of growth in human cells. Since these attenuated strains do not replicate well in human hosts, they induce immunity but not disease when given to individuals. There may be a slight possibility that the pathogenic virus can reemerge by a further series of mutations even though attenuated virus strains contain multiple mutations in their genome. Further, attenuated viral vaccines can cause significant damage by inducing viral opportunistic infections in those that are immunodeficient [39]. Live-attenuated viral vaccines are currently in use for smallpox, measles, mumps, rubella, varicella, herpes zoster, polio, influenza (intranasal), yellow fever, and rotavirus. The vaccines targeting diseases that cause cutaneous manifestations are discussed in this section and throughout the chapter.

Smallpox

Edward Jenner, in 1796, was the first to demonstrate that inoculation of cowpox virus into human skin could lead to protection from subsequent smallpox infection [40]. Jenner named the inoculation substance *vaccine*, based on the Latin word *vacca*, meaning "cow." The vaccines used for smallpox vaccination are derived from vaccinia virus, a species similar to cowpox. The virus that causes smallpox is the variola virus, which belongs to the Poxviridae family and *Orthopoxvirus* genus, which also includes the vaccinia, cowpox, and monkeypox viruses. The smallpox vaccine, consisting of several types of strains of the live attenuated vaccinia virus, has served as the prototype of success of a viral vaccine; it was employed in the eradication of the disease. Prior to immunization, smallpox infection killed hundreds of millions of people unremittingly. The eradication of smallpox has been viewed as one of the greatest achievements in medicine.

Approximately two decades ago, after the complete elimination of smallpox, vaccine production ceased [41]. However, due to the recent concerns about biologic warfare and the use of smallpox as an agent, the danger of this disease has not been eliminated. Thus, renewed interest has been developed in production of the smallpox vaccines. ACAM2000 (Acambis) is the currently licensed vaccine used for immunization against smallpox in public health, health-care-response teams, and laboratory workers involved with vaccinia virus research. It is derived from the formerly used vaccine Dryvax, with the main difference being vaccine preparation; ACAM2000 is prepared in cell culture rather than calf lymph, which gives it a lesser risk of causing rare but serious complications [42].

Contraindications to the use of this vaccine in the absence of circulating smallpox include allergies to polymyxin B sulfate, streptomycin sulfate, chlortetracycline hydrochloride, and neomycin sulfate. Patients in an immunocompromised state or women who are pregnant or

Table 49.2 Childhood immunization schedule for diseases with cutaneous manifestations

Dose Vaccine	Dose 1	Dose 2	Dose 3	Dose 4	Dose 5	Boostert

Meningococcal	Single dose[b]	X	X	X	X	X
Hepatitis A	2 doses between 12 and 23 months[c]		X	X	X	X
Human papillomavirus	Total of 3 doses[d]					

Source: Adapted from Department of Health and Human Services Centers for Disease Control and Prevention: 2007 Recommended Immunization Schedules for Children in the United States

Hib Haemophilus influenzae type B; *MMR* measles, mumps, rubella

[a]This last dose is only needed in high-risk groups. Pneumococcal polysaccharide vaccine (PPV) can be administered to children >24 months of age who are in the high-risk groups

[b]MPSV4 should be given to patients ages 2–10 who have terminal complement deficiency, asplenia, and to other certain high-risk groups. Patients over age 10 can receive either MPSV4 or MCV4. Strongly suggest meningococcal vaccine administration before start of high school or before freshman year of college

[c]Two doses between 12 and 23 months of age should be given 6 months apart

[d]In females, a three dose regimen can be initiated starting at age 9. The second dose should occur 2 months after the first dose with the third dose to follow 6 months later

intend to become pregnant or who are breastfeeding should also not receive the vaccine. The vaccine should be administered concurrently with antihistamines or glucocorticoids to individuals who have allergic symptoms to the above compounds and have contact with individuals with smallpox. Further, the use of the smallpox vaccine is cautioned in persons with a history of eczema or atopic dermatitis; in persons who have acute, chronic, or exfoliative skin conditions; in persons who are using topical ocular steroid medications; and in persons who are younger than 18 years of age [43].

Measles, Mumps, and Rubella

Vaccination for the three classic childhood diseases of measles, mumps, and rubella (MMR) includes live attenuated viruses, and was introduced in the 1960s. The annual reported cases of these infections have declined by more than 98 % in the United States and Europe [44]. This decrease in incidence is largely due to the recommendation that all states require a two-dose MMR vaccination prior to children entering school. The two-dose MMR vaccine is advocated to induce immunity in the small percentage of individuals who do not respond to one or more components of the first dose. The most updated recommendations from the CDC are vaccination with the first MMR dose at 12–15 months and the second dose at 4–6 years of age [45]. Table 49.2 summarizes the childhood immunization schedule for MMR, as well as other vaccines described in this chapter [46]. Immunization evokes a mild subclinical infection that is noncommunicable.

Since the vaccines are composed of live attenuated viruses, they are not recommended for pregnant women or those planning to become pregnant within the next 3 months. The primary concern with pregnant women has been the risk of eliciting the congenital rubella syndrome (CRS). However, a study of 321 women who received the vaccine 3 months prior to or after conception demonstrated no congenital malformations compatible with congenital rubella infection [47]. Another contraindication is a history of anaphylactic hypersensitivity to neomycin. Persons with asymptomatic HIV infection or with mild immunosuppression can get vaccinated with MMR. Further, healthy persons with minor illnesses with or without fever, and those with an allergy to eggs can receive the vaccine as well. The risk of severe anaphylactic shock reaction is exceedingly low in individuals with a history of allergy to eggs [45].

The recommendation is to observe these patients for up to 90 minutes after immunization [48]. Also, despite suggestions that the MMR vaccine has a reported association to autism, studies have proved strong evidence against that hypothesis [49–53].

Measles

The measles virus is very efficient in transmission, and has been noted to be the most infectious disease of humankind in regard to the minimal number of virions required to elicit infection [54]. Since humans are the only reservoirs for the measles virus, global eradication is a realistic goal. In the U.S., measles is no longer considered an indigenous disease due to universal childhood

immunization programs [55], and the reported incidence of measles has decreased by >99 % since the measles vaccine has become available until a recent surge in reported cases since 2013 owing largely to travelers from abroad and outbreaks among children whose parents refused immunization. Data from the CDC regarding 2014 demonstrated 644 confirmed cases, which exceeded the previous highest annual total number of cases since 2000 [56]. Unfortunately, however, the current rapid spread of measles among unvaccinated persons in the U.S. resulted in another large outbreak in 2015.

Subsequent to receiving two doses of the vaccine, 95–99 % of individuals develop serologic evidence of immunity to measles [57, 58]. Immunity is viewed as lifelong, and comparable to an acquired infection with the wild-type virus [59]. Rare cases of measles infection have been reported in patients with previously documented postimmunization seroconversion [60, 61].

Adverse effects after measles vaccination are usually mild, and include fever (5–15 %) [62], transient viral exanthems [44], and less commonly encephalitis or encephalopathy (less than one per one million vaccines) [63]. Further, a small number of cases have been described of the occurrence of subacute sclerosing panencephalitis (SSPE) in individuals with a history of vaccination but no known history of infection [64–66]. A more detailed review of these cases demonstrated that some cases had unrecognized natural measles infection prior to vaccination, and the SSPE was directly correlated to the infection [45]. Widespread measles immunization has practically eliminated SSPE in the U.S., and the live measles vaccine does not increase the risk of this adverse event [45].

Mumps

A live attenuated mumps vaccine (Jeryl-Lynn strain) was introduced in 1967 and is prepared in a chick embryo cell culture. Immunization evokes a mild subclinical infection that is noncommunicable. Early clinical efficacy studies have shown that 97 % of children and 93 % of adults develop serologic evidence of immunity after vaccination [67–69] and serologic and epidemiologic evidence suggests that immunity persists for at least 30 years after immunization [70–73].

Adverse reactions are usually mild and rare after vaccination, and include low-grade fever, mild parotitis, and viral exanthem. Serious adverse reactions, namely neurologic events are extremely rare and have not been causally associated with the mumps vaccine [74, 75].

Rubella

The RA 27/3 (rubella abortus 27, explant 3) rubella vaccine is grown in human diploid fibroblast cell culture. It induces a response in more than 97 % of recipients [54, 68]. Immunity in vaccinated individuals is believed to be lifelong and has been demonstrated to persist for at least 16 years [76, 77].

Adverse events following rubella vaccination include fever, lymphadenopathy, and viral exanthemas, usually between 5 and 12 days after vaccination [74, 78]. Arthralgias and arthritis occur more frequently with adult vaccinees, especially women, ranging from 25 to 40 % in this population [79–81].Although no longer common, failure to develop 50–60 % of immunity to rubella by vaccination leaves women of childbearing age susceptible to developing rubella infection during pregnancy. This causes congenital rubella in children born of mothers who contract rubella during early pregnancy.

Varicella-Zoster Virus

Prior to the prevalent use of varicella vaccine, annual U.S. figures for varicella infection included an estimate of 4 million cases, 11,000 hospitalizations, and 100 deaths [82]. The annual incidence of varicella has decreased significantly since the use of this vaccine. The vaccine, Varivax, developed by Takahashi in 1974 and approved in 1995, is a live attenuated Oka strain vaccine that has been shown to be very safe and effective [83–85]. In May 2006 the Food and Drug Administration (FDA) approved a vaccine, Zostavax (Merck) which is 14 times more concentrated than the varicella vaccine, against herpes zoster in individuals 60 years age and older [86]. After further studies showed its efficacy in a younger cohort, the vaccine was subsequently approved by the FDA for use in individuals aged 50–59 in 2011. Cell-mediated immunity is increased following vaccination in immunocompetent older adults, and the incidence and severity of herpes zoster [87–91] is reduced. The vaccine lessened the overall incidence of herpes zoster by 51.3 % and notably reduced the pain and discomfort by 66.5 % among subjects in whom herpes zoster developed. The zoster vaccine had low rates of serious adverse events, which were similar to the placebo vaccine.

Long-term follow-up data of the varicella vaccine depicted protection against chickenpox for at least 17–19 years, and, furthermore, all of the subjects vaccinated continue to have persistent antibodies and delayed-type skin reaction to the varicella-zoster antigen [92]. In a double-blind, placebo-controlled study of the Oka vaccine in 914

U.S. children, the varicella vaccine demonstrated an efficacy of 100 % at 9 months [93, 94]. Following 7 years of vaccination, 95 % of the subjects remained without chickenpox clinically [81]. Additional studies in the U.S. have demonstrated that the Oka vaccine induces humoral and cell-mediated immunity in healthy children [94–97], with protection for at least 8 years, while other data have suggested effectiveness decreases markedly after 1 year post-vaccination [98]. Further, case series depict that vaccinated individuals have less severe varicella (<50 lesions, no fever, and shorter duration of illness) than those who are unvaccinated [99, 100].

The vaccine is recommended as part of the childhood immunization schedule, and all susceptible children from 12 months of age to 18 years of age should receive the varicella vaccine. The first dose of the Oka vaccine should be administered at 12–15 months and the second dose should be given at 4–6 years of age [86]. Those over the age of 13 years should receive two doses, 4–8 weeks apart, to generate seroconversion rates and antibody responses comparable to those attained in healthy children [83–85]. In the US, childhood vaccination with a single dose continues to provide up to 95 % protection 10 years after immunization; children with two doses can see up to 98 % protection [101]. The vaccine is also recommended for susceptible adults, notably those in high-risk situations (e.g., health care personnel); children who have no prior history of chickenpox and are required to be present in school; and immunosuppressed subjects, particularly those with acute lymphocytic leukemia (ALL) [102–104]. The varicella-zoster virus (VZV) vaccination is safe for all patients with lymphocyte counts >700/mm [3]. Further, recent data suggest that varicella vaccine is >95 % effective for prevention of disease and 100 % for prevention of moderate or severe disease in susceptible contacts when given within 36 h of exposure [105].

A combination vaccine with the live attenuated viruses of MMR and VARIVAX is also available (ProQuad; Merck) and it is administered to individuals 12 months to 12 years of age. Post-licensing studies have shown the combination vaccine to be as effective as separate injections of MMR and Varivax [106].

Varicella transmission is approximately one- fourth the rate of natural varicella (20–25 % vs. 87 %) [107] if a rash develops in the immunized individual. In children, the incidence of primary varicella is between 18 and 77 per 1 million person years of follow-up [108]. Herpes zoster can later develop from this vaccine type virus or from natural wild-type varicella-zoster virus [109, 110]. Although there are reports of herpes zoster in healthy children vaccinees, the incidence is less than that seen in children with prior chickenpox, suggesting that vaccinated children may have a decreased risk for herpes zoster [111].

The most common side effects from the vaccine include mild tenderness, erythema, induration at the injection site (19.3–24.4 %), fever (10.2–14.7 %), and a localized or generalized varicella- like rash (3.8–5.5 %). The transmission rate of the varicella vaccine virus from a healthy vaccinated individual is low, but may be more likely if a rash appears subsequent to vaccination, particularly in those who are immunocompromised. Vaccinated individuals should avoid close contact with susceptible high-risk individuals for up to 6 weeks. The vaccine is contraindicated in pregnant women or any woman planning to become pregnant within 3 months since the vaccine uses a live attenuated virus and natural varicella can cause fetal harm [111].

A separate adjuvant subunit vaccine has recently been shown in Phase 3 clinical studies to be advantageous in reducing the risk of herpes zoster in adults over 50 years of age by up to 97 % [112]. The efficacy of this vaccine was shown to be similar across age group stratifications, making it more effective than Zostavax which has waning efficacy as patients increase in age. While still currently under investigation, this new adjuvant subunit vaccine represents a significant improvement in providing protection to those at highest risk for developing herpes zoster.

Yellow Fever Virus

A live attenuated vaccine produced from the 17D strain of yellow fever virus is available for subcutaneous administration. It is recommended for travelers to areas where yellow fever is endemic or enzootic, such as tropical parts of South America and Africa. Booster immunizations are required every 10 years. This vaccine is contraindicated in persons allergic to eggs, in pregnant women, in immunocompromised persons, and in children younger than 4 months of age.

Bacteria

The only currently used live-attenuated bacterial vaccine in the U.S. is against the causative agent of typhoid fever, *Salmonella typhi*. This vaccine, given orally, was first developed through chemical mutagenesis in vitro. Protection is conferred by mucosal and serum antibodies as well as cell-mediated immunity [113]. The induction of mucosal antibodies offers protection against infection and disease [114].

Inactivated Vaccines

Both inactivated viral and bacterial vaccines consist of viruses and bacteria, respectively, treated so that they are unable to replicate. They are less potent in the effector response than the live-attenuated vaccines, and consist of vaccines currently in use against hepatitis A, *Haemophilus influenzae* type b (Hib), influenza (intramuscular), Japanese encephalitis, meningococcus, pneumococcus, polio (subcutaneous or intramuscular), rabies, tetanus/diphtheria toxoids, and typhoid fever (intramuscular). Again, in this section, the focus is on the vaccines targeting diseases that cause cutaneous manifestations.

Viruses

Hepatitis A

Both the inactivated and attenuated forms of hepatitis A vaccines have been developed and studied, although only the inactivated vaccine is licensed and available in the U.S.

(Havrix and Vaqta). These vaccines are propagated in human diploid fibroblast culture and inactivated by formalin. Immunization typically involves two doses given 6 –12 months apart in adults and in children aged 1 year and older. Studies of both available vaccines depict excellent safety profiles in addition to comparable immunogenicity and efficacy rates. Overall, 97–99 % of those vaccinated develop protective levels of antibodies 1 month after the first dose, and 99–100 % are protected 1 month after second dose [115–120]. Long-term data are limited, but one recent study showed that protection following primary hepatitis A vaccination persists for more than 10 years [121].

The hepatitis A vaccine is recommended for individuals at least 1 year of age living in or traveling to high endemic areas for hepatitis A. Further, individuals with chronic liver disease due to causes other than hepatitis A, persons engaging in high-risk sexual activity, residents of a community experiencing an outbreak of hepatitis A, and users of illicit injectable drugs are strongly advised to receive hepatitis A vaccination. In addition, in some states and regions, the hepatitis A vaccine is recommended for routine pediatric use.

Adverse effects with hepatitis A vaccination are typically mild, and no serious adverse side effects have been credited to the vaccine in clinical trials [122]. Side effects include soreness at the injection site, headache (14 %) and malaise (7 %) in adults, and feeding problems (8 %) and headache (4 %) in children.

Bacteria

Anthrax

Pasteur in 1881 demonstrated the protective efficacy of the first anthrax vaccine when he injected sheep with heat-attenuated *Bacillus anthracis*. In the 1930s, wide use of vaccine composed of attenuated strains markedly decreased the incidence of anthrax in domesticated animals in industrialized countries. The licensed human vaccine, anthrax vaccine adsorbed (AVA), also known as BioThrax since 2002, is a culture supernatant of a toxigenic, avirulent, nonencapsulated *B. anthracis* strain, V770–NP1–R, derived from the Sterne strain [123]. A vaccine similar to AVA is used in the United Kingdom, produced from culture supernatant-derived human vaccine (PL 1511/0058) [124].

Anthrax vaccinations are recommended for individuals working in the production of *B. anthracis* cultures, those engaged in activities with a high risk of aerosol exposure, individuals in the military, and other groups of persons with a calculable risk [125]. Preexposure vaccinations are currently not recommended for emergency first responders, medical practitioners, and civilians. However, due to the bioterrorist attacks in 2001 and limited supply of anthrax vaccine, supplemental recommendations of the Advisory Committee on Immunization Practices endorse the anthrax vaccine in combination with antimicrobial postexposure prophylaxis (PEP) for unvaccinated persons at risk for inhalational anthrax [126].

Anthrax vaccine adsorbed has numerous limitations despite being relatively efficacious and safe [127]. The schedule of AVA administration, which consists of subcutaneous injections at 0, 2, and 4 weeks and boosters at 6, 12, and 18 months (with recommended annual boosters to maintain immunity), is probably suboptimal. The enduring protective efficacy in humans is unknown. AVA contains other cellular elements that aid in the fairly high rate of local and systemic adverse reactions [127], including injection-site hypersensitivity, edema, pain, headache, arthralgia, asthenia, and pruritus. Approximately 20 % of vaccinees develop mild cutaneous reactions such as erythema, edema, and induration. In <1 % of recipients, systemic side effects of fever, chills, nausea, and body aches occurred [128]. Due to these limitations, newer anthrax vaccines that involve a purified form of the anthrax toxin are currently being developed, some of which have passed Phase 1 trials [129].

Conjugate Vaccines (Fig. 49.1) [1, 130]

Many bacteria, including *Neisseria meningitidis* and *Haemophilus* species, have an outer capsule composed of polysaccharides that are species and type specific for particular strains of the bacterium. The goal of vaccination is to generate antibodies against the polysaccharide capsule of the bacteria since the most effective defense against these organisms is opsonization of the polysaccharide coat with antibody. However, children under 2 years of age do not mount a good response against capsular polysaccharide, which is a T-cell–independent antigen. An effective way to overcome this problem is to conjugate bacterial polysaccharide (chemically) to protein carriers, which offer peptides that can be recognized by antigen-specific T cells. Thus, a T-independent response is converted into a T-cell–dependent antipolysaccharide response [1, 39].

