Preface

Building on Our Foundation

In 2008, we published the first edition of *Clinical and Basic Immunodermatology*. Over the past 9 years, much has changed in the basic science and clinical arenas, stimulating Steve Tyring and me to update our textbook. We have the good fortune that Dr. Daniel H. Kaplan, a highly accomplished immunodermatologist, joined our editorial team, which has augmented our knowledge in the field and expanded our network of experts to address the ever-broadening horizons of cutaneous immunology.

There continues to be a tremendous number of advances in the fields of cellular, molecular, innate, and adaptive immunity, as well as immunopharmacology, which have been translated to a better understanding and treatment of a number of dermatologic diseases. There are also a number of new therapeutic agents that are targeted therapies, or have an immune mechanism. All of these developments have occurred in the backdrop of the information age. Our goals of this textbook remain the same as with the first edition of *Clinical and Basic Immunodermatology*. We have recruited national and international experts to author chapters on their respective areas of expertise. Hence, our approach for this important endeavor is that of a multiauthored collection of chapters that would be integrated into this book. Our goal is to present the latest information related to fundamentals of the skin immune system, as well as a disease-focused textbook in the same concise, readable, and easily digested format that was initially developed by Dr. Dahl with his original *Clinical Immunology* textbook in 1981. We have recruited new experts to provide information summarized in their chapters. We have added new subject matter such as the expanded role of innate lymphocytes in the immune system and their role in dermatologic disease, a section on antimicrobial peptides, a chapter focused on auto-inflammatory diseases, as well as a chapter on the role of cell death in skin homeostasis and dermatologic diseases.

We thank the authors for their outstanding contributions. We remain grateful to Dr. Dahl for his vision and his original book, which has had profound influence on generations of dermatologists. We have strived to enhance the teaching of cutaneous immunology, particularly as related to skin disease, to the next generations of young dermatologists who will be caring for patients afflicted with immune-based skin diseases. We would be delighted if our textbook triggered the kind of interest in immunology that was stimulated in us, the editors, during our training.

Over the next few years, we look forward to watching the progress unfold in the field of immunodermatology that will lead to the third edition of our textbook *Clinical and Basic Immunodermatology*.

Innate and Adaptive Components of the Cutaneous Immune Barrier: The Central Role of Dendritic Cells

1

Georg Stingl, Marie-Charlotte Brüggen, and Mariana Vázquez-Strauss

Abstract

Immune responses initiated in the skin can be extremely powerful at both a local and systemic level. One of the milestones in elucidating the mechanisms underlying this phenomenon was the discovery of the T cell response-inducing function of Langerhans cells (LC). In the meantime, we know that the family of dendritic antigen-presenting cells in the skin is much bigger and, in addition to LC, includes dermal dendritic cells (DDC), CD141+DC, CD14+DC, inflammatory DC and plasmacytoid DC. Depending on the cellular and molecular milieu, these cells can function as either sensitizing or tolerizing elements. Signals transmitted from (innate) receptors recognizing damage- or pathogen-associated patterns are involved in directing these different functions in DC. Toll-like pathogen recognition receptors (TLR) have been particularly well investigated in this regard. The distinct distribution of TLR on LC and other DC subsets allows the immune system to elegantly orchestrate the regulatory and pro-inflammatory functions of these cells. Intriguingly, TLR signaling in DC/LC not only allows to initiate adaptive immune responses, but also directly induces innate effector functions. This is demonstrated by our findings on the mechanisms underlying basal cell carcinoma (BCC) regression upon treatment with the pharmacological TLR7 agonist imiquimod. We observed that in imiquimod-treated BCC, plasmacytoid DC directly kill tumor cells via the apoptosis-inducing molecule TRAIL. Melanoma cells can also become TRAIL-susceptible, but the magnitude of this phenomenon varies from patient to patient. Our recent findings show that TRAIL susceptibility of melanoma cell lines can be increased upon exposure to the anti-inflammatory compound diclofenac.

Taken together, we begin to understand the exact position of LC and DC in the highly complex circuits of the immune system in the skin and how these cells could be manipulated for therapeutic purposes.

Abbreviations

APC	Antigen-presenting cell
BCC	Basal cell carcinoma
CHS	Contact hypersensitivity
DC	Dendritic cell
DDC	Dermal dendritic cell
dsRNA	Double-strain RNA
LC	Langerhans cell
LPS	Lipopolysaccharides
LTA	Lipotechoic acid
MHC	Majory histocompatibility complex
PAMP	Pathogen-associated molecular pattern
pDC	Plasmacytoid dendritic cell
PRR	Pattern recognition receptor
S.	Staphylococcus
ssRNA	Single-stranded RNA
TLR	Toll-like receptor
TRAIL	Tumor necrosis factor related apoptosis inducing ligand
UV	Ultraviolet
poly I:C	Polyinosinic:polycytidylic acid

Introduction

One of the first documented examples revealing the potency of immune responses initiated in the skin is the successful smallpox vaccination by Edward Jenner [1]. In this heroic experiment performed on the son of his gardener, Jenner introduced scraping material obtained from an infectious cowpox pustule (of a dairymaid) into the skin. A few weeks later, upon re-inoculation with material from a fresh smallpox lesion, the boy was protected from the disease.

It took quite a while until it was realized that immunization via the skin can result in a stronger, longer lasting immune response than immunization via other routes. This is impressively illustrated by the induction of cancer immunity, which succeeded following the repeated intracutaneous, but not extracutaneous application of cancer (murine sarcoma) homogenates [2]. During the following decades, considerable efforts were made to unravel the mechanisms underlying this phenomenon.

The enigma seemed resolved when it was discovered that epidermal dendritic cells (namely Langerhans cells (LC)) can evoke very robust proliferative responses in naive and sensitized T cells [3, 4], which were greater in magnitude than those induced by mononuclear phagocytes (see also Chap. 9, Dendritic cells). Streilein et al. could show in a murine model of allergic contact dermatitis termed contact hypersensitivity (see Chap. 22) that the epicutaneous application of a hapten only led to sensitization when the skin of the application site contained LC but not when it was devoid of these cells [5]. Based on these findings, the idea evolved that an antigenic encounter in the skin/epidermis invariably results in LC-mediated T cell activation and thereby sensitization. Were this concept true, one would expect an army of hetero- or even autoreactive T cells to constantly populate, attack and injure the skin. Luckily, this is not the case. The possibility that the mere presence of LC is not necessarily predictive of the occurrence of productive T cell responses came from the observation that LC evoked robust T cell stimulation only upon receipt of activating stimuli [6]. These stimuli include the disruption of skin homeostasis and the exposure to danger signals (e.g. immunogenic haptens, microorganisms) that results in the release of proinflammatory cytokines and other mediators. By contrast, resting LC [7], LC from corticosteroid-treated patients [8] or LC from ultraviolet (UV) irradiated skin (via keratinocytic RANKL expression, [9]) lead to an expansion of CD4+/CD25+/GITR+/FoxP3+ regulatory T cells (Treg) capable of down-modulating proliferative and cytotoxic T cell responses. The exclusive role of LC in the initiation of T cell responses via the skin was further questioned by the discovery of a second DC population in normal human skin, namely CD1+ dermal dendritic cells (DDC). DDC are equally potent as LC with regard to their immunostimulatory capacity *in vitro* but exhibit certain phenotypic features that allow distinguishing them from LC (cf. Fig. 1.1a). The relative contribution of LC and DDC in the elicitation of sensitizing and tolerizing skin-derived immune responses is a matter of conjecture and heavy debate. On the one hand, the positive correlation between epidermal LC density and the success rate of epicutaneous sensitization (e.g., contact hypersensitivity (CHS), epicutaneous vaccination) clearly argue in favor of an important role of LC in this process. On the other hand, elimination of epidermal LC in mice by genetic manipulation results in an enhanced CHS response as compared to wild-type mice [10].

From a conceptual viewpoint, it makes perfect sense to assume that danger signals not reaching beyond the epidermis, i.e. the site of LC, will not mobilize all the armed forces the immune system is capable of activating. On the other hand, virulent microorganisms that breach the dermo-epidermal junction and thereby can reach DDC should trigger a massive host defense response that can successfully eliminate the pathogen. From this perspective, one would expect that LC mainly act as regulatory antigen-presenting cells (APC) inducing a state of antigen-specific non-responsiveness. Following this reasoning, DDC should remain inert under homoeostatic conditions and mature into potent sensitizing DC upon receiving appropriate activation signals. The “black and white” picture of the roles of LC vs. DC is probably not tenable under all circumstances. As an example, in response to an overwhelming microbial insult, LC can engage themselves

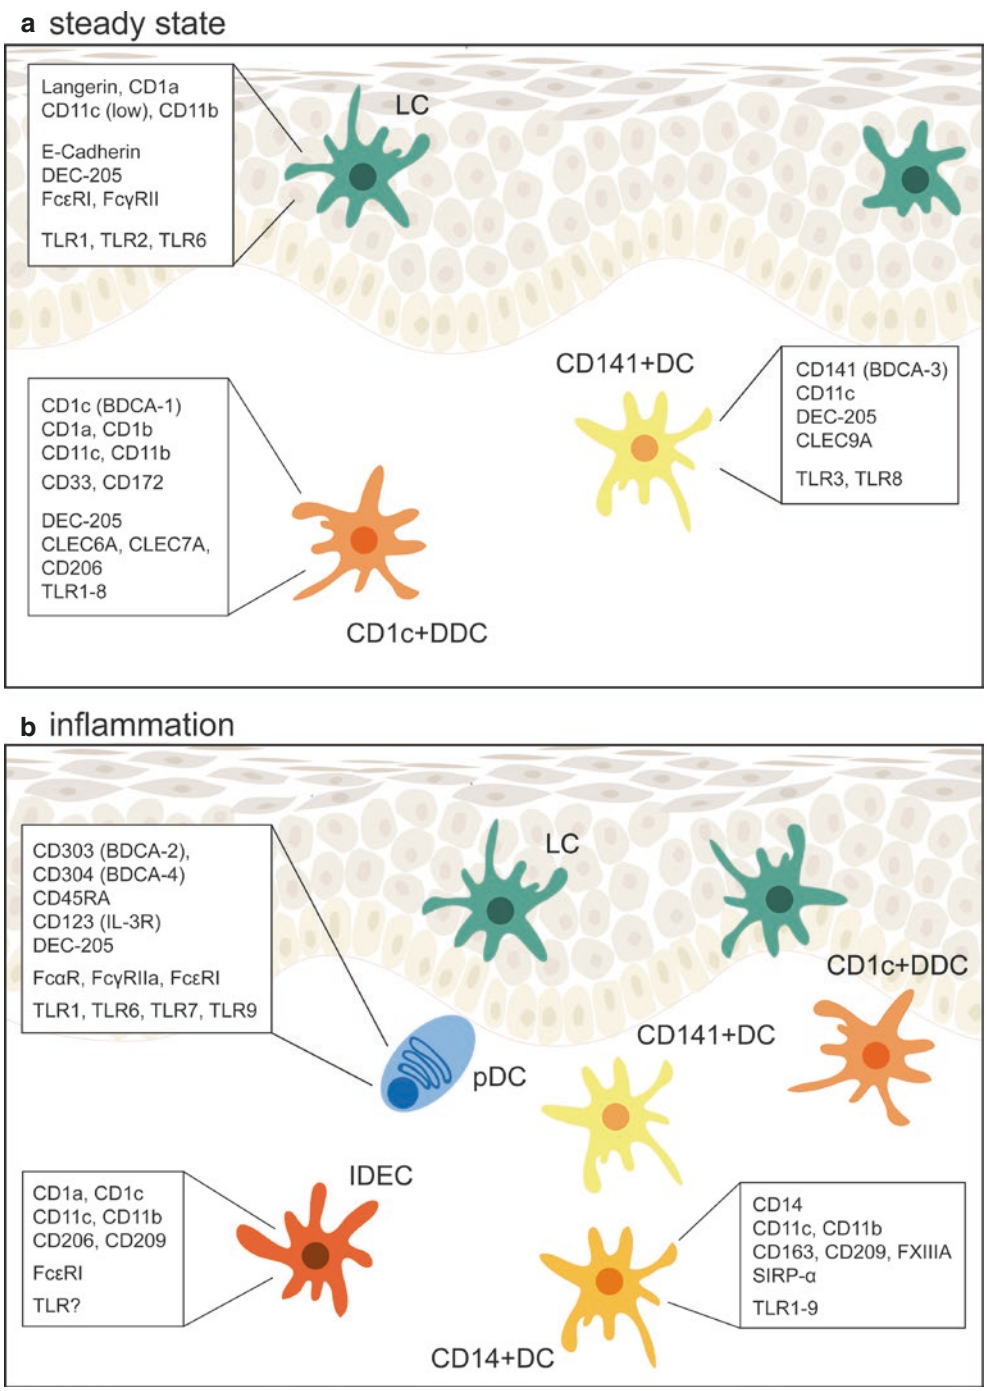

Fig. 1.1 LC and DC populations in human skin. (**a**) LC and DC residing in human skin in the steady state and (**b**) infiltrating the skin during inflammation. The main suface markers and pattern recognition receptors of the respective subpopulations are depicted

in the promotion of a T effector cell response [7]. Although we have gained more insight into the LC and DC network in the skin, we are still far from understanding it in all its complexity. This is illustrated by the recent finding of another (although quantitatively minor) DC subset residing in steady-state skin, i.e. CD141+ DC (Fig. 1.1a) [11]. These DC seem to be mainly engaged in antigen cross-presentation [12].

In an inflammatory setting, skin-resident LC, DDC and CD141+ DC undergo phenotypic and functional changes. In addition, various other types of DC are entering the stage (cf. Fig. 1.1b). These blood-derived DC include the so-called plasmacytoid DC (pDC), various DC with an inflammatory phenotype (inflammatory DC, IDEC) and CD14+ (monocyte-derived) DC. All of them exhibit distinct features with regard to their antigen presentation properties and interaction with other immune cells (for review, cf. [13, 14]). They play major roles in the pathogenesis of various skin conditions such as atopic dermatitis (Chap. 22) and psoriasis (Chap. 21). Their involvement

in these diseases will be discussed in the respective chapters of this book.

Toll-Like Receptors: Bridging Innate and Adaptive Immunity

Pattern Recognition Receptors: Sensing the Danger

Until quite recently, it was essentially unknown by which mechanisms danger signals (such as immunogenic haptens and microorganisms) trigger the activation and maturation of LC and other DC in the skin and ultimately initiate an adaptive immune response. A series of discoveries (for review, cf. [15, 16]) has shed new light on this issue by revealing that DC function and development are essentially modulated by innate immune receptors recognizing damage- or pathogen-associated molecular patterns (DAMP and PAMP; listed in Table 1.1) (see Chap. 2). Among this growing family of pattern recognition receptors (PRR), the so-called toll-like pathogen recognition receptors (TLR) have been particularly well investigated. Ten TLR have been described in humans so far (listed in Table 1.2). TLR can be broadly divided into two groups (extra- vs. intracellular). Extracellular TLR (TLR1, 2, 4, 5, 6) essentially recognize bacterial and fungal products. Briefly, TLR2 combined with TLR1 or TLR6 mostly recognizes motifs of gram-positive bacteria (e.g. lipoproteins, lipotechoic acid (LTA)), while TLR4 senses gram-negative bacteria-associated lipopolysaccharides (LPS). Bacterial flagellin is recognized by TLR5. The intracellular receptors TLR3 and TLR7-9 recognize mostly virus-derived nucleic acids, i.e. double-stranded RNA (dsRNA; TLR3), single-stranded RNA (ssRNA) (TLR7-8) and CpG oligodeoxynucleotides (TLR9).

The potency of TLR-mediated danger signals in triggering immune responses cannot be reduced to their impact on DC and other cells of hematopoietic origin. In fact, keratinocytes [17] express a series of TLR (at the mRNA level: TLR1-6 and 9-10; functionally: TLR3, 4, 5 and 9, [17, 18]). Engagement of their respective ligands can trigger (as illustrated in the following paragraphs) both innate and adaptive responses.

As far as LC and DC are concerned, studies investigating their TLR expression have yielded partially divergent results [18–21], probably due to differences in the experimental setting, e.g. culture conditions. It seems clear that LC and the various DC subsets do not share the same TLR expression patterns (cf. Fig. 1.1a, b) and, in consequence, exhibit differ-

Table 1.1 Pattern recognition receptors (PRR) and their principal ligands

A) Principal PRR families

Group of PRR	Examples of PRR	Principal PAMP/DAMP(s)
Nucleotide-binding oligomerization domain (NOD)-like receptors (NLR)[a]	NOD1 (CARD4) NLRP1B (NALP1) NLRP3 (NALP3)	iE-DAP, GM-tripeptide Anthrax letal toxin MDP, DNA, RNA, toxins
Retinoic acid inducible gene I (Rig1)-like receptors (RLR)	DDX58 (RIG-1) DHX9, DHX36	Short ds-RNA, ss-RNA DNA
C-type lectin receptors (CLR)	CD207 (langerin), CD209 (DC-SIGN), CLEC6A	Fucose, mannose High mannose High mannose
Toll-like receptors (TLR)	(cf. below)	

[a]For details, cf. [16, 55]

B) TLR

Localization	TLR subtype	Principal PAMP(s)	Mostly expressed on
Extracellular	TLR1/TLR2[a]	Lipoproteins	Gram-positive bacteria, mycobacteria
	TLR2	Lipoproteins, peptidoglycan (PGN)	Gram-positive bacteria
	TLR4	Lipoproteins, lipopolysaccharides (LPS)	Gram-negative bacteria
	TLR6/TLR2[a]	e.g. lipoteichoic acid (LTA)	Gram-positive bacteria, mycoplasma
	TLR10	Not known	
	TLR5	Flagellin	Flagellated bacteria
Intracellular	TLR7	Single-stranded RNA (ssRNA)	Viruses
	TLR8	ssRNA	Viruses
	TLR9	CpG oligodeoxynucleotide	Bacteria; DNA viruses
	TLR3	Double-strain RNA (dsRNA)	Viruses

[a]Heterodimerized; for review, cf. [15]

ent reactions to microbial or other immunogenic stimuli. This distinct distribution of TLR on DC allows the immune system to elegantly orchestrate innate and adaptive responses, which is why growing efforts have been put into the development of vaccine formulations making use of these mechanisms.

TLR as Gatekeepers of Tolerance Towards Bacteria?

According to the idea that LC are responsible for maintaining tolerance and DDC for initiating immune reactions, one would expect that LC do not react to the epidermal invasion of harmless, gram-positive bacteria belonging to the commensal skin flora. This theory seems to be supported by the finding that DDC abundantly secrete IL-6 and TNF-α when exposed to bacterial components (such as Pam3CSK, a synthetic TLR1/2 ligand, LPS and PGN [21]), while LC secrete IL-6, -8 and -10 only upon exposure to PGN [18, 21]. PGN-induced IL-10 could, via its inhibitory effect on the antigen presentation function of LC [22], contribute to LC-modulated tolerance towards commensal bacteria. The concept that TLR-mediated signals can contribute to maintaining tolerance is further strengthened by evidence from keratinocyte studies. The latter have shown that in keratinocytes engagement of LTA belonging to the commensal bacterium *Staphylococcus (S.) epidermidis*, but not to *S. aureus* induces an inhibitory effect on TLR3-triggered IL-6 and TNF-α expression [23] and even promotes the expression of antimicrobial peptides [24].

Orchestration of TLR-Transmitted Signals in Viral Infections

As far as viral infections are concerned, it was even before the discovery of TLR that the so-called pDC were identified as a rich source of the type I interferon IFN-alpha (IFN-α) in response to viruses (review in: [25]). IFN-α is a potent tool in the antiviral defense and acts against viruses both indirectly (by enhancing adaptive immune functions) and directly. Later, it was found that the abundant IFN-α production in pDC is triggered by signals from TLR recognizing virus components, i.e. ssRNA (TLR7) and CpG oligonucleotide (TLR9). In contrast, DDC as well as freshly isolated LC do not seem to undergo phenotypic or functional changes in response to direct exposure to these TLR ligands [18]. In the presence of CpG-stimulated keratinocytes however (which abundantly produce IL-1α, TNF-α and GM-CSF), LC up-regulate major histocompatibility complex (MHC) class II and the costimulatory molecule CD86 [26]. The complexity of TLR-transmitted "danger signals" is illustrated by the finding that dsRNA, the virus-associated ligand for TLR3, does not elicit any response in pDC (for review, cf. [25]) but instead enhances different functions in LC and DDC. In LC, the synthetic TLR3 ligand polyinosinic:polycytidylic acid (poly I:C) induces changes that promote an adaptive antiviral response. These include maturation, IL-6 production and upregulation of CD70 (a potent promoter of $CD8^+$ T cell responses) [27]. Meanwhile, exposure of CD141+ DC to poly I:C results in IFN-γ production in CD141+ DC [11] and enhances (in a skin explant model) maturation and migration [20]. Keratinocytes respond to poly I:C by up-regulating surface molecules such as MHCII, CD40 and the Fas receptor [17] and by abundantly secreting TNF-α and IL-6 [23].

TLR-Transmitted Danger Signaling Beyond Skin Infections

A role of TLR danger signals has been demonstrated in various skin conditions beyond infections including acne vulgaris (Chap. 24), roseacea, skin cancers and psoriasis (Chap. 21) (for overview, cf. [28]). In the case of CHS, it had long been known that immunogenic haptens induce the secretion of proinflammatory cytokines in keratinocytes, LC [29] and DC and that skin inflammation is required for the development of sensitization to a hapten. The molecular events behind this remained obscure. An involvement of certain TLR in CHS was indicated by studies revealing that TLR2/TLR4 double-deficient mice are completely resistant to CHS development (see also Chap. 23). The finding that germ-free mice still develop CHS pointed towards a role of endogenous (and not necessarily microbial) ligands in eliciting inflammation during the sensitization phase. In mice, some allergens (such as 2,4,6-trinitro-1-chlorobenzene, oxazolone, and fluorescein isothiocyanate) seem to indirectly activate TLR [28]. Meanwhile, Goebeler et al. were able to demonstrate in elegant experiments that Ni^{2+} ions directly bind to the human TLR4 and, by doing so, initiate a signaling cascade resulting in the generation of proinflammatory signals [30]. The respective role of keratinocytes, LC and DC in TLR-mediated inflammation during the sensitization phase of CHS remains to be elucidated. The lack of TLR expression on LC for instance did not dampen CHS development in a mouse model [31].

In atopic dermatitis (see also Chap. 22), patients exhibit reduced expression of TLR2 on keratinocytes and monocytes/macrophages [32, 33]. TLR2 recognizes *S. aureus*-associated patterns and enhances the expression of certain tight junction molecules [34]. The deficiency of TLR2 in atopic dermatitis patients could thereby not only contribute to their susceptibility to *S. aureus* infections but also reinforce barrier dysfunction, a major feature of the disease.

TLR-Driven Innate Effector Functions of DC

Imiquimod: A Pharmaceutic TLR Ligand

In the early 1990s, it was reported that incubation of peripheral blood leukocytes with certain imidazoquinolines (e.g. imiquimod, resiquimod) results in the production of IFN-α by these cells. Soon, it became clear that imiquimod acts as an artificial ligand of TLR7 [35], single-strand sensing receptor important in triggering IFN-α in pDC [36].