Haemophilus Influenzae

In the second generation of Hib vaccines, the polyribosylribitol phosphate (PRP) vaccine has been covalently conjugated with various protein molecules to form the Hib conjugate vaccine. This has resulted in a vaccine that is able to stimulate the immunologic system to produce a T-dependent response, for use in infants [131]. Four different types of the Hib conjugate vaccine have been licensed for use: PRP conjugated to the diphtheria toxoid (PRP-D), PRP conjugated to the outer membrane protein of *Neisseria*

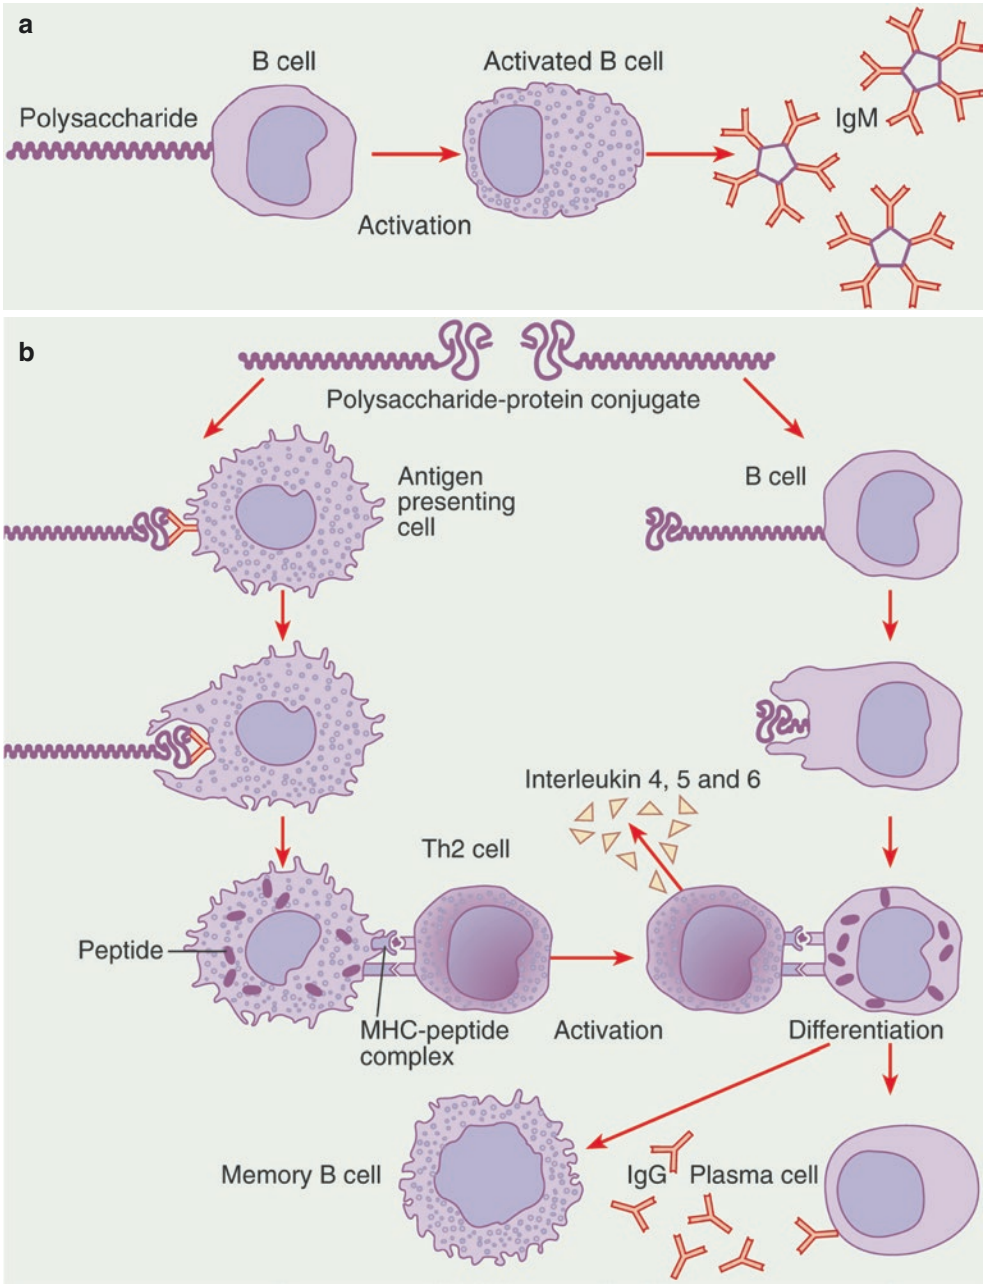

Fig. 49.1 Antibody responses to polysaccharide antigens and polysaccharide–protein conjugates. (**a**) A polysaccharide antigen binds to an immunoglobulin M (IgM) receptor on the surface of a B cell in lymphoid tissues. Once B cells are activated, they produce and then secrete IgM antibody molecules. The individual Fab segments of the IgM molecule have only a moderate affinity, but because there are 10 such segments, an IgM molecule has a high avidity. (**b**) In contrast, some polysaccharide–protein conjugates are taken up by dendritic cells, which present peptides from the protein portion of the conjugate to type 2 helper T (Th2) cells. Other conjugate molecules bind to B cells that have IgM receptors specific for the carbohydrate moiety and will undergo endocytosis and be processed by the B cell; the resulting peptides will be expressed with major histocompatibility complex (MHC) class II molecules on the surface of the B cell

meningitidis group B (PRP- OMP), PRP conjugated to tetanus toxoid (PRP-T), and PRP oligosaccharides conjugated to mutant diphtheria toxin CRM (HbOC) [132]. Recommended immunization involves three doses of the Hib vaccine given at 2, 4, and 12 months of age [46].

Neisseria Meningitidis

Bacterial meningitis remains a severe threat to global health, with an estimated 500,000 cases worldwide with at least 50,000 deaths and as many cases of neurological damage [133]. *Neisseria meningitidis* is responsible for 60–65 % of

cases of bacterial meningitis, and it is the only bacterium that is able to generate epidemics of meningitis [134].

It is also associated with a petechial eruption or more severe hemorrhagic lesions on the trunk and lower extremities.

The significant determinant of virulence in *N. meningitidis* is the polysaccharide capsule. Among the 13 distinct *N. meningitidis* serogroups that have been defined on the immunohistochemistry of their polysaccharide group, groups A, B, C, W135, and Y account for over 90 % of severe meningitis and septicemia. Two meningococcal vaccines, each containing antigens to serogroups A, C, Y, and W-135, are licensed in the U.S. In 2015 the FDA approved the first vaccine that provides immunity against serogroup B, which accounts for an estimated one third of cases of meningococcal disease. This recombinant serogroup B vaccine, Bexero (Novartis) has been licensed for use in Europe, Canada, and Australia; before being licensed for use in the US, it was used to control two separate outbreaks of meningococcal disease within the US and had been allowed by the FDA to treat certain outbreak situations [135, 136].

Over 30 years ago, the first meningococcal polysaccharide vaccine (MPSV4 or Menomune, Sanofi Pasteur), was developed against serogroups A and C among U.S. military recruits [137–139]. It is approved for all ages in which meningococcal vaccine is currently recommended. Further, the vaccine is safe and bestows protection to 90–95 % of people. However, there are limitations to the vaccine. First, the vaccine offers a short duration of immunity: 1–3 years in children younger than 5 years of age [134, 140] and 3–5 years in adolescents and adults. Second, like other polysaccharide vaccines, this vaccine could not elicit memory T cells, and even after repeated injections, booster responses are low [141, 142]. In addition, like other polysaccharide vaccines, this vaccine does not prevent mucosal colonization and hence does not offer herd immunity by breaking up the transmission of *N. meningitidis* [143, 144]. This vaccine is a logical option for individuals requiring protection for a limited amount of time.

The second vaccine, meningococcal conjugate vaccine A, C, Y, and W135 (MCV4 or Menactra, Sanofi Pasteur), was approved in January 2005 for use in individuals 11–55 years of age. This conjugate vaccine contains the same antigen as that found in the meningococcal polysaccharide vaccine, but it is conjugated to 48 μg of diphtheria toxoid [145]. What is different regarding this vaccine is that immunity is more durable, and revaccination can generate a rise in antibody level. Although not yet proved, it is suggested that, like other conjugate vaccines, it is likely that this vaccine will offer more durable protection than the polysaccharide vaccine alone and will further reduce nasopharyngeal carriage, allowing herd immunity to occur.

The serogroups A and C vaccines have demonstrated estimated clinical efficacies of >85 % among school-aged children and adults and are useful in controlling outbreaks. Serogroups Y and W-135 polysaccharides are safe and immunogenic among adults and children aged >2 years. The advantages of the meningococcal conjugate vaccine have led the Advisory Committee on Immunization Practices (ACIP) of the CDC to extensively widen the recommendations for immunization, with routine vaccination of all persons aged 11 through 18 years old, composed of a single dose at age 11–12 years and a booster dose at age 16 [146].

Both vaccines are currently recommended for use in control of outbreaks as a result of *N. meningitidis* serogroups A, C, Y, and W-135 [145]. However, due to its enhanced booster effect, the conjugate vaccine is favored when revaccination is indicated for individuals who have received the meningococcal polysaccharide vaccine before and who remain at higher risk. Long-term follow-up studies are still needed for those that have been immunized with the meningococcal conjugate vaccine to establish if boosters are needed.

Adjuvants

Purified antigens are not typically immunogenic on their own, and thus most acellular vaccines require adjuvants to enhance their immunogenicity. Alum, the adjuvant most often used, delays the release of an antigen and enhances the generation of antibodies. Most adjuvants are thought to act on antigen-presenting cells, particularly on dendritic cells. Adjuvants manipulate the immune system into reacting as though there were an active infection, and just as different classes of infectious agents elicit different types of immune response, different adjuvants may stimulate different types of response.

Recombinant Subunit Vaccines

Another route to vaccine development is the identification of the T-cell peptide epitopes that stimulate protective T-cell–mediated immunity. T cells recognize their target antigens as small protein fragments or peptides presented by major histocompatibility complex (MHC) molecules at the cell surface, and thus these peptide epitopes, once identified, can then be tried as vaccines. Using peptides has many advantages and some drawbacks [1]. Advantages include that the peptide is chemically defined, stable, and safe and contains only important B-cell and T-cell epitopes. Drawbacks include the complexity in mimicking the conformation of antigen polymers found with many viruses, that B-cell epitopes recognized by neutralizing antibodies are

sometimes discontinuous sequences, and the vulnerability of peptides to proteolysis. Several administrations, likely with an adjuvant, may be required. Since 1990, over 100 chemically synthesized short peptide vaccines have been initiated into phase I clinical trials, less than 20 have advanced into phase II, and none has entered phase III clinical trials [147].

Subunit vaccines have often made use of recombinant-DNA technology. Immunogenicity can be improved and the immune response aimed at induction of both cell-mediated and humoral responses through the formation of aggregates such as immunostimulating complexes, virus-like particles, antigen-coated beads, or lipid-encapsulated antigens under many conditions. Linked peptides are also being tested in the field of subunit vaccines; for instance, aggregates of linked peptides from group A streptococcus as a vaccine against rheumatic fever have demonstrated promising results in animal models [148, 149].

Viruses

Human Papillomavirus

According to the WHO, cervical cancer is the fourth most common cause of death in women globally from cancer, and it is the cause of death of approximately 265,000 women per year [150]. Almost half a million new cases of invasive cervical cancer develop each year, and in the U.S. it was estimated to afflict over 11,800 women in 2010 [151]. Epidemiologic studies have proved that persistent HPV infection is the main cause of almost all cervical carcinogenesis [152–154].

Approximately 40 of the 100 HPV genotypes have an affinity for infecting the mucosal epithelium and subsequently causing genital infection. The major types associated with malignancy (16, 18, 31, 33, 45, 52, and 58) and condyloma (6 and 11) are relatively few in number, which has allowed for more focused strategies for immunization against these specific types [111].

Papillomaviruses are nonenveloped double-stranded DNA viruses with the genome comprised of three regions: the long control region (LCR), the early region (E), and the late region (L). The early region consists of genes *E1* to *E8*, which encode nonstructural proteins. The late regions code for the major (L1) and minor (L2) proteins that compose the viral capsid. The advancement in producing the prophylactic HPV vaccine came from findings that L1 self-assembles into empty capsids, named virus-like particles (VLPs), when it is expressed from eukaryotic vectors such as recombinant vaccinia, baculovirus, and yeast [155, 156]. The VLPs do not contain viral DNA and are noninfectious; their similarity to virions offers a neutralizing epitope that subsequently produces an antibody response.

Gardasil® (Merck) is a quadrivalent vaccine that targets HPV types 16, 18, 6, and 11. It is a yeast-expressed vaccine, which was approved by the FDA in 2006 for use in girls and young women of ages 9–26, and is marketed as a vaccine for prevention of cervical cancer, precancerous genital lesions, and genital warts due to HPV types 6, 11, 16 and 18. Per the ACIP, the recommended age of vaccination for females is 11–12; catch-up vaccination is also recommended for females aged 13–26. It is given in three doses; provisional recommendations from ACIP include giving the second and third dose of the vaccine at months 2 and 6, respectively [157].

In one study involving greater than 12,167 adolescents and women of ages 16–23, Gardasil prevented 100 % ($n = 5301$) of cases of cervical intraepithelial neoplasia (CIN) grades 2 and 3 linked with HPV types 16 and 18 compared to 21 cases in the placebo group ($n = 5258$). All subjects elicited 100 % antibody responses to the HPV strains 6, 11, and 16, and 99.1 % developed strain 18 antibodies. Protection has been observed for at least 6 years following vaccination. Males were also studied in the Gardasil trials; one study analysis involving 4,065 males aged 16–26 showed 85–90 % efficacy in preventing external genital lesions from HPV strains 6, 11, 16, and 18 [158–160]. This subsequently led to the FDA approval of Gardasil for males aged 9–26 years in October 2009 for protection against genital warts, anal cancer, and some potentially precancerous lesions such as high-grade penile-perianal/perineal intraepithelial neoplasia.

Gardasil has been shown to be generally safe, and well tolerated, with pain, swelling, and erythema at the site of injection being the primary side effects. Females who have an equivocal or abnormal Pap test can receive the quadrivalent vaccine, but data from clinical trials do not suggest that the vaccine will have a therapeutic effect on existing Pap test abnormalities; it would only provide protection against other HPV types not already acquired. Females who are immunocompromised can be vaccinated; however, the immune response may be less than in those who are immunocompetent. Further, those with moderate or severe illness should not be vaccinated until after the illness improves. Provisional contraindications to Gardasil include those with immediate hypersensitivity to yeast or another vaccine component. Gardasil is not recommended for use in pregnancy since data for vaccination during pregnancy is limited, and lactating women cannot receive the vaccine either [157].

In an effort to address the need for a vaccine effective across other oncogenic HPV types, Merck began clinical testing in 2007 of a nine-valent vaccine targeting HPV types 6, 11, 16, 18, 31, 33, 45, 52, and 58. An international randomized double-blinded phase III trial involving 14,840 female subjects ages 16–26 compared the nine-valent vaccine to Gardasil in regards to incidence of HPV-type disease, mean antibody tiers, and safety profiles [161]. Results of this study demonstrated the nine-valent vaccine to be 97% effective in the prevention of cervical, vaginal, and vulvar

neoplasms caused by HPV types 31, 33, 45, 52, and 58, as well as having non-inferior protection to Gardasil in the prevention of diseases caused by HPV types 6, 11, 16, and 18. Mean antibody titers to HPV types 6, 11, 16, and 18 as well as safety profiles were similar between Gardasil and the nine-valent vaccine. A separate study which enrolled 2,604 male and female children ages 9–15 compared mean antibody titers after nine-valent vaccine administration to those seen in subjects aged 16–26 and showed higher titers in the younger cohort. Another large-scale study involving 14,215 women comparing the nine-valent vaccine to the quadrivalent vaccine also demonstrated prevention of high-grade cervical, vulvar, and vaginal disease related to HPV types 31, 33, 45, 52, and 58 among those receiving the nine-valent vaccine and similar protection against HPV types 6, 11, 16, and 18 with both vaccines [162]. These positive results led to the FDA approval of the nine-valent vaccine in December 2014, marketed as Gardasil 9® [163].

Cervarix® (GlaxoSmithKline) is a bivalent VLP vaccine that was FDA-approved in 2009 for the prevention of infections from HPV types 16 and 18. While similar to Gardasil, Cervarix differs in its preparation, coverage, and dosing schedule. It is produced within insect cells that are infected with L1 recombinant insect virus vectors and carries the same age recommendations as Gardasil, per the ACIP [164].

The PATRICIA trial, a large Phase III clinical trial involving Cervarix, demonstrated up to 100 % efficacy compared to controls against CIN grade 3+ caused by HPV types 16/18 among women who initially were HPV negative ($n = 11644$). Additionally, the vaccine demonstrated 93.2 % efficacy within this cohort against CIN grade 3+ regardless of HPV type in the lesion. Cervarix was also shown to be safe, with pain, swelling, and erythema being the most common side effects and vaccine-related serious adverse events seen in less than 0.1 % of subjects [165]. Unlike Gardasil, Cervarix is not indicated for the prevention of genital warts in both sexes or genital lesions caused by HPV in males.

Contraindications to Cervarix include history of severe allergic reactions to any of the vaccine components. Caution is exercised in individuals with latex allergies, as the tip caps of the prefilled syringes contain dry natural rubber latex. Similarly to Gardasil, use in pregnant subjects is not recommended due to lack of safety data and the immune response may be decreased in immunocompromised individuals.

Hepatitis B

The annual incidence of individuals infected with hepatitis B virus (HBV) in the U.S. was estimated to be 200,000–300,000 prior to the development of the hepatitis B vaccine [166]. In 1981, a plasma-derived hepatitis B vaccine was licensed in the U.S.; the vaccine was highly effective in inducing immunity, but was associated with several limitations. Large-scale production was not feasible because of the insufficient supply of suitable carrier plasma. Further, despite the chemical treatment of plasma products for safety, there was a small concern regarding the risk of HIV transmission. Both of these issues were resolved with the licensure of the recombinant yeast hepatitis B vaccine (Merck) [167].

This vaccine was the first licensed recombinant viral vaccine prototype as well as the first effective viral vaccine for a sexually transmitted disease. Clinical studies in high-risk homosexual men illustrated three-dose vaccine efficacy of 82–93 % in preventing acute hepatitis B [168, 169]. Approximately 95 % of immunocompetent adults develop significant antibody titers following a three-dose hepatitis B vaccination. An estimated 99 % of children [170] respond to the vaccination, while only 50–70 % of those over age 60 develop immunity [171, 172]. Factors linked with lower likelihood of seroconversion include immunosuppression, renal failure, prematurity with low birth weight, age older than 40 years, obesity, and smoking [173–175]. In these individuals, annual antibody testing should be completed, and a booster dose administered for those with antibody levels <10 mIU/mL.

Long-term efficacy is expected from the duration of immunity afforded by the hepatitis B vaccine, although few studies are available on this topic [176]. Antibodies levels decline rapidly in the first year following vaccination, and then decline at a slower pace in the following years [176]. A study involving high risk individuals (1st year medical students) showed that only approximately 60 % of students had protective levels of antibodies 20 years after immunization [177]. However, the loss of detectable antibodies years after hepatitis B vaccination does not necessarily signify a lack of immunity. Most of the persons vaccinated are protected by immunologic memory in B lymphocytes, which mount an anamnestic response to natural infection [178]. It should be noted, however, that rare cases of hepatitis B infection have been reported in previously vaccinated patients [179, 180]. These individuals usually have subclinical disease, and none has developed chronic infection or serious complications [175].

The immunization regimen includes three doses, given at months 0, 1, and 6. Hepatitis B vaccination is recommended for individuals living in or traveling to areas of high endemicity for hepatitis B, health care personnel, morticians, persons engaging in high-risk sexual activity, persons with chronic liver disease due to causes other than hepatitis B, prisoners, users of illicit injectable drugs, police and fire department personnel who participate in first aid, and all children 0–18 years of age. Due to the widespread use of the vaccine in children, a thimerosal-free vaccine was approved in 1999 by the FDA (Merck and GlaxoSmithKline). Thimerosal is a preservative that contains mercury, which had driven the limitation of its use in children [181].

Adverse effects after hepatitis B vaccination are usually mild and well tolerated. The most common side effects include fatigue (15 %), headache (9 %), and fever (1–9 %) [182, 183]. A postmarketing clinical surveillance of 4.5 million doses of hepatitis B vaccine over 5 years depicted no serious or severe reactions attributable to the vaccine. Reports of a causal relationship between hepatitis B vaccine and a variety of autoimmune diseases have been disproven, and furthermore this vaccine does not increase the risk of multiple sclerosis [184], nor does it cause a relapse of underlying multiple sclerosis [185].

In 2001 the FDA licensed a new combination vaccine that protects individuals at least 18 years of age against hepatitis A virus and hepatitis B virus. This vaccine, Twinrix (GlaxoSmithKline), combines two already approved vaccines, Havrix, and Engerix-B, in order for persons at high risk for exposure to both viruses to be immunized against both at the same time and reduce the number of injections needed. This vaccine is administered at months 0, 1, and 6. Data from 11 clinical trials indicate that 99.9 % of vaccinees develop seroconversion against hepatitis A virus and 98.5 % against hepatitis B surface antigen, with persistence up to 4 years (GlaxoSmithKline Biologics, unpublished data, 2001).

Lyme Disease

Lyme disease is the most common vector-borne human disease in the U.S., with 22,014 cases reported to the CDC in 2012 [186]. Since 1982, the annual incidence of Lyme disease has increased more than 25-fold [187].

Although a recombinant vaccine, Lymerix, for prevention of Lyme disease was approved in 1998, for many reasons including cost, need for frequent revaccinations, and a highly publicized but theoretical risk of precipitating autoimmune arthritis, sales of Lymerix declined rapidly after its initial introduction, and its manufacturer removed the vaccine from the market in 2002 [188, 189]. As a result, there has been renewed interest in developing new strategies for the reduction of Lyme disease, for instance, the use of oral delivery of an OspA vaccine to reduce carriage of *Borrelia burgdorferi* in its reservoir hosts [15]. Newer injectable OspA vaccines have entered Phase 1 trials and have shown promising results, inducing high antibody titers while causing no vaccine-related serious adverse events [190].

Investigational Vaccines

Live-Agent Vaccines as Vectors of Other

Vaccine Antigens

Wide interest exists in the use of vaccines composed of attenuated viruses or bacteria as carriers (vectors) of other antigens. More than 20 different RNA and DNA viruses as well as bacteria are used experimentally as vectors, including poxviruses. All of these strains infect but do not replicate in human cells [191, 192]. Since approximately 10 % of the large poxvirus genome can be replaced by foreign DNA, genes encoding protective antigens from several different organisms could be placed in a single vaccine strain. This approach allows immunization against several different pathogens at one time, but such a vaccine could not be used twice since the vaccinia vector itself elicits long-lasting immunity that would neutralize its effectiveness on a second dose. Further, live-attenuated strains of *Salmonella* have been used as vectors of tetanus toxoid, *Listeria monocytogenes*, *Bacillus anthracis*, *Leishmania major*, *Yersinia pestis*, and *Schistosoma mansoni* to provide mucosal response due to its oral administration [1, 39].

Immunization with DNA

Vaccination with DNA is one of the most promising novel immunization techniques against pathogens in which conventional vaccination regimens have failed. A DNA plasmid encoding a desired protein is injected into the muscle or skin of an animal, where it subsequently enters host cells and directs the synthesis of its polypeptide antigen. Once the plasmid antigen is processed and presented by transected host cells, a cellular and humoral immune response against the antigen is elicited. The DNA vector is bacterial-derived and outfitted with eukaryotic or viral promoter/enhancer transcription elements that direct the high-efficiency transcription of the plasmid-antigen within the nucleus of the host cell. The most common way of administering DNA vaccines has been parenterally, but noninvasive routes of delivery involving the topical application of pure DNA plasmid to skin or mucosa have been illustrated (Fig. 49.2) [1, 193].

This approach has many potential advantages, including low cost, stability, and inability to return into virulence. A possible disadvantage would be integration of the DNA into the genome of the host cell, leading to transformation or tumorigenic events, but such occurrences have not yet been observed [1].

Sequential Immunization

There are also a group of pathogens that do not respond to the vaccine approaches described thus far. These pathogens include HIV, *Mycobacterium tuberculosis*, and the malaria parasite, all which traditionally evade the humoral response elicited by traditional vaccines [194]. Thus, over the past few years there has been a drive to generate vaccines targeting the cell-mediated immune system for these and related pathogens. With the advent of vaccines, repeated administration with the same vaccine (homologous boosting) has proven to be very effective for boosting humoral response. However, this approach is not effective at boosting cellular immunity since prior immunity to the vector appears to impair robust antigen presentation and the generation of appropriate inflammatory signals. One approach to evade this problem has been to sequentially administrate vaccine,

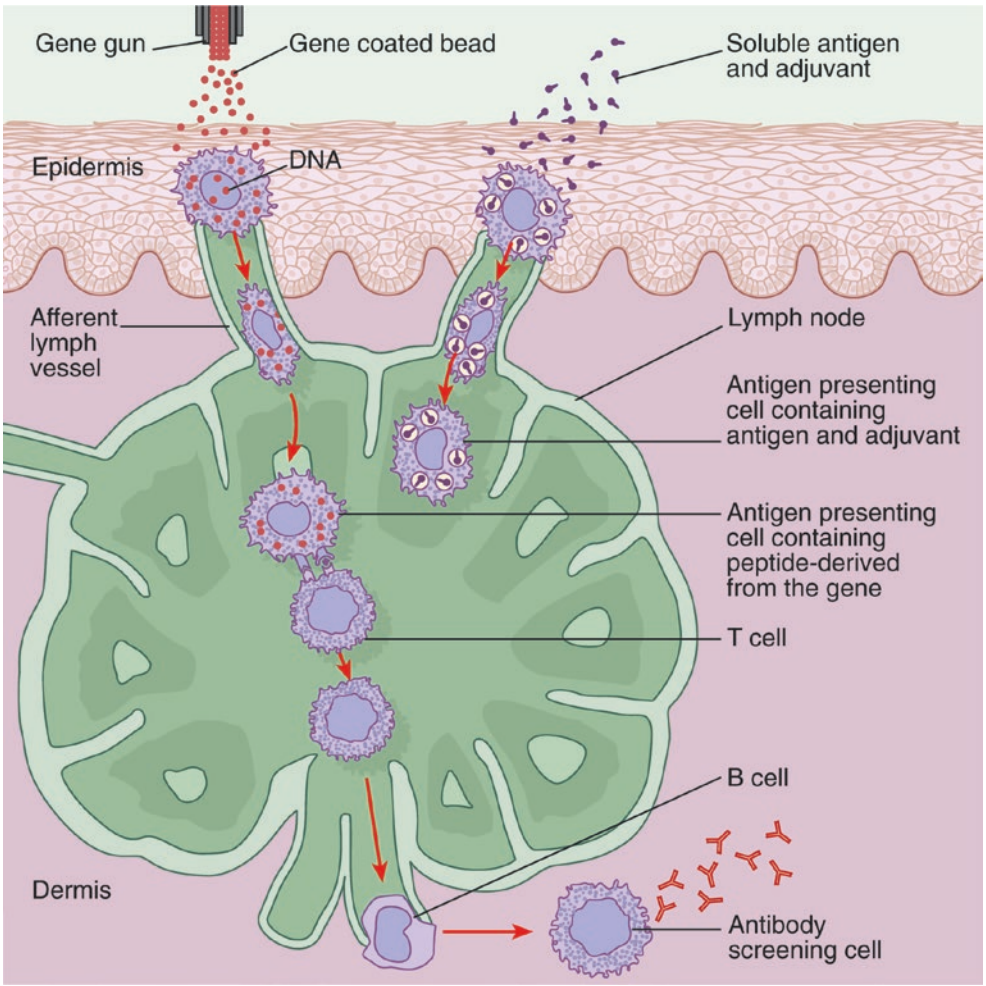

Fig. 49.2 Activation of helper T cells after the application of antigen-coated beads with the aid of a "gene gun" or the application of soluble antigen to the skin as an alternative to vaccination with a needle. A gene gun is used ballistically to accelerate the transdermal passage of microscopic gold beads coated with DNA plasmids (about 600 copies per bead) through the stratum corneum into the epidermis, where some are taken up by resident dendritic (Langerhans') cells. Alternatively, a soluble antigen together with an adjuvant, usually cholera toxin, is applied to the skin (transcutaneous immunization). Some antigen reaches the epidermis and also undergoes endocytosis by Langerhans' cells. During migration to the draining lymph node through the afferent lymphatics, these cells mature and express receptors for chemokines. The foreign DNA is expressed, and the antigens are degraded, some of which bind to MHC antigens. These activated T cells can interact with an activated B cell to induce a humoral response (Copyright © 2001 Massachusetts Medical Society. All rights reserved)

usually weeks apart, using different antigen-delivery systems (heterologous boosting). This method is referred to as prime-boosting, and is very effective at generating high levels of T-cell memory (Fig. 49.3) [195]. Although many of the initial studies were to develop a vaccine to control malaria, this method of vaccine development was applied to a variety of other pathogens [196].

Much advancement has been made in vector design and progress, and several vectors have proven to be effective, which include replication-defective adenoviruses, fowlpox viruses, vaccinia virus, influenza virus, Sendai virus, and naked DNA [195, 197–201]. Vaccination strategies where a DNA prime is boosted with a poxvirus vector are particularly effective and have surfaced as the major approach for generating protective $CD8^+$ T-cell immunity. DNA, for unclear reasons, appears to be more effective at priming immune responses versus as a boosting agent [202]. The general efficacy of prime-boost vaccination in humans is still not yet determined; the initial results of clinical trials in progress have been promising [203, 204].

AIDS/HIV

Currently over 35 million people suffer from HIV/AIDS, which is the primary cause of death in sub- Saharan Africa and ranks as the fourth major cause of death in the world. Approximately 6,300 people/day (2.3 million persons/year, including 600,000 children less than 15 years of age) become infected with HIV, with more than 95% of them residing in nonindustrialized countries [205]. The production of a safe, effective, easily administered and affordable HIV/AIDS vaccine is greatly

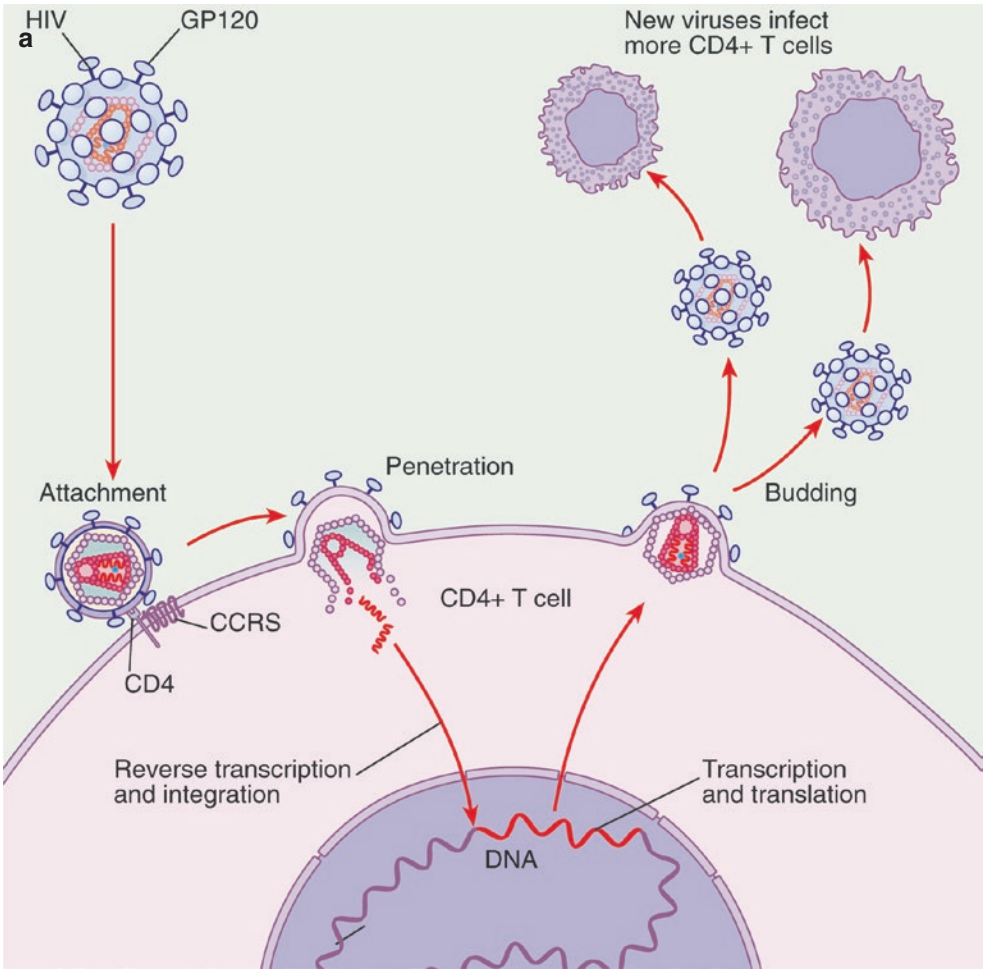

Fig. 49.3 Prime–boost vaccination strategies synergistically amplify T-cell immunity to specific antigens. Priming with the first vaccine results in the presentation of both the target antigen (*red triangles*) and vector antigens (*blue triangles*) on antigen-presenting cells (APCs). The APCs then stimulate naive T cells in the lymph nodes and drive the expansion of both target-specific T cells (*red cells*, high-avidity cells are indicated by the darker red) and vectorspecific T cells (*blue cells*). Subsequent boosting with a second vaccine results in the re-presentation of the target antigen (*red triangles*) and antigens from the second vector (*green triangles*) on APCs. These APCs then drive the expansion of target-specific memory T cells (*red cells*) and vector-specific naive T cells (*green cells*). This results in both a synergistic expansion of the T cell specific for the target antigen and selection of T cells that have greater avidity for the antigen. The situation with priming and boosting vectors that induce strong T-cell responses to themselves, as well as the target antigens, is shown. However, it should be noted that many vectors, such as DNA and some of the popular replication-defective viral vectors, induce little or no response to the vectors themselves. This is probably a key issue underlying their efficacy (From Woodland [202]. Copyright 2004, with permission from Elsevier)

needed. Figure 49.4 [206] illustrates three approaches currently being studied in the development of an AIDS vaccine.

Nanoparticle Vaccines

Nanotechnology has gained increasing popularity within the health sciences within the past decade. The small size of nanoparticles allows them to reach virtually anywhere within the body at a subcellular level and have opened the door to a plethora of potential medical uses. One such field is in vaccinology, where nanoparticles have been developed to act as delivery systems or adjuvant immunostimulants. Nanoparticles can be synthesized to carry a variety of antigens such as *Plasmodium vivax*, tetanus toxoid, *Bacillus anthracis*, and hepatitis B virus [207–210]. Advantages of nanoparticles include sustained antigen release, protection of antigen, and the ability for targeted uptake by the lymphatic system to increase efficiency of antigen response [211]. The promise held by nanotechnology has spurred further research on how nanoparticles interact with the body at micro- and macrocellular levels and formulating consistent synthetic methods for nanoparticles.

Therapeutic Vaccines

All of the vaccines used up to the 21st century were used primarily for prevention. In recent years, several new candidate vaccines have undergone trials and are being developed for infections that are already acquired. One such vaccine, GEN-003 (Genocea), has been developed for herpes simplex-2 (HSV-2) infections. It is a recombinant vaccine composed of T- and B-cell antigens adjuvanted with Matrix-M2 and administered sequentially. During a phase I/IIa clinical trial ($n = 143$), subjects receiving the vaccine achieved up to 65 % reduction in genital lesions rate and 40 % reduction in viral shedding from baseline compared to placebo; reduction persisted through a 6-month follow-up period. Safety data indicated a benign side effect profile and tolerability at all doses. Further studies are currently being conducted to determine

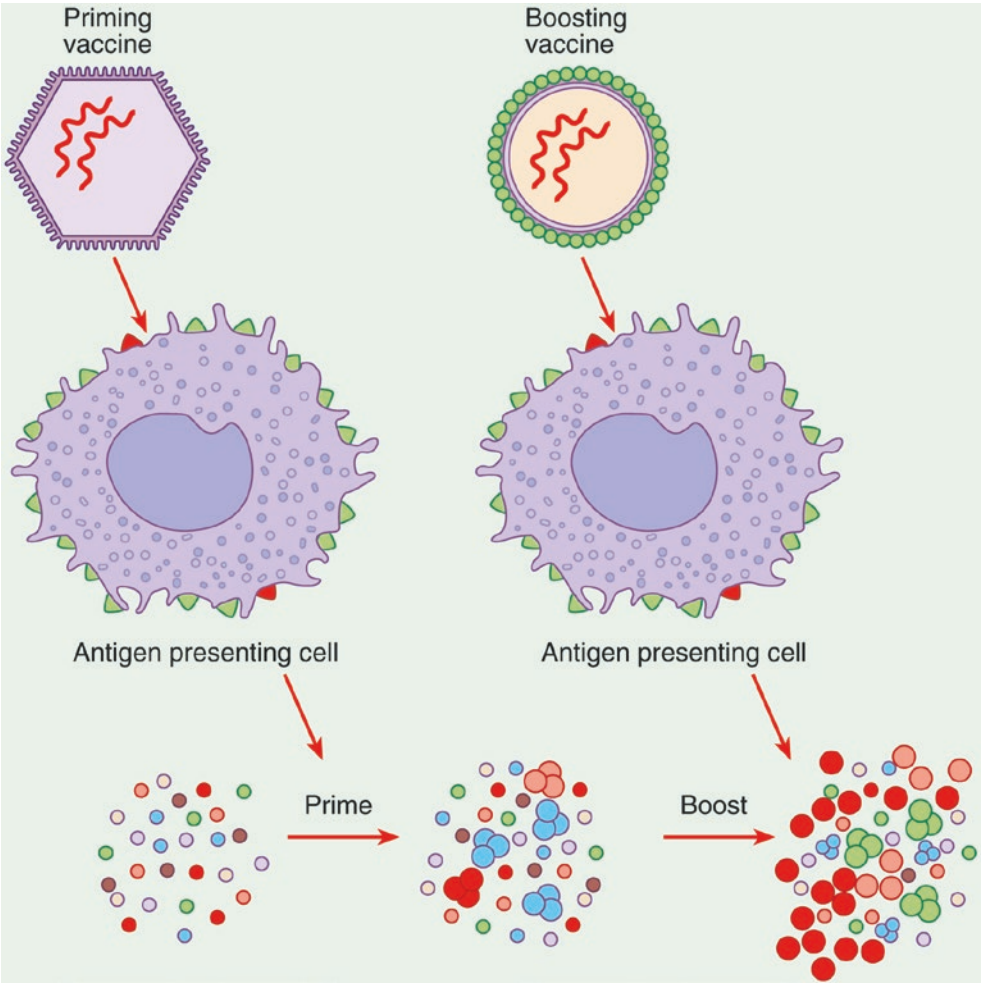

Fig. 49.4 Approaches to HIV-vaccine development. The mechanism of normal HIV infection is shown (**a**), along with the mechanisms of three types of potential vaccines: a subunit vaccine containing a synthetic protein from the CD4–binding site on the envelope of the virus (**b**), a naked DNA vaccine, and a recombinant vaccine with a bacterial or viral vector (**c**) [185] (Copyright © 2005 Massachusetts Medical Society. Fig. 49.6 Steps in the development of a cellular immune response against tumor-associated antigen. Multiple steps and processes are involved in the generation of an immune response directed against tumor antigens, offering multiple opportunities for therapeutic enhancement. For example, immunization can be used to present tumor-associated antigens to DCs (*1*). Tumors can deploy a number of immunosuppressive factors, including TGF-β and activators of STAT3 phosphorylation, which inhibit DC maturation (*2*). Small-molecule inhibitors of these factors can be used to promote DC maturation and enhance antitumor activity. T-cell expansion (*3*) can be supplemented by adoptive transfer of activated antitumor T cells, expanded or genetically modified in culture to recognize tumor antigens. Immunostimulatory monoclonal antibodies (such as agonists of CD40, CD137, or OX40) and cytokines (such as IL-12, IL-15, IL-21) can also enhance the performance of active immunotherapies or the action of adoptively transferred T cells. Finally, new studies have demonstrated the clinical potential of checkpoint modifiers that interfere with key immunosuppressive mechanisms (such as CTLA-4 and PD-1) and prolong CTL activity (*4*). *Abbreviations*: *CD40L* CD40 ligand, *CTL* cytotoxic T cell, *DC* dendritic cell, *IFN-γ* interferon-γ, *MDSC* myeloid-derived suppressor cell, *MHC* major histocompatibility complex, *MHCI* MHC class I, *MHCII* MHC class II, *NK* natural killer cell, *PD-1* programmed cell death protein 1, *TCR* T-cell receptor, *TGF-β* transforming growth factor β, *TH1* type 1 T helper cells, *TREG* regulatory T cells (Reprinted by permission from Macmillan Publishers Ltd: Melero et al. [219], copyright 2014)

optimal dosing of the vaccine prior to large scale clinical trials [212].