Given the crucial role of IFN-α as a first line defense against viral infections, imiquimod has been developed into a topical cream compound (Aldara®) for the treatment of viral acanthomas such as genital warts [37]. In the years to come, Aldara® cream was also proven to be efficacious in superficial basal cell carcinomas (BCC), lentigo maligna and actinic keratoses (review in: [38]).

pDC as Effector Cells in Imiquimod-Induced Tumor Regression

We as well as other investigators set out to unravel the mode of action of topical imiquimod. In a first series of experiments, we observed that application of Aldara® cream to murine ear skin for only a few days causes massive infiltration of neutrophils, macrophages and, particularly noticeable, pDC. In subsequent experiments we transplanted a (murine) melanoma cell line into the skin of mice. After several weeks, melanomas had appeared and were then treated with either Aldara® cream or vehicle. Aldara® but not the vehicle regularly induced resolution of tumors not exceeding a volume of 130 mm^3. Again, pDC were conspicuously present around and within the regressing melanoma cell islands [39]. All these findings led us to hypothesize that pDC were, in one way or the other, involved in Aldara®-induced tumor regression. In a subsequent study, we treated sporadic superficial BCC from seven patients with topical imiquimod for a total of 6 weeks and examined the clinicopathologic features of the tumor during the course of therapy [40]. After 2 weeks of treatment, BCC lesions showed signs of severe inflammation that quickly resolved after termination of therapy and left behind an area of normal-appearing skin histopathologically free of cancer cell nests (Fig. 1.2a). Immunohistological analysis of lesional skin after 2 weeks of imiquimod treatment revealed changes similar to those seen in our murine model. This was evidenced by a considerable number of apoptotic cancer cells and tumor cell islands surrounded and/or infiltrated by a dense inflammatory infiltrate that contained considerable numbers of inflammatory DC of both the myeloid and the plasmacytoid type (Fig. 1.2b, c). When we evaluated by immunohistochemistry the expression of lytic molecules, we surprisingly found granzyme B and perforin mainly on myeloid DC and TRAIL (tumor necrosis factor related apoptosis inducing ligand) mainly on pDC. Strikingly, the apoptosis-inducing TRAIL-receptor 1 was expressed on BCC (Fig. 1.2c). These in vivo data received experimental support by *in vitro* studies demonstrating the capacity of imiquimod to induce TRAIL on peripheral blood pDC in a strictly IFN-α-dependent manner. TRAIL-expressing, but not unstimulated pDC were perfectly capable of lysing MHCI – bearing tumor cell targets [40, 41] implying that TRAIL-positive pDC in BCC are directly responsible for the killing of the cancer cells. The presence of the pro-apoptotic TRAIL receptor 1 on BCC cells supports this notion [40] as do studies in melanoma-bearing mice treated with imiquimod [42].

Melanoma

In the case of human melanoma, the situation is more complex. We have recently reported that pDC that had been rendered TRAIL-positive by imiquimod stimulation were capable of lysing certain melanoma cell lines, but not others [41]. Further investigations revealed that these differences in TRAIL sensitivity are due to distinct expression patterns of pro-apoptotic TRAIL receptors on different melanoma cell lines and, more importantly, of pro- and anti-apoptotic effector molecules within these cell lines (Fig. 1.3a, b) [43, 44]. When searching for ways to increase the TRAIL susceptibility of resistant cell lines, we found in accordance with previous reports [45] that the anti-inflammatory compound diclofenac was able to do so (Vazquez-Strauss et al., in preparation). In fact, diclofenac led to an enhanced expression of pro-apoptotic TRAIL receptors on melanoma cells as well as to an upregulation of pro-apoptotic and, vice versa, a downregulation of anti-apoptotic molecules within the cancer cells [46]. It will be interesting to explore whether the beneficial effect of diclofenac in the treatment of certain cancers is, at least partly, due to this phenomenon and, if so, whether ways can be found to maximize this tumoricidal effector mechanism.

Conclusions and Outlook

As a result of intensive and increasingly sophisticated research, we begin to understand the cellular and molecular pathways operative in immune responses starting and terminating in the skin. It has become apparent that a highly complex interplay between the innate and adaptive immune system is required to maintain skin homeostasis and initiate host defense. LC and other DC play a central role in this complex network due to their multifaceted roles under physiologic and pathologic conditions.

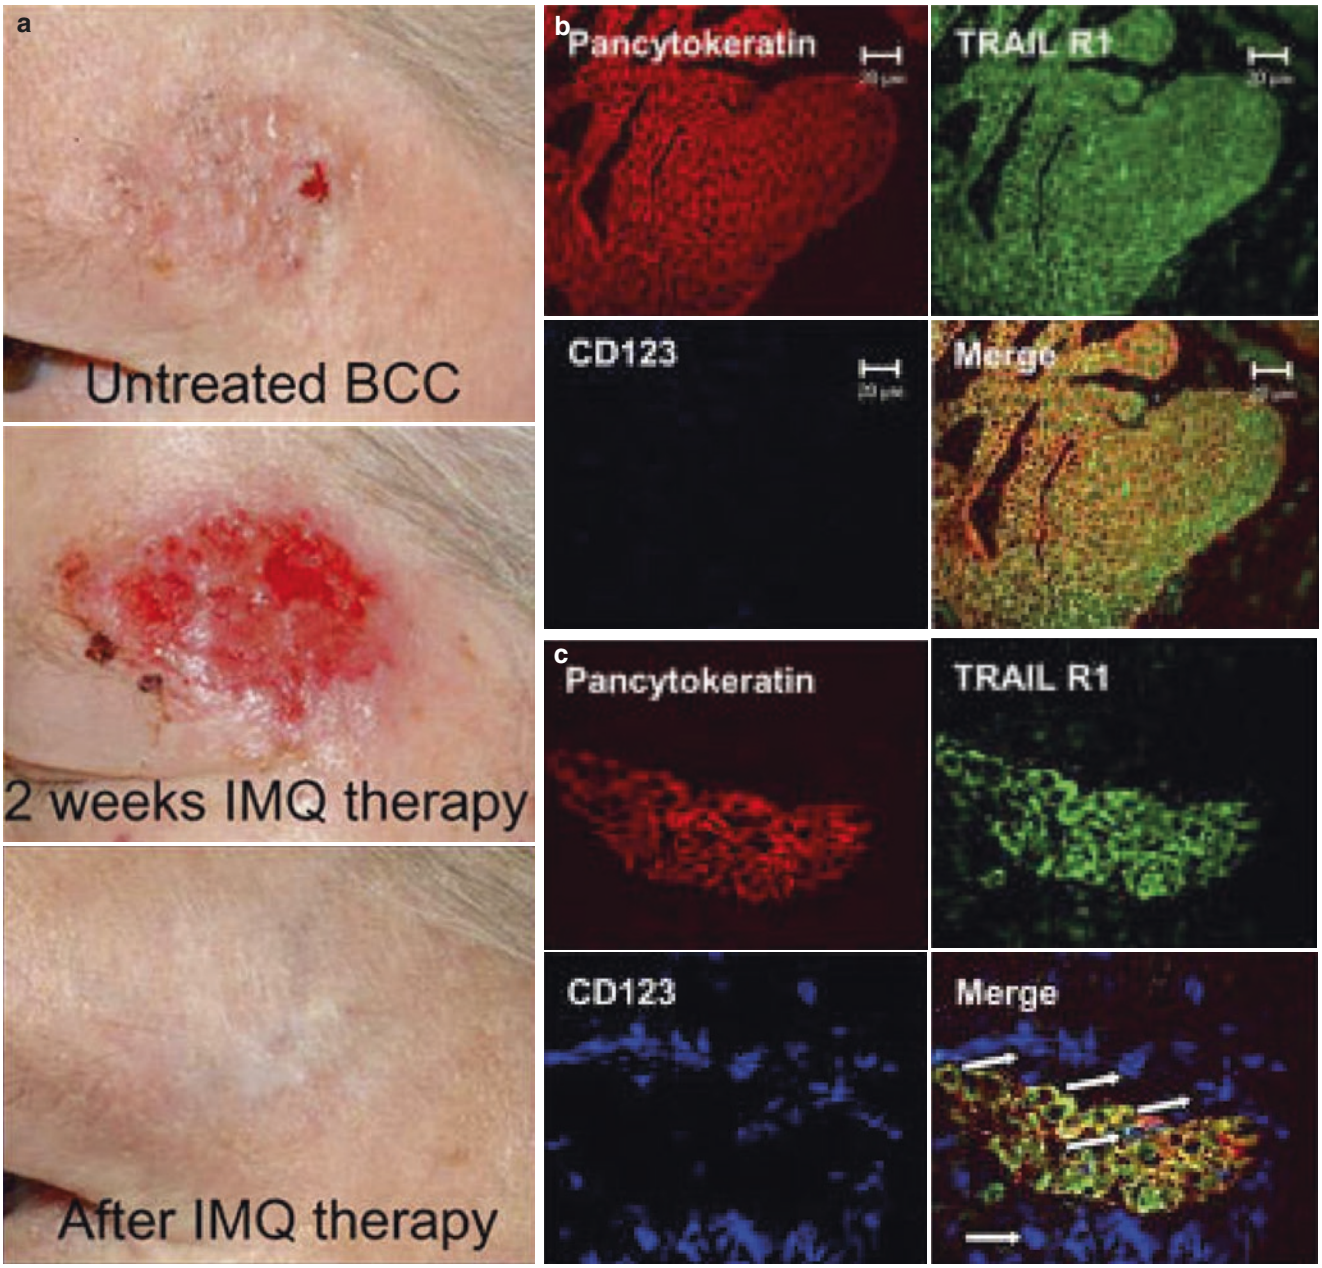

Fig. 1.2 Effects of imiquimod on BCC. (**a**) Imiquimod topically applied to superficial BCC five times a week for a period of 6 weeks led to a local inflammatory response, which resulted in a complete clinical and histopathological tumor clearance in all patients treated. The clinical pictures are representative for all patients (n = 7) treated with imiquimod. Immunofluorescence triple labeling of (**b**) untreated and (**c**) imiquimod-treated BCC with anti-pancytokeratin (TRITC), anti-TRAIL-R1 (A488) and anti-CD123 (Cy5) reveals TRAIL-R1+ BCC cells surrounded by CD123+ cells (*arrows* in **c**) (© 2007 Stary et al. [40])

In the recent past, methods have been developed to exploit the functional diversity of LC and other DC subpopulations for therapeutic purposes. This is exemplified by the development of new and better intradermally delivered vaccines (for review, [47]). In this setting, instead of simply injecting an antigen, the latter is selectively "addressed" to LC and/or certain DC subpopulations. Depending on both the type of ligand to which the antigen is coupled and the nature of the target structure, this allows to direct DC antigen-presenting function in one or the other direction. A good example is the engagement of C-type lectin receptors on DC surfaces such as DEC-205/CD205, langerin/CD207, DC-SIGN/CD209, Dectin, Clec9A, DCIR 1 and 2. These receptors facilitate antigen uptake and sometimes (e.g. TLR3 and TLR7,8 agonists, CD40) induce maturational events in these cells. Clinically, this results in robust humoral and cellular CD4+

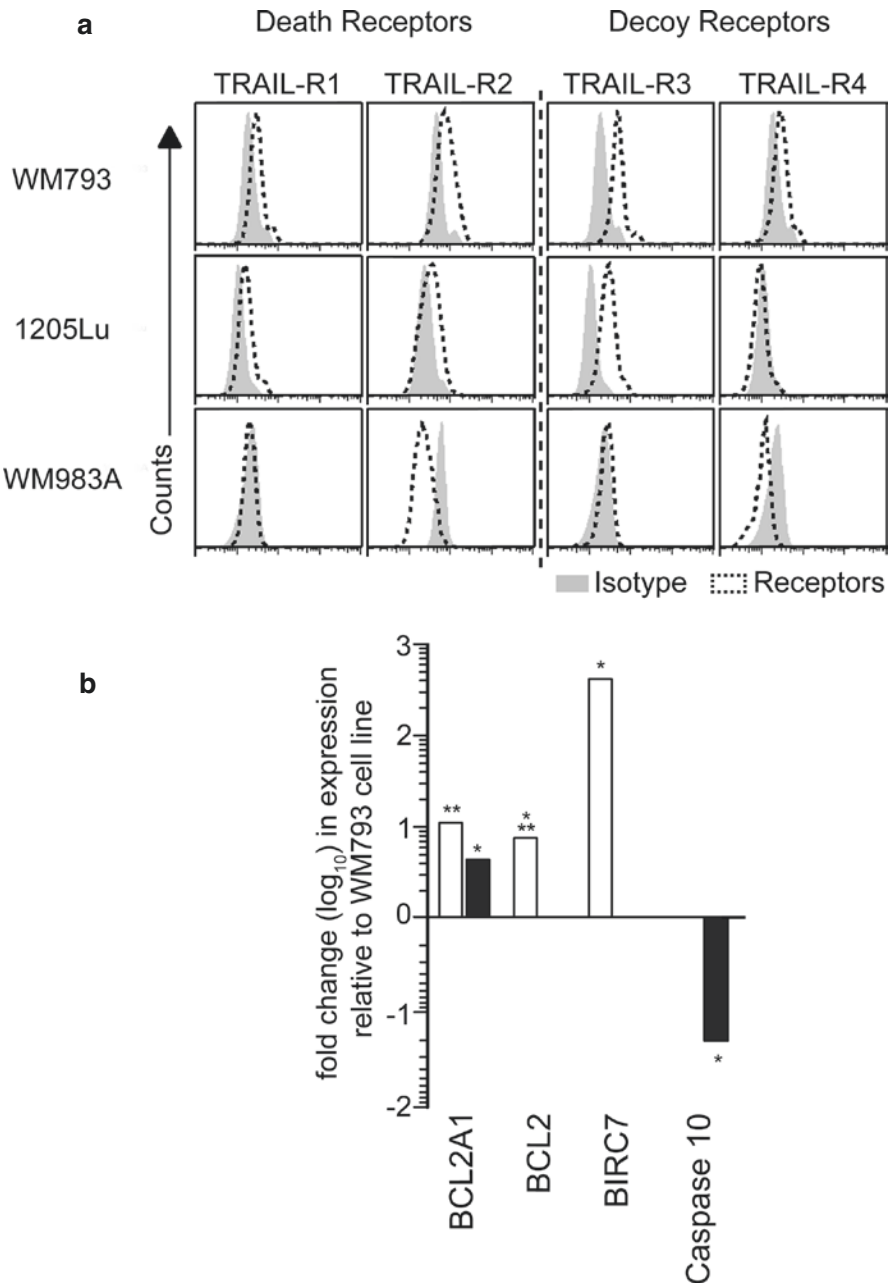

Fig. 1.3 Expression of TRAIL receptors and apoptosis-related genes in TRAIL-resistant and -susceptible melanoma cell lines. (**a**) The expression of TRAIL receptors was assesed by flow cytometry in in two resistant melanoma cell lines (WM983A and 1205Lu) and one susceptible melanoma cell line (WM793). Death receptors (TRAIL-R1, TRAIL-R2) and decoy receptors (TRAIL-R3, TRAIL-R4) for TRAIL were analyzed. Histograms representative for three experiments are shown. (**b**) Using qPCR array technology, the expression of 91 apoptosis-related genes was screened in the same three melanoma cell lines (TRAIL resistant: WM983A and 1205Lu; TRAIL-susceptible: WM793). Three biological replicates were performed. Data represent the mean fold (log_{10}) change in mRNA expression of the depicted molecules in the resistant cell lines as compared to the susceptible WM793 cell line. Some of the most significantly up- and down-regulated genes (>4-fold change in expression) are displayed. *p<0.05; **p<0.01; ***p<0.001

and CD8+ T cell responses. In the absence of adjuvants, however, targeting DEC-205+ DC *in vivo* can induce tolerance [48]. Activation of Clec9A promotes potent antibody responses and facilitates cross presentation [49]. Particularly efficient in this latter regard is the CD40 receptor, probably because of its relatively poor uptake and intraendosomal degradation [50]. By contrast, targeting the lectin-like receptor DC-asialoglycoprotein favors the generation of IL-10-producing CD4+ suppressor cells [51]. Other approaches resulting in either sensitization or tolerization include the use of nanoparticles [52, 53] as well as of cholera toxin [54]. On the other hand we could show that the use of TLR7, 8 agonists can drive innate effector functions in certain DC, i.e. their transformation into killer cells. Thus, the prospect to an efficacious DC-based immunotherapy, tailored to the needs of the individual patients, is realistic, yet challenging.

Questions

1. Which one of the following statements on LC in the skin is correct?
   A. UV-irradiation and the treatment with corticosteroids enhance the ability of LCs to induce cytotoxic T cell responses

B. LC are exclusive stimulators of Th1 cells
C. Under certain conditions, LC can induce the expansion of Tregs and down-regulate proliferative and cytotoxic T cell responses
D. In contrast to keratinocytes, LC cannot produce any inflammatory cytokines
E. LC are found in the dermis but not in the epidermis

2. Which statement regarding TLR is true?
   A. TLR are exclusively expressed on cells of hematopoietic origin
   B. While TLR signaling is a major modulator of innate immune responses, it does not have any effect on adaptive immune responses
   C. TLR recognizing lipids are located on the outer cell membrane while those recognizing proteins are found intracellularly
   D. The different DC subsets in skin express the same TLR repertoire
   E. TLR belong to the PRR family that includes receptors recognizing damage- and pathogen-associated molecular patterns

3. Which statement does not describe parts of the mechanism underlying the imiquimod-induced clinical regression of BCC?
   A. Imiquimod acts as an artificial TLR7-ligand
   B. Imiquimod induces pDC to kill BCC cells in a mostly TRAIL-mediated fashion
   C. Imiquimod induces the killer molecule TRAIL on peripheral blood pDC in an IFN-α-dependent manner
   D. Imiquimod-treated BCC become selectively infiltrated by NK cells
   E. Imiquimod application leads to the apoptosis of BCC cancer cells

Toll-Like Receptors

2

Jessica Shiu and Anthony A. Gaspari

Abstract

There are two major arms of the immune system: the innate immune response and the adaptive immune response. Innate immunity is the first line of defense against microbes and serves to limit infection within the early hours after exposure to a pathogen. It is classically associated with the recognition of pathogens by phagocytic cells via specific receptor recognition molecules or through complement fixation. Essential components of the innate immune response include neutrophils, natural killer cells, natural killer T cells, mast cells, complement, and antimicrobial peptides. Innate immune activation via pattern recognition receptors results in a specific expression of co-stimulatory molecules and cytokines. This inflammatory milieu shapes the subsequent adaptive response, which involves B cell activation and T cell-mediated recognition of foreign antigens presented on major compatibility complexes (MHC) I and II on the cell surface of antigen-presenting cells (APCs). Activated B and T lymphocytes then undergo clonal expansion to provide an antigen-specific immune response.

Dermatitis • Inflammation • Proteins • Toll • Keratinocyte

There are two major arms of the immune system: the innate immune response and the adaptive immune response. Innate immunity is the first line of defense against microbes and serves to limit infection within the early hours after exposure to a pathogen [1]. It is classically associated with the recognition of pathogens by phagocytic cells via specific receptor recognition molecules or through complement fixation [1–3]. Essential components of the innate immune response include neutrophils, natural killer cells, natural killer T cells, mast cells, complement, and antimicrobial peptides. Innate immune activation via pattern recognition receptors results in a specific expression of co-stimulatory molecules and cytokines. This inflammatory milieu shapes the subsequent adaptive response, which involves B cell activation and T cell-mediated recognition of foreign antigens presented on major compatibility complexes (MHC) I and II on the cell surface of antigen-presenting cells (APCs) [3–5]. Activated B and T lymphocytes then undergo clonal expansion to provide an antigen-specific immune response.

The discrimination between innate and adaptive immunity has long been recognized but the mechanisms that linked the two major arms of immunity were largely unknown until Charles Janeway first proposed the theory of pattern recognition in 1989 [2]. He suggested that highly conserved microbial molecular constituents called pathogen associated molecular patterns (PAMPs) activate germline-encoded receptors on innate cells coined 'pattern recognition receptors' (PRRs). Janeway's pattern recognition theory was later confirmed by the discovery of the toll-like receptor (TLR) family as well as other PRRs such as NOD1 and the family of NOD-like receptors (NLRs) [6–8]. TLRs represent

Key Points

- Toll-like receptors (TLRs) represent a key receptor family of the innate immune response that recognize pathogen associated molecular patterns as well as damage associated molecular patterns
- TLRs play essential roles in shaping both innate and adaptive immune responses
- TLRs work through two pathways:
  - Adaptor protein myeloid differentiation factor 88 (MyD88) to activate transcription factor NF-κB and MAP kinases (used by all TLRs except TLR3)
  - Adaptor protein TIR domain-containing adaptor protein inducing interferon-beta (TRIF) dependent pathway used by TLR3 and TLR4 that results in type I interferon expression
- TLRs play diverse roles in multiple dermatologic diseases and mutations in TLR signaling pathways have been mapped in human patients, some examples include:
  - TLR2, TLR9 and TOLLIP polymorphisms have been identified in atopic dermatitis patients
  - Activation of TLR4 by nickel, cobalt and palladium in allergic contact dermatitis
  - LL-37, an antimicrobial peptide, complexes with self DNA and activates plasmacytoid dendritic cells to create a DAMP, and drive psoriatic inflammation
- Studies in modulating TLRs for treatment strategies have yielded promising results in a variety of dermatological diseases including treatment of psoriasis, melanoma etc.

a key component of the innate immune system involved in sensing danger. Depending on the particular stimulatory antigen involved, specific downstream components of the signaling pathway are activated, which leads to the generation of an inflammatory response that shapes the subsequent adaptive immune response. Thus, TLRs play an essential role in bridging the gap between innate and adaptive immunity. In support of this notion, studies have implicated TLRs in a variety of human diseases – TLR5 mutations have been linked to an increased susceptibility to Legionnaire's disease [9] while TLR3 deficiency has been associated with herpes simplex encephalitis [10]. In the skin, TLRs have been shown to impact a variety of skin diseases and some widely used dermatologic drugs may possibly exert their therapeutic effects through TLR signaling (Table 2.1) [76]. This chapter will review recent evidence that demonstrates how TLRs affect a variety of skin diseases and infections.

Discovery of TLRs in Humans and Its Expanding Role in Immunity

After Janeway proposed the theory of pattern recognition, based on what was then known about other innate immune receptors, his group was in search for cell-surface receptors expressed on APCs that resulted in NF-κB activation [77]. Lemaitre et al. first identified the antifungal function of Drosophila Toll and demonstrated that it plays a key role in regulating antibacterial gene expression through the NF-κB-like signaling pathway [78]. This seminal discovery paved the path for the discovery of its human counterpart in which Janeway et al. [79] demonstrated that the mammalian Toll homolog induced expression of genes encoding B7 and cytokines that affect the adaptive immune response, providing confirmation for the theory of pattern recognition. Researchers began a fervent search for the ligand of human Toll (now known as TLR4). The first clue came when researchers found that C3H/HeJ mice were unresponsive to bacterial lipopolysaccharide (LPS) and mapped the genetic locus required for LPS responsiveness to *TLR4* [80, 81]. Subsequent studies that attempted to clarify this ligand-receptor interaction proved to be difficult until the other protein in the receptor complex, MD2, was discovered [77, 82]. Since then, studies by many groups have identified multiple other members in the TLR family and elucidated many of their ligands [83]. For their efforts in discovering the toll receptors in Drosophila, Bruce Beutler and Jules Hoffmann won the Nobel Prize in Physiology or Medicine in 2011. TLRs are now the most well characterized PRRs and it is established that different TLR members recognize a variety of PAMPs. Up to 13 TLRs have been identified in mice but only 10 are present in humans as TLR11, 12 and 13 have been lost from the human genome [84]. In contrast, the C-terminal of TLR10 in mice is disrupted by a retrovirus insertion and is nonfunctional. For a detailed look at the history of TLRs, see Table 2.2.

As our understanding of TLRs has expanded in the past couple of decades, increasing evidence has indicated that TLRs are not limited to recognizing PAMPs but can also bind to signals released from damaged tissues, a notion first pioneered by Polly Matzinger who proposed the danger theory as an alternative to the mechanism of immunity initiation [92]. Non-pathogen associated material that leads to tissue injury and other endogenous ligands released during cellular injury such as chromatin bound high mobility group 1 and heat shock proteins also bind and activate TLR signaling [93–97]. Thus, in addition to being the first line of defense against pathogens, TLRs also survey the expression of danger-associated molecular patterns (DAMPs) seen in tissue injury (Fig. 2.1). TLR activation by DAMPs results in sterile inflammation that may play a role in chronic skin

Table 2.1 Toll-like receptors (TLRs) in dermatological disease

TLR	Disease	Comments
1	Tuberculoid	TLR1 favors Th1 phenotype [11]
	Leprosy	*TLR1* I602S mutation protects from *M. leprae* [12]
	Psoriasis	TLR1 expression increased in keratinocytes [13]
	Lyme disease	*TLR1* polymorphism associated with severe disease [14, 15]
	Syphilis	Increased neurosyphilis risk in *TLR1* polymorphisms [16]
2	Acne vulgaris	*P. acnes* stimulates TLR2 and causes hypercornification of sebaceous glands [17]
		Retinoids exert anti-inflammatory effects via TLR2 [18–20]
	Atopic dermatitis	*TLR2* R753Q mutation associated with severe disease [21–23]
		TLR2 signaling necessary for skin barrier repair [24–26]
		TLR2 skews cytokine profile towards a Th2 phenotype [27–30]
	Psoriasis	Increased TLR2 expression in keratinocytes [13]
	Staphylococcus aureus infection	TLR2 deficiency led to increased susceptibility [31, 32]
	Lepromatous leprosy	Associated with $Arg^{677}Trp$ mutation in Korean population [33]
		$Arg^{677}Trp$ mutation: decreased cytokine production [34]
	Syphilis	Lipoproteins stimulate TLR2 [35]
		Increased neurosyphilis risk in *TLR2* polymorphisms [16]
	Lyme disease	Outer surface proteins stimulate TLR2 [36]
		Patients with $Arg^{753}Gln$ mutation secreted less proinflammatory cytokines [37]
	Candidiasis	Phospholipomannans and glycans stimulate TLR2 [38, 39]
	HSV	Glycoproteins stimulate TLR2 [40, 41]
		$TLR2^{-/-}$ animals are more susceptible to HSV encephalitis [42]
3	Psoriasis	Mutation in *AP1S3*, gene required for TLR3 trafficking, associated with pustular psoriasis [43]
	HSV	$TLR3^{-/-}$ astrocytes fail to produce type I IFN [44]
		Humans with TLR3 deficiencies are more susceptible to HSV encephalitis [10]
4	Acne vulgaris	*P. acnes* LPS stimulates TLR4 [45]
	Allergic contact dermatitis	Nickel, cobalt and palladium binds and activates TLR4 signaling [46–48]
	Psoriasis	Increased HSPs that can activate TLR4 signaling [49, 50]
	Syphilis	Lipoproteins stimulate TLR4 [35]
	Candidiasis	Polysaccharides activate TLR4 [38, 39]
		Important for neutrophil recruitment [51]
	UV exposure	TLR4 hyporesponsiveness leads to impaired TNFα production [52]
		TLR4-MyD88 axis deficiencies led to increased cell survival and upregulation of necroptic markers [53]
		TLR4 deficiency led to increased nucleotide excision repair [54]
6	Syphilis	Increased neurosyphilis risk in *TLR6* polymorphisms [16]

(continued)

Table 2.1 (continued)

TLR	Disease	Comments
7	Psoriasis	Imiquimod, TLR7 agonist, drives psoriasis formation [55, 56]
	Systematic lupus erythematous (SLE)	pDCs bind self nucleic acids to stimulate IFN production via TLR7 and 9 [57]
		Small nuclear RNA binds and activates TLR7 and 8 [58]
		Gene duplications of TLR7 increases autoantibody production [59]
		Chronic TLR7 and 9 stimulation leads to glucocorticoid resistance [60]
		Dual TLR7 and TLR9 inhibitor led to decreased autoantibody production in animals and being tested in humans [61, 62]
	Melanoma	Imiquimod and 852A, TLR7 agonist, has been shown to have antitumor effects [63, 64]
	Mycosis fungoides	Imiquimod shown to have clinical responses [65]
	UV exposure	Imiquimod enhances DNA repair and decreased DNA damage [66]
8	SLE	Small nuclear RNA binds and activates TLR7 and 8 [58]
9	Atopic dermatitis	Polymorphisms associated with disease [67]
	Psoriasis	DNA complex with LL-37 stimulates TLR9 to drive IFNα-mediated inflammation [68]
	SLE	pDCs bind self nucleic acids to stimulate IFN production via TLR7 and 9 [57]
		Paradoxical role as TLR9 deficient mice promoted SLE development [69, 70]
		Chronic TLR7 and 9 stimulation leads to glucocorticoid resistance [60]
		Dual TLR7 and TLR9 inhibitor led to decreased autoantibody production in animals and being tested in humans [61, 62]
	Melanoma	PF-3512676, TLR9 agonist, currently being tested in melanoma patients with other modes of therapy [71–73]
	Mycosis fungoides	TLR9 agonist demonstrated to have antitumor activity [74, 75]

Table 2.2 Historical timeline: discovery of Toll-like receptors

	Discovery
1979	Identification of the *dorsal* mutation [85]
1984	Characterization of *toll* mutation and other dorsoventral mutations
1989	Janeway proposes the theory of pattern recognition [2]
1993	Demonstration that NF-κB is required for Drosophila antimicrobial resistance 209
1996	Drosophila *Toll* identified; found to be required for resistance to fungal infections [78]
1997	Human homologue of *Drosophila* Toll, signals activation of adaptive immunity [79]
1998	TLR4 is lipopolysaccharide receptor [80, 86]
1999	MD2 identified as coreceptor for TLR4-LPS interaction [82]
2000	TLR9 recognizes bacterial DNA [87]
2000	TLR2 can pair with TLR6 to recognize bacterial proteins [88]
2000	TLR2 can also associate with TLR1 [88]
2001	TLR3 mediates response to viral double-standed RNA [89]
2001	TLR5 detects flagellate protein in whiplike tails of bacteria [90]
2004	TLR8 (humans), TLR 7 (mice) recognize single-stranded RNA [91]
2011	Bruce Beutler and Jules Hoffmann awarded the Nobel Prize in Medicine for their role in the identification of TLRs

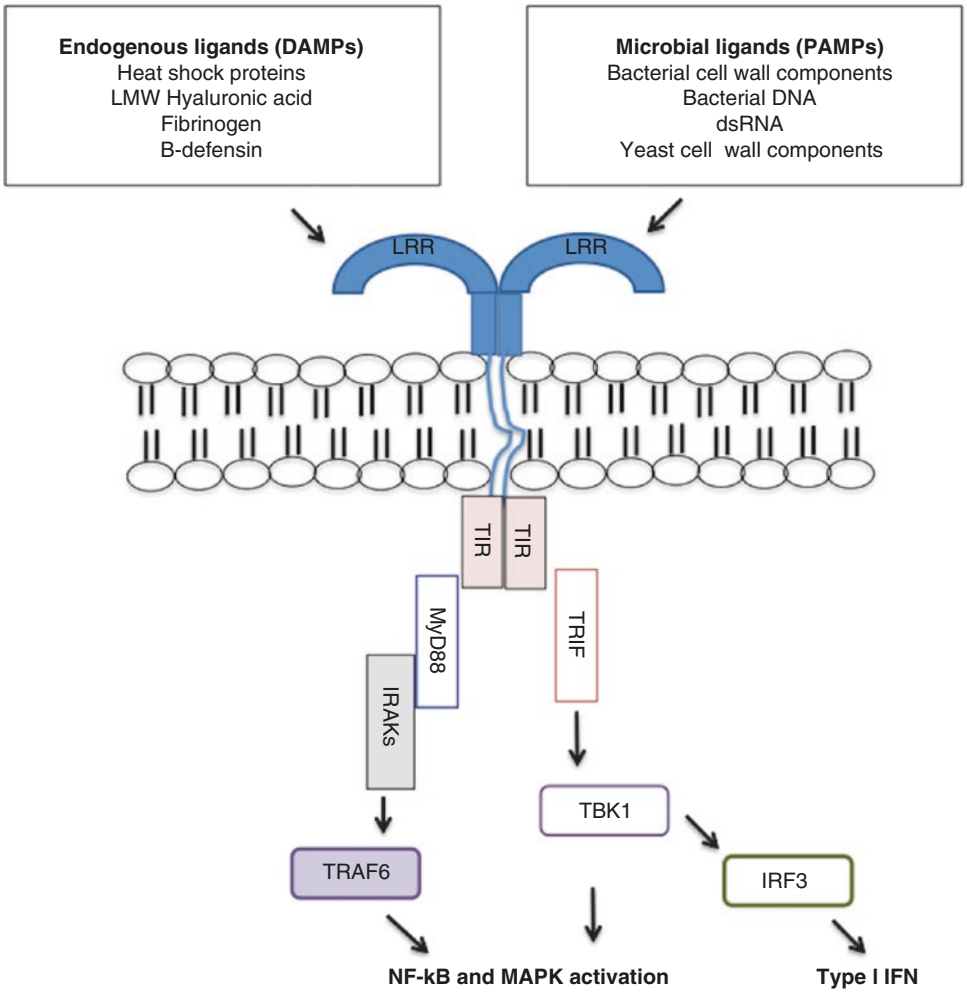

Fig. 2.1 Schematic diagram of TLR activation by various established endogenous and exogenous ligands

diseases such as psoriasis (Fig. 2.2) [99]. For a detailed look at PAMPs and DAMPs that activate specific TLRs, please see Table 2.3.

Toll-Like Receptors in Innate and Adaptive Immunity

As mentioned previously, the pattern recognition theory and identification of TLRs provided the missing link between innate and adaptive immune responses. It is now established that specific ligands activate distinct TLRs and other PRRs, which result in the expression of molecules that shape and fine-tune the adaptive immune response depending on the stimulus involved. On the innate immunity side, activation of TLRs leads to the release of antimicrobial peptides and chemokines that recruit phagocytic cells to the site of infection [120]. TLR activation also induces maturation of dendritic cells to potent APCs via the upregulation of surface expression of MHCII and costimulation markers such as CD80 and CD86 [121].

TLR-mediated effects on the adaptive immune response can be shaped via APCs or T cells directly. It is well known that physical interaction between APCs and T cells requires two signals with signal 1 being the antigen specific signal via MHCII and signal 2 being the expression of costimulation molecules on dendritic cells [122]. TLR stimulation in dendritic cells results in increased expression of MHCII, CD80 and CD86 and is instrumental in promoting both signals required for robust antigen-specific T cell responses [5, 76]. TLR activation on dendritic cells also influences cytokine production, which provides key signals for helper T cell differentiation into different phenotypes with distinct effector functions [123]. For example, TLR-activated dendritic cells produce IFNγ in response to *E.coli* LPS stimulation which is associated with T helper cell 1 (Th1) differentiation while *P. gingivalis* LPS induces expression of IL-5, IL-13 and IL-10, cytokines classically associated with Th2 differentiation [124]. Stimulation of APCs with TLR ligands also leads to interleukin-6 (IL-6) secretion, which can result in the loss of suppressor activity by regulatory T cells, allowing for a

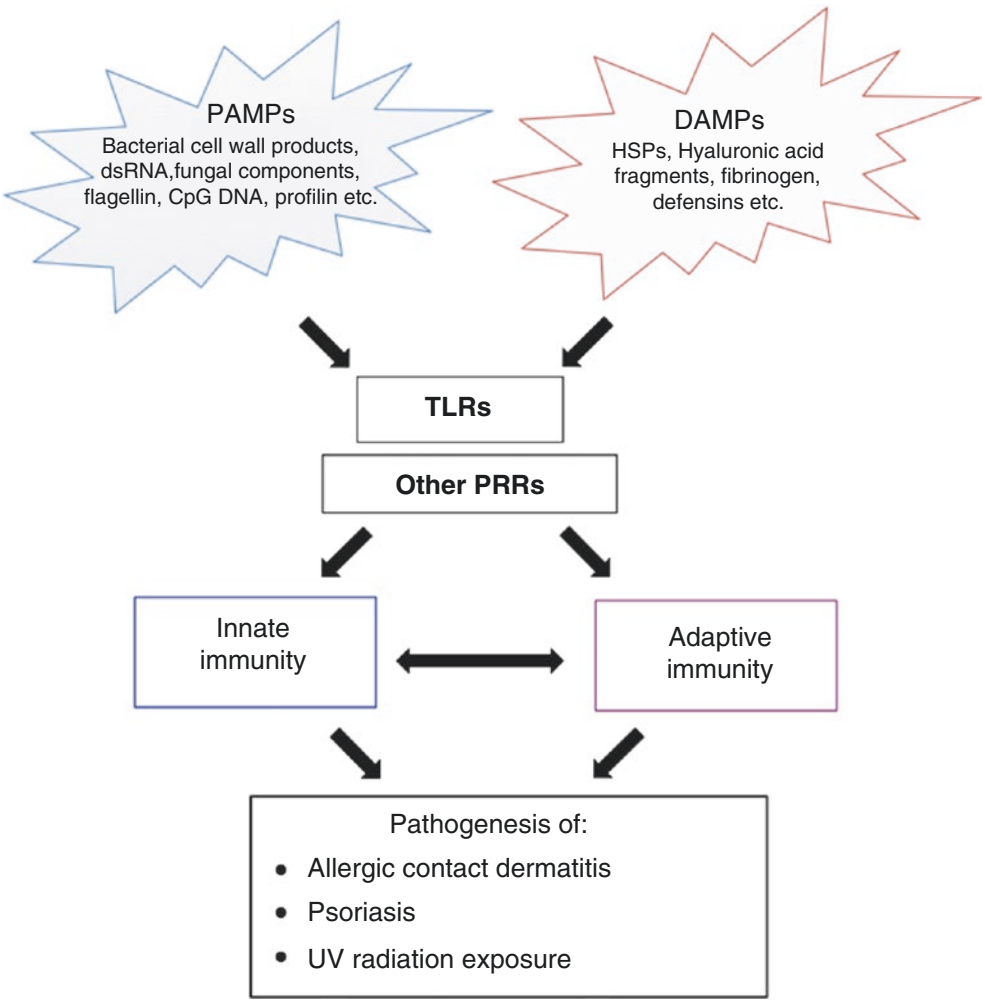

Fig. 2.2 The interplay of PAMPs and DAMPs in the activation of TLRs as well as other PRRs. Activation of these receptors influences both arms of immunity and dysregulation of these pathways can lead to inflammation and the development of a variety of dermatological diseases [98]

more effective immune response [125]. Alternatively, TLRs are also expressed in T lymphocytes and TLR ligands can modulate T cell function directly [126]. Direct TLR2 stimulation of T lymphocytes in the absence of APCs has been shown to induce proliferation of regulatory T cells [127]. Intrinsic B cell TLR activation mediates B-cell proliferation and antibody production to T-dependent antigens and similar results were seen in human B cells [128, 129]. Thus, while TLRs are traditionally associated with the innate immune response, they also play key roles in shaping the adaptive immune response and can directly affect the functions of both T and B lymphocytes.

Expression of Human TLRs in Skin

Based on their cellular localization, TLRs can be broadly classified into two groups [84]. TLRs 1, 2, 4, 5 and 6 are expressed on the cell membrane and recognize predominantly microbial membrane components. TLRs 3, 7, 8 and 9, on the other hand, are expressed in intracellular components such as the endoplasmic reticulum, endosomes and lysosomes and primarily recognize microbial nucleic acids. As the primary physical barrier against the environment, it is not surprising that many cell types residing in the skin express a variety of TLRs to survey for pathogens as well as tissue damage signals.

In the epidermis, keratinocytes constitutively express messenger RNA (mRNA) for TLRs 1–6, 9 and 10 [13, 130]. With the exception of TLR10, many studies have demonstrated that keratinocyte TLRs are functional and respond to their respective ligands [130, 131]. Langerhans cells (LCs) express TLRs 1–10 but are most responsive to TLRs 2, 3, 7 and 8 ligands [132, 133]. In the dermis, stimulation of skin/muscle fibroblasts with ligands to TLRs 2, 3, 4, 5 and 9 led to production of specific chemokines [134, 135]. Expression of human TLRs has also been detected on skin resident and trafficking immune cells such as neutrophils, macrophages, dendritic cells, dermal endothelial cells, mucosal epithelial cells, B cells, and T cells (Table 2.4) [133, 145].

Table 2.3 TLRs: exogenous ligands (PAMPs) vs. endogenous ligands (DAMPs)

TLR	Exogenous ligands	Endogenous ligands	Signaling pathway	
1	Triacyl lipoproteins (w/TLR2)	hBD3	Heterodimerizes with TLR2; MyD88-dependent signaling	[100, 101]
2	Triacyl lipoproteins (w/TLR1) Diacyl lipoproteins lipoteichoic acid, zymosan (w/TLR6)	HMGB1, HSPs, Hyaluronan, Biglycan, Versican, Antiphospholipid antibodies	Heterodimerizes with TLR1 or TLR6; MyD88-dependent signaling	[93, 97, 102–106]
3	dsRNA	Endogenous mRNA from tissue necrosis	TRIP dependent signaling to induce antiviral genes	[100, 107, 108]
4	LPS, viral envelope proteins	HMGB1, HSPs, Hyaluronan, Biglycan, Heparan sulphate, hBD2, fibronectin, s100 proteins Fibronectin extra domain A	MyD88 and TRIF/TRAM dependent signaling	[93, 97, 102–104, 109–113]
5	Flagellin	None identified	MyD88-dependent signaling	[100, 114]
6	Diacyl lipoproteins Zymosan Lipoteichoic acids	HMGB1, HSPs, ECM (with TLR2)	Heterodimerizes with TLR2; MyD88-dependent signaling	[100, 106]
7	ssRNA	Antiphospholipid antibodies ssRNA	MyD88-dependent signaling	[58, 115, 116]
8	ssRNA	Antiphospholipid antibodies ssRNA	MyD88-dependent signaling	[58, 115, 116]
9	CpG-DNA	DNA released from acetaminophen-induced hepatoxicity Mitochondrial DNA Immune complexes	MyD88-dependent signaling	[93, 117, 118]
10	Unknown	Unknown	MyD88-dependent signaling	[119]

HMGB1 high mobility group box 1, HSPs heat shock proteins, double stranded RNA (*dsRNA*), *LPS* lipopolysaccharide, *hBD3* human β-defensin 3, *hBD2* human β-defensin 2, *ECM* extracellular matrix

Table 2.4 TLR expression in different cell types

Cell type	TLR1	2	3	4	5	6	7	8	9	10
Keratinocytes [13, 130]	+	+	+	+	+	+			+	+
Melanocytes [136, 137]		+	+	+	+		+		+	+

N [144]	+	+		+	+	+	+	+	+	+
B cell [143]	+	+	+	+	+	+	+	+	++	++
T cell [133, 143]	+	+	+	+	+	+	+	+	+	+

++ strong expression, + expressed, +/– low level expression, *LC* Langerhans cell, *MC* mast cell, *FB* fibroblasts, *mDC* myeloid dendritic cell, *pDC* plasmacytoid dendritic cell, *MΦ* macrophage, *N* neutrophil

[a]Representative of all myeloid DCs, TLR expression varies within myeloid DC subsets

[b]TLR1-10 transcripts are detected but predominantly express 1, 2, 4, 5 and 8

Toll-Like Receptor Signaling

All members of the TLR family are type I transmembrane proteins and contain: (1) extracellular leucine-rich repeats that mediate the recognition of PAMPs, (2) a transmembrane domain and (3) an intracellular tail that contains the Toll/IL-1R (TIR) domain, which bears homology to the IL-1 receptor [84, 146]. Activating ligands lead to homo- or

heterodimerization of one TLR with another TLR and result in the dimerization of TIR domains, which serve as the scaffold for downstream adaptor proteins. Important adaptor proteins in TLR signaling include myeloid differentiation factor 88 (MyD88), TIR domain-containing adaptor protein inducing interferon-beta (TRIF) and TRIF-related adaptor molecule (TRAM). MyD88 and TRIF represent distinct signaling pathways that TLRs utilize that result in activation of specific gene programs in response to different activating stimuli.

MyD88 is an adaptor protein that is used by most TLRs with the exception of TLR3 for the initiation of downstream signaling. It should be noted that TLR4 is unique in that its activation results in both MyD88-dependent and TRIF-dependent pathways. In the MyD88 dependent pathway, MyD88 activation results in the recruitment of interleukin-1 receptor-associated kinases 1 (IRAK1) and IRAK4 [147]. IRAK4 then activates IRAK1, leading to IRAK1 autophosphorylation and the dissociation of both members from MyD88 and downstream interaction with tumor necrosis factor receptor–associated factor 6 (TRAF6), an E3 ubiquitin ligase [146]. This signaling complex results in the activation of NF-κB and mitogen-activated protein kinases (MAPKs) and the production of inflammatory cytokines (Fig. 2.1) [84]. Although all TLRs utilize MyD88 as an adaptor protein, it is important to recognize that each TLR utilizes different combinations of adaptor proteins and kinases to generate an immune response that is appropriate for the initial activating stimuli. For instance, activation of TLR2 by lipoproteins leads to TNFα expression while CpG stimulation of TLR9 results in the expression of IFN-α and TNFα [148].

The TRIF-dependent signaling pathway is mainly utilized by TLR3 and TLR4. TLR3 activation results in TRIF recruitment and subsequent activation of TANK-binding kinase 1 (TBK1) and interferon regulatory factor 3 (IRF3), a transcription factor required for induction of type I IFNs [148]. TLR4 requires an additional adaptor protein TRAM to stabilize its interaction with TRIF. The discovery of TRIF provided the first molecular explanation for why only TLR3 and TLR4, but not TLR2, can induce IFN-β secretion. Indeed, TRIF-deficient mice were incapable of secreting IFNβ upon stimulation by TLR3 and TLR4 ligands [149]. The TRIF-dependent pathway also results in the activation of NF- κB and MAPKs.

Negative Regulators of TLR Signaling

TLR-mediated signaling plays a key role in the regulation of immunity and excessive TLR signaling has detrimental effects that contribute to autoimmune and inflammatory disease development [150, 151]. Not surprisingly, TLR signaling pathways are tightly controlled and multiple negative regulators of TLR signaling exist at various levels to ensure that immune homeostasis is maintained [100]. IRAK-M, Toll-interacting protein (Tollip) and Suppressor of Cytokine Signaling 1 (SOCS-1) are examples of well-described inhibitors of the TLR signaling pathway. IRAK-M, for instance, is thought to prevent the dissociation of IRAK4 and IRAK1 from MyD88 [152, 153]. Accordingly, IRAK-M$^{-/-}$ macrophages secrete higher levels of inflammatory cytokines and IRAK-M$^{-/-}$ animals are more vulnerable to inflammatory-mediated damage in lupus and lung infection models [154–156]. It is thought that specific genotypes of IRAK-M are associated with sepsis risks (see Table 2.5).

Another negative regulator in the TLR pathway is Toll-interacting protein (TOLLIP), which limits MyD88-dependent NF-κB activation at two different levels [181, 182]. First, overexpression of TOLLIP has been shown to inhibit TLR4– and TLR2–mediated NF-κB activation. TOLLIP also binds directly to IRAK1 to inhibit IRAK1 autophosphorylation and downstream recruitment of signaling proteins required for NF-κB activation [182, 183]. In contrast to IRAK-M$^{-/-}$ mice, TOLLIP deficient animals did not exhibit any overt inabilities to limit the inflammatory response [184]. However, TOLLIP$^{-/-}$ macrophages secreted lower levels of IL-6 and TNFα when stimulated with low doses of LPS, suggesting that TOLLIP is involved in fine-tuning inflammation in response to different levels of stimulation. Polymorphisms of TOLLIP have been associated with atopic dermatitis and inflammatory bowel diseases (see Table 2.5 for other negative TLRs and their association with human diseases). As the role of negative regulators in disease pathogenesis becomes increasingly clear, there is promise that specific targeting of these molecules may lead to the development of new therapeutics.