Modern uses of vaccines are not limited to only infections. Cancer is an area that has gained popularity as a therapeutic target for vaccines (Fig. 49.5). Dysregulated cell growth in malignancy produces proteins, or tumor-associated antigens, which are not expressed to a great degree in healthy individuals. Vaccines targeting these tumor-associated antigens have shown efficacy in producing an immune response in humans, and epidemiologic data suggests these responses may reduce the risk of developing cancer as well as improve survival rates [213]. Figure 49.6 demonstrates several ways how tumor-associated antigens elicit a cellular immune response. Prophage (Agenus) is an autologous vaccine for glioblastoma multiforme prepared from protein isolates from the patient's own cancer cells. Phase II trials since 2011 have reported as much as doubled life expectancy and a median progression-free survival of nearly 2–3 times longer compared with traditional therapies alone [214, 215]. A separate vaccine for melanoma, Allovectin ® (Vical), was designed to be injected directly into lesions to restore an MHC class 1 complex into tumor cells, creating a target for the patient's immune responses [216]. A multicenter phase II study ($n = 133$) demonstrated complete or partial responses greater than expected compared to spontaneous regression; however a multinational phase III trial completed in 2013 failed to demonstrate a statistically significant improvement in response and survival rate compared to first-line chemotherapy [217, 218]. Despite the results of Allovectin, therapeutic tumor vaccines continue to offer promise of new options for cancer treatment and phase III trials involving prostate, breast, lung, pancreatic, colorectal, and lymphoma are currently being studied [219].

Conclusion

Vaccines are one of the leading tools for maintenance of public health, and they have made a tremendous contribution to reducing the incidence of numerous diseases. While there has been much success with immunization, there are still many diseases uncontrolled by vaccination, and there are still challenges regarding implementing vaccine programs and dispelling fears about immunization side effects. Most associations between vaccines and adverse events are not demonstrated to be causal. Nevertheless, suspected relationships between vaccines and adverse events need to be reported to the Vaccine Adverse Event Reporting System (telephone 800–822–7967) in order to maintain an excellent safety record of vaccines.

Approximately 200 years of research have allowed us to direct the immune system for the gain of the people, and to have a clearer comprehension of microbial pathogenesis and host responses. From the continual presence of experimental and clinical trials, we can expect to see safe and effective vaccines for numerous infectious and non-infectious diseases in the future.

Questions and Answers

1. Which of these statements best describes the purpose of a vaccine conjugate?
   A. **Offer recognizable peptides for antigen-specific T-cells to aid in creating an adaptive immune response**
   B. Carries vaccine antigen across cellular membranes
   C. Provides protection against degradation of vaccine components

2. Which of the following is NOT a live-attenuated vaccine?
   A. MMR
   B. Small pox vaccine
   C. Varicella-Zoster vaccine
   D. **Hepatitis A**
   E. Salmonella typhi

3. Which of these statements is true regarding the nine-valent HPV vaccine?
   A. The nine-valent vaccine was shown to be approximately 5 % less efficacious in the prevention of cervical, vaginal, and vulvar diseases in HPV types 6, 11, 16, and 18 when compared with Gardasil
   B. **The nine-valent vaccine was shown to be of similar efficacy in the prevention of cervical, vaginal, and vulvar diseases in HPV types 6, 11, 16, and 18 when compared with Gardasil, in addition to providing prevention of cervical, vaginal, and vulvar disease in HPV types 31, 33, 45, 52, and 58**
   C. The nine-valent vaccine was shown to be of similar efficacy in the prevention of cervical, vaginal, and vulvar diseases in HPV types 6, 11, 16, and 18 when compared with Gardasil, and only 50 % efficacious in providing prevention of cervical, vaginal, and vulvar disease in HPV types 31, 33, 45, 52, and 58
   D. The nine-valent vaccine was shown to be of similar efficacy in the prevention of cervical, vaginal, and vulvar diseases in HPV types 6, 11, 16, and 18 when compared with Gardasil, and not efficacious in providing prevention of cervical, vaginal, and vulvar disease in HPV types 31, 33, 45, 52, and 58

Intravenous Immunoglobulin: Dermatologic Uses and Mechanisms of Action

50

Irene K. Mannering, Yang Yu, and Sergei A. Grando

Abstract

Intravenous immunoglobulin (IVIg) is a fractioned blood product consisting of pooled, polyvalent, IgG antibody. It is being increasingly utilized as off-label therapy of a variety of dermatological conditions including autoimmune mucocutaneous blistering diseases, autoimmune connective tissue diseases, Stevens–Johnson syndrome, toxic epidermal necrolysis, cutaneous vasculitides, skin infections and several other dermatoses, such as chronic urticaria, atopic dermatitis, pyoderma gangrenosum, scleromyxedema. Randomized trails are generally lacking. IVIg is a relatively safe and well-tolerated therapy inducing and maintaining a prolonged clinical remission, and has a corticosteroid-sparing effect. The mechanism of action of IVIg is multifactorial and includes: (1) reduction of autoantibody concentration, (2) modulation of cytokine production and (3) prevention of keratinocyte apoptosis. Normal degradation and removal from the body of all kinds of IgG antibodies after IVIg infusion results in a selective decrease of relative titer of pathogenic antibodies, because the level of normal antibodies is maintained by those present in the IVIg preparation. To prevent a "rebound" effect resulting from the negative feedback stimulation of B cells, IVIg should be combined with a cytotoxic immunosuppressive drug.

Intravenous immunoglobulin • Polyvalent IgG antibody • Corticosteroid-sparing effect • Treatment • Autoimmune mucocutaneous blistering diseases • Autoimmune connective tissue diseases • Stevens–Johnson syndrome • Toxic epidermal necrolysis • Cutaneous vasculitides • Skin infections • FcRn • Cytokines

Introduction

Intravenous immunoglobulin (IVIg) is a fractioned blood product consisting of pooled, polyvalent, IgG antibody extracted from the plasma of over 10,000 blood donors per batch. Historically, it was used to treat primary and secondary immune deficiencies, however, its use has expanded tremendously over the past several decades. Today it is being increasingly utilized as off-label therapy for a variety of autoimmune and inflammatory conditions, especially in dermatology (Table 50.1).

In contrast to standard immunotherapy for autoimmune and inflammatory conditions, IVIg is not immunosuppressive. It is also safe to use in pregnancy and is not associated with reproductive organ suppression, nor is it carcinogenic. It is generally accepted that the use of IVIg should be reserved for those cases that: (1) fail conventional therapy; (2) have severe side effects or contraindications to conventional therapy; and/or (3) have rapidly progressive disease.

IVIg exhibits several effects with the most well described being: (1) complement blockade and degradation; (2) neonatal Fcγ receptor saturation; (3) induction of

Table 50.1 Dermatologic diseases treated with IVIg

Autoimmune connective tissue disorders
Cutaneous lupus erythematosus
Dermatomyositis
Mixed connective tissue disease
Nephrogenic fibrosing dermopathy
Scleroderma (Systemic sclerosis)
Autoimmune mucocutaneous blistering diseases
Bullous pemphigoid
Epidermolysis bullosa acquisita
Lichen planus pemphigoides
Linear IgA bullous disease
Mucous membrane (Cicatricial) pemphigoid
Paraneoplastic autoimmune multiorgan syndrome (a.k.a. Paraneoplastic pemphigus)
Pemphigoid (Herpes) gestationis
Pemphigus foliaceus
Pemphigus vulgaris
Vascular disorders
Anti-neutrophil cytoplasmic autoantibody (ANCA) positive vasculitides:
Microscopic polyangiitis
Wegener's granulomatosis
Behçet's disease
Churg–Strauss syndrome
Cutaneous polyarteritis nodosa
Degos' disease
Leukocytoclastic vasculitis
Livedoid vasculopathy
Drug-induced skin disorders
Drug reaction eruption with eosinophila syndrome/Anticonvulsant hypersensitivity syndrome
Erythema multiforme
Kaposi sarcoma due to immunosuppression
Methotrexate-induced acral erythema
Stevens–Johnson syndrome
Toxic epidermal necrolysis (Lyell's syndrome)
Miscellaneous dermatoses
Alopecia universalis
Atopic dermatitis
Calcinosis cutis
Chronic urticaria:
Angioedema with hypereosinophilia
Autoimmune urticaria
Chronic idiopathic urticaria
Delayed pressure urticaria
Solar urticaria
Graft-versus-host disease
Hyper-IgE syndrome
Kawasaki's syndrome
Necrobiosis lipoidica diabeticorum
POEMS syndrome: *polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin changes*
Polymorphous light eruption
Pretibial myxedema
Psoriasis
Pyoderma gangrenosum
Scleromyxedema
Wiskott–Aldrich syndrome
Skin infectious and infection-related diseases
Lyme disease
Measles
Necrotizing fasciitis
Rubella
Staphylococcal scalded skin syndrome (SSSS; Ritter's disease)
Streptococcal toxic shock syndrome (STSS)
Varicella

Table 50.2 Standard IVIg infusion protocol

Administer IVIg product at 400–500 mg/kg/day on 4–5 consecutive days up to the total dose of 2 g/kg/month times 6–18 months
Premedicate patient with 25 mg Benadryl (diphenhydramine) and 500 mg Tylenol (acetaminophen) 15–30 min prior to starting the infusion
Place peripheral i.v. and maintain with 0.9 % sodium chloride
Infusion Rate: start at 0.5 ml/kg/h, then increase by 15 ml/h every 15 min until target rate of 150–200 ml/h, as tolerated. Maximum rate is 200 ml/h
Observe vital signs prior to infusion. Blood pressure and pulse every 30 min until stable infusion rate, then every hour
Watch for signs of fluid overload, cardiovascular symptoms, allergic reactions, skin rash, fever, and moderate to severe headache
For adverse events, stop the infusion. Can restart the infusion at the same or lower rate if the symptoms subside

immunomodulatory Fc receptors; (4) inhibition of B cells; and (5) altering T cell function, cytokine production and migration.

IVIg is given intravenously over several hours, gradually increasing the rate of infusion up to 200 ml/h. It is given daily for 2–5 days usually at 400 mg/kg/day up to 2 g/kg per month. The dose can be repeated in 2–4 weeks, depending on the disease and patient. Its half-life is 3–4 weeks. Multiple cycles are usually required with up to 50 or more sometimes needed. Table 50.2 outlines the standard infusion protocol for the administration of IVIg. IVIg can be administered in a hospital if there is extensive disease, concomitant very high steroid doses, or other serious medical problems. More commonly, it is administrated at an infusion center or at a patient's home under medical supervision.

The annual cost of multiple infusions of IVIg in patients with autoimmune bullous diseases is estimated to be between $33,000–$85,000. This may seem high initially however; the cost is significantly less than the cost of conventional therapy when factoring in management complications and adverse events associated with conventional immunosuppressive therapy [1]. The cost nevertheless results in extensive scrutiny by health insurance companies, requiring significant evidence that several other therapies have failed. Even when approved, the length of treatment may still be restricted.

IVIg is a relatively safe and well-tolerated therapy. Severe adverse events associated with the use of IVIg are rare. Most side effects can be minimized by decreasing the rate of infusion and by giving it over 4–5 days. Additional measures to decrease adverse events include modifications in dilution and using preservative free preparations. Not all IVIg preparations are equal with formulations available in the United States differing in immunoglobulin A (IgA) content, need for reconstitution, method of viral inactivation, osmolarity and sugar content.

In a study of 9892 infusions given to 174 patients, the most commonly reported adverse event was headache, which occurred in 8.9 % of infusions and was reported more often in patients with a history of migraines [2]. Acute self-limited cutaneous reactions such as urticaria also occurred in a small subset of patients.

Other immediate and delayed side effects can be seen with IVIg. Immediate effects include flushing, chills, fever, nausea, vomiting, dizziness, sweating, hypertension, chest pain, back pain, and muscle aches. These are related to the infusion rate and can be minimized by decreasing the rate. Headache and acute cutaneous reactions, such as urticaria, are generally best managed with prophylactic pre-medication with acetaminophen and diphenhydramine.

More serious immediate adverse effects include aseptic meningitis, thrombosis and stroke, anaphylaxis and acute renal failure. These events are rarely reported in association with IVIg, however do warrant consideration and close monitoring in high-risk patients. Thromboembolic events have been reported with the use of IVIg. This rare complication is reported to occur when a large dose is administered at a rapid rate, suggesting it might be related to high plasma viscosity [3]. To avoid this complication, high-risk patients should be treated only if necessary and monitored closely. In addition, low dose, low viscosity reconstituted preparations infused at a slow rate can decrease the risk of this serious adverse event. The risk for thromboembolic events is more common in those with a history of cardiac disease, stroke, thrombosis, and advanced age.

Anaphylactic reactions have been reported when IVIg was administered to patients with an IgA deficiency. Current preparations contain less than 2.5 % of IgA. Anti-IgA antibodies produced in patients with IgA deficiency subsequently react with the infused IgA. Evaluation of IgA deficiency prior to administration of IVIg will eliminate this potential complication.

Acute renal failure results from osmotic injury secondary to sucrose. Sucrose accumulates and causes osmotic nephrosis in the renal tubules, leading to reversible renal failure, usually within a week of administration of IVIg. Patients with pre-existing renal insufficiency, diabetes mellitus, older age or those concomitantly taking nephrotoxic agents should have their renal function closely monitored. These patients should receive a sucrose-free preparation administered slowly and at the lowest effective dose.

Delayed side effects include anemia, cardiac insufficiency due to fluid overload, renal insufficiency from immune complex deposition, and viral infections. Anemia is due to anti-ABO antibodies. The risk for infection is decreased with the recent use of detergent treatments and ultrafiltration.

Autoimmune Mucocutaneous Blistering Diseases

Autoimmune mucocutaneous blistering diseases represent a diverse group of rare diseases that involve the mucous membranes and skin. The immunologic basis is well established with each having a unique group of targeted antigens within the epidermis and dermis. The clinical course, presentation, morbidity, and mortality varies greatly within each disease. Conventional treatment for autoimmune blistering diseases is centered around the use of systemic steroids and immunosuppressive agents. These agents can cause serious side effects, some of which may be fatal.

More recently, IVIg has emerged as an important agent in the treamtent of blistering diseases. An expanding number of reports on the efficacy of IVIg in autoimmune cutaneous blistering disorders (pemphigus vulgaris, pemphigus foliaceus, bullous pemphigoid, mucous membrane pemphigoid, linear IgA dermatosis, epidermolysis bullosa acquista; paraneoplstic autoimmune multiorgan syndrome) parallel its increased utilization. More is known about the use of IVIg in pemphigus and pemphigoid than in any other autoimmune cutaneous blistering disease.

Pemphigus antibodies target several antigens on the cell surface of keratinocytes [4, 5]. These antibodies can also penetrate the cell membrane and bind to antigens on the mitochondrial outer membrane, thus triggering the intrinsic apoptosis pathway [6, 7]. Both anti-desmoglein and anti-mitochondrial antibodies are pathogenic because their adsorption abolishes the ability of pemphigus IgG to cause acantholysis in in vitro and in vivo models of pemphigus. Keratinocytes with damaged mitochondria shrink from the lack of energy and because activation of apoptotic cascades leads to collapse of the cytoskeleton. In turn, antibodies to adhesion molecules such as desmogleins prevent cell re-attachment by steric hindrance at the attachment points on nascent desmosomes. The neonatal Fc receptor (FcRn) expressed by keratinocytes is essential for both the disease-causing activities of pemphigus and pemphigoid autoantibodies and the therapeutic action of IVIg [8]. Most recently, we have demonstrated that these receptors can assist pemphigus IgG in reaching mitochondrial targets. Therefore, saturation of these receptors by IVIg may prevent pathogenic antibodies against intracellular antigens to reach their targets.

IVIg is a safe and effective treatment for autoimmune blistering diseases resistant to systemic immunosuppresion [9–11]. Failure of conventional therapy is defined as continued new blister formation, extension of existing lesions or lack of healing while on a moderate dose of prednisone, specifically, up to 1.5 mg/kg/day for at least 3 weeks. However, due to the rarity and severity of these diseases, well designed prospective trails evaluating its use are generally lacking. As a monotherapy, IVIg rapidly controls disease activity in those with pemphigus vulgaris, pemphigus foliaceus, and bullous pemphigoid within a few weeks [12–14]. Reported benefits of IVIg include a improved clinical outcome, decrease in pathogenic autoantibodies, and a steroid sparing effect [9, 12–15, 21]. In cases of pediatric pemphigus, IVIg delays the need for immunosuppression [16].

A recent review indicates treatment for pemphigus ranges from 1 to 2 g/kg/cycle over 2–5 days, at 3–4 week intervals [1]. However, the dose can be lower, and cycles can be extended by several weeks while maintaining effectiveness [17]. The most effective way to use IVIg is unknown though most favor the use of IVIg at a dose of 2 g/kg/cycle. Ahmed and Dahl [17] proposed the use of IVIg at a dose of 2 g/kg divided over 3–5 days every 4 weeks until disease control is obtained. The interval between infusions is then slowly increased to 6, 8, 10, 12, 14 and 16 weeks, and stopped afterwards. If the disease flares, the frequency of infusions is increased until control is obtained and then the tapering regimen is again resumed. A randomized, double-blind, placebo-controlled trial found that patients treated with one cycle of IVIg at 400 mg/kg/day for 5 days stayed on protocol longer without any additional treatment than the placebo group and also had suppression of autoantibodies levels [10]. These findings suggest a single cycle of IVIg maybe effective in the treatment of pemphigus.

Pemphigus and other autoimmune skin blistering diseases appear more likely to respond when IVIg is used concomitantly with additional treatments. When IVIg is used in combination with systemic steroids and/or immunosuppressive agents, a response rate of 91 % was reported, compared to a response of 56 % when it was used as monotherapy [18]. It has been well documented that IVIg causes a rapid decline in pathogenic autoantibody levels. Following this decline there is often a rebound increase. Therefore, the use of an agent that suppresses the rebound increase in pathogenic antibodies should lead to a sustained response to therapy. Indeed, co-administration of a cytotoxic agent improves the ability of IVIg to lower serum levels of pathogenic autoantibodies in pemphigus [19]. The combination of IVIg with rituximab has been shown to induce a sustained remission in the treatment of pemphigus vulgaris [20]. In that study, 11 patients were treated with two cycles of rituximab 375 mg per square meter of body-surface area every 3 weeks followed by once monthly infusions of IVIg at 2 g/kg every fourth week. All had rapid resolution of skin lesions and long-lasting disease remission off all therapy (mean 31 months). This regimen allowed rapid tapering of systemic steroids and immunosuppressive agents within 2 months.