TLR and Dermatologic Diseases

Acne Vulgaris

Acne vulgaris, a common disorder involving the pilosebaceous unit, is one of the most prevalent conditions in dermatology (see also Chap. 24). It affects more than 45 million people in the United States and is characterized by the presence of inflammatory papules, pustules, nodules and noninflammatory comedones [76, 185]. The pathogenesis of acne is multifactorial but it is generally thought to involve increased sebum production, altered follicular keratinization and an inflammatory response to *Propionibacterium acnes*, a Gram-positive anaerobe that is a part of normal skin flora, a finding that has been confirmed by recent skin microbiome mapping projects [186, 187]. It is thought that the host immune response [188], and not *P. acnes* overgrowth, is the main determinant of disease as PBMCs from acne vulgaris patients produce higher levels of IFNγ, IL-12 and IL-8.

Table 2.5 Negative regulators of Toll-like receptors

Negative regulator	Mechanism of action	Role in human diseases	References
Protein regulators			
IRAK-M	Prevents IRAK1/IRAK4 dissociation Negatively regulates alternative NF-κB activation after TLR2 stimulation	G/G genotype associated with increased sepsis risk A/A genotype is protective against sepsis Possible role in IBD	[153, 157–160]
MyD88s	MyD88 antagonist	Upregulated in septic patients	[161–163]
TOLLIP	Autophosphorylates IRAK1	Polymorphisms mapped in Atopic Dermatitis IBD	[164, 165]
A20	De-ubiquitylates TRAF6	Polymorphisms and mutations associated with rheumatoid arthritis, psoriasis, Sjogren's Syndrome, SLE, lymphomas	[166, 167]
SOCS1	Suppresses IRAK by promoting their degradation	Decreased SOCS1 expression in SLE MS, RA	[168, 169]
SIGIRR	Orphan receptor that suppresses inflammation	No clear demonstrated role in human disease	[170, 171]
ABIN-1	Ubiquitin binding protein that inhibits TLR/C/EBPβ signaling	Protects again psoriasis	[172, 173]
MicroRNAs Targets 3′-untranslated regions to modulate gene expression			
miR-146	Inhibits IRAK1 and TRAF6	RA Psoriatic arthritis	[174–176]
miR-9	Blocks NF-κB	Leukemias Cancer	[177, 178]
miR-21	Blocks NF-κB and PCDC4	Cancer	[175, 179]
miR-155	Stimulates TNFα Blocks TAK1 activation	Cancer	[180]

IRAK-M IL-1R-associated kinase M, *MyD88s* myeloid differentiation factor 88 short, *TOLLIP* Toll-interacting protein, *SOCS1* suppressor of cytokine signaling 1, *ABIN*-1 A20 binding and inhibitor of NF-κB-1, *SIGIRR* single immunoglobulin IL-1 related receptor, *SLE* systemic lupus erythematous, *IBD* inflammatory bowel disease, *RA* rheumatoid arthritis, *MS* multiple sclerosis

However, the notion that the host immune response is the main contributor of disease has been challenged by a recent study that showed that acne vulgaris patients harbor different *P. acnes* strains compared to healthy controls [189].

Early studies demonstrated that soluble factors produced by *P. acnes* stimulated proinflammatory cytokine production but the exact mechanisms were poorly understood [190, 191]. After the discovery of TLRs, Kim et al. demonstrated that *P. acnes*-mediated induction of proinflammatory cytokines was dependent on TLR2 expression and that TLR2 was abundantly expressed on perifollicular macrophages [192]. It was thought that *P. acnes* possessed two potential cell wall components, LPS and peptidoglycan (PG), that can serve as ligands and activate TLR2 and TLR4 to mediate its downstream proinflammatory response [76]. Indeed, distinct strains of *P. acnes* with presumably varied modifications in their cell wall components differentially induced upregulation of hBD2, and IL-8 mRNA levels in keratinocytes in a TLR2- and TLR4-dependent manner [45]. Subsequent studies have also found that expression of TLR2 and TLR4 in keratinocytes increased in the epidermis of inflammatory acne lesions and *P. acnes* exposure led to an increase in TLR2 expression [192, 193]. Other than proinflammatory cytokine production, PAMP stimulation also caused hypercornification of sebaceous glands in a TLR2-dependent manner [17]. While the host immune response is an essential component of acne vulgaris pathogenesis, the molecular mechanisms that differentiate healthy controls and acne vulgaris patients remain poorly characterized. As mentioned earlier, recent studies have showed that different *P. acnes* strains are found in acne vulgaris patients and there is evidence that these strains can modulate cutaneous innate immunity differentially [189, 194]. Specifically, Jasson et al. demonstrated that only some strains have the capacity to recruit TLR2 receptors and trigger a downstream inflammatory response [194]. It will be interesting to see if the differential capacity of TLR2 recruitment by various *P. acnes* strains affects keratinocyte proliferation in pilosebaceous units and have clinical implications in acne vulgaris treatment strategies in the future.

Interestingly, retinoids, one of the treatments commonly used for acne vulgaris, have been shown to exert anti-inflammatory effects by decreasing local expression of TLR2

in vitro [18, 19]. These results were recently confirmed in human patients – systemic administration of isotretinoin in acne patients resulted in downregulation of TLR2 cell surface expression on monocytes and decreased levels of IL-1β, IL-6, IL-12 as well as IL-10 release [20]. Of note, systemic isotretinoin decreased TLR2 cell surface expression to levels comparable to those seen in healthy controls. A similar reduction in proinflammatory cytokines was also evident and this effect was sustained for 6 months after the cessation of therapy.

Atopic Dermatitis

Atopic dermatitis (AD) is a common chronic inflammatory skin condition that affects up to 3 % of adults and 15–25 % of children in the United States (see also Chap. 22) [195, 196]. Multiple defects have been identified in AD patients, including impaired skin barrier function, reduced expression of antimicrobial peptides, concomitant skin infections and Th2 skewing. Moreover, it has been demonstrated that up to 90 % of AD patients are colonized with *Staphyloccus aureus* in both lesional and nonlesional skin, whereas only 5 % of healthy controls exhibit colonization [197]. The molecular details underlying AD pathogenesis are currently under investigation but defects in the TLR signaling pathway have been identified in AD patients. AD patients have decreased TLR2 expression on their circulating monocytes and are impaired in their proinflammatory response to known TLR2 ligands [198, 199]. Werfel and colleagues further reported that a missense mutation in the *TLR2* gene (*R753Q*) is associated with AD patients with a more severe phenotype, higher serum levels of immunoglobulin E (IgE), and greater susceptibility to *S. aureus* colonization [21–23]. TLR9 and TOLLIP polymorphisms have also been shown to be associated with AD patients [67, 164].

TLRs also directly affect skin barrier function by modulating both physical and chemical properties of barrier function [195]. TLR2 signaling has been shown to increase the expression of tight junction proteins and enhance skin barrier repair [24, 25]. Accordingly, $TLR2^{-/-}$ mice demonstrated impaired repair responses to epidermal injury by tape-stripping, suggesting that TLR2 may contribute to a chronic itch-scratch cycle often seen in AD patients. Other than TLR2, TLR3 signaling in response to dsRNA stimulation from epidermal injury also stimulates the expression of genes involved in permeability barrier repair [26]. In addition, TLR signaling is necessary for the keratinocyte production of antimicrobial peptides (AMPs), a key component of cutaneous chemical barrier function. Previous studies demonstrated that human β-defensin-2 (hBD2) and cathelicidin LL-37 (two AMPs important in keratinocyte defense against *S. aureus*) were significantly decreased in acute and chronic lesions of AD when compared to controls and patients with psoriasis [200]. LL-37 and hBD2 production, in turn, is dependent on intact TLR2 signaling after *S. aureus*, *S. epidermis* and skin injury [201–203].

Consistent with their tendency towards a Th2 immune response, AD patients often suffer from other atopic diseases such as allergic rhinitis, asthma and seasonal allergies. Early lesions in AD have a Th2 cytokine profile, which has been shown in murine models to promote preferential binding to *S. aureus* [27]. In support of the key role Th2 cytokines (IL-4, IL-13 and TSLP) play in AD pathogenesis, patients with moderate to severe AD treated with dupilumab, an antibody that targets the Th2 cytokine IL-4, showed remarkable improvement in their symptoms [28]. Increasing evidence suggests that TLRs affect the balance between Th1 and Th2 cytokines in the skin. For example, TLR2 stimulation by purified *S. aureus*-derived diacylated lipopeptitde induces expression of Th2 cytokines like thymic stromal lymphopoietin (TSLP) by keratinocytes [29]. TLR2 ligands also play a role in exaggerating and prolonging Th2-mediated inflammation in AD [26]. TLR2 also has complex roles in modulating other arms of immunity and has been shown to affect mast cell degranulation as well as subsequent IgE antibody production by B cells [30]. Collectively, these data indicate that TLRs, especially TLR2, influence multiple aspects of AD pathogenesis, including barrier function, *S. aureus* colonization as well as skewing of the immune response towards a Th2 phenotype. Further dissection of how TLRs affect the various altered skin functions in AD will likely lead to development of new therapeutic strategies.

Allergic Contact Dermatitis

Allergic contact dermatitis (ACD) is a common skin disorder caused by type IV delayed hypersensitivity reactions to skin-exposed chemical allergens (see also Chap. 23) [204]. In the clinically silent phase of sensitization, dendritic cells migrate to skin-draining lymph nodes and present contact allergens to naïve T lymphocytes, which may take weeks to months of repeated exposures to low molecular weight compounds. Upon re-exposure to the contact allergen, effector T cells are recruited back to the skin to mediate the type IV delayed hypersensitivity reaction (known as the 'elicitation phase') seen in ACD. It is estimated that more than 3000 contact allergens have been described; some of the common contact allergens include nickel, fragrances and hair dyes [98]. Martin et al. [205] first demonstrated a role for TLRs in ACD by showing that mice lacking both TLR2 and TLR4 failed to develop contact hypersensitivity (CHS), the experimental model used to study ACD. Importantly, CHS development was dependent on IL-12 expression that was stimulated by either TLR2 or TLR4 activation of dendritic cells as dendritic

cells from TLR2$^{-/-}$ TLR4$^{-/-}$ double knockout animals were resistant to CHS stimulation in wild type animals. Interestingly, CHS developed normally in germ free animals, suggesting that TLR2 and TLR4 activating signals were most likely derived from endogenous ligands such as DAMPs rather than microbial ligands. Further analyses revealed that contact allergens lead to reactive oxygen species (ROS) production, which stimulates the degradation of high molecular weight hyaluronic acid (HA) to low molecular weight HA products [206]. Low molecular weight HA, in turn, can serve as endogenous ligands for TLR2 and 4 signaling and potentiate an inflammatory cascade [207, 208]. A recent study by Gallo and colleagues [209], however, has challenged this notion that HA alone can cause ACD. The group overexpressed hyaluronidase, an enzyme involved in the generation of low molecular weight HA in mice, and showed that small HA fragments alone did not lead to spontaneous cutaneous inflammation resembling CHS. However, the addition of antigen along with small HA fragments accelerated allergic sensitization in a TLR4-dependent manner. Thus, rather than acting as the inflammatory stimuli for ACD, low molecular weight HA controls the antigen presentation capacity of the skin.

Other than DAMP-mediated activation of TLRs, nickel, cobalt and palladium have all been shown to bind and activate human TLR4 [46–48]. Specifically, binding of human TLR4 to nickel was mediated by histidine residues missing in murine TLR4 and provided molecular evidence for why mice are naturally resistant to nickel-induced CHS [48]. Whether nickel alone is sufficient in driving CHS remains unknown although the natural resistance to nicked-induced CHS seen in mice can be overcome by the addition of LPS [210], suggesting that microbial ligands that activate TLR4 may help to amplify the stimulus to promote sensitization to contact allergens [98]. Together, these studies provide evidence that contact allergens like nickel, DAMPS such as low molecular weight HA and PAMPs are all capable of activating TLRs in ACD. However, the relative contribution of each in either the sensitization phase or elicitation phase remains unknown and whether different TLR-expressing skin cells maybe involved in specific phases present exciting future research opportunities for learning more about ACD pathogenesis.

Psoriasis

Psoriasis is a chronic, recurrent, inflammatory disease characterized by dry, scaly, circumscribed erythematous plaques predominantly located in the scalp, nails, extensor surfaces of the limbs, umbilical region, and sacrum (see also Chap. 21). The pathogenesis of psoriasis, which is characterized by the predominance of Th1/Th17 cytokine profiles, involves hyperproliferation and parakeratosis of keratinocytes, which ultimately leads to thickening of the epidermis [99]. Many advances have been made in understanding the mechanisms involved in psoriasis and developments of new immunosuppressive and biologic treatments. Not surprisingly, TLRs have also been found to play a role in the pathogenesis of psoriasis. A study demonstrated that TLR1 and TLR2 expression was increased in the suprabasal layer of keratinocytes in psoriasis patients compared to skin isolated from normal controls [13]. In contrast, TLR5 expression in basal keratinocytes from psoriatic patients was decreased compared to healthy controls. Other studies have found increased TLR1, 2, 4, 5 and 9 expression in keratinocytes isolated from psoriatic lesions [211]. A recent study also identified mutations in the gene *AP1S3*, a protein involved in TLR3 trafficking, that are associated with pustular psoriasis [43]. Furthermore, application of imiquimod, a known TLR7 agonist, is known to trigger psoriasis in both humans and animal models [55, 56]. It is thought that imiquimod activates TLR7 signaling on DCs to drive psoriatic plaque formation by activating the production of IL-17 and IL-22 by innate lymphoctyes. ABIN-1, a negative regulator of TLR signaling, protects against psoriasis development by preventing exaggerated NF-κB and MAPK signaling in response to TLR7 agonists [172]. Therefore, TLR expression on various cell types in the skin may drive psoriatic pathogenesis and it is plausible that different cell types maybe involved in different phases of disease progression.

In contrast to AD patients who are more susceptible to *S. aureus* infections (see above), it is generally accepted that psoriatic plaques are relatively resistant to *S. aureus* infection [212]. It is thought that increased AMP production such as hBD2 and syndecans seen in psoriatic plaques is partially responsible for this phenotype [213, 214]. Keratinocyte growth factor, TGFα, has been found at high levels in psoriatic lesions and is responsible for increased TLR5 and TLR9 expression as well as TLR-dependent release of AMPs and proinflammatory cytokines [215]. While the increased production of AMPs is beneficial against pathogenic microorganisms, it has been postulated that they may also contribute to inflammation by modulating host immune receptors such as TLRs [185]. For example, LL-37 has been shown to complex with self DNA to create a novel DAMP and activate plasmacytoid dendritic cells (pDCs) via the TLR9 pathway and drive inflammation in psoriatic skin by stimulating IFNα production [68]. A recent study showed that LL-37 and an alternatively processed cathelicidin peptide KS-30 also stimulate keratinocytes to produce more type I IFNs but this was not dependent on its complexed DNA that was important for pDC activation [216].

Other than AMPs, heat shock protein (HSP) expression is also thought to contribute to TLR-mediated inflammation. HSP is induced by exposure to microbial pathogens and

other stressful stimuli [49]. Heat shock protein 27, 60, 70 and 90 have been shown to be overexpressed in psoriasis [49, 50] and can trigger an innate immune response through TLR4 on APCs, resulting in the secretion of TNFα, IL-12, and other Th1 cytokines. They also may act on the adaptive immune response by serving as autoantigens for self-reactive T cells that migrate into psoriatic lesions.

These discoveries are opening doors for novel treatments in psoriasis (see Chaps. 43). It is thought that systemic and topical retinoids used in the treatment of psoriasis may control inflammation through their inhibitory effects via TLR2 [76]. Monomethylfumarate (MMF), a bioactive metabolite of fumaric acid ester, is an immunotherapy for psoriasis that causes decreased production of Th1 cytokines and lymphocytopenia [217]. Monomethylfumarate was shown to decrease DC response to LPS and decreased IL-12p70 and IL-10 production. Etanercept, a TNFα inhibitor that has been successful in psoriasis treatment, has been shown to be associated with decreased LL-37 expression, which may dampen TLR9 activation and further suppress the chronic inflammatory response in psoriasis [218]. Thus, TLR dysregulation appears to play a role in psoriasis pathogenesis although whether a predominant TLR is involved remains unclear. Continued research in these areas will yield interesting findings that will impact treatment options for psoriasis patients.

Bacterial Infections

Bacterial cell wall components were the original ligands shown to stimulate TLR signaling [80, 81]. Accordingly, TLRs have been implicated in the pathogenesis of multiple bacterial diseases.

S. aureus Infections

S. aureus, a gram-positive extracellular bacteria, is the causative agent of a variety of skin infections, including impetigo, folliculitis and cellulitis (see Chap. 16) [219]. It is estimated that 20% of the population is persistently colonized, harboring *S. aureus* on the skin and the nares, while 50% are intermittent carriers [185]. *S. aureus* lipoproteins, peptidoglycan and lipoteichoic acid signal through TLR2/6 and TLR2/2 dimers [220, 221]. Accordingly, TLR2 deficient mice were more susceptible to *S. aureus* infection and harbored higher bacterial loads in blood compared to wild type controls [31, 32]. Animals deficient in MyD88, the key adaptor protein required for all TLR signaling with the exception of TLR3, were also more susceptible to *S. aureus* infection and demonstrated a neutrophil recruitment defect that was not seen in TLR2$^{-/-}$ mice. In corroboration of these animal studies, MyD88-deficient and IRAK4-deficient patients are more susceptible to *S. aureus* infections [222]. Mutations in the IRAK4 kinase that led to premature stop codons have been shown to increase susceptibility to pyogenic infections caused by *S. aureus* as well as *Streptococcus pneumonia* [223]. Cells from patients with this disease did not respond to any known ligands from TLRs 1 to 6 and 9. Consistent with an immune deficient phenotype, these patients suffered recurrent pyogenic infections with minimal febrile or inflammatory responses.

Leprosy

Leprosy, or Hansen's disease, caused by *Mycobacterium leprae*, is a chronic, debilitating disease that encompasses a spectrum of clinical manifestations [76]. At one end, tuberculoid leprosy (TL) presents in patients with a strong cell-mediated immune response, resulting in high resistance to *M. leprae* and few, localized, paucibacillary lesions. At the other end of the spectrum, lepromatous leprosy (LL) patients have a weak immune response, resulting in disseminated, multibacillary disease, including cutaneous and nerve involvement [224]. Other forms of the disease with unstable resistance include borderline tuberculoid, borderline, and borderline lepromatous. The former is Th1 mediated (e.g., IFNγ, IL-12, IL-18, and granulocyte-macrophage colony-stimulating factor), whereas the latter is Th2 driven (e.g., IL-4 and IL-10). There is accumulating evidence to suggest that whether a patient develops one response over the other may be in part due to variations in the TLR signaling pathway.

In 1999, it was discovered that mycobacteria activated macrophages through TLR2, resulting in production of TNFα, a proinflammatory cytokine [225]. An introduction of a dominant negative mutation in TLR2 rendered the receptor unresponsive to *M. tuberculosis*. Furthermore, a mutation in Arg^{677}Trp in TLR2 has been associated with LL in the Korean population [33]. A separate study confirmed that this mutation halts the ability of TLR2 to respond to both *M. leprae* and *M. tuberculosis*, confirming the clinical importance of this polymorphism [224].

Upon stimulation with *M. leprae*, patients with the Arg^{677}Trp TLR2 mutation were found to have decreased production of IL-2, IL-12, IFNγ, and TNFα, and increased IL-10 (an anti-inflammatory cytokine) when compared to those with the wild-type TLR2 [34]. Thus, the mutated TLR2 favored a Th2 phenotype, which is consistent with the observed LL phenotype. Based on these findings, TLR2 appears to play a critical role in the alteration of cytokine profiles and determination of the type of leprosy that develops.

M. leprae products were shown to activate both TLR2 homodimers as well as TLR1-TLR2 heterodimers [11]. Interestingly, TL lesions had higher TLR1 and TLR2

expression compared to LL lesions, suggesting that the expression of TLR2 and TLR1 contributes to the host response. Moreover, this study demonstrated that type 1 cytokines enhance TLR1 and TLR2 activation, whereas the Th2 cytokines inhibited activation. Therefore, not only does innate TLR signaling affect the adaptive immune response, but also the adaptive immune response, through cytokine release, may also influence the innate response. Further evidence that TLRs play a role in *M. leprae* pathogenesis was shown in a recent genetic study. Wong et al. showed that individuals homozygous for the *TLR1* I602S mutation, a functional TLR1 knockout, were protected from *M. leprae* infection, suggesting that *M. leprae* may have utilized TLR1 signaling to enhance its pathogenesis [12]. These findings underline the complexity of the interaction between TLRs and *M. leprae* pathogenesis through evolution and provide additional proof that TLRs are involved in bridging the gap between innate and adaptive immunity.

Syphilis

Syphilis is a contagious, sexually transmitted disease caused by the obligate human pathogen *Treponema pallidum* [76]. There are three stages of syphilis. In primary syphilis, a painless genital ulcer, called a chancre, appears 18–21 days after infection. Secondary syphilis can appear as various cutaneous eruptions—macular, papular, or polymorphous—often with lesions on the palms and soles. Tertiary syphilis occurs 3–5 years after infection. Patients may develop gummas, or necrotic lesions in the skin, mucous membranes, bones, or joints. Other complications of syphilis include neurologic and cardiac involvement.

It is appreciated that the outer cell wall structures of spirochete bacteria like *T. pallidum* are vastly different from the typical outer membranes of Gram-negative bacteria [226]. It is thought that *T. pallidum* has developed multiple strategies to evade the host immune response. For instance, *T. pallidum* lacks LPS and contains a paucity of immunogenic proteins compared to other spirochete bacterium [227]. Thus, during syphilitic infection, *T. pallidum* membrane lipoproteins (LPs) serve as principal proinflammatory mediators [35]. Indeed, it was demonstrated that *T. pallidum* LPs stimulated TLR2- and TLR4-expressing immature murine dendritic cells (DCs) to release proinflammatory cytokines such as IL-12, IL-1β, TNFα, and IL-6. It was long thought that opsonization of spirochete bacteria was essential for *T. pallidum* clearance but mechanistic studies were missing until Silver et al. recently demonstrated that TLR-MyD88 signaling is crucial for phagocytosis and bacterial clearance [227]. MyD88-deficient animals exhibited increased inflammation with a stronger infiltration of neutrophils and lymphocytes but still harbored a high bacterial load due to the inability of MyD88$^{-/-}$ macrophages to opsonize *T. pallidum*. Consistent with these findings, a recent clinical study found that *TLR1*, *TLR2* and *TLR6* polymorphisms are associated with an increased risk of neurosyphilis development, suggesting that the TLR1/TLR2 and TLR2/TLR6 heterodimers are important in protecting against *T. pallidum* [16].

Yersinia pestis

Y. pestis is a gram-negative bacillus that causes plague, a disease that killed millions of people in the "Black Death" pandemic. It is transmitted by the bite of the rat flea *Xenopsylla cheopis*. Clinically, painful buboes form in the axillae or groin, although other skin lesions such as vesicles, plaques, petechiae, and purpura can be seen. *Yersinia* outer membrane protein, V antigen, targets TLR2 and CD14 on the surfaces of APCs [228]. Interestingly, *Y. pestis* has specific variations in its LPS lipid A structure to evade TLR4-mediated host immune recognition [229].

Lyme Disease

Lyme disease is a tick-borne illness caused by the spirochete *Borrelia burgdorferi* and is loosely divided into three stages. The primary stage is characterized by constitutional symptoms and erythema chronicum migrans. The second stage occurs for 5–6 months after the rash resolves. In the tertiary phase, cardiac, neurologic, and rheumatologic complications can occur. Like other spirochetes such as *T. pallidum*, *B. burgdorferi* does not have LPS in its outer membrane structure to stimulate TLR4. *B. burgdorferi* outer surface protein A (OspA) stimulates TLR2 to activate inflammatory signaling [36]. Stimulation with *B. burgdorferi* lysate was found to increase the expression of TLR1 and TLR2 in all peripheral blood monocytes and human brain cells, but not neurons [230]. Consistent with the aforementioned *in vitro* data, TLR2 deficient animals harbored much higher loads of *B. burgdorferi* and TLR2$^{-/-}$ macrophages produced lower levels of proinflammatory cytokines [231]. Peripheral blood monocytes (PBMCs) isolated from patients with TLR2 Arg^{753}Gln mutations also secreted less proinflammatory cytokines [37]. Interestingly, the lower levels of TNFα and IFNγ were protective against late stages of disease such as lyme arthritis development.

Candidal Infections

Candida albicans is a dimorphic fungi that causes cutaneous and mucocutaneous candidiasis and causes severe infections in immunocompromised individuals (see Chap. 19). It has been demonstrated that the immune response against

yeast phospholipomannans and glycans involves TLR2, causing upregulation of TNFα via the NF-κB pathway [38, 39]. Candidal cell polysaccharide mannan most likely activates TLR4 as anti-CD14 and anti-TLR4 antibodies (but not anti-TLR2 antibodies) blocked mannan-induced cytokine production [38, 39]. When stimulated with *C. albicans*, TLR4 defective macrophages expressed lower levels of neutrophil chemokines and impaired neutrophil recruitment [232]. Consistent with the animal model data, killing of *C. albicans* in human keratinocytes was shown to be dependent on TLR2 and TLR4 [51]. More recent work has also implicated a role for TLR7 in IL-12 production in response to fungal RNA [233]. TLR7 and TLR9 deficient animals harbored higher fungal load compared to wild type animals but whether this was dependent on IL-12 was not studied. Together, these studies suggest that TLRs work differently to foster an immune response against *C. albicans* – TLR4 activation leads to recruitment of neutrophils; TLR2 mediates the production of TNFα and TLR7 is important in the IL-12 response against candidal infections.

Herpes Simplex Virus

Viruses are obligate intracellular parasites that rely on host protein machinery to complete their replication cycles (see Chap. 17). Due to their intracellular location, viral nucleic acids are usually recognized in intracellular components such as endolysosomes by various TLRs. Viral proteins released during replication may also stimulate TLRs on cell surfaces. Herpes simplex virus type 1 (HSV-1) and type 2 (HSV-2) are double-stranded DNA (dsDNA) viruses that commonly infect skin and mucosa. HSV-1 generally produces vesicular outbreaks at the orolabial or ocular mucosa, whereas HSV-2 typically infects genital mucosa and renders patients more susceptible to other sexually transmitted infections. However, both strains of the virus can infect either physical location.

Herpes simplex virus glycoproteins gH/gL and gB have been shown to stimulate TLR2 and activate NF-κB signaling [40, 234]. TLR2-mediated NF-κB activation, however, may have detrimental effects as TLR2 knockout mice with decreased cytokine responses are resistant to HSV encephalitis [42]. Plasmacytoid dendritic cells recognize HSV through TLR9 to activate interferon production [235, 236]. In contrast to TLR2 deficient animals, TLR9−/− were more susceptible to HSV infection [237, 238]. Furthermore, TLR2/TLR9 double knockout animals exhibited 100 % mortality and had decreased NK cells as well as global cytokine levels. Thus, while TLR9 plays a protective role against HSV infection, the role of TLR2 is complex and further dissection of its role in different cell types is necessary. The importance of TLR signaling is further demonstrated by the fact that a HSV-1 protein, ICP0, that is expressed early during infection accelerates the degradation of MyD88 and inhibits NF-κB activation [239]. Interestingly, Iwasaki et al. [240] showed that HSV is detected in a serial recognition system by DCs – viral glycoproteins are first detected by TLR2 and then viral DNA is recognized by intracellular TLR9. The authors suggested that this serial recognition system helps to mount an optimal antiviral response. Together, this body of work indicates that while TLR2 and TLR9 may have differential effects on the antiviral response, they also work synergistically and the loss of both receptors leads to detrimental effects in the host.

Other than the TLR2 and TLR9 interaction, TLR3, which recognizes dsRNA, has also been shown to play an important role against HSV infection [44]. Vaginal inoculation of $TLR3^{-/-}$ mice led to higher viral loads in the central nervous system compared to healthy controls. Of note, global cytokine production was unaltered in $TLR3^{-/-}$ mice but $TLR3^{-/-}$ astrocytes were unable to produce type I IFN after HSV infection, thereby rendering the host susceptible to extensive CNS infection. Importantly, TLR3 is also protective against HSV in humans as children born with TLR3 deficiencies were more susceptible to HSV encephalitis [10].

Autoimmune Diseases- SLE

The autoimmune connective tissue diseases (AI- CTDs) are a group of clinical disorders that all have circulating autoantibodies (autoAbs) (see Chap. 30). Such disorders include systemic lupus erythematosus (SLE), dermatomyositis, systemic sclerosis, rheumatoid arthritis, mixed connective tissue disease, Sjögren's disease and more [76]. SLE is a disease commonly seen in dermatology, in which patients may exhibit several key diagnostic signs and symptoms, including antinuclear antibody positivity, malar and discoid rashes, photosensitivity, oral ulcers, arthritis, serositis, and renal, neurologic, hematologic, and immunologic disorders. It is generally accepted that IFNα and pDCs contribute to the pathogenesis in SLE – pDCs recognize self-nucleic acids in a TLR7 and TLR9 dependent manner, which leads to the upregulation of IFN production as well as B cell production of anti-DNA and anti-RNP antibodies [57, 61]. These autoantibodies maybe directed against self antigens such as small nuclear ribonuclear protein particles (SnRNP) called U1 and Sm and this interaction leads to the formation of immune complexes with DNA or RNA from dying cells [241]. Recent evidence suggests that TLR7, TLR8 and TLR9 play key roles in mediating an abnormal immune response mediated by pDCs and neutrophils to endogenous ligands, leading to chronic activation that triggers autoimmunity in the skin [57, 242].

Previous work revealed that specific RNA sequences within snRNPs stimulate TLR7 and TLR8 to activate immune cells, such as pDCs and monocytes, to secrete high levels of IFNα and TNFα respectively [58]. Intriguingly, *TLR7* and *TLR8* are both encoded on the X chromosome, which may partially account for why 90 % of SLE cases occur in women [243]. A deletion of a single copy of *TLR7* in mice led to increased survival and reduced autoantibody production and splenocyte proliferation [244]. A direct correlation existed between TLR7 expression and autoAb production, further implicating that TLR7 plays a pathogenic role in SLE. Gene duplication of TLR7 in a specific strain of mice also led to increased autoantibody production [59]. Compared to TLR7, the role of TLR9 in SLE pathogenesis is more complex. TLR9 has been shown to bind single-stranded unmethylated CpG-DNA containing a phosphodiester backbone, a process that is inhibited by chloroquine and quinacrine, suggesting a possible mechanism for the therapeutic effect of these drugs seen in some autoimmune diseases, such as lupus [245]. Moreover, TLR9/MyD88 signaling was crucial for generation of pathogenic autoantibodies in SLE [246]. Based on these studies, it was expected that TLR9 deficient animals would exhibit less severe SLE. Paradoxically, TLR9 deficiency promoted SLE in multiple lupus models, suggesting that the role of TLR9 was more complex [69, 70]. Most recently, it was shown that although TLR9 was indeed required for autoAb formation, TLR9 also plays a role in B cell-mediated tolerance by controlling the life-span of autoreactive B cells [247]. TLR9 also suppressed TLR7-mediated autoAb production and thus has dual roles in SLE pathogenesis [248].

In support of the aforementioned animal data, SLE patients also expressed high levels of TLR7 and 9 [249]. Interestingly, chronic TLR7 and TLR9 stimulation of pDCs led to resistance to glucocorticoid treatment [60]. Inhibition of TLR7/TLR9 with a small immunoregulatory sequence in animal models improved autoantibody production as well as kidney damage and a similar inhibitor has been tested in patients with promise [62]. Other drugs targeting TLR signaling are also under development for SLE and will hopefully lead to drug regimens with more favorable side effect profiles for SLE patients in the future [250].

Melanoma and Mycosis Fungoides

Melanoma is a skin cancer caused by neoplastic transformation of melanocytes and has been increasing in incidence and mortality over the years [251]. It is thought that genetic factors and intermittent high-dose UV irradiation during childhood are both important etiologic factors in melanoma. Although melanoma only accounts for 4 % of all skin cancers, it causes more than 70 % of skin cancer related deaths as metastatic disease often carries a poor prognosis [252]. Since melanocytes express functional TLR2, 3, 4, 5, 7, 9 and 10, it has not surprising that TLR ligands have the ability to modulate melanoma pathogenesis [136, 137]. Indeed, LPS has been shown to stimulate melanocyte IL-8 production in a TLR4 dependent manner [253]. Agonists of TLR 3, 4, 7, 8 and 9 have showed promise as cancer immunotherapy agents and are regarded as having high potential by the National Cancer Institute [254].

Manipulation of TLRs is currently being investigated as a therapeutic option for melanoma as TLR agonists can activate dendritic cells in sentinel lymph nodes (SLNs) of melanoma patients [255]. In animal studies, addition of CpG DNA and poly-I:C (TLR9 and TLR3 ligands respectively) to peritumoral injections have been shown to increase cutaneous tumor rejection and animals remained tumor free after 50 days [256]. TLR7 agonists such as 852A and imiquimod have also been shown to have antitumor effects [63, 64, 66, 252]. Topical application of imiquimod in melanoma patients enhanced influx of CD4+ and CD8+ T cells to the skin as well as SLNs [252]. While commonly used as a topical agent, imiquimod has chemical properties that are not favorable for systemic administration [63], which led to the testing of other TLR7 agonists such as 852A. 852A was well tolerated in metastatic melanoma patients and induced systemic inflammatory responses [64]. In animal models, 852A had significant antitumor activity and stimulated higher levels of type I IFN release [63].

PF-3512676 is an immunomodulating synthetic oligonucleotide that acts as a TLR9 agonist [257]. It is currently under development for the treatment of cancer both as monotherapy and in combination therapy, as well as an adjuvant for vaccines. It acts through TLR9 receptors present on B cells and plasmacytoid dendritic cells to stimulate B-cell proliferation, IFNα and natural killer (NK) cell activity. Used alone as a therapeutic agent, PF-3512676 had a favorable safety profile but only elicited moderate response rates in patients with advanced melanoma [71]. As an adjuvant to other therapeutic modalities, PF-3512676 was shown to be safe in melanoma patients using other modes of therapy such as CTLA-4 blockade [72, 73].

TLR modulators are also being tested in other skin malignancies. Mycosis fungoides (MF) is the most common form of cutaneous T-cell lymphoma (CTCL) and is characterized by malignant clinical proliferation of skin trafficking T-cells [258]. Skin lesions in MF include patches, plaques, tumors, hypopigmented lesions, and erythroderma. Treatment options range from light therapy,

retinoids, nitrogen mustard, topical steroids to systemic interferon [65]. TLR agonists have shown promise as a therapeutic approach – a preliminary pilot study of six patients with patch and plaque stage MF treated with topical imiquimod, a TLR7 agonist, 5 % cream three times a week for 12 weeks reported a histologic and clinical response rate of 50 % [65]. A phase I clinical study administered TLR9 agonist CpG oligodeoxynucleotide (ODN) to MF patients and demonstrated antitumor activity [74]. MF patients who failed standard treatment in a subsequent study using ODN had increased pDC infiltration as well as a decrease in regulatory T cells [75]. Skin lesion regression was noted in one-third of patients but the overall clinical response assessment was limited in this study due to the small patient size. Future studies may yield promising therapies for MF patients who do not respond to standard treatment approaches.

Ultraviolet Radiation

Ultraviolet radiation (UVR) is an established carcinogen that causes genetic lesions in keratinocytes and contributes to skin cancer development (see Chap. 10) [259]. UVR causes the formation of cyclobutane pyrimidine dimers (CPDs) and DNA single-strand breaks [260], which activates DNA repair enzymes that are vital for maintaining genome integrity. Irreversibly damaged keratinocytes that cannot be repaired undergo cell death and are sloughed off to maintain an intact skin barrier. Additionally, it has long been known that UVR causes widespread immune suppression by depleting Langerhans cells (LCs), inhibiting APC antigen presentation and upregulating immunoregulatory cytokines such as IL-10 [259]. UVR stimulates the upregulation of HSPs from keratinocytes that are known to stimulate TLRs (see section "Psoriasis") and lead to the release of IL-10 and TNFα [76]. Moreover, C3H/HeJ mice that are TLR4-hyporesponsive exhibit impaired TNF-α production after UVB exposure and are resistant to UVB suppression of CHS [52]. More recent studies have demonstrated that UVR can damage self noncoding RNA that contain stem-loop structures and activate TLR3 as DAMPs [261]. Additionally, TLR signaling may determine the form of cell death that takes place after UVR damage as deficiencies in TLR4-MyD88 axis led to increased cell survival along with upregulation of markers of necroptosis [53]. Therefore, multiple TLRs are activated after UVR exposure and have multiple downstream effects that may affect the development of malignant lesions.

The power of UV light and the importance of DNA repair machinery is demonstrated in xeroderma pigmentosum (XP), a rare, autosomal recessive disorder characterized by photosensitivity, premature skin aging, and malignant tumor development due to an inability to repair DNA damage induced by UV light [76]. Gaspari et al. [262] discovered that NK cells from XP patients had a defect in IFN production in response to poly-I:C (a TLR3 ligand) stimulation. Subsequent studies have further expanded on the role of TLRs in XP and the DNA repair machinery. TLR4 deficient animals expressed higher degrees of nucleotide excision repair after UV damage due to activation of XP complementation group A (XPA) expression [54]. The ligand involved in TLR4 stimulation was not studied but it will be interesting to determine whether PAMPs or DAMPs are involved in TLR4 activation after UVL damage. In contrast to the inhibitory role of TLR4, TLR7 agonist imiquimod was shown to enhance DNA repair gene expression and decreased DNA damage detected in local lymph nodes when applied topically [66]. Other repair functions in response to UV damage has been shown to be dependent on TLRs as well as TLR3 was shown to be required for effective skin barrier repair after UVR exposure [263]. Collectively, evidence suggests that TLRs play an important role in sensing and modulating the downstream response to UVR damage. Whether these TLR modulating properties by UVR can be harnessed to protect against DNA damage and prevent tumor development in XP patients remain to be investigated.

Conclusion

Since the discovery of TLRs more than 20 years ago, the family of PRRs continues to grow and be implicated in human disease. Evidence continues to accumulate to suggest that TLRs, the most well characterized group of PRRs, play an essential role in bridging innate and adaptive immune responses. Up to 13 mammalian TLRs have been identified and it is believed that TLRs 1–10 are functional in humans and that TLRs not only respond to PAMPs but also endogenous ligands produced after tissue damage coined DAMPs. Both PAMPs and DAMPs can contribute to the activation of TLRs, which has downstream effects on both innate and adaptive immunity (Fig. 2.2). Dysregulation in TLR activation can lead to the development of dermatological diseases such as psoriasis and allergic contact dermatitis. Thus, TLRs play an integral role in countless dermatologic diseases but many questions remain and future studies are necessary to address precise molecular mechanisms that are involved. It is certain that many more discoveries will be made to further characterize and understand this group of receptors, their role in skin diseases, as well as the potential to manipulate signaling through these TLRs to use them for diagnostic and treatment purposes.

Questions

1. Which of the following represent a negative regulator (inhibitor) of TLR function?
   A. IRAK-M
   B. TOLLIP
   C. SOCS-1
   D. All of the above
   E. None of the above

Correct answer: D-All of the above. IRAK-M, TOLLIP and SOCS-1 are all TLR negative regulators

2. Which skin disease have TLR negative regulators been associated?
   A. Non-melanoma skin cancer
   B. Psoriasis
   C. Atopic Dermatitis
   D. Cutaneous T-cell lymphoma

Correct answer: (C)-TOLLIP mutations have been associated with Atopic dermatitis. However, the exact role of these mutations in the pathophysiology of this common skin disease remains unclear

3. How do TLRs mediate pro-inflammatory cytokine production in acne vulgaris?
   A. PAMPs from P. acnes activate TLR2 and TLR4, inciting the production of pro-inflammatory cytokines
   B. PAMPs from S. aureus induce TLR2 activation
   C. TLRs are not involved in the pathophysiology of acne
   D. PAMPs from the pilosebacious unit activate TLR7,8,9

Correct answer: (A)-*P. acnes* microbial products such as LPS and peptidoglycan activate TLR2 and TLR4 to active the production of proinflammatory cytokines in the skin. It is thought that P. acnes strains in healthy controls may regulate TLR expression differently when compared to P. acnes strains in acne vulgaris patients

4. In allergic contact dermatitis (ACD), what is the predominant TLR involved in the pathophysiology of nickel allergy?
   A. TLR4
   B. TLR7
   C. TLR2
   D. TLR9
   E. None of the above

Correct answer: (A) Nickel, cobalt and palladium can bind and activate human TLR4s and activation of CHS. dependent on histidine residues that are specifically found in human TLR4, thus explaining why mice are naturally resistant to nickel-induced CHS

5. Why are mice genetically resistant to ACD to Nickel?
   A. Nickel does not penetrate mouse skin
   B. Their TLR are not activated by nickel
   C. Their Tregulatory cells suppress the response
   D. Mice have a high level of nickel in their diet

Correct answer: (B)-TLR4 in mice lacks the amino acid histidine in the extracellular domain. In humans, TLR4 normally expresses the amino acid histidine. TLR4 activation by nickel is dependent on histidine residues that are specifically found in human TLR4, thus explaining why mice are naturally resistant to nickel-induced CHS

6. How are TLRs involved in DNA repair?
   A. TLR sense DNA damage
   B. TLR activation directly induces a DNA repair response
   C. TLR activation triggers inflammation, which may stimulate DNA repair
   D. TLR7 agonists applied can increase DNA repair in the skin
   E. All of the above
   F. None of the above

Correct answer: (D)-TLR engagement may stimulate DNA repair by multiple mechanisms. This phenomenon is relevant to UV light exposure, and recovery of skin derived antigen presenting cells

7. Which of the following diseases is associated with impaired TLR signaling via TLR3?
   A. Discoid lupus
   B. Alopecia areata
   C. Psoriasis
   D. Xeroderma pigmentosa

Correct answer: (D)-XP patients NK cells are defective in IFN production in response to TLR3 stimulation

Innate Lymphoid Cells in the Skin

3

Szun S. Tay, Sioh Yang Tan, Nital Sumaria, Ben Roediger, and Wolfgang Weninger

Abstract

The skin forms the body's primary interface with the environment and, as such, is equipped with a network of immune cells to provide the first line of defense against infection and injury. Recently, a new family of lymphocyte-like immune cells has been described that does not express rearranged antigen receptors. These cells have been termed innate lymphoid cells (ILC), and comprise several subsets that are defined by the expression of certain transcription factors and cytokines. Emerging evidence has implicated ILC in the pathogenesis of inflammatory and neoplastic skin diseases. Here, we review the biology of ILC and their role in skin pathophysiology.

Keywords

Innate lymphoid cells • Cytokines • Cell receptors • Cell markers • Skin disease • Immune cell development • NK cells

Introduction

ILC are a heterogeneous family of innate effector cells that are characterised by their lymphoid morphology and absence of rearranged antigen receptors. ILC lack expression of lineage markers for T cells, B cells, myeloid cells and dendritic cells [85]. ILC have the ability to respond rapidly to environmental and pathogenic stimuli or other cytokines by producing 'signature' effector cytokines. Based on their cytokine secretion profiles and the expression of key transcription factors involved in their function, ILC have been grouped into three major subsets. Group 1 ILC, which include conventional natural killer (NK) cells, express the transcription factor T-bet and produce the Th1 cytokine IFN-γ; Group 2 ILC express the transcription factor GATA-3 and secrete the Th2 cytokines, in particular IL-5 and IL-13; Group 3 ILC express the retinoic acid receptor-related orphan nuclear receptor RORγt and secrete the Th17-associated cytokines IL-17 and/or IL-22. All three ILC subsets have been identified in mice and in humans, and are predominantly located at tissue barriers where they have roles in preserving epithelial integrity, restricting commensal bacterial spread, and providing immune defence against pathogens. ILC are also crucial for lymphoid tissue formation. ILC are some of the earliest responders to tissue injury, infection or tumorigenesis, prior to establishment of adaptive immune responses. Cytokines produced by ILC can also regulate stromal cells during homeostasis, or promote tissue remodelling and wound healing after injury or infection. Whilst ILC function in an antigen-independent manner, their cytokine responses may set the stage for subsequent adaptive

immune responses that might be conditioned by the cytokine milieu.

In addition to the gastrointestinal mucosal tissue and the lungs, ILC are also enriched in murine and human skin compared to the blood. Healthy human skin has been shown to harbour all three ILC subsets described, although their functions in the skin are not yet well understood. However, based on the roles of ILC in other organs, it is likely that skin-resident ILC are also involved in maintaining skin homeostasis, barrier integrity and in sensing of environmental and pathogenic insults. The inappropriate accumulation and activation of ILC contributes to several inflammatory conditions in the gut and lung. Recent studies have demonstrated that increased abundance of ILC2 and ILC3 are associated with skin lesions of patients suffering from atopic dermatitis and psoriasis, respectively. Therefore, increased understanding of ILC regulation and function during homeostasis, inflammation and infection could lead to better therapies and improved diagnoses of inflammatory skin conditions.

ILC Classification and Identification

ILC are absolutely dependent on signalling through the common cytokine gamma-chain (γc) for development, and these $CD45^+$ lineage-negative (Lin^-) ILC, with the notable exception of NK cells, also express the alpha chain of the IL-7 receptor (IL-7Rα, or CD127). Most murine ILC subsets also express CD90 (Thy1), Sca-1 and variable levels of the stem cell growth factor receptor, c-Kit (or CD117). In humans, all ILC subsets, except a subset of group 1 ILC, express CD127.

ILC are currently classified into three groups based on their distinct patterns of cytokine production [84]. Members of the three ILC groups also express distinct families of transcription factors and depend on different sets of transcription factors for their development and maintenance. The phenotypes of murine and human ILC are summarised in Table 3.1. ILC have been identified and characterised using a number of gene and protein expression studies, fate-mapping approaches, and in reporter and knockout mice [84], some details of which are described in the following sections.

Group 1 ILC

ILC1s produce the Th1 signature cytokine IFN-γ and express the transcription factor T-bet. They include conventional NK cells as well as several recently-discovered IFN-γ-producing ILC1 subsets in the tonsils and intestines. ILC1 have also been found in human skin.

Conventional NK cells are the prototypical members of Group 1 ILC as they produce large amounts of IFN-γ. They co-express the T-box transcription factors T-bet and eomesodermin (Eomes), which, together with E4bp4 (Nfil), is required for their development and/or maturation [86]. All NK cells depend on IL-15 signaling for their development, survival and maintenance. Mouse NK cells are identified by their expression of the natural cytotoxicity receptors (NCRs) NKp46, and in certain mouse strains, NK1.1. Mature $CD11b^{hi}CD27^{lo}$ and immature $CD27^{hi}CD11b^{lo}$ NK subsets are found in the spleen and bone marrow, whereas "tissue-resident" NK subsets are found in the liver, salivary glands, skin and uterus. In addition, there is a population of thymic-derived $CD127^+$ NK subset in mice. In humans, NK cells are identified by CD56 and CD16 expression. Both $CD56^{bright}CD16^-$ and $CD56^{dim}CD16^+$ NK cells are found in the blood and tissues. The $CD56^{dim}$ NK cells are highly cytotoxic and release perforin and granzyme upon encountering target cells, whereas $CD56^{bright}$ NK cells specialise in IFN-γ production in response to IL-12 and IL-18 [13]. NK cells also express germ line-encoded inhibitory and activating receptors of the C-type lectin-like family and immunoglobulin superfamily, which include the killer inhibitor receptors (KIR) (e.g., the Ly49 and CD158 series of molecules) and activating receptors (e.g., NKG2D, NKG2c) that control NK cell licensing and proliferation [46].