IVIg has also been shown to effectively treat mucous membrane pemphigoid, bullous pemphigoid and epidermolysis

bullosa aquisita. Several studies have demonstrated that in severe mucous membrane pemphigoid, IVIg is more effective at resolving lesions, preventing progression, and producing longer remissions than conventional immunosuppressive therapy [12]. A review of 5 cases of patients with bullous pemphigoid, at one institution, found 4 out of the 5 had either partial or complete response to treatment with IVIg in conjunction with an immunosuppressant [21]. In a single prospective study, the use of IVIg at 2 g/kg/cycle every 4 weeks in 10 patients with bullous pemphigoid led to a significant decline in pemphigoid antibodies at 3 months and complete sustained serologic and clinical remission at 11 months [22]. An additional observation showed that these autoantibodies declined at a greater rate when IVIg was combined with immunosuppressive agents compared to its use as monotherapy [23]. Similar results have been observed in the treatment of recalcitrant epidermolysis bullosa aquisita either alone or in combination with oral corticosteroids at doses of 1–2 g/kg [12, 24].

Drug Hypersensitivity Reactions

IVIg is being increasingly used to treat several drug hypersensitivity reactions such as toxic epidermal necrolysis (TEN), Stevens-Johnson syndrome (SJS) and drug reaction with eosinophilia and systemic symptoms (DRESS). TEN and SJS are acute and life-threatening mucocutaneous reactions, most commonly due to drugs. These conditions are characterized by fever and full thickness necrosis and detachment of the epidermis. The two conditions differ by the extent of skin involvement, management, etiology and prognosis. TEN is more severe with skin involvement being greater than 30 % and has a mortality rate as high as 50 % [25, 26]. Transcutaneous fluid loss can be large causing significant electrolyte abnormalities, renal insufficiency and hypovolemia. The large amount of cutaneous involvement also puts patients at risk for infection, which can ultimately lead to sepsis.

The exact pathogenesis of TEN and SJS is only partially understood with evidence pointing to a T cell mediated process that leads to keratinocyte apoptosis. TEN is initiated either by non-covalent, direct interaction of a drug with a specific MHC I allotype or by covalent binding of a drug metabolite to a cellular peptide, forming an immunogenic molecule [26]. Treatment of TEN/SJS includes discontinuation of the suspected medication, supportive therapy and transfer to a hospital with intensive care or burn units.

Several studies report successful treatment with IVIg, with mortality rates ranging from 0 to 12 % [27–30]. A randomized trial and two retrospective studies, found that patients treated with IVIg in addition to standard therapy had more rapid disease resolution compared to patients not given IVIg [31–33]. A recent meta-analysis with meta-regression of 13 studies found that IVIg at dosages of greater than 2 g/kg significantly decreases mortality in patients with SJS or TEN [34]. The most accepted total dose for the treatment of TEN and SJS is 3–4 g/kg per day, given early in the disease. In children, somewhat lower doses ranging from 0.5 to 2.2 g/kg per cycle have been shown to be safe and effective [35]. In TEN and SJS, IVIg is thought to reduce Fas-mediated keratinocyte apoptosis by blocking the binding of FasL to Fas.

The reports on IVIg use in patients with SJS or TEN are inconsistent. A large retrospective analysis of patients in the European Study of Severe Cutaneous Adverse Reactions (EuroSCAR) evaluated the use of corticosteroids, IVIg, and supportive therapy alone, and found that the group treated with IVIg did not have improved mortality when compared to the supportive therapy group [30]. A retrospective analysis of 64 patients at one center found no benefit from IVIg at any dose in the treatment of TEN or SJS/TEN overlap [36]. There were also no differences with regard to delays in treatment or the duration of IVIg therapy.

DRESS is characterized by a widespread cutaneous eruption, eosinophilia and systemic involvement. Its etiology also is not clear but hypothesized to involve drug detoxification enzyme abnormalities with accumulation of reactive drug metabolites, sequential reactivation of herpes viruses, and genetic predisposition [37]. DRESS has a 10 % mortality rate, most commonly from fulminant hepatitis with hepatic necrosis [37]. Initiation of systemic corticosteriods is the mainstay of treatment. Patients have been effectively treated with adjunctive high dose IVIg [38–42]. IVIg can be used as an alternative steroid-sparing agent or in cases unresponsive to systemic steroids. IVIg provides immune protection, has anti-inflammatory properties and increases immunoglobulin levels in patients with this condition [38]. A case report found monotherapy with IVIg successful [38], but a multicenter prospective open study of 6 patients found no benefit [43]. In DRESS, IVIg may provide benefit via anti-viral antibodies in addition to its more general anti-inflammatory and immunomodulatory effects [38, 44].

Cutaneous Lupus Erythematosus

Lupus erythematosus (LE) is a chronic inflammatory autoimmune disorder that can manifest as a systemic disease or be limited to the skin. Several cutaneous subtypes of LE exist, each of which is partly defined by depth of cutaneous involvement. The three most well described cutaneous variants include acute, subacute, and discoid LE. Its etiology is multifactorial with genetic and environmental factors playing a role. Polymorphisms of the major histocompatibility

complex leading to increased immune response to self-antigens, deficiencies of complement components, gender, and autoantibodies are all thought to play a role [45, 46]. In regards to autoantibodies, anti-Ro, anti-La, anti-dsDNA and anti-nucleosome antibodies are thought to play a role in skin disease [45]. Autoantibodies lead to increased cell apoptosis and reduced immune tolerence [45]. Dysregulation of T cells may also play a role in the pathogenesis of LE [46, 47].

The initial treatment approach in limited cutaneous LE is photoprotection and the use of topical corticosteroids and calcineurin inhibitors. In widespread, scaring or refractory cases systemic therapy is necessary. For years antimalarials, primarily hydroxychloroquine, have been the gold standard. In patients who fail antimalarials, therapeutic options include oral retinoids, thalidomide, immunosuppressive agents such as mycophenolate mofetil or methotrexate, dapsone, rituximab, clofazimine, sulfasalazine and systemic corticosteroids [48]. IVIg is a consideration in these difficult to control cases as well.

IVIg has been used to successfully treat cutaneous lupus, either as monotherapy or in conjunction with an immunosuppressant, however controlled studies are necessary to fully evaluate its efficacy [49–54]. Three cases described by Lampropoulos et al. [53] highlighted the use of IVIg in the treatment of refractory subacute cutaneous LE. In two of the cases, IVIg at 0.4 g/kg/day for 5 days resulted in rapid improvement of the disease. However in the third case, initial treatment with 2 g/kg IVIg repeated every 4 weeks was not effective and so a single high dose was given, which resulted in greater than 80 % improvement [53]. An open prospective study of 12 patients receiving an initial dose of 1 g/kg body weight followed by 400 mg/kg monthly, for at least 6 months, found that at least five patients experienced complete clearing. Two had a partial response and three had a limited response. The benefit however was temporary in these cases with relapse occurring shortly after stopping [49]. IVIg has also been used to successfully manage lupus profundus, a type of cutaneous LE in which there is deep involvement of the dermis and subcutaneous fat. A case report describes clinical improvement with IVIg given monthly for 6 months followed by 3 month pulses [52].

Several reports describe positive results when using IVIg for the treatment of systemic LE [55, 56]. An observational, retrospective, clinical study of 52 patients treated with at least one cycle of 2 g/kg found complete remission in 28 % of patients, and partial remission in an additional 38 % [57]. IVIg is also helpful in ameliorating myocarditis, lupus nephritis, and lupus-induced bone marrow suppression [58–64]. IVIg treatment is also reported to improve cutaneous findings in systemic LE such as ulcers, urticaria, and malar rash [65, 66]. The optimal dose for treatment of cutaneous LE is yet to be determined. Typical IVIg dosages are 0.4–2 g/kg given monthly for several months. Positive effects are usually observed within a few days, but these often do not persist after IVIg therapy is discontinued. One study of patients with systemic LE achieved remission for over 2 years in 11 out of 18 patients that had an initial response to therapy [57]. Overall, IVIg appears to be a useful adjunctive or alternative therapy in LE cases that do not respond to traditional treatments. Systemic LE patients demonstrate a significant decline of anti–double stranded DNA autoantibodies after treatment with IVIg in the majority of case reports and mouse models [67]. The mechanism is thought to be due to inhibition of B cell receptors, the cells producing the pathogenic autoantibodies, or cytokine signaling [68, 69].

Dermatomyositis

Dermatomyositis (DM) is a multisystem autoimmune disease affecting skeletal muscle, skin and other organs. It most commonly presents as a symmetric proximal extensor inflammatory myopathy and a characteristic photo distributed violaceous cutaneous eruption favoring the face, scalp, and extensor surfaces. There is an amyopathic form in which only cutaneous findings are present, with the muscle disease being absent or subclinical. It has a bimodal distribution with both childhood and adult-onset variants. DM is a complement-dependent microangiopathy mediated by early activation of the complement system with deposition of the C5b-9 membrane attack complex on the endomysial capillaries, which ultimately leads to muscle ischemia and inflammation [70].

First-line therapy for DM is high dose corticosteroids. Although the majority of DM patients respond to corticosteroids, up to 20–30 % will not [71]. In cases that are unresponsive to corticosteroids or a serious steroid related side effect occurs, an immunosuppressant, usually methotrexate or azathioprine, should be started. Both corticosteroids and immunosuppressants are effective in controlling the myopathy, however cutaneous involvement can be particularly refractory to these therapies [72].

IVIg is used as a second line therapy in patients with refractory DM despite treatment with corticosteroids, methotrexate and/or azathioprine, or in those with contraindications to cytotoxic drugs [73]. Several reports justify the use of IVIg early in the course of the disease. IVIg can be considered as a first-line treatment, although IVIg monotherapy has not been shown to be effective [74]. IVIg exerts its action by inactivating immune complexes and decreasing complement amplification. This effect of IVIg was highlighted in vivo in repeated muscle biopsy specimens from DM patients. Membrane attack complex deposits decreased and neovascularization and restoration of muscle cytoarchitecture was observed [75]. In DM, IVIg is usually administered at 2 g/kg over 2–5 days monthly, typically for 3–6 months. If no benefit is noted within 6 months discontinuation of treat-

ment should be considered. The positive outcomes seen with IVIg therapy can be realized for several months after discontinuing therapy. Relapses can occur, however the disease is usually less severe and the need for steroids or immunosuppressive agents is usually decreased.

A double-blind placebo-controlled study by Dalakas et. al assessed the efficacy of 2 g/kg IVIg infusions monthly for 3 months in 15 patients with steroid resistant DM. In the IVIg treatment group, there was significant improvement in muscle strength and active skin lesions [76]. A retrospective review evaluating the effect of IVIg on refractory cutaneous DM in patients with classic and amyopathic DM was performed. All 13 patients treated with 2 g/kg IVIg every 4 weeks (given as 1 g/kg/day for 2 consecutive days) demonstrated improvement, with complete clinical response achieved in 8 [77]. The response to IVIg was very rapid, with all patients improving after the first cycle [77]. IVIg has also been shown to be effective when combined with high dose steroids in treating life-threatening DM associated esophageal dysfunction [78]. More recently, subcutaneous administration of IVIg via a pump, at the usual monthly dose fractionated into equal weekly intervals, was shown to be effective in treating DM and polymyositis [79].

Cutaneous Vasculitis

Cutaneous vasculitis represents a group of disorders characterized by inflammation of small, medium, or large vessels. This condition can be a systemic disease with secondary cutaneous manifestations, restricted only to the skin, or be a primary cutaneous disease with secondary systemic involvement. Systemic findings are broad and nonspecific but commonly include arthralgias, fatigue, hypertension, abdominal pain, renal insufficiency, and neurologic dysfunction. Cutaneous findings are dependent upon the size of the affected vessels. The most common cutaneous manifestations include erythema, purpura, ulcerations, and necrosis. Patients with cutaneous vasculitis often show increased sedimentation rate, anemia, and decreased albumin. The pathophysiology is thought to be due to immune complex deposition in the vessels or anti-neutrophil cytoplasmic antibodies (ANCAs). Immune complex deposition activates the complement system, which in turn leads to mast cell degranulation and neutrophil activation. The end result is vessel wall necrosis. In ANCA mediated vasculitis, cytoplasmic proteins from neutrophils become expressed on the cell surface, leading to antibody formation and then neutrophil mediated vessel damage via release of inflammatory cytokines including IL-1, TNF-α, and IFN-γ, reactive oxygen species, and up regulation of adhesion molecules ELAM-1 and ICAM-1 [80, 81].

Treatment of vasculitis depends on the severity of the disease. In more severe and chronic cases, medium to high-dose glucocorticoids and adjuvant immunosuppressants such as cyclophosphamide or azathioprine are the standard therapy. IVIg is shown to be beneficial in the treatment of organ-specific and systemic vasculitis [82–85]. IVIg has been used to treat ANCA-positive Wegener's granulomatosis and microscopic polyangiitis [63, 82, 84, 86–92], Churg–Strauss Syndrome [93–98], polyarteritis nodosa [99–106], antineutrophil cytoplasmic antibody-negative nonleukocytoclastic vasculitis [107], Henoch–Schönlein purpura [108], leukocytoclastic vasculitis [109, 110], urticarial vasculitis [111, 112], Behçet's disease [113], and Kawasaki disease [114, 115].

There is clear evidence that IVIg is beneficial in the treatment of ANCA-positive vasculitides and Kawasaki disease. For the other vasculitidies, there are few studies looking at the efficacy of this treatment. Case reports suggest it may inhibit disease progression [108]. IVIg inhibits TNFα and IL-1 induced proliferation of endothelial cells and reduces expression of adhesion molecules, chemokines, and proinflammatory molecules. Regulatory T cells may also play an important role in the effectiveness of IVIg [116, 117].

IVIg is an alternative or adjunctive treatment for ANCA-associated vasculitis, with significantly less toxicity than standard therapy. A randomized clinical trial investigated the efficacy of IVIg (total dose 2 g/kg) in patients with recalcitrant Wegener's granulomatosis and microscopy polyangiitis. The study found partial or complete remission in 82 % of the IVIg group versus 35 % of the placebo group at 3 months. Despite these results, disease activity, frequency of relapse, and exposure to immunosuppression was the same in both groups, indicating that the benefit of IVIg was not maintained beyond 3 months [82, 98]. A prospective, open-label study of patients with Wegener's granulomatosis and microscopic polyangiitis looked at the efficacy of adjunctive IVIg along with a standard immunosuppressive therapeutic for remission maintenance. At 9 months, 62 % were in complete remission, with 53 % maintaining remission at 24 months [118]. IVIg was used to successfully treat 12 patients with rapidly progressive glomerulonephritis from ANCA-positive vasculitis [91]. In another report, patients with Churg–Strauss syndrome were treated with IVIg in addition to corticosteroids, with or without cyclophosphamide [94]. In that study, motor neuropathy was improved in 13 of 15 patients and cardiac function improved in all five patients with heart failure.

In vitro studies have found IVIg inhibits ANCA induced neutrophil activation and cytokine release [119]. Using IVIg early in the course of ANCA-positive vasculitis may stop apoptotic cell death and reduce damage, particularly in serious forms such as Wegener's granulomatosis [90]. Therefore, the use of IVIg may be justified as a first-line agent in this systemic vasculitis. It also offers an alternative to cytotoxic agents when contraindications exist. IVIg is usually administered for a total dose of 2 g/kg as a single dose or repeated in

4-week intervals. The patient response should be assessed after several intervals [120].

Kawasaki disease, also known as mucocutaneous lymph node syndrome, is an acute vasculitis of the small and medium sized vessels that typically presents in children between 6 months to 5 years of age. IVIg and high-dose aspirin together is considered the most appropriate and effective regimen for patients with this condition [121]. The standard treatment is 2 g/kg IVIg given as a single infusion within 10 days of symptom onset. Administration of IVIg after 10 days may alleviate symptoms, but it is not as effective in preventing coronary artery disease [122, 123]. In one study, 1 g/kg dose was just as effective [124]. Longer intervals may be used as well [125]. Although IVIg is the most effective treatment for reducing acute symptoms, 10–20 % of patients are resistant to initial IVIg treatment, putting them at risk for developing coronary artery disease [126]. Elevated IL-6, TNF-α, percentage of circulating neutrophils, and plasma clusterin are found in cases resistant to IVIg treatment [126–128]. Combination therapies may prove efficacious in resistant cases [129, 130].

Atopic Dermatitis

Atopic dermatitis (AD) is a common chronic inflammatory skin disease that usually starts in childhood. It is a complex genetically-determined disease often associated with other atopic disorders including asthma and allergic rhinoconjunctivitis [131]. Its most common features are pruritus and a chronic and relapsing dermatitis characterized by erythematous edematous papules/plaques, xerosis, and lichenification. Its exact etiology is unclear but thought to be due to an impaired epidermal barrier and dysfunctional stratum corneum that allows antigens to enter and activate immune cells.

A multi-faceted approach is needed to treat AD with the main focus being on avoiding triggers, a daily moisturizer to repair the skin barrier defect, topical steroids and topical calcineurin inhibitors, and education. Adjunctive modalities are used in severe refractory cases. These include systemic immunosuppressants (methotrexate, cyclosporine, oral corticosteroids, azathioprine, mycophenolate, etc.), phototherapy, IVIg, and targeted therapy with rituximab and omalizumab.

High dose IVIg, either as monotherapy or in conjunction with immunosuppression, has been reported to be effective in treating patients with recalcitrant disease, especially children [132–134]. However, there is a paucity of double-blind, placebo-controlled trials evaluating the use of IVIg for the treatment of AD. A report of 3 cases of adults treated with 2 g/kg monthly demonstrated improvement of skin lesions, reduction of concomitant systemic medications, and a decrease in serum IgE [135]. A randomized, placebo controlled study of 40 children with moderate to severe AD treated with three doses of 2 g/kg IVIg at 1 month intervals found that disease severity improved at 3 months [136]. A retrospective study of 10 children with severe refractory AD found similar results. Patients were treated with IVIg monthly for up to 24 months and found to have significant clinical improvement along with decreases in serum IgE. The clinical benefit varies with results lasting anywhere from 6 months to 4 years or longer [136–139]. On the other hand, a study of 10 patients evaluating the use of IVIg in adults with severe AD found that a single high-dose treatment did not significantly improve symptoms [140]. IVIg may provide benefit in AD patients by downregulating T cell function, particularly IL-4, and IL-5 and through its general immunomodulating effects [135]. Further randomized studies examining the effective dose, dosing intervals for initiation of therapy and maintenance are needed.

Mechanisms of Therapeutic Action of IVIg in Mucocutaneous Autoimmune and Inflammatory Diseases

The mechanism of action of IVIg is not completely understood but thought to be due to: neutralization of bacterial superantigens or other infectious agents, inhibition of TNF-α production, neutralization of pathogenic autoantibodies, regulation and modulation of Fc receptors, downregulation of proinflammatory cytokine production, suppression of the function of B lymphocytes, enhancement of regulatory T cells with inhibition of other T cells via T-cell receptor signaling, antioxidative effects, inhibition of TH_{17} differentiation, inhibition of differentiation of dendritic cells and suppression of the endocytosis of nucleosomes [69, 119, 121, 141, 142].

In immunobullous diseases, several mechanisms are thought to drive the decline in autoantibody levels and disease activity. A dramatic and rapid effect of treatment with IVIg is the selective decrease in autontibodies, leaving normal protective antibodies unaffected [23, 143, 144]. This correlates well with IVIg's fast therapeutic effect. The rapid decrease suggests that this is due to increased catabolism of antibodies rather than decreased production [145]. A clinical study of 12 patients found that IVIg decreased anti-desmoglein 3 by 45 % and anti-desmoglein1 by 32 % from baseline within 2 weeks of the last cycle [146]. The lack of activity against long-term autoantibody production necessitates the use of cytotoxic immunosuppressants to supress production of new pathogenic autoantibodies during the catabolic phase [147].