An additional ILC1 population, distinct from NK cells, was identified in 2013, in the tonsils and gut mucosa [6, 22, 45]. These ILC1 also express T-bet and NK cell-associated

Table 3.1 Surface phenotype of mouse and human ILC

		Mouse		Human	
		Unique	Shared	Unique	Shared
ILC1	NK	IL-12Rβ2	CD127 (not on NK) CD90 (not on NK, ILC1) CD117 (not on NK, ILC1, NCR- ILC3)	IL-12Rβ2	CD127 (not on some NK) IL-1R (all but NK) NKp46, NKp44 (on NK and NCR+ ILC3 only)
	ILC1	IL-12Rβ2		IL-12Rβ2	
ILC2		ST2, IL-17RB, ICOS, CD25		CRTH2, ST2, IL-17RB

Adapted from Spits et al. [84]

markers and produce IFN-γ but are developmentally and/or functionally distinct from NK cells. In particular, ILC1 derive from an Id2-expressing progenitor that does not give rise to NK cells and are dependent upon GATA-3 for their development, in contrast to NK cells. Phenotypically, non-NK ILC1 cells lack surface expression of the NK cell-specific Ly49 receptors, and possibly death receptors. Most ILC1s, including NK cells, also express the surface receptor IL-12Rβ2, consistent with their responsiveness to IL-12 stimulation.

One of the human non-NK ILC1 populations identified by Fuchs et al. within human tonsils was the NKp44$^+$CD103$^+$ subset [22]. The NKp44$^+$CD103$^+$ cells also secreted high amounts of IFN-γ when stimulated by IL-12 and IL-15, producing similar levels to that produced by blood CD56^{hi} conventional NK cells. Some of these NKp44$^+$CD103$^+$ cells expressed perforin and granzymes and could degranulate, but unlike NK cells, they did not respond to IL-18 stimulation. These cells were also distinct from ILC3 (see below) as they did not respond to IL-23 stimulation, and they expressed higher levels of T-bet and lower levels of RORγt and the aryl hydrocarbon receptor (AhR) when compared to ILC3. Importantly, these cells were conserved in *Rorc*$^{-/-}$ and *Ahr*$^{-/-}$ mice which lacked ILC3. The murine counterparts of the NKp44$^+$CD103$^+$ subset were identified as CD160$^+$NKp46$^+$NK1.1$^+$ cells in the intestine and tonsil. These cells were absent in Nfil3- or T-bet-deficient mice but still present in IL-15Rα-deficient mice, in contrast to conventional NK cells. Non-NK ILC1 localized specifically in the epithelial layer of the tonsils and in the intraepithelial layer of the small intestine, and had a phenotype that resembled tissue-resident memory CD8$^+$ T cells (i.e., high levels of αEβ7 integrin and CD49a).

Independently, Bernink et al. [6] identified a population of cells in human tonsils that expressed T-bet and produced IFN-γ when stimulated with IL-12. After human ILC2 (CRTH2$^+$) and ILC3 (cKit$^+$NKp44$^+$) were excluded from their analyses (discussed below), two additional populations were observed in the tonsils: the cKit$^+$NKp44$^-$ and cKit$^-$NKp44$^-$. The cKit$^-$NKp44$^-$ population produced IFN-γ but was distinct from the ILC1 population identified by Fuchs et al.: these cells did not express NKp44 and localized to the lamina propria instead of the intraepithelial layer of the small intestine. These cells were also distinct from NK cells, as they did not express perforin and granzyme, nor did they express the NK cell markers CD16, CD94 and IL-15Rα. Interestingly, Bernink et al. observed that a portion of these ILC1 could differentiate from cKit$^+$NKp44$^-$RORγt$^+$ ILC3 precursors that had been isolated from both foetal gut and tonsil when they were stimulated with IL-2 and IL-12. This plasticity of ILC1 development from ILC3 to form an "ex-RORγt" subset was consistent with that reported in a RORγt fate-mapping study [95], where ILC3 cells in mice were shown to convert into IFN-γ producers (potentially ILC1). Therefore, there is some degree of plasticity between the ILC1 and ILC3 subsets, and the level of T-bet expression was suggested to promote the ILC3 to ILC1 differentiation (see later). Nonetheless, there also remains a separate ILC1 population that develops independently of RORγt. Notably, no ILC1 were found in the foetal gut, suggesting they may develop after colonisation with commensals.

Another group of researchers identified non-NK ILC1 after investigating the role of T-bet in ILC3 development [45]. They found that a third of NCR$^-$ ILC3 and almost all NCR$^+$ ILC3 in the lamina propria expressed T-bet (see later). They also described a population of CCR6$^-$RORγt$^+$T-bet$^+$ ILC that differentiated from the CCR6$^-$RORγt$^+$ ILC. These cells emerged postnatally under control of the aryl hydrocarbon receptor (AhR) in response to environmental stimuli (presumably commensal microbiota) and IL-23 stimulation. The increased expression of T-bet in this population in turn promoted expression of IFN-γ and NKp46.

Therefore, ILC1s are currently believed to contain IL-7Rα$^+$ conventional NK (cNK) cells, intraepithelial ILC1s [22] and "ex-RORγt" ILC3s [6, 45, 95].

Group 2 ILC

ILC2 produce the Th2 cytokines IL-5, IL-13, as well as IL-4, IL-9 and amphiregulin in response to IL-25 and IL-33, which may be further augmented by TSLP. ILC2 depend on the transcription factors GATA-binding protein 3 (GATA3) and the RORα for their development and function [35, 58, 99]. What is now known as ILC2 were first observed in 2001 as a non-B/non-T population that produces IL-5 and IL-13 in response to intranasal IL-25 administration [21]. In 2006, a population of Lin$^-$cKit$^+$CD90.2$^+$ cells was described in the context of helminth infection in mice, whereby IL-25-dependent expulsion of *Nippostrongylus brasiliensis* occurred independently of B and T cells [20]. However, it was not until 2010 that ILC2 cells were properly phenotyped and functionally characterised, in which they were identified as "natural helper" cells [60], "nuocytes" [61] or "innate helper" cells [69], before the consensus term ILC2 was coined.

Murine ILC2 consistently lack expression of lineage markers CD3, B220, CD11b, Ter119 and Gr-1 [60, 69]. They express CD127 and the IL-17BR (IL-25R) and ST2 (IL-33R) receptors, consistent with their ability to respond to IL-25 and/or IL-33, respectively. Murine ILC2 cells, defined as a Lin$^-$Sca$^-$1$^+$Thy1.1$^+$CD127$^+$T1/ST2$^+$ population, were first found in the mesenteric fat-associated lymphoid clusters, mesenteric lymph nodes, spleen, liver and intestines of mice, and have since been detected in the bone marrow, liver, blood, airways and the skin. There is some variability in

expression of other markers on ILC2, which may be due to the activation status and tissue-specificity of ILC2. For instance, lung ILC2 express lower expression of Sca-1 and CCR9 compared to those from the mesenteric lymph nodes (mLN); and skin ILC2 express CD103. Murine ILC2 also express the high-affinity IL-2 receptor alpha chain (IL-2Rα, CD25) [73], ICOS, and variable levels of major histocompatibility class II molecules and c-Kit (CD117) [33, 53, 54, 61], consistent with the fact that they do not rely upon stem cell factor (SCF) signaling for survival [60, 69, 72]. ILC2, in contrast to the other ILC subsets, do not express CD2, which further serves to discriminate ILC2 cells from conventional NK cells and most T cells [72]. ILC2 also lack the NK and ILC1-associated markers NK1.1 and NKp46, and unlike ILC1 and ILC3, they have not been shown to develop into other ILC.

The human ILC2 equivalents were first identified in the foetal gut and lung tissue [58] as a $Lin^{-}CD127^{+}CD45^{hi}$ population that also expressed transcripts encoding IL-13, IL-17RB, ST2 and CRTH2 but low levels of RORγt. ILC2 have also been identified in human blood, skin, lungs and nasal mucosa. In humans, ILC2 cells are identified by lack of expression of lineage markers CD3, CD19, CD94, CD1a, CD11c, CD123, BDCA2, CD14, FceR1 and CD34 and their expression of CD127, the pan-human-ILC marker CD161 and, uniquely, CRTH2 [58]. Similar to murine ILC2, human ILC2 also express CD25 [59] and variable levels of c-Kit, but do not express NKp44. Human ILC2 cells, like their murine counterparts, are also responsive to IL-25, IL-33 and TSLP, indicative of functional receptors to these cytokines [55, 57, 58, 89].

Group 3 ILC

ILC3 depend on the transcription factor RORγt and produce IL-17 and/or IL-22 in response to IL-1β and IL-23 stimulation [34, 82]. ILC3 are a complex family. The prototypical member is the lymphoid tissue-inducer (LTi) cell that is crucial for lymphoid organ formation during embryogenesis (Peyer's patches, lamina propria) and in the neonate (cryptopatches and isolated lymphoid follicles), and that also has a role in lymphoid organ repair after infection [51, 52]. These cells express CD127, CD117, α4β7, CD4 and CCR6 in mice, although a population of $CD4^{-}$ LTi also exists. Two other non-LTi ILC3 subsets, distinguished as those that express natural cytotoxicity receptors (NCR) and those that do not, were also identified in nonlymphoid tissues, i.e., the gut mucosa and tonsils [10, 14, 50, 75, 77] where they are important for barrier protection. They include $CCR6^{+}CD4^{-}$ cells and the $CCR6^{-/lo}$ population that are rare in the foetal liver but expands rapidly during the first month of life dependent upon the expression of AhR. The $CCR6^{-/lo}$ ILC3s are further subdivided into an $NKp46^{-}$ and $NKp46^{+}$ subsets, i.e., NCR^{-} ILC3 and NCR^{+} ILC3.

The NCR^{-} ILC3 cells do not express IL-17 or CD4 but produce IL-22. The subset now collectively termed NCR^{+} ILC3 were also known as NCR22 cells, $NKp46^{+}$ ILC, ILC22s and NKR-LTi. Although these cells expressed NKp46, they are functionally distinct from NK cells as they do not express cytotoxic molecules such as perforin, granzymes and death receptors. These cells also did not produce IFNγ or TNFα, but instead expressed IL-22. They are also developmentally distinct from NK cells, as fate-mapping experiments using RORγt-reporter mice showed that many of these cells had a history of RORγt expression whilst NK cells never did [50, 76, 77].

ILC Development, Diversification and Plasticity

The lineage-specific development, function and maintenance of ILC depend on a restricted set of transcription factors. Strikingly, these are the same set of transcription factors, i.e., T-bet, GATA-3 and RORγt, that are expressed by distinct $CD4^{+}$ T helper (Th) cells, to coordinate the developmental and functional diversification of Th1, Th2 and Th17 subsets (Fig. 3.1). These transcription factors regulate a similar gene expression program in ILC as they do in T cells, resulting in unique developmental programs, which endow the individual ILC subsets with their specific effector functions. This striking parallel has led to the notion that ILC represent innate counterparts of Th cells, and are important for early immune defence, whilst setting the stage for coordination of the cytokine milieu between innate and adaptive immunity.

ILC are derived from the common lymphoid progenitor (CLP), which is derived from a pluripotent haematopoietic stem cell that has successively shed erythroid and myeloid potential. All ILC also rely on the common γ-chain (γc) used by various cytokine receptors and show a developmental requirement for the transcriptional regulator Id2 (inhibitor of DNA binding 2). Accordingly, genetic ablation of Id2 cripples the development of all known ILC lineages [100]. ILC are also absent in γc-deficient mice [76]. Expression of Id2 in the CLP is thought to inhibit its developmental potential of CLP into T and B cells while favouring ILC generation [35].

Earlier work had identified CLPs that expressed the integrin α4β7 in the foetal liver that were able to differentiate into NK cells and all subsets of $ROR\gamma t^{+}$ ILC [68]. The severe reduction of $\alpha4\beta7^{+}$ CLPs in *Id2*-deficient mice indicates that Id2 lies upstream of Rorγt in the developmental pathway [11]. Hoyler et al. had also previously identified a precursor of ILC2 cells, termed ILC2P. Clues to the identity of the 'elusive' common ILC precursor was recently further revealed. The use of the Id2 reporter mouse by Klose et al. led to

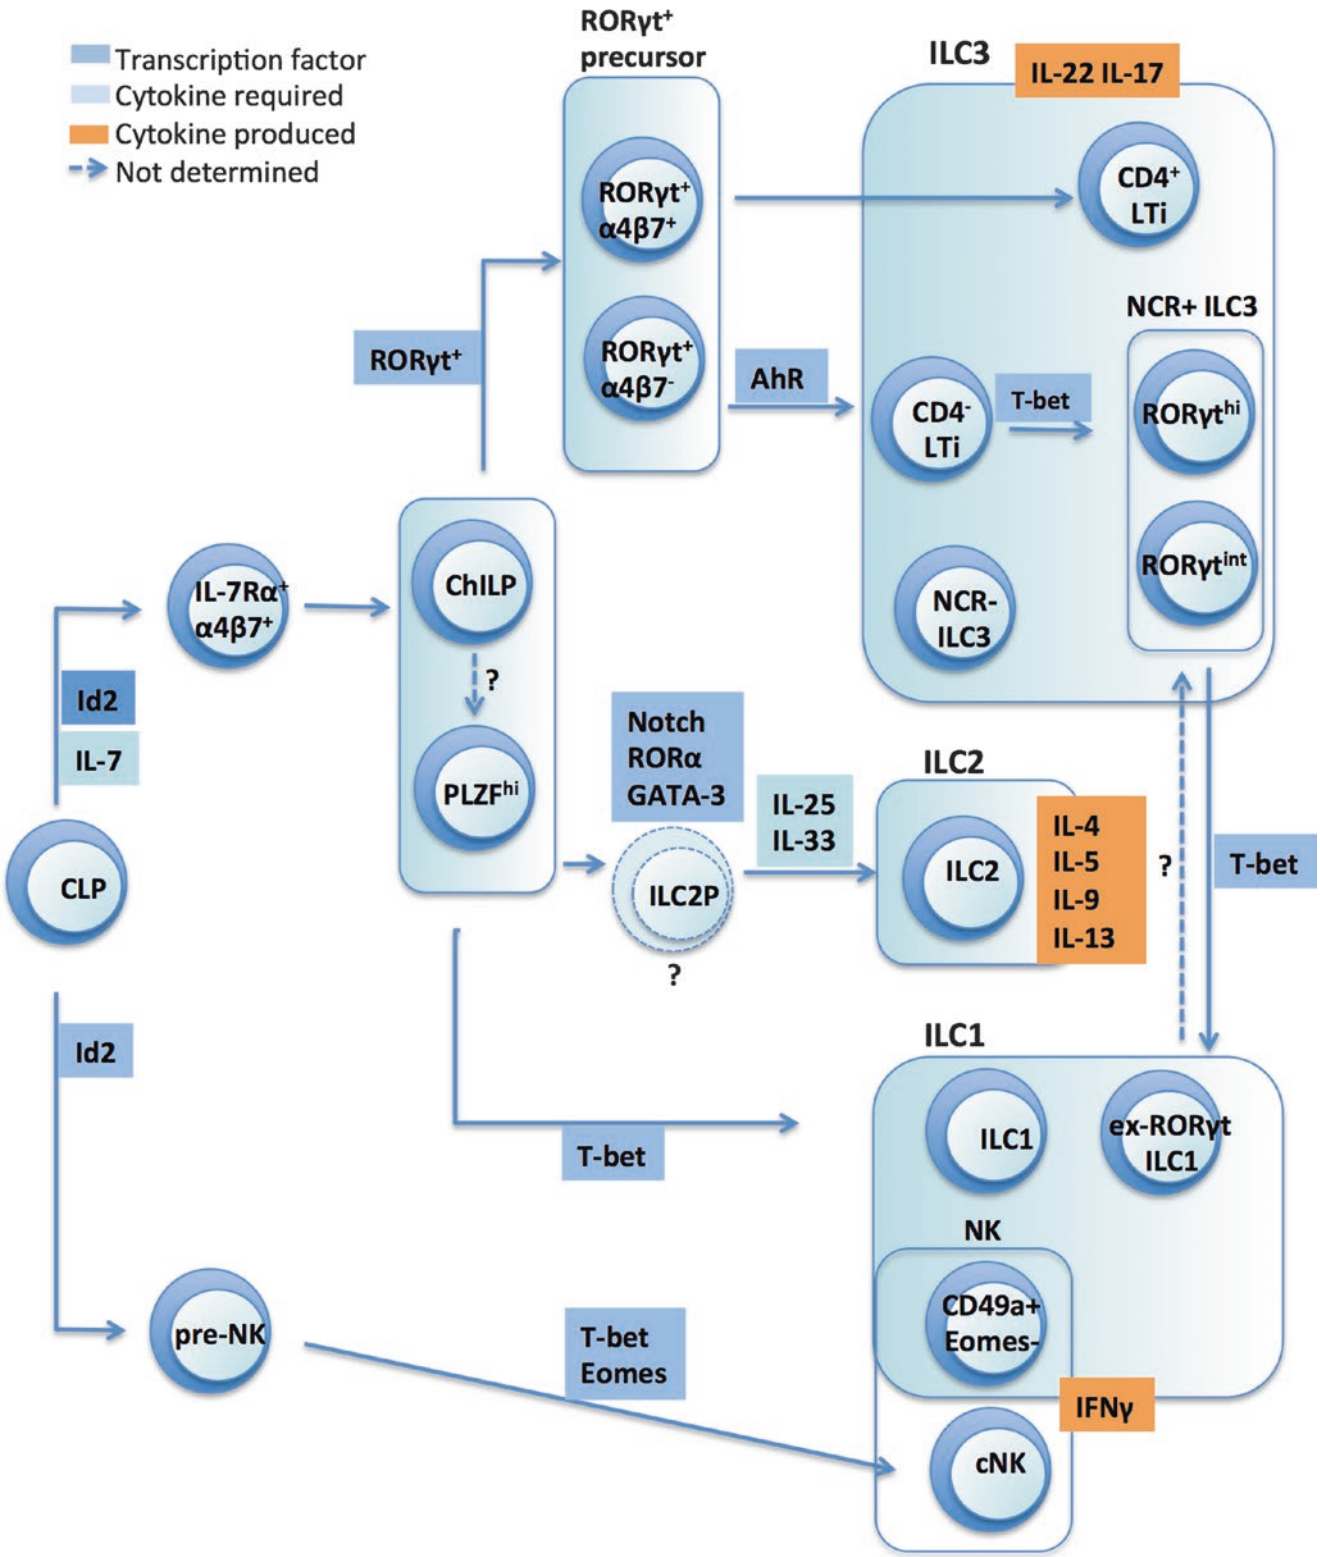

Fig. 3.1 ILC development is orchestrated by transcription factors. Inhibitor of DNA binding 2 (*Id2*), Retinoid-related orphan receptor (*ROR*), eomesdersmin (*Eomes*), Aryl hydrocarbon receptor (*AhR*), conventional NK cell (*cNK*), common helper-like innate lymphoid cell precursor (*ChiLP*), ILC2 precursor (*ILC2P*)

identification of a rare Id2$^+$α4β7$^+$Lin$^-$IL-7Rα$^+$ population in the bone marrow, which they termed ChILP (for common helper ILC precursor) [44]. Whilst the ChILP expresses the integrin α4β7, it does not express Flt3 or CD122, the recently described NK progenitor marker. It also does not express CD25 and may hence be distinct from the CD25$^+$IL-33R$^+$ ILC2P described by Hoyler et al. [35]. In adoptive transfer studies, the ChILP gave rise to ILC2 cells and ILC3 cells (including both LTi and NKp46$^+$ ILC3 subsets), as well as an unusual non-NK ILC1 subset (which was CD49a$^+$NKp46$^+$T-bet$^+$IL-7Rα$^+$ but did not express Eomes). Notably, the ChILP did not give rise to conventional NK cell subsets.

Bendelac and colleagues created PLZF (promyelocytic zinc finger) fate-mapping reporter mice, chiefly to pursue their interest in NKT development [12]. As predicted, they found that NKT cells expressed GFP and were also 'fate-mapped', but, unexpectedly, also discovered a large fraction of GFP$^-$ ILC that were fate-mapped, i.e., had expressed PLZF at some stage during their development. They showed that there was a PLZF^{hi} population within the α4β7$^+$Lin$^-$IL-7Rα$^+$ progenitor cells that gave rise to ILC2 cells, mucosal CD4$^-$ ILC3 cells, and the same peculiar NKp46$^+$CD49a$^+$ ILC1 liver subset described by Diefenbach and colleagues [44]. Therefore, both the ChILP and the PLZF^{hi} progenitors were α4β7$^+$Lin$^-$IL-7Rα$^+$ and generated ILC2, ILC3, and the peculiar hepatic NK subset (now thought to correspond to tissue-resident NK cells), but did not give rise to conventional NK cells, suggesting they may be overlapping populations. Indeed, a large fraction of ChILP express PLZF. On the other hand, PLZF^{hi} precursors also express Id2 and could be differentiated from PLZF$^-$α4β7$^+$Lin$^-$IL-7Rα$^+$ cells in vitro. Since the ChILP generates a broader range of ILC3 cells (including CD4$^+$ LTi cells), it may be possible that the PLZF^{hi} ILC precursor is a subset of the ChILP population but this remains to be determined.

Downstream of this committed ILC progenitor, the induction of GATA3, RORα, T-bet and RORγt transcription factors, together with contributions from the Notch signalling pathway and additional transcription factors such as TCF-1 and TCF-7, governs the polarization of individual ILC subsets (described below and recently reviewed by Tanriver and Diefenbach [87]).

NK cells and ILC1 Unlike ILC, NK cells do not require RORγt or IL-7 for their development but are dependent upon IL-15. There are several developmentally distinct NK subsets, including bone marrow and thymic-derived NK cells, conventional and tissue-resident subsets, that are developmentally driven by the transcription factors Tbx21, and Eomes, and as recently determined, E4bp4 (Nfil3), which promotes transcription of Eomes and Id2 GATA-3 [36]. A pre-pro NK cell (Lin$^-$CD122$^+$NK1.1$^-$CD49b$^-$Id2$^-$GFP$^+$) was also recently identified in the Id2-GFP reporter mouse [9]. Eomes is up-regulated during the transition of CD49b$^-$ immature NK cells to CD49b$^+$ mature NK cells during which they acquire effector function [26]. In contrast, T-bet expression is already found in immature NK cells and T-bet regulates the egress of mature NK cells from the bone marrow [91]. Recently, two groups identified a subset of liver CD49a$^+$ NK cells that developed independently of Eomes and E4bp4 (Nfil3), and that were thus distinct from 'conventional' Eomes$^+$ NK cells [15, 80]. This peculiar liver NK population was also generated from committed ILC precursors identified by Bendelac's and Diefenbach's groups and further studies might reveal if there are additional NK cell-restricted ILC precursors [12, 44].

From their investigations of ILC3 development using RORγt fate-mapping, Klose et al. identified CD127$^+$ ILC1s, primarily found in the intestine, that are distinguished from *bona fide* NK cells [45]. Hence, whilst all IL-15Rα$^+$ NK cells are RORγt fate map negative (RORγt^{fm-}) and did not have a history of RORγt expression, two additional CD127$^+$NK1.1$^+$NKp46$^+$ ILC1 subsets were identified as either RORγt^{fm+} or RORγt^{fm-}. In humans, Fuchs et al. further identified a subset of intraepithelial ILC1s (CD3$^-$CD56$^+$NKp44$^+$CD103$^+$) that expressed T-bet but did not express RORγt. Their development required expression of E4bp4 and T-bet. This subset produced IFN-γ after stimulation with IL-15 and IL-12, displayed some cytotoxic activity, but was still present in IL-15Rα-deficient mice. Bernink et al. identified another ILC1 subset (CD127$^+$Kit$^-$NKp44$^-$) that resided in the lamina propria of the intestine and expressed T-bet and low levels of RORγt mRNA [6]. Interestingly, cells with this phenotype could also be derived from the RORγt$^+$ ILC3 upon IL-12 stimulation. These "ex-RORγt+" cells indicate that there exists some developmental plasticity between ILC3 and ILC1, which has not been described for ILC2.

ILC2 are developmentally dependent upon on the transcription factors Id2 [35, 60], GATA-3 [35] and RORα [28, 29, 97]. In contrast to ILC3s, ILC2s are not well represented in the newborn gut but are generated in the bone marrow. An ILC2 precursor (ILC2P) was identified in earlier studies in the bone marrow, which is defined as Lin$^-$Sca-1^{hi}Id2^{hi}GATA-3^{hi} ('LSIG cell'). This precursor expressed IL-33R and IL-17RB but lacked KLRG1 expression. IL-33 stimulation could convert these cells into strong producers of IL-5 and IL-13. GATA-3 is required for the differentiation of ILC2Ps, as well as the peripheral maintenance of mature ILC2s [35]. Furthermore, two recent studies revealed the additional functions of GATA-3 in dose-dependent control of ILC2 development and intracellular phosphorylation pathways [23, 43]. ILC2 also express high levels of RORα, which is required for their development. Staggerer mice (*Rora*$^{sg/sg}$), which carry a functional null mutation of RORα, have an intrinsic defect in the development of ILC2s and are also impaired in their

ability to clear worm infection [97]. In addition to GATA-3 and RORα, T-cell factor 1 (TCF-1), acting downstream of Notch signalling, is also required for ILC2 development.

ILC3 depend on the transcription factor RORγt. ILC3 include LTi cells that are crucial for lymphoid organ formation [45, 95] and in the foetal liver, the Lin$^-$α4β7$^+$IL-7Rα$^+$ progenitor differentiates into LTi precursors upon Id2 and Notch signaling [11]. The additional RORγt$^+$ ILC3 population resides in the intestinal lamina propria and can be further subdivided into CCR6$^+$CD4$^-$ cells and a CCR6$^{-/lo}$ population that expand in the intestines during the first month of life, requiring AhR expression. The CCR6$^{-/lo}$ ILC3s are further subdivided into NKp46$^-$ and NKp46$^+$ subsets, i.e., NCR$^-$ ILC3 and NCR$^+$ ILC3. In addition to RORγt, expression of T-bet is also important for the generation of some ILC3. Hence, T-bet is highly expressed by NCR$^+$ ILC3 in the mouse lamina propria [45, 79], and together with TCF-1 is also involved in the differentiation of some NCR$^-$ ILC3 to NCR$^+$ ILC3 [45, 70, 79]. It has been suggested that an increasing T-bet gradient controls the sequential upregulation of NKp46 and NK1.1 on NCR$^-$ cells with the concomitant downregulation of RORγt [45, 95]. Rankin et al. recently showed that T-bet was indeed an essential transcription factor essential for the NCR$^+$ ILC3 population, as NCR$^+$ ILC3 were absent in T-bet-deficient mice. The progenitor of LTi, NCR$^-$ ILC3 and NCR$^+$ ILC3 had been a matter of controversy, but in the same study, Rankin et al. showed that NKp46$^+$ ILC3 was derived only from the CD4$^-$ LTi population. Therefore, NCR$^+$ ILC3 and CD4$^-$ LTi were distinct from CD4$^+$ LTi and may be generated from *bona fide* Rorγt$^+$α4β7$^-$ subset which also gives rise to a significant population of NKp46$^+$ cells.

The lineage relationships between ILC populations and the developmental plasticity between ILC subsets that might be driven in response to environmental stimuli, is an exciting area of research. Recent information on the developmental pathways of mouse ILC has further led researchers to suggest that NK cells and CD127$^+$ ILC could be considered innate forms of CD8 and CD4 T cells, respectively [31]. It is fascinating that the same conserved set of cell fate-determining transcription factors were 'selected' to drive the development and diversification of innate lymphoid cells, as well as T cells, their more contemporary counterparts.

ILC in the Healthy Skin

Three groups recently determined the composition of ILC subsets in human adult skin, which was found to harbour all the ILC subsets described to date [18, 89, 94]. Dyring-Andersen et al. analysed cells isolated from dermal explants that were cultured in IL-2 for 11 days [18]. Since the lineage cocktail they used for exclusion of non-ILC did not include the NK cell markers, NK cells were also included in their analyses. The expression of CD56 and RORγt was used to delineate the ILC3, ILC2 and NK cell subsets. Hence, RORγt$^+$CD56$^+$ cells were identified as the NCR$^+$ ILC3 population. This NCR$^+$ ILC3 were also shown to express NKp44, NKp46 and CD117. The RORγt$^+$CD56$^-$ cells that were CD117$^+$ were termed NCR$^-$ ILC3, whereas RORγt$^-$CD56$^-$ cells were identified as NK cells after the exclusion of ILC2 (which lacked NCR expression) within this population. In healthy skin, ILC2 and NCR$^-$ ILC3 were the most prevalent subsets and total ILC was estimated to constitute ~9 % of the CD45$^+$ cells. In contrast, Teunissen et al. and Villanova et al. examined freshly prepared cells from whole skin, or cells prepared from separated dermis and epidermis, in addition to explant cultures. In both studies, skin ILC were first identified as CD45$^+$Lin$^-$CD127$^+$ populations, thereby excluding most NK cells. The CD45$^+$Lin$^-$CD127^{hi} ILC were reported to represent ~1.3 % of CD45$^+$ cells. In both of these studies, skin ILC2 were identified by CRTH2 expression, and the remaining subsets were distinguished by CD117 and NKp44 expression: CD117$^+$NKp44$^+$ cells were identified as NCR$^+$ ILC3 and CD117$^+$NKp44$^-$ cells were identified as NCR$^-$ ILC3, whereas subsets that lacked expression of both CD117 and NKp44, but expressed CD161, were identified as non-NK ILC1. The ILC2, ILC1 and NCR$^-$ ILC3 populations were present in similar proportions in freshly isolated dermal cells. However, NCR$^+$ ILC3 were notably rare in these samples. Instead, NCR$^+$ ILC3 were present in significant proportions in dermal explant cultures, consistent with the representation of ILC3 in explants observed by Dyring-Andersen et al. Teunissen et al. further showed that isolated NCR$^-$ ILC3 could convert into NCR$^+$ ILC3 when stimulated with IL-1β and IL-23 in vitro. This plasticity between ILC3 and ILC1 was similar to that reported for NCR$^-$ ILC3 isolated from human tonsils and foetal intestine, which could differentiate into NCR$^+$ ILC3 after IL-1 and IL-23 stimulation [6]. Villanova et al. also showed that CD3$^-$IL17$^+$ cells could be found in both the dermis and epidermis of healthy skin, whereas CD3$^-$IL-22$^+$ cells could only be identified in the epidermis, but not the dermis [94]. Compared to the blood which contained <1 % of ILC, the skin was enriched for ILC. The blood also comprised ILC that had skin-homing potential, as ILC in healthy control blood expressed CLA at high frequencies (~33 %) compared to T cells (11–18 %). CLA expression was particularly high on the NCR$^-$ ILC3 subset. Thus, ILC could potentially migrate into and populate the skin, although the cues that guide this process are still unknown.

ILC2, ILC3 and NK cells have also been positively identified in the mouse dermis [40, 64, 72, 90]. ILC2 and ILC3 accumulation have been described in a few studies in the context of atopic dermatitis and psoriasis, respectively. As

the skin ILC populations are only recently beginning to be mapped, some key functions of ILC in other tissues will be discussed in the following sections to provide insight into their potential roles within the skin.

Functional Specialisation of ILC and Their Potential Roles in the Skin

Group 1 Innate Lymphoid Cells

In addition to IFN-γ, NK cells produce cytotoxic molecules including granzyme A, perforin and death receptors, which are crucial to their key function of eliminating infected cells or tumours. Their function within the skin is less clear, and whether NK cells are involved in the pathogenesis of inflammatory diseases, such as psoriasis, remains controversial. NK cells have been detected in psoriatic skin [8, 63, 90], and are thought to exacerbate skin inflammation. Some leukocytes isolated from biopsies from psoriatic skin showed a $CD56^{bright}$ $CD16^{-}$ phenotype, which classifies them as either *bona fide* NK cells and/or ILC1 [63]. Nevertheless, a cell population that expressed the NK inhibitory receptors CD158b, CD94 and NKG2A, therefore more likely representing NK cells, were also found in psoriatic lesions [8]. In contrast, a recent study observed a substantially lower percentage of $CD57^{+}CD56^{+}CD16^{+}$ NK cells in lesional psoriatic skin compared to control skin. NK cells were also decreased in the peripheral blood of psoriatic patients [49]. Some evidence in support of a role for NK cells in psoriasis pathogenesis came from a (SCID) mouse xenograft model, whereby NK cells from psoriatic, but not normal donors that were injected into autologous non-lesional human skin grafts could induce histopathology that resembled psoriasis. In summary, the role of NK cells in the skin during homeostasis and inflammation remains unclear.

The other ILC1 subsets are distinct from NK cells in development and function. These cells have been described in mucosal tissue, and the non-NK ILC1 subset has also been identified in human skin. Non-NK ILC1s express T-bet and produced IFN-γ upon IL-12, IL-15 or IL-18 stimulation [6, 22, 45]. These ILC1 populations include the $NKp44^{+}CD103^{+}$ cells first described within human tonsils. Their murine counterparts reside in the intraepithelial layer of the tonsil and small intestine. Based on their tissue localisation and their phenotype, which resembles tissue-resident memory $CD8^{+}$ T cells (T_{RM}; $\alpha E\beta 7^{hi}CD49a^{hi}$) that are observed after viral infection, the ILC1 cells identified in human skin might be viewed as the innate counterparts of T_{RM} which are poised for prompt effector functions. It is possible that epidermis-associated ILC1 might provide early responses to stress or infection. Notably, some of these ILC1 bear hallmarks of TGF-beta imprinting (i.e., they express CD103, CD9 and NEDD), suggesting that skin ILC1 might be modulated by this cytokine, similarly to Langerhans cells.

The second subset of ILC1 was identified by Bernink et al. in human tonsils, and in the intestinal lamina propria, but was not localized to the epithelium [6]. These cells also produced IFN-γ in response to IL-12 (instead of IL-18 and IL-15) but were not cytotoxic. The third description of ILC1 was by Klose et al., who identified a population of $CCR6^{-}ROR\gamma t^{+}T\text{-}bet^{+}$ ILC1 that differentiated from the $CCR6^{-}ROR\gamma t^{+}$ ILC. In the gut at least, these ILC1 may impact protection and pathology. For instance, CCR6-$ROR\gamma t^{+}$ ILC that produced IFN-γ mediated protective immunity against *Salmonella typhimurium* infection by promoting mucus secretion. These early IFN-γ responses might sensitize antigen-presenting cells and shape the local microenvironment to influence subsequent effector T cell responses. Conversely, ILC1 can also contribute to intestinal pathology. Both the intraepithelial $CD56^{+}NKp44^{+}CD103^{+}$ subset and the $CD56^{-}c\text{-}Kit^{-}NKp44^{-}$ subset in the lamina propria were increased in the inflamed ileum mucosa of patients with Crohn's disease. Murine ILC1 have also been shown to accumulate in two mouse models of gut pathology, i.e., DSS-induced gut inflammation in mice reconstituted with human PBMC, and in an innate immune-mediated colitis model, in which $RAG^{-/-}$ mice were administered agonistic anti-CD40. Whether they have similar dual roles in the skin remains to be elucidated.

Group 2 ILC Functions

ILC2 are found in the respiratory and gastrointestinal tissues as well as in skin. Whilst ILC2 were originally described as important in protective type 2 immunity against helminth infection, studies from mouse models of asthma and atopic dermatitis also suggest a role for ILC2 in promoting allergic inflammation.

ILC2 in Airway Allergic Inflammation

Allergic inflammation is characterized by increased expression of Th2 cytokines (IL-4, IL-5, and IL-13), resulting in tissue eosinophilia, mast cell degranulation, mucus production and IgE production. Although allergic responses are traditionally thought to be primarily driven by $CD4^{+}$ Th2 cells, there is increasing evidence that ILC2 are also important, as they too produce significant amounts of IL-5 and IL-13, both constitutively and upon activation. ILC2 have been shown to contribute to type 2 lung inflammation in murine models of allergic airway inflammation induced by different allergens, including fungal [4], house dust mite, glycolipid [41], or ovalbumin [2, 28, 29, 42] in the absence of T cell-derived cytokines. In these models, ILC2 can be activated by epithelial-derived cytokines IL-25, IL-33, and TSLP to produce

IL-5 and IL-13, as well as IL-9, effector cytokines which contribute to airway hyperreactivity, eosinophilia and mucus production. Under certain conditions, lung ILC2 are also able to produce IL-4, for instance, when stimulated with TSLP and leukotriene D4 [17]. Overall, these reports suggest that ILC2 can direct distinct pathogenic lung inflammatory responses depending on their various cytokines produced. On the other hand, ILC2 has been shown to produce the EGFR ligand amphiregulin to promote epithelial regeneration after allergen or viral challenge [17, 59]. Therefore, ILC2 can have dual roles in pathogenecity and repair in epithelial tissues, and the dysregulation or inappropriate activation of ILC2 are associated with allergic responses that are classically thought to be driven by $CD4^+$ Th2 cells.

ILC2 in the Skin

Apart from the gastrointestinal tract, lymphoid tissue, lungs and airway mucosa, ILC2 have been identified in both murine and human skin. In murine skin, ILC2 preferentially localise in the dermis, where they constitute 5-10 % of all dermal $CD45^+$ cells [72]. Murine dermal ILC2 are highly enriched in the skin compared to the blood and to other tissues (with the exception of fat tissue). Consistent with the developmental requirements of all ILC subsets, dermal ILC2 are absent in $Id2^{-/-}$, $IL7^{-/-}$ and $Rag\text{-}1^{-/-}$ mice. Interestingly, dermal ILC2 were enriched in $RAG^{-/-}$ mice, suggesting that they may share and compete for survival factors with T cells that are otherwise present in wildtype murine skin.

The ILC2 in murine dermis differ slightly from those found in other organs: they express CD103, which recognizes E cadherin, and they are c-Kit negative, suggesting that there are local factors that dictate ILC2 phenotype and function in the skin. Dermal ILC2 also express CXCR6, which enabled Roediger et al. to capture ILC2 behaviour in the dermis of $CXCR6\text{-}eGFP^{+/-}$ mice using intravital multiphoton microscopy [72]. The dermal ILC2 cells displayed a patrolling movement which was slower compared to T cells. They were also observed to make prolonged contacts (of up to 30 min) with mast cells. Functionally, during steady-state, ILC2 were found to be the primary contributors to homeostatic IL-13 production in the skin. Roediger et al. further found that IL-9 enhanced mast cell release of IL-6 and TNF-α *ex vivo*, while IL-13 had the opposite effect and suppressed mast cell release of IL-6 and TNF-α [72]. It was postulated that one of the functions of ILC2 in steady-state could be to suppress mast cell activation through constitutive IL-13 production.

ILC2 have also been identified in healthy human skin [40, 74, 89]. Human skin ILC2, like other ILC subsets, does not express the common leukocyte lineage markers. Human ILC2 express CD127 and CD161, and are further distinguished from other ILC by expression of CRTH2, ICOS, CD25, IL33R, TSLPR and IL-25R. Compared with the paucity of circulating ILC2 in the blood (<0.2 % of lymphoid cells), ILC2s are highly enriched in healthy human skin tissue (up to almost 3 % of lymphoid cells). Furthermore, a significant proportion of skin ILC2 expressed the skin-homing chemokine receptors CCR4, CCR10 and CLA, and thus may be distinct from circulating ILC2. Interestingly, Salimi showed that whilst human ILC2 do not express the NK cell-related KIRs, NKp46 and NKp44, they expressed KLRG1 [74]. The authors demonstrated that the interaction of E-cadherin, an adhesion protein important for maintaining epithelial integrity, with KLRG1 on ILC2 inhibited production of cytokines and amphiregulin in vitro. They proposed that expression of KLRG1 may provide a barrier-sensing mechanism, whereby the normal activity of ILC2 is dampened by keratinocytes or LCs that migrate through the dermis. Upon the loss or cleavage of E-cadherin during skin inflammation, such as that often observed during atopic dermatitis [92], ILC2 inhibition may be discontinued, resulting in their inappropriate activation [74].

The enrichment of ILC2 in the skin suggests they may have important roles in homeostasis and barrier defence. It has also been proposed that ILC2 may have a role in skin homeostasis, as they also produce amphiregulin, may participate in skin remodelling by stimulating keratinocyte proliferation and promoting wound healing responses. Studies that expand upon our understanding of their interactions with other skin-resident cell types would help us decipher their roles and how they contribute to immune responses and maintenance of barrier function in the skin.

ILC2 in Atopic Dermatitis

There have only been a few studies characterising ILC2 during skin inflammation, and these were performed in the context of atopic dermatitis (AD), a chronic inflammatory skin condition associated with skin barrier disruption, eosinophilic infiltration, and high serum IgE levels. This disease affects up to 30 % of children of the industrialized world and is precipitated by both genetic and environmental factors [19]. Barrier dysfunction is a key early event in the pathogenesis of AD which is further complicated by inflammation driven by type 2 cytokines. Indeed, null mutations in the filaggrin gene that is involved in barrier integrity are found in patients with severe AD [38].

The three key ILC2 activators, IL-25, IL-33 and TSLP, are produced by a variety of cell types found in the skin, including dermal fibroblasts, epithelial cells and myeloid cells. IL-25 is a member of the IL-17 family and has been associated with Th2-like inflammation and disease. IL-33 is a member of the IL-1 family that binds the ST2 receptors that are preferentially expressed on Th2 cells and a range of innate immune cells. IL-33 is involved in Th2 polarisation, and also acts as an alarmin when released during tissue necrosis, or when cleaved by caspase 1 during programmed

cell death. TSLP is also thought to be involved in type 2 responses. It has been proposed that epithelial damage can lead to the production of these "initiating cytokines" (IL-25, IL-33, TSLP), which are potent activators of ILC2. Indeed, during AD, elevated levels of IL-25, IL-33 and TSLP, in addition to both pro-inflammatory and Th2 cytokines have been reported [78, 83].

ILC2 in humans also express CRTH2, the receptor for prostaglandin D_2. $CRTH2^+$ ILC2 isolated from human skin have been shown to respond to IL-33 and TSLP stimulation by secreting IL-13 [89]. ILC2 lines generated from the skin also produced IL-13 when stimulated by PMA/ionomycin, and TSLP could synergise with IL-25 to increase their production of IL-13. Interestingly, in one study, IL-33 did not further enhance IL-13 production by skin-derived ILC2 lines [40], which was somewhat different to the responses of human ILC2 isolated from nasal polyps and blood, in which IL-33 and TSLP synergistically enhanced type 2 cytokine production [55]. In contrast, Salimi demonstrated a hierarchy of human ILC2 responses upon *ex vivo* stimulation, with IL-33 being most potent at inducing cytokine production and ILC2 migratory behaviour [74]. Activation of CRTH2 by prostaglandin D_2 has been shown to synergise with IL-25 and IL-33 to induce IL-13 release from circulating ILC2 [3]. Recently, Ogg and colleagues demonstrated that endogenous prostaglandin D_2 released by mast cells could stimulate $CRTH2^+$ ILC2 isolated from human skin to migrate and produce a variety of pro-inflammatory cytokines, in addition to IL-4, IL-5 and IL-13 [98]. Together, the results indicate that ILC2 primary cells or cell lines cultured from human skin can be regulated by TSLP, IL-25, IL-33 and prostaglandin D_2. The differences between studies could indicate flexibility in ILC2 responses to different stimulators, or the presence of different subsets that may have intrinsically different cytokine profiles within the skin.

In recent human studies, Kim et al. and Salimi et al. reported that ILC2 numbers were increased in human AD skin lesions compared to healthy control skin [40, 74]. Although ILC2 function was not determined, Salimi et al. noted that ILC2 from AD lesions had upregulated expression of some receptors (ST2, IL17BR, TSLPR, and KLRG1), and it is tempting to speculate that such ILC2 are primed to be more responsive during skin inflammation [74]. Using a suction blister model, patient skin was challenged with house dust mite extract, one of the most common aeroallergens associated with exacerbation of AD symptoms. Increased ILC2 infiltration was documented within 26 h. This rapid increase suggests there was recruitment of ILC2 from the blood, rather than local expansion at the site of allergen exposure. Therefore, ILC2s are resident in human skin but the frequencies of ILC2s are elevated in the setting of AD and could be expanded after allergen challenge.

The role of ILC2 in AD has also been investigated in mouse models. Using MC903-induced dermatitis as a TSLP-dependent model of AD-like inflammation, it was shown that dermatitis was associated with ILC2 infiltration [40, 74]. Furthermore, significantly reduced inflammation was observed when ILC2 were depleted using anti-CD90.2 and anti-CD25 antibodies in $Rag\text{-}1^{-/-}$ mice [59] and RORα-deficient chimera mice [97]. Kim et al. also showed that TSLP was an essential cytokine for inducing skin inflammation and that this response was independent of IL-33 [40] in C57BL/6 mice, which was also noted by Salimi in experiments performed in the C57BL/6 background [74]. Nevertheless, overexpression of IL-33 in the skin in transgenic mice expressing IL-33 driven by a keratin 14 promoter recapitulates many features of atopic dermatitis, such as dermal eosinophilia, increased Th2 cytokines, spontaneous itching, epidermal thickening, increased mast cells, high blood histamine and total IgE levels [37]. In this model of IL-33-driven AD-like inflammation, IL-5-producing ILC2 were significantly increased in the lesional skin, peripheral blood, and regional lymph nodes, and dermatitis with eosinophil infiltration was improved by the administration of an anti-IL-5 antibody. Some of these conflicting findings were partially resolved by Salimi et al., who showed that IL-25 and IL-33 acted redundantly in the skin to mediate ILC2 activation [74]. Roediger et al. showed that dermal ILC2 could also be expanded by IL-2 and that this resulted in higher levels of type 2 cytokines in the skin and was associated with spontaneous dermatitis in mice, indicating that ILC2 can drive pathology in vivo. Collectively, these findings also indicate that multiple upstream triggers can promote ILC2 activation and expansion.

Collectively, it is tempting to propose that TSLP, IL-33 and IL-25, by promoting ILC2 activation, could contribute to AD. Current evidence does not indicate whether ILC2 represent a late event in established disease or if they contribute to the initiating/primary inflammatory responses in AD. Nonetheless, the possible redundancy of cytokine-mediated activation of ILC2 may have important therapeutic implications.

Group 3 ILC Functions

In addition to lymphoid tissue inducer cells, several mucosal ILC3 subsets have also been identified in murine and human tissues. In humans, these include the $CD56^+RORγt^+$ and the $NKp44^+RORγt^+$ cells found in the tonsil, Peyer's patches and small intestine. ILC3s accumulate in the inflamed intestine of patients with Crohn's disease and produce IL-17 [24]; ILC3 that produce IL-22 have been found in healthy intestinal tissues. In murine models, ILC3 and their signature cytokine IL-22 are crucial for gut tissue protection. IL-22 produced by ILC3 prevents the systemic dissemination of commensal

microbes and is thus important for their anatomical containment [81]. IL-22 produced by NCR$^-$ ILC3 that were stimulated by IL-23 was also important for defence against infection by the bacterium *Citrobacter rodentium* in RAG2$^{-/-}$ mice that lack T and B cells [77]. Conversely, ILC3 can be proinflammatory and have been linked to autoimmune disease. In a model of innate intestinal inflammation using infection with *Helicobacter hepaticus*, IL-23 promoted IL-17 production by a subset of ILC3s that was responsible for pathology [7]. IL-17 production by ILC3 is not always detrimental, however, and has been shown to be important for protection against mucosal Candida infections [25]. Therefore, ILC3, which are often found in close proximity to epithelial tissue, can display dual and complex roles in epithelial protection and inflammation.