The FcRn receptor is present on many cell types, inlcuding keratinocytes and endothelial cells. It functions to regulate serum immunoglobulin levels by protecting immunoglobulin from degradation. By increasing the concentration of IgG, these receptors become saturated, and are no longer able to protect IgG from degradation. This leads to increased catabolism of all antibodies. Because pathogenic antibodies are not replenished by IVIg therapy, levels of these

antibodies decline, preventing their activation. In addition, IVIg may increase the expression of the inhibitory FcRIIB receptor on effector cells, resulting in decreased clearance of opsonized platelets [148]. This same mechanism could act to decrease activation of anti-keratinocyte primed phagocytes.

Within the natural autoantibody population, there are antibodies that can bind the variable region of other antibodies. This anti-idiotypic interaction may interfere with autoantibody binding to autoantigen, preventing effector function. It may also cause anti-idiotype cross-linking of surface IgG, leading to apoptosis of autoimmune B cells [149, 150]. There is also evidence that antibodies in pooled IVIg may interact with pathogenic autoantibodies, blocking their function [151].

In addition to reducing autoantibody concentration, IVIg has been shown to alter cytokine profiles [152–154]. IL-2, IL-3, IL-4, IL-5, IL-10, TNF-β, and GM-CSF are downregulated, but not IFN-γ or TNF-α. In some diseases, the major effect of IVIg modulation may be regulation of Th1 and Th2 cytokines [155]. IVIg may increase differentiation of dendritic cells [156]. At the higher levels used in treating autoimmune diseases, however, IVIg blocks maturation of dendritic cells *in vitro*, resulting in increased IL-10 and decreased IL-12 secretion [157].

All of the above mechanisms deal primarily with the effect of IVIg on antibodies, lymphocytes, or antigen-presenting cells. Additionally, IVIg appears to act directly in the skin, preventing autoantibody induced cell death. Notably, antibodies from pemphigus patients induce cell death through apoptosis and oncosis, termed apoptolysis [158]. Apoptolysis develops due to the combined and synergistic effects of autoantibodies and auto/paracrine mediators secreted by autoantibody stimulated keratinocytes, including TNF-α and Fas ligand [159]. Analysis of the activity of enzymes in apoptotic or oncotic pathways from keratinocytes treated with IgG antibodies from patients with pemphigus vulgaris demonstrated that the patients could be grouped according to whether their antibodies activated apoptosis-inducing caspase-3 and caspase-8 or oncosis-inducing calpain [158]. This indicates that the pathogenic antibodies can activate both pathways separately, which may account for the variability in clinical presentation and response to treatment of patients with pemphigus vulgaris.

It has been demonstrated that IVIg protects keratinocytes from pathogenic autoantibodies by preventing the autoantibody-induced apoptolysis [158]. Normal human IgG prevented the pemphigus vulgaris autoantibody induced increase of pro-apoptotic caspases and pro-oncotic calpain, while increasing the expression of the anti-apoptotic FLIP-I and anti-oncotic calpastatin [158]. These changes correlated with decreased induction of acantholysis in vitro, in keratinocyte cultures, and in vivo, in the mouse model of experimental pemphigus. Thus, protection of the target cells through upregulation of the endogenous caspase and calpain inhibitors may be a novel mechanism of therapeutic action of IVIg [15].

In vivo experiments demonstrated that pemphigus vulgaris antibodies cause an unopposed upregulation of mTOR selectively in basal keratinocytes associated with apoptosis, which can be abolished due to pretreatment with the mTOR inhibitor sirolimus [160]. This important observation justified a clinical trial of sirolimus in patients with pemphigus vulgaris. Initial results demonstrated that combination of therapy of 2 mg/day of sirolimus and 2 g/kg/month of IVIg provides for a good therapeutic response allowing complete withdrawal of systemic steroids [161]. This suggests that the combination of these agents is effective for acute pemphigus vulgaris because of the immunosuppressive activity and the protection provided against keratinocyte antibody-induced apoptolysis.

Questions

1. How is IVIg therapy given?
   A. Intravenously over several hours, gradually increasing the rate of infusion up to 200 ml/h
   B. Daily for 2–5 days. Usually at 400 mg/kg/day up to 2 g/kg per month
   C. Cycles can be repeated in 2–4 weeks
   D. Multiple cycles are usually required: from 3–5 to 30–50 and more
   E. All of the above
   F. None of the above

2. IVIg can be used in pregnancy.
   A. True
   B. False

3. What affects the safety of IVIg therapy?
   A. IgA content
   B. Concentration
   C. Sugar content
   D. Frequency and administration rate.
   E. All of the above
   F. None of the above

4. IVIg can be made to work better by combining it with:
   A. systemic corticosteroids
   B. topical corticosteroids
   C. cytotoxic immunosuppressors
   D. antibiotics
   E. multivitamins

Answers

1. E
2. A
3. E
4. C

Immunobiology and Immune Based Therapies of Melanoma

51

David L. Chen, Cheryl Armstrong, and Mariah R. Brown

Abstract

Despite efforts in preventative care, the incidence and mortality rate of melanoma have continued to rise. However, in the past decade, an increasing understanding of melanoma immunology has resulted in tremendous bench to bedside advancements in melanoma therapies. Many of these new treatment modalities have proven efficacious, leading to seven new melanoma therapies receiving FDA approval within the past 5 years. This chapter explores our current understanding of melanoma immunology, with an emphasis on tumor microenvironment and the ability of melanoma to evade immune surveillance. The remainder of the chapter focuses on how this understanding of melanoma immunology has been translated into clinical therapies. These agents include cytokines such as interleukin-2 and interferons, checkpoint inhibitors such as anti-CTLA4 and anti-PD1 antibodies, and vaccines. For each melanoma therapy, mechanism of action, efficacy, side effects, dosing strategy and future directions will be discussed.

Keywords

Cancer • Melanoma • Skin disease • Immune based therapies • T-lymphocytes • Dendritic Cells • Adhesion Molecules • Chemotherapy • Gangliosides • Biochemotherapy

While melanoma accounts for only a small percentage of all cutaneous malignancies, it remains an important health issue due to its high mortality rate. In 2016, there were 76,380 new cases of malignant melanoma diagnosed, and 10,130 deaths attributed to melanoma [1]. These statistics are particularly concerning, as they represent a greater than 25 % increase from data only 8 years ago [2]. Cutaneous malignant melanoma originates from melanocytes, neural crest derived pigment cells residing in the basal layer of the epidermis. Our current understanding of melanoma development involves a step-wise progression through stages of growth, including cellular atypia, radial growth, vertical growth, and the development of metastases [3]. This model corresponds to the American Joint Commission on Cancer (AJCC) staging classification of melanoma that defines primary cutaneous melanoma as Stage I or Stage II disease, lymph node metastases as Stage III disease, and distant metastases as Stage IV disease [4–6]. This transition of melanocytes into neoplastic melanoma cells that initially grow in the skin and later metastasize to distant sites involves complex host-tumor cell interactions. Our understanding of host-tumor cell interactions has progressed rapidly in recent decades, and translating these basic science developments into clinical treatment of melanoma has yielded promising results. Insights into the host immune response to malignant melanoma have led to the development of new approaches to melanoma therapy.

Melanoma Immunology

It is widely accepted that melanoma cells and the immune system are intricately connected. For instance, systemic immune suppression from human immunodeficiency virus infection is associated with an increased rate and more aggressive behavior of malignant melanoma [7–9]. Melanoma cells are capable of triggering host immunologic responses—depigmentation and regression of primary melanomas provide supporting evidence that host immune surveillance can occur [10, 11]. Finally, different types of immune cells have been noted to infiltrate tumor sites in malignant melanoma, and an increased number of tumor infiltrating immune cells has been associated with an improved prognosis, even in more advanced disease [12]. Indeed, different components of the immune system are activated in response to melanoma cells, and basic investigations of these immune responses are critical to the development of immune-based therapeutic approaches to melanoma.

T-Lymphocytes and Dendritic Cells

Numerous studies have shown that T-lymphocytes play a major role in melanoma immunology and immunotherapy. T-lymphocytes have been observed to accumulate in melanoma lesions and lyse autologous tumor cells *in vitro*, as well as to cause tumor regression when transferred *in vivo* in 30 % of melanoma patients [13]. Cytotoxic T-lymphocytes (principally CD8+) cells respond primarily to target cells with specific antigens associated with class I major histocompatibility complex (MHC) proteins. Activation of cytotoxic T-lymphocytes results in destruction of target cells that have altered MHC I antigen expression. Helper T-lymphocytes (CD4+ cells) respond primarily to class II MHC proteins and the associated antigens on the antigen presenting cells (APCs). Activated CD8+ cytotoxic T-lymphocytes and CD4+ helper T-lymphocytes produce a variety of cytokines that function to amplify and modify the immune response to the growing tumor [14, 15]. Melanoma cells, however, may thrive and proliferate by evading host immune surveillance and defense, as demonstrated by the fact that brisk immune activation in clinical trials does not always result in successful clinical response [16]. This evasion occurs by a number of mechanisms, including antigen loss, downregulation of MHC expression, and reduction of the T-helper 1 (Th1) arm of the immune response [17]. In addition, a subpopulation of human regulatory T-lymphocytes (Tregs), characterized as $CD4^{+}CD25^{+}$ T-lymphocytes, typically has the function of suppressing self-reactive T-lymphocytes [18]. However, Tregs may suppress anti-tumor immune responses, as seen in animal models of melanoma [19]. Patients with metastatic melanoma have increased numbers of these $CD4^{+}CD25^{+}$ T-lymphocytes that may influence responses to various immune modulating therapies [20]. More recently, T-lymphocytes were demonstrated to express cytotoxic T-lymphocyte antigen 4 (CTLA-4), which when bound to the B7 target on APCs, can lead to T-lymphocyte anergy, a T-lymphocyte poor microenvironment, and immunologic ignorance of tumor, in melanoma and other solid tumors [21]. Even in a T-lymphocyte rich environment, melanoma evasion may occur due to T-lymphocyte exhaustion and dysfunction due to the expression of programmed death-1 (PD-1) receptor on T-lymphocytes and the binding of its ligands, PD ligand (PD-L) 1 and PD-L2 that are expressed on tumor cell surface [21–23].

The role of B cells and humoral immunologic responses to melanoma cells remains undefined. Natural killer cells also appear to play a role in melanoma immune surveillance and the destruction of neoplastic cells with reduced MHC expression [24, 25].

Dendritic cells are active participants in the host immune response to melanoma. Dendritic cells are bone marrow derived leukocytes, which are potent APCs and play a critical role in initiation of T-lymphocyte immune responses [26]. In the skin, APCs are also known as Langerhans cells. Dendritic cells express high levels of both MHC class I and class II molecules, as well as T-lymphocyte costimulatory molecules [i.e., CD40, CD80 (B7-1), CD86 (B7-2)] [27]. Dendritic cells are capable of secreting a variety of cytokines, such as Interleukin (IL)-1 and IL-12, which serve as accessory factors for T-lymphocyte activation. Activated dendritic cells are mobile, monocyte-derived cells that traffic to lymphoid organs to present foreign or tumor cell antigens to specific populations of T-lymphocytes, which results in the activation of antigen specific effector T-lymphocytes [28]. It has been documented that dendritic cells themselves can infiltrate melanomas, although the purpose of this infiltration still needs to be defined [29]. Previous studies have suggested that melanoma-derived factors may convert dendritic cells from potent immune response inducers into tolerance-inducing APCs [26], which may limit the development of dendritic cell melanoma immunotherapies.

Adhesion Molecules

A number of distinct cellular adhesion molecules and cytokines have been implicated in the local growth and metastatic progression of melanoma cells. Tumor progression and the development of metastatic disease are often associated with loss of normal cellular controls. The alteration of tumor cellular adhesion molecule expression and function allows neoplastic cells to separate from the primary tumor mass to

establish metastatic lesions. With separation of the metastatic cells from the primary tumor mass, neoplastic cells are freed from local cell contact inhibitory mechanisms. Altered expression of adhesion molecules in neoplastic cells can also improve their ability to adhere to vascular endothelium facilitating metastases to distant sites. Many different tumor-associated cell adhesion molecules have been implicated in the progression of melanoma from radial growth, to vertical growth and then to metastases. These key adhesion molecules include integrins, cadherins and immunoglobulins such as ICAM-1 [30]. *In vitro* and *in vivo* studies have shown that melanoma cells alter their cell surface adhesion molecules as they progress through the different stages of growth, and that expression of certain cell surface molecules by melanoma can yield prognostic information [30, 31].

One example of a cell adhesion molecule associated with melanoma pathogenesis is MUC18/MCAM/CD146, a cell surface glycoprotein that mediates adhesion to different cell types. MUC18 is expressed on both vascular endothelia and activated T-lymphocytes, facilitating the extravasation and/or homing of activated T-lymphocytes [32, 33]. In contrast, the expression of MUC18 on melanoma cells is associated with tumor progression and increased metastatic potential in both humans and mice [34, 35]. The level of expression of MUC18 on primary melanoma tumors increases as the tumors increase in thickness and develop metastatic potential [34, 36]. The ability of human melanoma cell lines to form metastases in mice has been correlated with the level of expression of MUC18 [37]. In light of these findings, a human monoclonal antibody against MUC18, ABX-MA1, has demonstrated therapeutic promise in mouse models of melanoma [38].

Cytokines

Melanoma cells are capable of producing a variety of cytokines, which not only modulate the growth of tumor cells, but also act to promote or inhibit the host antitumor inflammatory and immune response [39]. These melanoma-derived cytokines have different biologic activities and can act as autocrine growth factors, growth inhibitors, growth promoters, or immunosuppressive factors. Some of these cytokines allow the melanoma cells to grow independently of exogenous growth factors.

Basic fibroblast growth factor (bFGF), IL-6, and chemokines such as IL-8 are capable of acting as melanoma autocrine growth factors. bFGF is expressed by melanoma cells, but not by melanocytes, and appears to provide a growth advantage to tumor cells [40, 41]. Some melanoma cell lines produce IL-6, which is a major immune and inflammatory mediator that appears to have conflicting roles in regulating melanoma growth and progression [42–44]. Previous studies indicate that IL-6 may be both a growth inhibitor and an autocrine growth stimulant for melanoma cells depending on the stage of tumor progression [45]. *In vitro* studies also demonstrate the ability of IL-8 to function as an autocrine growth factor for melanoma cells [46]. A positive correlation between melanoma IL-8 production and tumor thickness in primary cutaneous melanoma has been reported [47]. Additionally, IL-8 production has been shown to correlate with melanoma metastatic potential in nude mice [48] and with the induction of migration by melanoma cells [49].

Tumor derived transforming growth factor-β (TGF-β) and colony stimulating factors (CSFs) may also modulate the growth and progression of melanoma. The TGF-βs are potent regulators of the immune response, cellular proliferation, differentiation, and extracellular matrix synthesis and deposition [50]. The proliferation of most melanoma cell lines is inhibited by TGF-β [40, 51]. However, some melanoma cell lines established from metastatic tumors have been shown to become resistant to the growth inhibitory effects of TGF-β. This cytokine may even act as a growth stimulator in some of these advanced melanoma cell lines [52]. Since TGF-β has potent immunosuppressive activities, the production of this cytokine by melanoma cells may inhibit the host immune responses to the tumor. Some melanoma cells are capable of producing a number of CSFs including granulocyte-colony stimulating factor (G-CSF), granulocyte-macrophage-colony stimulating factor (GM-CSF), stem cell factor/mast cell growth factor, and monocyte-colony stimulating factor [43, 53]. Host anti-melanoma effects have been most clearly demonstrated with GM-CSF. Studies have shown that GM-CSF produced by melanoma cells can induce monocyte Tumor Necrosis Factor α (TNF-α) production, which may contribute to host anti-tumor responses [54]. GM-CSF gene transfection into melanoma cells results in significant inhibition of melanoma progression by activating host immune responses [55, 56]. In human pathological specimens, melanoma tumor thickness inversely correlates with GM-CSF melanoma cell production, suggesting that GM-CSF may have an anti-melanoma role in early primary lesions [47].

IL-10, which typically has a number of immunosuppressive properties, is another cytokine produced by some melanoma cells. Studies have also demonstrated that, in some circumstances, IL-10 appears to act as a growth factor for melanoma cells *in vitro* and can downregulate the expression of HLA-I, HLA-II, as well as ICAM-I [57]. Melanomagenesis is known to be involved in the IL-10 cytokine pathway. Ultraviolet (UV) radiation can decrease epidermal Langerhans (dendritic) cells and stimulate production, by both T-lymphocytes and a small population of melanoma cells, of immunosuppressive and tumor growth promoting IL-10. The result is a milieu that allows the initial

expansion of melanoma cells [58, 59]. Patients with advanced metastatic melanoma have also been found to have elevated serum IL-10 levels, which is rarely observed in healthy patients [60]. Thus, IL-10 predominantly has immunosuppressive and tumor promoting activities in the setting of melanoma [61].

Melanoma Associated Antigens

A number of antigens located on the cell surface of melanomas have been referred to as melanoma associated antigens (MAA). These antigens can be divided into two major categories: HLA-associated antigens that are recognized by T-lymphocytes and cell surface antigens such as gangliosides that do not directly activate T-lymphocytes [17, 62]. Unlike gangliosides, melanoma associated antigens recognized by T-lymphocytes are derived from proteins that do not normally reside on the surface of normal cells, and thus can evoke an immune response in association with particular MHC molecules on the cell surface. These peptide-based antigens can be grouped into three different categories: antigens expressed only on cells of melanocytic lineage (i.e. tyrosinase, TRP-1, TRP-2, Melan-A/MART1, and gp100), antigens expressed in different kinds of tumor cells but not in normal adult tissues outside of the gonads (i.e. MAGE, BAGE, GAGE, NY-ESO-1 and PRAME), and unique antigens found only on some tumor cells [17]. Interest in MAAs focuses around potential immunotherapies for melanoma, particularly vaccine therapy.

Cytotoxic T-lymphocyte clones that have been identified and expanded from melanoma patients may recognize specific antigens expressed on both melanoma cells and normal melanocytes [63]. Melanoma associated cytotoxic T-lymphocyte antigens include tyrosinase, tyrosinase-related protein 2, tyrosinase-related protein 1/gp75, silver/gp100 protein, Melan-A/MART1, and the Lerk proteins (lerk-1/protein B61 and Lerk-5/Eplg5/Elf2/HTK-L). Tyrosinase is an enzyme that converts tyrosine into dihydroxyphenylalanine (DOPA), the precursor of melanin. The gene that codes for tyrosinase is found in all melanoma cells as well as normal melanocytes, but is not expressed in other cell types. The silver/gp100 protein (also referred to as Pmel [64]) is a melanosomal matrix protein that acts as a solid-phase substrate for the accumulation of melanin [65]. The gp100 peptide is a melanocyte differentiation antigen that is recognized by HLA-A2 restricted T-lymphocytes [66]. Another gene that is expressed only in cells of melanocytic origin is Melan-A [67]. The antigen encoded by Melan-A is called MART-1. MART-1 is only found on normal melanocytes, melanoma cells and retinal cells [68]. MART-1 is presented by HLA-A2 and is capable of causing a strong T-lymphocyte immune response [69].

Antigens that are expressed almost exclusively on tumor cells and extensively on melanoma cells include products of the MAGE gene family. MAGE genes are all located on the long arm of the X chromosome and are only found on the testis in normal adult tissue. The MAGE proteins are commonly expressed on melanoma cells and less frequently on the surface of other tumor cells. The genes MAGE-1, 2, 3, 4, 6, and 12 are expressed in different tumors such as breast carcinomas, non-small cell lung carcinomas, head and neck tumors, sarcomas, and ovarian carcinomas [70–73]. The products of MAGE-1 and MAGE-3 have been found to produce proteins that bind the different MHC class I molecules expressed on melanoma tumor cells. Products of MAGE-1 have been reported to be expressed on 48 % of metastatic melanomas, while products of MAGE-3 are expressed in >90 % of metastatic melanomas [74, 75]. Even though some proteins produced from MAGE genes have been characterized, their function on the surface of tumor cells is unknown.

Melanoma Gangliosides

Melanoma cells also express a number of gangliosides on their cell surfaces. Gangliosides are glycolipids that are characteristically found in neural crest-derived tissues [14]. Gangliosides regulate cell growth by altering growth factor signals and are involved in cell adhesion and cell matrix interactions [76]. The monosialoganglioside GM3 makes up 90 % of the gangliosides found on normal melanocyte cell surfaces, while the disialoganglioside GD3 comprises only 5 % [76]. It has been shown that quantitative and qualitative changes occur in the expression of gangliosides during oncogenic transformation [77]. The predominant gangliosides in melanoma are GM3 and GD3. GM3 is found on virtually all melanoma cells. GD3 is found on few normal melanocytes and at lower levels than on melanoma cells. The minor gangliosides are expressed on most melanoma cells but less often in normal tissues. These minor gangliosides include GM2, GD2, GT3, and 9-O-Ac-GD3 [78]. As a result, melanoma gangliosides are a possible target for immunotherapy against melanoma, and work has focused on several of these molecules in vaccine therapy.

Treatment Strategies for Melanoma

When detected early, melanoma responds well to treatment. However, it becomes a difficult cancer to treat once it extends beyond the skin. In 2014, more than 9700 people are estimated to have died from malignant melanoma in the US, and the incidence of the disease continues to increase yearly [2, 79]. Surgical excision of thin primary cutaneous melanoma that is detected early in melanomagenesis

remains the most effective therapy. The 5 year and 10 year survival rate is 97 % and 93 %, respectively, for fully excised cutaneous melanoma that is 1 mm or less in thickness, without ulceration, having less than 1 mitotic figure per millimeter squared, and without nodal involvement or distant metastases [4, 6]. In contrast, patients with melanoma that has metastasized to the viscera have a drastically reduced survival: the 1 year survival rate is 33 % and the 5 year survival is only 10–15 % [4, 6]. Novel therapies for melanoma have begun to improve the poor prognosis associated with thicker, more invasive melanomas, as well as metastatic disease. Recent advances in our understanding of the immunobiology of malignant melanoma offer the potential for new and more effective approaches for disease management. As immunological treatments are being combined with non-immunological therapy clinically, we begin with a brief discussion of non-immunological treatments.

Non-immunological Treatments

Surgical Treatments

As noted above, melanoma has an excellent prognosis when detected early and treated with surgical intervention. The depth of the tumor determines the local surgical margins, and for most thin tumors surgery is considered curative [80]. Tumor depth is reported as Breslow depth, the measurement in millimeters of the tumor invasion from the granular layer of the epidermis. However, the presence of local lymph node metastases (Stage III disease) is a strong predictor of poor clinical outcomes. Lymph node involvement in patients with melanoma has a 5-year survival rate of 46 %, compared to greater than 90 % for patients without lymph node involvement. The technique of sentinel lymph node biopsy (SLNB) has been developed as a way to identify patients with clinically occult nodal involvement, and is a far less morbid surgical intervention than empiric complete lymph node dissection (CLND) [6, 81–86]. The SLNB technique involves the injection of a vital blue dye or radiolabeled agent into the area of the primary tumor. This labeling allows for identification and subsequent sampling of the sentinel node (or nodes) during or prior to wide local excision [87]. Studies have shown that if the sentinel node is negative, there is less than a 1 % chance of positive nodes elsewhere in the lymph node basin [87]. This technique has been primarily studied in melanomas that are at high risk for metastatic disease but still amenable to early intervention – melanomas of intermediate depth of 1–4 mm [81, 85, 88]. Based heavily on the data from the Multicenter Selective Lymphadenectomy Trial-1 (MSLT-1), the clinical practice guidelines from the American Society of Clinical Oncology and the Society of Surgical Oncology recommend that SLNB should be performed in patients with melanoma of intermediate depth, followed by CLND if the SLNB is positive. This trial has demonstrated that SLNB improves relapse free survival and regional disease control in melanoma, as well as providing prognostic and staging information for patient management [83, 85, 88–90]. However, in spite of significant optimism for this technique in the treatment of melanoma, clinical trials have not shown an overall survival benefit from SLNB, and, as a result, the technique remains a subject of much debate [91].

Traditional Chemotherapy

Dacarbazine (DTIC) is the only traditional chemotherapeutic agent approved for the treatment of advanced melanoma by the Food and Drug Administration (FDA). Clinical trials demonstrate that approximately 10–20 % of patients with metastatic melanoma have a measurable clinical response to the drug, but fewer than 5 % achieve complete responses [92]. Innumerable combinations of different chemotherapeutics have been tried in the treatment of metastatic melanoma [93]. In spite of this effort, a recent meta-analysis failed to show a survival benefit in several different multi-drug chemotherapy regimens when compared to DTIC alone [93]. There has also been interest in the drug temozolomide, an oral formulation of DTIC, in the management of melanoma. Temozolamide has not been shown to have improved efficacy over DTIC, but has been used for palliative treatment of melanoma with brain metastases, due to its improved ability to penetrate the central nervous system [94–97]. While traditional chemotherapy agents have not been shown to improve overall survival, they remain useful in select clinical cases as palliative options [96, 97].

Small Molecule Inhibitors

The mitogen-activated protein kinase (MAP-Kinase) pathway is a cellular signal transduction pathway that regulates cell division and differentiation. The majority of melanomas carry an activating mutation in the upstream serine-threonine protein kinase BRAF in this pathway, leading to uncontrolled cell growth and eventually tumor development. Genetic studies have shown that up to 90 % of the BRAF mutations in melanoma result from a substitution of glutamic acid for valine at amino acid position 600 (V600E mutation) [98]. This discovery has led to the development of small molecule inhibitors against the V600E target. The first of these agents, vemurafenib, demonstrated significant improvement in overall survival in patients with metastatic melanoma harboring the mutation as compared to DTIC in Phase III trials, leading to FDA approval for treatment of V600-mutated melanoma in 2011 [99–101]. Dabrafenib, another V600E small molecule inhibitor, was approved by the FDA for similar indications after demonstrating success in its Phase III clinical trial [102]. Vemurafenib is given orally at a dose of 960 mg twice

per day, while dabrafenib is given orally at a dose of 150 mg twice per day.

V600E-mutated melanomas eventually become resistant to BRAF inhibition, due to the development of bypass neuroblastoma RAS oncogene homolog (NRAS) pathway or downstream mitogen activated protein kinase kinase (MEK) mutation [103]. The discovery of this resistance prompted the development of trametinib, a small molecule agent that blocks downstream MEK targets. Trametinib is now approved by the FDA for salvage monotherapy and for use in combination with BRAF inhibitors in the treatment of metastatic melanomas harboring the V600E mutation [104, 105]. Trametinib is prescribed as 2 mg by mouth daily. Cobimetinib is another MEK inhibitor that has been shown to increase overall and progression-free survival when used in conjunction with BRAF inhibitors [106, 107].

C-KIT is a receptor tyrosine kinase that can activate downstream MAP-kinase pathway. Small molecule inhibitors of C-KIT, such as imatinib and nilotinib, were developed for the treatment of malignancies with c-kit mutations, most notably chronic myelogenous leukemia [108]. Recent discoveries of c-kit mutations, found in mucosal and acral melanomas, and melanomas arising from chronically sun-damaged skin, have led to studies of imatinib and nilotinib in melanoma therapy, although these remain in clinical trials at the present [109–111]. An overexpression of vascular endothelial growth factor (VEGF) has been found in some melanomas, and humanized monoclonal immunoglobulin bevacizumab, which targets VEGF-ligand, is also in clinical trials in patients with advanced melanoma [112, 113].

Immunological Therapies

Overview

Immunotherapeutic approaches to melanoma can be classified as those designed as adjuvant therapy after treatment of the primary lesion to prevent subsequent metastatic disease and those designed as immunotherapy for clinically apparent metastatic tumors. Adjuvant therapy is administered to patients at high risk for the development of metastatic disease, but who have no detectable disease at the time of surgical resection of the primary melanoma or after surgical resection of limited metastatic lesions such as to regional lymph nodes. High-risk melanoma patients include those with thick primary lesions in the skin, those with ulcerated melanomas, or those in which tumor cells are detected in regional lymph nodes. Current melanoma adjuvant treatment options are limited and, for the most part, ineffective.

Adjuvant therapeutic approaches for high-risk cutaneous melanoma have included clinical trials with interferons, specific and nonspecific immunotherapy, adjuvant chemotherapy and biochemotherapy, isolated limb perfusion, adjuvant radiation therapy, adjuvant hormonal therapy, and adjuvant retinoid therapy [114–116]. The development of active specific immunotherapy has resulted in melanoma vaccines employing purified gangliosides, shed tumor antigens, specific isolated tumor peptides, mechanical or viral melanoma cell lysates, antigen-primed dendritic cells, and allogeneic or autologous whole tumor cell preparations [117, 118]. More recently, vaccines are being made that target tumor-specific missense mutations, and these have been shown to increase anti-tumor immunity on a personalized level, bringing about the possibility for individualized melanoma immunotherapy that targets private tumor mutations [119].

Research into immune-based management of melanoma has focused not only on adjuvant therapy, but also in the treatment of advanced metastatic melanoma [80, 120]. These patients are a significant therapeutic challenge from an immunologic standpoint, because they are often immunosuppressed and debilitated. Nevertheless, a number of clinical immunotherapeutic trials for metastatic melanoma are currently in progress for patients with Stage IV disease, with some reaching FDA approval. The role of various cytokines as immunotherapy for melanoma treatment remains an active area of investigation [121], as well as the use of tumor vaccines and techniques such as adoptive immunotherapy [49, 118]. Antibodies that inhibit T-lymphocyte surface receptors, which when activated have a downregulatory effect, have also shown promise in melanoma therapy [122]. Whereas prior immunotherapies have shown little survival advantages over surgical therapy alone, novel new immunotherapy agents have shown great promise in demonstrating a survival benefit with an acceptable tolerability profile.

Immunotherapeutic Agents

Cytokines

The role of cytokines in immunotherapeutic approaches to cancer treatment remains an active area of investigation. Most of the data dealing with the role of melanoma-derived cytokines in the immunology of melanoma has been obtained by transfecting immunomodulating cytokine genes into neoplastic cells and then observing the biologic response in murine model systems. This approach has been useful to evaluate the *in vivo* consequences of tumor cell cytokine production in an animal host in a number of different tumor systems [123–127]. The *in vivo* consequences of tumor cell cytokine production have been evaluated for a number of cytokines including IL-2, IL-4, IL-18, IL-12, G-CSF, GM-CSF, M-CSF, IFNγ, IL-6, and IL-10 [55, 56, 123–131]. Although IL-2 and IFN-α are the only FDA approved cytokines for the treatment of melanoma, several other molecules in this family have also entered early clinical trials. IL-12 has shown promise in early studies, although systemic administration resulted in significant toxicities, including arthralgias,

neutropenia, arrhythmias, and hypotension [132]. However, new methods of targeted delivery, including electroporation and transfection of IL-12 plasmids directly into tumor, or the use of a fusion protein of IL-12 and an antibody that recognizes tumor-specific antigens, hold promise in minimizing side effects by limiting the action of IL-12 to the area immediately surrounding the tumor [133–135]. Recombinant human IL-18 had gone through Phase I and II testing and demonstrated only limited efficacy, although there remains interest in its use as an adjuvant agent [136, 137].

Interleukin-2

Currently, one of the few FDA approved treatments for metastatic melanoma is high dose systemic IL-2. High dose systemic intravenous IL-2 has been shown to induce a clinical response in 16 % of patients with metastatic melanoma, with 10 % of patients achieving partial response (reduction of tumor) and 6 % achieving complete response (resolution of tumor) [138]. While response rates to systemic IL-2 are low, recent studies demonstrate that the treatment appears capable of inducing durable responses in a small percentage of patients [139]. Follow-up data at 5 years indicates that, of the patients with metastatic melanoma who responded to IL-2 therapy longer than 30 months, none have had disease progression [121]. In order to determine which patients might benefit most from the treatment, attempts have been made to identify clinical, genetic or immune characteristics of melanoma patients who have a vigorous response to IL-2 [140, 141]. For instance, the majority of patients with metastatic melanoma receiving standard high dose IL-2 had an increase in immunosuppressive $CD4^+CD25^+$ Tregs, but those patients who achieved an objective clinical response had a significant decrease in Tregs [20, 142, 143]. Targeting patients who would be most likely respond to IL-2 would be beneficial, as IL-2 does not have a favorable toxicity and side effect profile. Most significantly, treatment results in severe vasodilation and capillary leak, leading to a septic shock profile with hypotension in 64 % of patients. These toxicities limit both the patients who can receive the medication and the medical centers eligible to administer this therapy [139]. Of note, intralesional IL-2 injection has been used with success and with decreased side effect profiles in case series to induce regression of in-transit metastases [144]. High dose systemic IL-2 is dosed as 600,000 international units (IU)/kg, given intravenously over 15 min every 8 h for a maximum of 14 doses. This is followed by 9 days of rest, with a maximum of 14 more doses. The patient is retreated if tumor shrinkage is observed.

Interferon

The FDA approved high dose interferon α-2b as an adjuvant treatment for thick melanoma lesions or positive nodal disease in 1995. The FDA approval stemmed from a Phase III trial demonstrating an improvement in disease free survival from 1.1 to 1.7 years and overall survival from 2.8 to 3.8 years with adjuvant interferon treatment after surgical excision [145]. However, subsequent trials have not supported these results and a recent meta-analysis concluded that interferon is associated with an increase in disease free survival, but not an improvement in overall survival [146, 147]. Additionally, attempts to modify the dosing of interferon in order to decrease toxicity and improve efficacy have not been successful. Trials with both intermediate and low dose levels of interferon-α have failed to show an improvement in survival [148–150]. In addition, side effects of interferon-α, including fever, chills, myelosuppression, neurologic deficit, and hepatotoxicity, are poorly tolerated, and affect a significant percentage of patients, with less than 40 % of patients able to complete at least 80 % of a full course of therapy [145]. As a result, the role of interferon-α as an adjuvant treatment in melanoma remains limited and controversial. Interferon-β had been shown to have inhibitory effect on melanoma cells in the Japanese population. However, genetic therapy with interferon-β has not shown significant efficacy in the treatment of metastatic melanoma in the United States [151, 152]. Today, efforts on combining interferon therapy with other immune-based therapies, as will be described later on, are underway [153]. The current standard dosing for interferon-α is an induction phase of 20 million IU/m^2 body surface area, through IV infusion for 5 consecutive days per week for 4 weeks, followed by a maintenance phase of 10 million IU/m^2 body surface area, through subcutaneous injection 3 times per week for 48 weeks.

GM-CSF

Granulocyte-macrophage colony-stimulating factor (GM-CSF) is a growth factor that functions as a potent inhibitor of the growth and progression of melanoma [55, 56]. This effect is mediated by the host immunological system and appears to involve activation of dendritic cells [154]. The anti-melanoma effects of GM-CSF have been evaluated in patients with high-risk Stage III and Stage IV disease, demonstrating an increase in disease-free and overall survival in a Phase II study of 48 patients [155]. Other studies have looked at GM-CSF as an adjuvant immunotherapy [156] and in perilesional injection of melanoma sites [157, 158]. Most current work focuses on the use of GM-CSF as an adjuvant therapy to increase immune response in vaccine trials [159].

Imiquimod

Imiquimod is an imidazoquinoline that is prepared in a topical formulation. Imiquimod binds to toll-like receptor 7 (TLR-7) on the surfaces of antigen presenting cells, inducing a signaling cascade that activates nuclear factor-kB (NF-kB). This activation leads to an upregulation of Th1 response cytokines, including TNF-α, IFN-α, IL-12, and IL-18, which

can then activate CD8 cells to become cytotoxic T-lymphocytes [160]. Imiquimod is FDA approved for use in the treatment of actinic keratosis, genital warts, and superficial basal cell carcinoma. Experimentally, imiquimod was found to be capable of inducing apoptosis in melanoma in initial *in vitro* and *in vivo* studies [161]. Subsequently, the off-label use of topical imiquimod for the treatment of melanoma, primarily the lentigo maligna variant of melanoma in situ, has been pursued. To date, the data on imiquimod's success has remained largely anecdotal case series, and studies have been hindered by insufficient patient follow-up time [162–165]. To date, no randomized controlled trials exist that compares imiquimod use versus surgical intervention, traditionally considered the gold standard for treatment of melanoma in situ [166]. Nevertheless, imiquimod remains an off-label option in patients with lentigo maligna who are not candidates for surgical therapy. Though case reports exist on the use of imiquimod for the treatment of metastatic melanoma, imiquimod is not recommended as therapy for invasive primary melanoma or metastatic melanoma [161, 166–169].

Biochemotherapy

Researchers have combined immunotherapy with other treatment modalities in an attempt to increase response rates. Several groups have administered IL-2 and IFN with traditional chemotherapy (i.e. dacarbazine or tamoxifen) for 'biochemotherapy.' Although some initial results were promising, larger trials have failed to show that the combinations selected result in longer survival times [170–173]. Pooled trial data has indicated increased response rates with biochemotherapy, but this comes at the cost of decreased quality of life and increased treatment related toxicity for patients [173].

Cytotoxic T-Lymphocyte Antigen 4 Blockade

Cytotoxic T-lymphocyte antigen 4 (CTLA-4) is a surface glycoprotein that functions as an inhibitor to T-lymphocyte activation, working in opposition to CD28 [174]. Specifically, T-lymphocyte activation requires a costimulatory signal of the CD28 molecules on their surfaces binding to B7/CD80 on APCs. However, in locations such as the microenvironment surrounding melanoma, T-lymphocytes can express CTLA-4 that binds B7/CD80 instead, inducing T-lymphocyte anergy by preventing the CD28-B7 costimulatory signal. This T-lymphocyte anergy then allows melanoma cells to evade the immune system [21, 175].

Initial studies in murine models demonstrated that antibody inhibition of CTLA-4 could enhance the destruction of certain tumors, particularly those that were more immunogenic [176]. *In vitro* studies in humans also evaluated if inhibition of CTLA-4 could enhance the immune cell response against 'self' antigens, such as gp100 and Mart-1, which are expressed by melanoma cells [177–179]. Overall response rates, defined as tumor shrinkage of at least 30 %, in early trials were found to be around 15 % after treatment with an antibody to CTLA-4 administered alone or with other agents, such as vaccines against tumor antigens, and, as expected, response rates appear to correlate with the development of auto-immunity [180, 181]. In human trials, ipilimumab, a recombinant human monoclonal antibody against CTLA-4, demonstrated a median overall survival benefit of 4 months by itself or in combination with gp100 peptide vaccine, compared to the active control arm that used gp100 peptide vaccine alone [179, 182, 183]. Compared to dacarbazine monotherapy, ipilimumab with dacarbazine increased overall survival [184]. These promising data led to FDA approval of the medication in 2011 for metastatic melanoma treatment. Long-term studies of ipilimumab have also demonstrated a surprisingly durable response with this treatment, with a 3-year survival of 22 % in a multi-study pooled analysis, and a 5-year survival of 18 % in a smaller single trial analysis. Of note, the survival analyses was done irrespective of tumor shrinkage [185, 186]. However, the autoimmune side effects induced by CTLA-4 blockade can be severe, ranging from uveitis, gastroenteritis, colitis, dermatitis, and hypophysitis. Over half of patients treated with ipilimumab developed autoimmune side effects, with 20 % discontinuing treatment due to drug-related adverse events, bringing into question the tolerability of CTLA-4 blockade for a significant number of melanoma patients [182, 187]. Furthermore, ipilimumab may have a very slow onset of action. *Prieto et al*. demonstrated that in clinical trials of ipilimumab, patients who achieved clinical remission did so on average 30 months after the start of their therapy [188, 189]. Ipilimumab is given as an intravenous injection at 3 mg/kg every 3 weeks for a total of 4 doses. In a recent Phase III trial evaluating the use of adjuvant ipilimumab following resection of Stage III melanoma, a dose of 10 mg/kg was used, and while recurrence-free survival was improved, 52 % of patients had to discontinue treatment due to drug-related adverse events and 5 of 475 patients in the treatment arm died from therapy related adverse events [190].

Tremelimumab was another anti-CTLA-4 antibody evaluated as possible immune modifying therapy for melanoma. In clinical trials, while the treatment was tolerable to patients and the durability of treatment response was longer than traditional chemotherapy (i.e. DTIC), tremelimumab offered no survival advantage over DTIC [191, 192].

Programmed Cell Death Receptor (PD) 1 and PD-Ligand (PD-L) 1 Blockade

The PD-1 receptor is a T-lymphocyte surface receptor that binds two ligands, PD-L1 and PD-L2, that are found on the surfaces of tumor cells, including melanoma, renal cell carcinoma, colorectal cancer, and non-small cell lung cancer

[193, 194]. PD-1 and PD-L1 binding in the tumor microenvironment leads to T-lymphocyte exhaustion and inhibition, allowing for tumor evasion of the immune system [195–197]. Nivolumab, a humanized monoclonal antibody targeting the PD-1 receptor to prevent PD-L1 binding, was developed to prevent T-lymphocyte inhibition, thus allowing for continued immune response to tumor. In the initial Phase I trial of nivolumab, 28 % of patients with advanced melanoma enrolled in the study attained tumor regression, with the majority having a durable response to therapy of more than 1 year [198]. In a follow-up study of advanced melanoma patients treated with nivolumab, median overall survival was noted to be 16.8 months, with 1 year and 2 year survival rates of 62 % and 43 %, respectively, in all patients enrolled [198, 199]. Maintenance of response off-therapy was found to be at least 16 weeks in patients who had discontinued treatment [200]. Impressively, nivolumab was noted to be efficacious in patients who had previously failed ipilimumab and vemurafenib [199, 201–203]. Adverse events associated with nivolumab therapy in melanoma patients include fatigue, rash, and diarrhea, and rarely thrombocytopenia [200]. Of all patients treated with nivolumab, 1 % died of drug-induced pneumonitis, although none were patients with melanoma [200]. Nonetheless, nivolumab appears extremely well tolerated in patients with melanoma, with only 7 % of patients requiring discontinuation of treatment due to treatment associated side effects, a significant improvement compared to other melanoma therapies such as dacarbazine or ipilimumab [199, 202, 203]. Recently, a Phase III trial of nivolumab confirmed its high response rate, durable and rapid response, and improved safety profile, leading to FDA approval in December 2014 for melanoma refractory to ipilimumab, vemurafenib, and other available melanoma treatments [202, 204–206]. Dosing of nivolumab is 3 mg/kg intravenously every 2 weeks, until disease progression or side effects become unacceptable.

Pembrolizumb, formerly known as lambrolizumab, is another anti-PD-1 humanized monoclonal antibody. In a Phase I trial, pembrolizumab was shown to have an overall response rate of 38 %, with the response rates reaching 52 % in the study cohort that received the highest dose treatment [205]. This trial did not exclude patients who had previously been exposed to ipilimumab and demonstrated that ipilimumab exposure did not affect response rate to pembrolizumab. In Phase II trials, pembrolizumab increased progression free survival was comparable to traditional chemotherapy in patients with metastatic melanoma who had previously failed ipilimumab and/or BRAF inhibition [207]. Through the FDA Fast Track Program, pembrolizumab was approved in September 2014 [208]. Phase III trials for pembrolizumab are also underway. Pembrolizumab is given to the patient as a 2 mg/kg intravenous infusion every 3 weeks until disease progression or when side effects become unacceptable.

Other attempts to target this pathway include the development of antibodies to PD-L1. A Phase I trial of BMS-936559, a fully humanized monoclonal antibody against PD-L1, demonstrated efficacy in patients with metastatic melanoma, with an average response rate of 17 % in all treated patients with various dosing regimens, and a maximum of 29 % response rate for patients treated at a dose of 3 mg/kg, with more than half of responders having a durable response for more than 1 year [209]. Adverse reactions attributed to treatment included fatigue, infusion reaction, rash, and potential immune mediated reactions such as hypothyroidism, hepatitis, myasthenia gravis, sarcoidosis, endophthalmitis, and diabetes mellitus. 61 % of patients had adverse reactions, although most reactions were low grade, and only 11 % of patients required discontinuation of therapy due to side effects [209].

Combination Therapy

Significant interest exists in combining CTLA-4 blockade with BRAF inhibition in the treatment of BRAF V600E harboring melanoma because of the differences in their mechanisms of action. In addition, pre-clinical studies have shown that BRAF inhibition enhances T-lymphocyte recognition of melanoma, suggesting the combination of the two treatments may be synergistic [210–212]. A Phase I study in the United States of this concurrent therapy was unfortunately terminated due to hepatotoxicity [212]. However, an Italian study has shown that sequential treatment with vemurafenib followed by ipilimumab, or ipilimumab followed by vemurafenib, appears to be more tolerable while retaining improved efficacy over single agent therapies [213]. *Hodi et al*. also demonstrated benefits with combining ipilimumab and GM-CSF. In the study arm with ipilimumab plus GM-CSF, overall survival at 1 year was 68 %, versus 51 % in the study arm with ipilimumab alone. There was no significant difference in adverse events between the different treatment arms in this trial [214].

Combination blockade of both CTLA-4 and PD-1 has been studied in a recent Phase I trial of nivolumab and ipilimumab. *Wolchock et al*. reported that, at maximum acceptable doses of nivolumab and ipilimumab, 53 % patients with metastatic melanoma had an objective responses, all with tumor reduction of greater than 80 % [215].

Similarly, there are significant interests in combining CTLA-4 blockade with PD-1 inhibitors, taking advantage of a complementary blockade of different T-cell checkpoint pathways to enhance antitumor immunity [216]. In a large multicenter, randomized controlled Phase III study of 945 patients with unresectable stage III or IV melanoma, combination nivolumab and ipilimumab therapy led to a median progression-free survival of 11.5 months, compared to 2.9 months with ipilimumab alone, and 6.9 months with ipilimumab [217]. In a subgroup analyses of patients with tumors positive for PD-L1, combination of nivolumab and

ipilimumab therapy led to a progress-free survival of 14.0 months [217]. This combination of therapy, however, was noted to have increased risks of treatment-related adverse events, most commonly diarrhea, fatigue, pruritus, and rash, and these adverse events led to discontinuation of therapy for 36 % of patients, compared to 8 % for nivolumab therapy alone, and 15 % for ipilimumab therapy alone [217].

Adoptive Immunotherapy

Adoptive cell therapy (ACT) against melanoma antigens is achieved by the isolation of immunocompetent T-lymphocytes from patients, *in vitro* expansion of specific subsets of these cells, and then re-infusion of these T-lymphocytes back into patients. The source of infused lymphocytes can be derived from the tumor itself, which yields tumor infiltrating lymphocytes (TILs), from lymph nodes draining the site of the primary lesion, or from the peripheral blood. Several clinical trials have investigated various types of adoptive immunotherapy as treatment for metastatic melanoma, as well as a possible adjuvant therapy for less advanced disease [218–221]. Early studies demonstrated that tumor specific cytotoxic T-cells harvested from lymph nodes draining areas of melanoma showed little or no tumor specific cytotoxic activity, but that culture of these cells with irradiated autologous tumor cells in the presence of IL-2 rendered them cytotoxic to autologous tumor [222]. Treatment regimens for melanoma have included intravenous infusion of tumor infiltrating lymphocytes with IL-2 and intralesional injection of IL-2-cultured lymphoid cells. These methods have shown promise in small clinical trials [223–226]. IFN-α has also been tested in Phase I/II clinical trials as a suitable replacement for IL-2, with a far less toxic side effect profile [227]. More recently, in a pooled analysis, response rates to ACT for metastatic melanoma have been reported to be 50 %, with complete response in 20 % of patients. For complete responders, 95 % remain disease free at 5 year follow-up [228, 229].

One primary limitation of ACT has been the inability to generate a sustained level of tumor infiltrating lymphocytes in patients undergoing therapy. This is a significant setback, as the persistence of tumor infiltrating lymphocytes has been correlated with clinical response for *in vitro* trials [230]. Circulating myeloid cells in the peripheral blood, as well as Treg cells, suppress CD8+ T-lymphocyte function and proliferation, decreasing the clinical response to ACT [231, 232]. As a result, myeloablation and lymphodepletion prior to T-lymphocyte transfer have been shown to improve success with ACT [233, 234].

Chimeric antigen receptors (CARs) are constructed of antibody single-chain variable fragment combined with T-cell receptor (TCR) and T-lymphocyte costimulatory domains. The variable fragment of the antibody single chain can be engineered to target a tumor surface antigen, allowing T-lymphocytes to recognize tumor cells and proliferate independent of MHC function and without the need for additional costimulatory signals [235]. This approach has been successful in hematologic malignancies and studies are ongoing to investigate the coupling of ACT with CAR in metastatic melanoma [228, 235, 236].

Specific Immunotherapy

Specific immunotherapy agents stimulate the host immune system to recognize and destroy neoplastic cells bearing tumor-associated antigens. Also referred to as active specific immunotherapy, this approach often involves vaccination with modified melanoma cells or melanoma-derived antigens. Melanoma vaccines are currently under investigation for the treatment of advanced metastatic melanoma (Stage IV) and as an adjuvant treatment of patients at high risk for metastatic disease after surgical treatment (Stage II and III). Multiple trials with melanoma vaccines have been completed in the past decade, although there has been minimal overall success in Phase III clinical trials.

Autologous Vaccines

One approach to generate a specific host immune response is to vaccinate patients with their own tumor cells or cellular lysates made from their own tumor cells, known as autologous vaccination. For this procedure, melanoma tumor cells are harvested from the patient, processed *in vitro* (often in combination with an immunostimulatory agent), and injected subcutaneously back into the patient as an autologous vaccine. The theoretical advantage of this technique is that it targets the specific antigens found on the patient's tumor cells. Some of the major limitations to this approach are the number of tumor cells required for vaccine preparation and the labor-intensive and technically challenging nature of culturing and expanding the patient's melanoma cells.

Early randomized trials with autologous whole tumor cells plus BCG (Bacille Calmette-Guérin) failed to demonstrate improvement in overall outcomes [237–239]. Modulating a patient's tumor cells to increase the immune response has been attempted by haptenation of tumor cells with dinitroflourobenzene (DNFB). Administering these modified tumor cells, after sensitizing the patient to DNFB, appears to increase immune response and potentially survival in patients who develop cell-mediated immunity to tumor antigens [240, 241]. Additional work has focused on extraction of a patient's heat shock proteins from melanoma cells to create an autologous vaccine [242]. The vaccine, known as OncophageTM, consists of autologous tumor-derived heat shock protein gp96. In clinical trials, HLA restricted T-cells against the vaccine were induced in 50 % of patients, but the tumor response was modest at best [243, 244]. Taking advantage of the anti-tumor properties of GM-CSF by transfecting autologous melanoma cells with the gene for this molecule has also been explored [245, 246].

Using retrovirus mediated gene transfer for transfection, investigators have been able to create an autologous vaccine that increases tumor necrosis and invasion by immune cells in early studies [245, 246].

Allogeneic Vaccines

An alternative approach to autologous melanoma vaccines is the use of tumor vaccines derived from allogeneic melanoma cells. The goal of this approach is to stimulate the host immune system with a variety of common melanoma antigens. In addition to making a vaccine that would be widely available to many patients, the foreign MHC expression on the surface of these tumor cells further augments the patient's antitumor immune response. Multiple investigators have initiated clinical trials utilizing allogeneic vaccines as monotherapy for metastatic disease, as well as adjuvant therapy after surgical excision of the tumor. Improvement in time to disease progression was shown in a double-blind, placebo controlled trial of a polyvalent shed antigen vaccine. This small trial of 38 patients demonstrated a 2.5 times increase in time to disease progression, from 0.6 to 1.5 years, in the vaccine group [247]. Melacine, a vaccine derived from two melanoma cell line lysates administered with a detoxified end toxin adjuvant, has been studied in Phase III clinical trials, with no improvement in outcomes in advanced disease as compared to chemotherapy [248]. In a large trial studying this vaccine as adjuvant therapy in Stage II disease, no improvement was noted in relapse free survival [249], although a statistically significant improvement was seen in patients expressing HLA A2 or HLA C3 [250]. Canavaxin, an allogeneic vaccine derived from three melanoma cells lines mixed with BCG, also failed to show success in Phase III trials [251].

Viral Oncolysates

Administration of viral oncolysates is another form of specific immunotherapy that has shown potential in stimulating a clinical anti-melanoma response when used as adjuvant therapy [252]. Viral oncolysates are produced by infecting cultured melanoma cells with a virus to generate a mixture of lysed cells plus virion that can be administered as vaccines. Vaccinia virus melanoma cell oncolysates have shown promise in Phase I/Phase II studies in patients with Stage I and Stage II melanoma, but not in a Phase III study with Stage III melanoma patients [253]. Previous studies have demonstrated that patients with Stage III metastatic melanoma with palpable lymph node disease have responded to post-surgical vaccination with Newcastle disease virus (NDV) melanoma cell oncolysate [254, 255]. This group of patients treated with allogeneic melanoma cell oncolysates produced by the 73 T NDV strain had a 55 % survival at 15 year follow-up as compared to historical controls with 6–33 % 10 year survival rates [256]. The anti-tumor mechanisms of action triggered by NDV oncolysate are unknown, although some studies indicate that it may act in part through the induction of certain cytokines with anti-tumor properties [257].

Talimogene laherparepvec (T-VEC, OncoVEX) takes a different approach to viral oncolytic vaccination. T-VEC is a bioengineered strain of herpes simplex virus type 1 (HSV-1) that expresses human GM-CSF. After injection directly into melanoma, the virus replicates and causes a direct lytic effect, while the GM-CSF produced by the virus attracts and matures APCs [258, 259]. The APCs, after phagocytosing lysed melanoma cells, prime the T-lymphocyte mediated immune response to melanoma [259]. Of note, the virus has been engineered so as not to infect host cells [260]. In Phase II clinical trials, a 26 % response rate was cited, with 1 year overall survival of 58 % and 2 year overall survival of 52 % [261]. The Oncovex Pivotal Trial in Melanoma (OPTiM) trial is an on-going randomized Phase III trial; preliminary data suggests clinical response with T-VEC is 26 %, compared to 6 % in the treatment group of treatment with GM-CSF. Fatigue, chills, and pyrexia were the most common adverse events [262].

Peptide Vaccines

The identification of genes encoding melanoma specific antigens has led to their use in specific immunotherapy. As previously discussed, these are antigens that are expressed on cells of melanocytic lineage or melanoma cells that have been shown to play a role in tumor immunology. Multiple clinical trials have studied the effect of immunization against melanoma peptides such as gp100 [263], MAGE [264], MART [265] and tyrosinase in patients with advanced melanoma [266]. Positive clinical outcomes with peptide vaccines have been few, as obstacles such as tumor escape, preexisting neutralizing antibodies and antigen loss variants hamper vaccine success [17]. A multicenter randomized controlled trial demonstrated some success with the gp100 vaccine combined with IL-2 in patients with localized advanced Stage III melanoma or Stage IV metastatic melanoma. Clinical responses were 16 % in the treatment group, compared to 6 % in the control group that received IL-2 only, with progression free survival increased from 1.6 to 2.2 months [267].

Recently, tumor specific missense mutations, translated as amino acid substitutions, are being used to stimulate host response to melanoma cells. *Carreno et al*. harvested peptides with amino acid substitution seen on individual melanoma tumors (i.e. tumor neoantigens), isolated peptides that had high HLA-A*02:01 binding, and created vaccines that targeted multiple tumor antigens [119]. The targeting of both dominant tumor specific neoantigens and subdominant neoantigens, in theory, would prevent loss of efficacy from tumor evolution. These vaccines were found to stimulate tumor-specific immunity to specific, individual melanomas,

leading to possibility of personalized immunotherapy [119]. Clinical trials are expected to be underway in the near future.

Ganglioside Vaccines

Other investigators have focused on melanoma gangliosides as vaccine targets. Although expressed in all tissues, gangliosides are often overexpressed in melanoma cells. The minor ganglioside antigen GM2 has been used as a melanoma vaccine, administered in conjunction with BCG [268] or conjugated with keyhole limpet hemocyanin [269], due to its role as the most immunogenic ganglioside [118]. The conjugated form of the vaccine has been studied in a Phase III trial against interferon for adjuvant therapy of high-risk melanomas, but results were disappointing [270]. The major ganglioside antigens GD2 and GD3 have also sparked interest as possible vaccine targets, although both molecules are less immunogenic than GM3. As a result, investigations have focused on methods to increase the antibody response to these molecules [271] or to use anti-idiotypic monoclonal antibody vaccines [272–274].

Dendritic Cell Vaccines

Dendritic cell-based melanoma vaccines are also under investigation as another type of specific immunotherapy for the treatment of advanced melanoma [275]. The rationale behind this strategy is that APCs modified to present specific melanoma antigens will more effectively stimulate naïve T cells to generate an anti-melanoma response. Numerous preclinical studies have demonstrated that various types of APCs can be loaded *ex vivo* with tumor antigens and administered to tumor-bearing hosts to elicit T cell-mediated tumor destruction [276, 277]. An initial study with advanced melanoma patients used professional APCs pulsed *ex vivo* with purified melanoma peptides or tumor lysates, which were then delivered by direct injection into the inguinal lymph nodes of patients [278]. This study paved the way for other clinical trials using APCs exposed to multiple melanoma peptides [279, 280] or autologous tumor lysates [281, 282]. Although it is difficult to compare trials given the use of different antigens and different dendritic cell lineages, it appears that dendritic cell vaccines induce tumor responses in about 9.5 % of patients [275].

Summary

Understanding the immunobiology of melanoma has resulted in meaningful progress in developing effective agents to treat this aggressive malignancy. The recent FDA approval of several novel immunotherapeutic agents for metastatic melanoma has revitalized the field of melanoma immunology. New targets, refinements of current approaches, and improved patient selection criteria are necessary to optimize and develop other clinically efficacious agents for melanoma.

Questions

(Q1) Interleukin-2 therapy is limited by what type of side effects?

(Q2) What is the mechanism of action of ipilimumab?

(Q3) What is the mechanism of action of nivolumab?

(Q4) Can combination immunotherapy be utilized in the treatment of metastatic melanoma?

(Q5) Describe how adoptive cell therapy (ACT) works in immunotherapy of melanoma?

Answers

(A1) Interleukin-2 can lead to severe vasodilation and capillary leak, leading to a septic shock profile in 64 % of patients

(A2) Ipilimumab is an antibody that inhibits cytotoxic T-lymphocyte antigen 4 (CTLA-4). CTLA-4 on T lymphocytes can bind B7 on antigen presenting cells, which leads to T-lymphocyte anergy. With CTLA-4 blocked, T-lymphocyte anergy is thereby inhibited

(A3) Nivolumab is an antibody that targets the Programmed Cell Death Receptor 1 (PD-1). With PD-1 receptor blocked, PD-1 cannot bind PD-L1, which can otherwise lead to T-lymphocyte inhibition

(A4) Yes. In a large multicenter, randomized controlled Phase III study, combination of ipilimumab with nivolumab led to a progression free survival of 11.5 months, which is significantly increased from 2.9 months with ipilimumab alone, and 6.9 months with nivolumab alone

(A5) Immunocompetent tumor infiltrating lymphocytes are isolated from melanoma patients and expanded *in vitro*, then re-infused back into the patient