In addition to a possible role in maintaining skin homeostasis and regulation of commensal bacteria, an important function of ILC in the skin might be to sense and amplify danger signals. ILC3 are activated by IL-23 and IL-1β, cytokines that can be produced by activated macrophages and DC in the skin. TLR agonists can activate macrophages, DC, or epithelial cells, which could lead to indirect activation of ILC3. Furthermore, ILC3 also express receptors that can directly sense endogenous or exogenous molecules. For instance, ILC3 express the aryl hydrocarbon receptor (AhR), which senses a range of metabolites, some of which may be diet or microbiota-derived. Engagement of the NKp44 receptor itself in the absence of cytokines has been found to be sufficient to induce TNF and IL-2 cytokine production, whereas cytokine stimulation (IL-23, IL-1, and IL-7) preferentially induces IL-22 and GM-CSF expression in ILC3. Thus, depending on stimuli, ILC3 may be able to switch between modes of cytokine production, and integrate or synergise signals received by engagement of cytokine receptors and NKp44. IL-22 belongs to the family of IL-10-related cytokines which have roles in maintenance of epithelial barrier function [1, 96]. The engagement of the IL-22 receptor which is exclusively expressed on epithelial cells leads to production of antimcrobial peptides, mucus, and cytokines, including the anti-inflammatory cytokine IL-10, and might therefore promote wound healing. Thus, ILC3, which are important in maintenance of the epithelial barrier function and in innate immune defence against extracellular pathogens in the gut, may also perform similar roles in the skin.

The Increasingly Recognised Role for ILC3 in Psoriasis Pathogenesis

Psoriasis is one of the most common chronic inflammatory disorders of the skin, affecting 2–3 % of people worldwide [62]. Psoriatic lesions are often highly inflamed and scaly due to keratinocyte hyperproliferation and epidermal acanthosis, accompanied by infiltration of different immune cell subsets [62]. Although psoriasis is a mutifactorial disease that is linked to both genetic and environmental factors, T cells were traditionally thought to be causally involved in psoriasis pathogenesis. In recent years, the role of innate immune cells, in particular γδ T cells and the group 3 innate lymphoid cells in psoriasis is increasingly being appreciated.

Th1 and Th17 cells, via their production of the pro-inflammatory cytokines IFN-γ, TNF-α, or IL-17, are thought to drive chronic inflammation in psoriasis. Increased numbers of circulating Th1, Th17 and Th22 cells have been measured in patients with psoriasis compared to controls [5, 39], and increased numbers of IL-22 and IL-17-producing CD8 T cells have been isolated from psoriatic skin compared to control skin [71], suggesting they too have a role in pathogenesis. Since its discovery in 2000, IL-23, a heterodimeric cytokine that shares a common p40 subunit with IL-12, has also been recognised as a key player in psoriasis. IL-23 is mainly produced by activated myeloid cells, as well as epithelial cells, endothelial cells and keratinocytes. Its expression is enhanced in psoriatic skin lesions compared to healthy skin [47, 67]. In the "IL-23/Th17" model of psoriasis [16], IL-23 produced by dermal dendritic cells induces T cell activation and production of IL-17, IL-22 and IFN-γ. These cytokines induce epidermal hyperplasia and act on keratinocytes, which in turn, sustain and amplify the inflammatory process by producing more IL-23. Activated keratinocytes also produce pro-inflammatory mediators, including members of the S100 family of defensins, antimicrobial peptides and chemokines, in particular, the chemokine CCL20, which is able to recruit more CCR6$^+$ Th17 cells [30]. Consistent with the important roles of TNF-α, IL-17 and IL-23/12 in maintaining psoriatic pathology, therapies using antibodies directed against TNF (etarnercept, [27]), against the common p40 subunit of IL-12 and IL-23 (ustekinumab, [48, 65]), and recently, against the IL-17 receptor (brodalumab, [66]), have been clinically successful in treating severe psoriasis [88].

ILC3 respond to IL-23 (and IL-1β) stimulation by producing IL-17A and IL-22. The potential role of ILC in psoriasis was first demonstrated in murine models, in which topical application of imiquimod, a TLR7/9 agonist, induces IL-23-dependent psoriasiform lesions. Whilst Th17 cells played a role in inflammation and pathology, psoariasiform skin inflammation was still observed in treated Rag-2$^{-/-}$ mice, despite the absence of lymphocytes and NKT cells [32, 64]. In these mice, RORγt$^+$ γδ T cells and RORγt$^+$ ILC were shown to be the innate source of IL-17 and IL-22, consistent with an earlier report that T cells were not required for IL-22-dependent formation of skin lesions [93]. Pantelyushin et al. further demonstrated that backcrossing the Rag-2$^{-/-}$ with IL2Rγc$^{-/-}$ mice, which lack ILC, eliminated the response to imiquimod [64]. Repeated intradermal injections of IL-23 also induce psoriasisform inflammation

that was preserved in Rag-2$^{-/-}$ mice. As mice do not naturally develop psoriasis, it was unclear if these findings would be relevant in humans.

Three recent papers provided evidence for a pathogenic role of ILC3 in human psoriasis. These papers showed that ILC3, but not the ILC1 and ILC2 populations, were increased in the lesional and non-lesional skin of patients with psoriasis compared to healthy controls. This skewing toward the NCR$^+$ ILC3 subset was not observed in patients with contact nickel allergy. NCR$^+$ ILC3 were also increased in peripheral blood of psoriatic patients, a significant proportion of which expressed CLA and therefore had skin-homing potential. From these results, it was unclear if a local cytokine milieu was established in the skin to alter the local ILC balance, or if the increased NCR$^+$ ILC3 in the skin arose from local conversion of NCR$^-$ ILC3 (they converted into NCR$^+$ ILC3 upon *ex vivo* stimulation), or if indeed, ILC3 were generated elsewhere to migrate into the skin.

Both skin and blood NCR$^+$ ILC3 produced IL-22 when stimulated with IL-1β and IL-23, whereas NK and ILC2 did not. Villanova et al. suggested that ILC in the blood were major contributors to IL-17 and IL-22 production, accounting for ~20 % of IL-17-producing cells and ~40 % of IL-22-producing cells respectively, but they did not trace this to individual ILC subsets [94]. Teunissen et al. did not directly demonstrate ILC3-derived IL-17A in human psoriasis skin [89]. Nonetheless, these results indicate that human ILC3 may serve as a significant source of pathogenic cytokines in psoriatic skin. The ILC1 population, which is primarily induced by IL-12, was not altered in psoriasis, raising the possibility that the effects of IL-23 may dominate in this disease. Based upon the capacity of IL-23 to drive differentiation and secretion of IL-17A/IL-22 from ILC3s, it would be interesting to determine if IL-12/23 inhibitors, or novel inhibitors that only target IL-23, would also target ILC3s in psoriasis. Importantly, both Teunissen et al. and Vilanova et al. demonstrated a correlation between disease severity (measured by the psoriasis area severity index (PASI)) score with ILC3 numbers. Villanova et al. further showed a 75 % decrease in ILC3s numbers that corresponded to disease improvement after anti-TNF-α therapy [89, 94]. Together, these findings indicate that the accumulation and/or activation of NCR$^+$ ILC3 contribute to psoriasis, and understanding these relationships might guide the use of therapeutics to restore ILC balance in the skin. For instance, topical therapy with vitamin D3 analogues that are currently used to treat milder forms of psoriasis may increase TSLP and decrease IL-23, restoring balance of ILC subsets toward ILC2.

In conclusion, all members of the ILC family are present in healthy human skin and may have several important functions in tissue homeostasis. To date, studies of inflammatory skin disorders have revealed the outcome of ILC dysregulation: ILC2 are accumulated in human and experimental AD; ILC3 are accumulated in psoriasis plaques; and they have the ability to drive disease independent of other lymphocytes.

Learning Objectives Classification of NK cells and other ILC subsets
- Development of ILC
- Transcription factor profile of ILC
- Functions of ILC in normal skin
- Role of ILC in skin inflammation

Review Questions

1. How does the developmental pathway of NK cells and ILC differ from B cells and T cells?
   A. Their developmental pathway is identical to B-cells and T-cells
   B. They lack a rearranged antigen receptor
   C. Their cell surface markers are different
   D. Their transcription factors are unique

Correct Answer: (B) NK cells and ILC lack rearranged antigen receptors, since they are innate immune cells

2. What are the key subsets of ILC?
   A. Group 1 ILC (IFN-gamma producing)
   B. Group 2 ILC (IL-4, IL-5, IL-9, IL-13 producing)
   C. Group 3 ILC (IL-17 and IL-22 producing)
   D. All of the above
   E. None of the above

Correct Answer: (D) All of the above are critical polarized subsets of ILC

3. How are ILC functionally similar to TCR αβ T cells?
   A. Can proliferate and secrete cytokines
   B. Exist as polarized subsets
   C. Interact with conventional T-cells
   D. Express unique transcription factors
   E. All of the above

Correct Answer: **(E)** All of the above. ILC share many features with conventional TCR αβ T cells

4. What is the evidence that ILC participate in the pathogenesis of atopic dermatitis?
   A. Activated ILC2 are increased in atopic dermatitis lesions
   B. ILC1 over-produce IFN gamma from the peripheral blood of atopic dermatitis patients
   C. Deficient ILC2 activation is found in atopic dermatitis
   D. ILC3 are critical in early atopic dermatitis skin lesions

Correct Answer: (A) Activated ILC2 are increased in atopic dermatitis skin lesions compared to uninvolved skin

Gamma-Delta T Cells in the Skin

4

Sioh-Yang Tan, Szun S. Tay, Nital Sumaria, Ben Roediger, and Wolfgang Weninger

Abstract

The skin forms the body's primary interface with the environment and, as such, is equipped with a network of immune cells to provide the first line of defence against infection and injury. While the role of conventional alpha-beta (αβ) T cell receptor (TCR) expressing lymphocytes in skin homeostasis and pathology has been studied in great detail, emerging evidence also points to an important role of gamma-delta (γδ) TCR expressing T cells. The aim of this chapter is to review the biology of γδ T cells in the pathophysiology of the skin.

Keywords

T cells • Gamma-delta T cell receptor • Skin • NKG2D • Cell receptors • Cell markers • Skin disease • Cytokines

Introduction

Gamma delta (γδ) T cells are a population of unconventional T lymphocytes that are enriched at mucosal surfaces and possess both innate and adaptive properties. Unlike conventional αβ T cells, γδ T cells express a TCR comprising paired γ and δ chains of limited diversity. γδ T cells recognise ligands in an MHC unrestricted manner, independent of the CD4 and CD8 coreceptors.

γδ T cells have unique ontogenic, phenotypic and functional features that make them ideal sentinel cells for stress surveillance in the periphery. They are able to mount rapid effector responses towards biochemically heterogeneous antigens of self and microbial origin without the need for clonal expansion. The majority of γδ T cells exist in a pre-programmed state of semi-activation, allowing them to respond with rapid kinetics. The ability to rapidly detect unprocessed antigens allows γδ T cells to serve as a first line of defence, before the delayed response of αβ T cells can occur. Nevertheless, γδ T cells also show adaptive, memory-like properties and are capable of limited clonal proliferation. γδ T cells thus display pleiotropic potential to develop into effector cells, antigen presenting cells and, at a later phase of the immune response, facilitators of tissue repair and healing [33, 42, 54, 104, 144, 154].

γδ T Cell Development

Although tissue-specific γδ TCR repertoire oligoclonality is often seen in human and mice, in cattle and sheep, in which γδ T cells make up 20 % of peripheral blood T cells and 40 % of T cells, the γδ TCR repertoire is heterogeneous. Most γδ T cells are generated from the thymus, although extrathymic

A.A. Gaspari et al. (eds.), *Clinical and Basic Immunodermatology*, DOI 10.1007/978-3-319-29785-9_4

pathways of γδ T cell production exist [5, 31]. The ontogenesis of γδ T cells in the thymus precedes that of the αβ T population, and commences on embryonic day 14 in mice. αβ and γδ T cells share a common precursor, and TCR γ, δ and β rearrangement is initiated at the CD4/CD8 double negative (DN) 2 stage. At the DN3 stage, successfully rearranged TCR β on the cell surface pair with the surrogate α chain (pTα) to form the pre-TCR signalling complex, which promotes survival, proliferation and differentiation. Upon expression of this surrogate receptor, the cells commit to the αβ lineage, progress through the 'β-selection' checkpoint and enter the $CD4^+CD8^+$ DP stage, where they undergo selection and are subsequently exported as mature CD4 or CD8 single positive (SP) T cells. For cells committing toward the γδ lineage, the surface expression of TCR γ and TCR δ suffice without the requirement for a surrogate TCR complex. Fate-mapping analysis showed that γδ T cells do not undergo a DP stage in ontogeny, suggesting that they emerge directly from the DN precursor stage, consistent with the DN phenotype of γδ T cells in the periphery [31].

The molecular changes driving fate commitment of γδ T cells are still being elucidated. Two models have been proposed to explain the mechanisms underpinning lineage choice made by DN cells: the stochastic model and the signal strength model [55, 76]. There is evidence that lineage commitment may be initiated in thymic precursors independent of TCR-mediated signals. Differential expression of the IL-7 receptor among DN2 thymocytes that have yet to express TCRs is associated with a propensity to adopt an αβ or γδ cell fate, with cells expressing higher levels of IL-7Rα biased towards the γδ lineage [72]. Others found that differential Notch receptor-ligand activation mediates the divergent differentiation between γδ and αβ fates in human thymic cells [141, 142]. More recently, CD73 was reported to be an early marker of cells that have newly committed towards a γδ cell fate in the thymus [25]. SOX13 is a high mobility group (HMG) transcription factor differentially expressed between αβ and γδ thymocytes. High expression of SOX13 in DN2 cells correlates with a γδ lineage bias. In SOX13-overexpressing transgenic mice, the αβ lineage is ablated, while SOX13 deficiency reduces γδ T cell number in a gene dose-dependent manner. SOX13 antagonises TCF-1 (T Cell Factor-1), another HMG transcription factor that is required for αβ T lineage development [92]. The precise role of SOX13 in γδ lineage commitment remains unclear, as recent analyses of mice with a spontaneous *sox13* mutation have revealed that it may not be required to commit to the γδ lineage but may be important for acquisition of effector function in some γδ T cell subsets [45].

γδ T cells expressing invariant TCR and with distinct tissue tropism are generated in a specific temporal order and are exported to the periphery in waves [1]. This sequential development of γδ T cell subsets is partly due to ordered Vγ-region gene expression but recent evidence suggests that other factors such as foetal versus adult thymic precursors, or age-specific thymic stromal components, may also have a role [50, 54, 61]. In mice, the first wave of γδ T cells consists of $Vγ5^+Vδ1^+$ (Tonegawa's nomenclature used here*) cells destined to seed the epidermis as dendritic epidermal T cells (DETC). This is followed by a second wave of cells rearranging Vγ6Vδ1 that are exported to the mucosal tissue of the uterus, tongue and the lungs [64]. Both the first and second waves of γδ T cells are generated perinatally and consist exclusively of monoclonal canonical TCR sequences. Upon homing to the destination tissue, these cells expand and continuously self-renew by slow cycling *in situ* throughout the lifetime of the host [132].

At around birth, rearrangement of Vγ7 and Vγ1 occurs, resulting in γδ T cells that seed the gut epithelium. This is followed by the postnatal production of $Vγ4^+$T cells that become circulatory γδ T cells in peripheral blood and secondary lymphoid organs. These TCRs have gene segments with highly diverse junctional sequences. Unlike the first two waves of γδ T cells, which are slow-cycling and radioresistant, the circulatory γδ T cells in the spleen and lymph nodes are radio-sensitive, and are amenable to replenishment by adult bone marrow derived precursors [132].

In humans, the first population of γδ T cells emerging from the foetal thymus express Vδ1 paired with multiple different Vγ chains and home to epithelial tissues in the skin and intestine [42, 58]. $Vδ1^+$ cells comprise a large proportion of human intraepithelial γδ T cells but a minor fraction of peripheral blood, where $Vδ2^+$ cells predominate.

In contrast to their scarcity in the adult, γδ T cells make up the majority of peripheral T cells in the neonate and may have an important immuno-protective role in early life, conferring resistance towards intestinal protozoa such as *Eimeria vermiformis* and *Cryptosporidium parvum* [112, 152]. Neonatal γδ T cells also show stronger and more pleiotropic functions compared to their αβ counterparts, suggesting that these cells are competent for immune protection at a time while the αβ T compartment is still immature [41].

γδ TCR Repertoire Generation and Modes of Antigen Recognition

The γδ TCR shares conserved structural features with the αβ TCR. The TCR γ chain, like the TCR α chain, is generated by VJ recombination while the TCR δ chain and TCR β chain through VDJ recombination.

Although a common pool of V genes is available to be used as TCR α and TCR δ gene segments, in actuality the usage does not overlap, limiting the TCR δ pool to 8 genes in mice and 10 in humans. In addition, heterogeneity of TCR γδ is further constrained by restrictions in Vγ and Vδ pairing.

However, the Complementarity Determining Region (CDR) 3 region of the TCR δ gene has the highest potential diversities among all the known TCR/Immunoglobulin chains, owing to the large number of D genes available, the availability of the D genes to be read in all three open reading frames, and nucleotide insertions and deletions at the VJ junctions of TCR γ chain [21]. Nonetheless, the actual γδ TCR repertoire has more limited diversity compared to the αβ T repertoire.

γδ and αβ TCRs have distinctive structural features that impact on their modes of ligand recognition. It is known that the length of CDR3 profoundly affects its shape and hence its ligand recognition capacity. The CDR3 region of both TCR α and TCR β chains are short and constrained in length, being evolutionarily selected for engagement of the peptide:MHC complex. The CDR3 of TCR γ and TCR δ are of uneven lengths, and the longer TCR δ chain has a heterogeneous length distribution, consistent with the capacity of these receptors to recognise a diverse range of ligands [2, 117]. This makes them structurally similar to immunoglobulins, which are also capable of a broad range of ligand recognition.

The spectrum of ligands recognised by γδ TCR includes self- and microbial-derived danger-associated patterns, stress-associated molecules, and evolutionarily conserved, invariant antigens or metabolite intermediates [21]. The recognition of such molecules, often associated with early events of barrier rupture, inflammation or tissue damage, without need for processing or restricted presentation by antigen presenting cells (APCs), is highly relevant to the role of γδ T cells as sentinel cells in stress surveillance at peripheral sites.

Unlike the engagement between αβ TCR and peptide:MHC complex, various γδ TCRs bind peptide:MHC complexes in unconventional manners [21]. For example, the recognition of insulin peptide by the Vγ4$^+$Vδ10$^+$ SP9D11 mouse γδ T cell clone is independent of APCs [160]. On the other hand, the interaction between mouse LBK5 γδ TCR and moth cytochrome peptide:IE(k) complex is non-peptide-specific and of low affinity [52]. Operating by yet another different mode of recognition, the binding of human Vδ1$^+$ TCR to lipid:CD1d complex is constrained by the lipid ligand [139].

The KN6 and G8 γδ TCR clones recognize T10 and T22, MHC-like antigens that lack peptide-binding groove, in association with beta-2-microglobulin (β2m) with high affinity. Stress-inducible MHC-like MICA and MICB are recognized by other γδ TCR independent of β2m. Indeed, γδ T cells have been shown to respond to a variety of other stress-associated molecules. These include intracellular proteins such as apolipoprotein A-1 (apoA-I), mitochondrial ATP synthase, low-molecular-weight phosphorylated molecules from host and microbial metabolic pathways, endothelial protein C receptor (EPCR) and histidyl tRNA synthase [21].

γδ TCR Ligation and Programming of Effector Function

Positive and negative selection by MHC-restricted presentation of agonist ligands in the thymus shape the repertoire of αβ T cells. Unlike αβ TCR, the canonical γδ TCR repertoire in the foetal thymus is generated mainly by genetic recombination of variable gene segments and not by thymic selection. Although earlier studies in γδ TCR transgenic systems found evidences of positive and negative selection in a manner similar to αβ T cells [30, 107], the relevance of agonist:MHC -mediated selection was contradicted by the absence of a γδ T cell deficit in mice which lack the β2m molecule required for assembly and surface expression of MHC I [124]. In addition, wildtype mice and *Tcrd*$^{-/-}$ mice contain the same V region recombination and junctional sequences for the first two waves of invariant γδ TCR cells, indicating a lack of repertoire shaping by selection [63].

In the mouse, 0.1–1 % of adult γδ T cells recognise the non-classical MHC-like antigens T10 and T22 in a β2m-dependent manner. Using a T22 tetramer staining reagent to enumerate antigen-specific γδ T cells in non-transgenic strains that do or do not express these antigens, Jensen et al. [68] found no evidence of a requirement for ligand-mediated selection in the generation and development of these cells. Unexpectedly however, ligand recognition in the thymus profoundly affects cell fate. Ligand-naive cells in the periphery produce IL-17 upon TCR-mediated activation, while ligand-experienced cells produce IFN-γ. This cytokine production pattern is wired in the thymus and persists in the peripheral γδ T cells even after infection and inflammation [68, 114].

The importance of ligand-mediated programming of effector function is evident in the development of DETC. The Vγ5 TCR of these cells likely recognizes an as yet to be discovered antigen on keratinocytes [53, 59]. DETC must contact antigen in the thymus for full maturation and export. Skint1 is a butyrophilin-like molecule expressed by keratinocytes and thymic epithelial cells (TECs). In the presence of skint1, foetal thymic γδ T precursors expressing the Vγ5 TCR are pre-programmed into IFN-γ producers prior to being exported to the epidermis to become DETC [138]. Skint1 ligation induces upregulation of the transcription factor Egr3, which corroborates with NFAT and NFkB activation to suppress SOX13 and RORγt and upregulate T-bet, diverging the cells from a constitutive IL-17 producing phenotype into an IFN-γ producing pathway. The Egr3-Id3 pathway is necessary and sufficient to confer Notch-independent differentiation into IFN-γ producing effectors [80]. The transcriptional reprogramming is concomitant with a change in surface phenotype, as the suppression of SOX13 relieves the inhibition on upregulation

of CD27 and NK1.1. In the absence of skint1, the cells remain SOX13$^+$, RORγt$^+$, CD27$^-$, SCART2$^+$, and develop into IL-17 producing cells. The Taconic farm substrain of FVB mice harbours a genetic mutation in the *skint1* gene, and consequentially a deficit of IFN-γ producing Vγ5$^+$ cells in the DETC compartment. Instead their DETC comprises a heterogeneous TCR γδ repertoire and these cells produce IL-17. Nonetheless at present it is unclear if skint1 directly contacts the TCR of DETC.

A third population of γδ T precursors is pre-programmed in the foetal thymus into semi-activated cells capable of rapid production of both IL-4 and IFN-γ [40, 48]. These thy1(dull) cells express a very restricted TCR comprising Vγ1 and Vδ6.3/6.4, and are thought to undergo agonist selection, upregulating the expression of the transcription factor PLZF (promyelocytic zinc finger), which is also essential for the differentiation and acquisition of effector function in iNKT cells [77]. Agonist-ligand binding is often considered to induce a strong TCR signal, however, paradoxically, the attenuation of TCR signal strength such as in Id3$^{-/-}$ or Itk$^{-/-}$ mice promoted the development of NKT-like γδ cells [3, 111, 146]. In addition to TCR-mediated signalling, the development of NKT-like γδ cells is also dependent on costimulatory SAP-SLAM interaction [3].

Of note, not all γδ T cells are pre-wired in the thymus into IFN-γ versus IL-17 producing effectors. For instance, oral infection with *Listeria monocytogenes* induces the expansion of a population of CD27$^-$CD44$^+$ γδ T cells in the mesenteric lymph nodes (LN) capable of making both IFN-γ and IL-17 [128]. Heterogeneity among subsets of γδ T cells will be discussed below.

TCR-Dependent and Independent Activation of γδ T Cells

According to the classical two-signal model of T cell activation, T cells require signal 1 via the TCR and signal 2 via costimulator molecules for activation and avoidance of anergy and/or apoptosis. In addition, optimal activation of CD8$^+$ T cells may require signal 3 in the form of inflammatory cytokines such as IL-12 or type I interferon [27]. This paradigm of activation of αβ T cells does not capture the more variable means of γδ T cell activation, which may occur in a costimulation-independent or even TCR-independent manner.

Apart from the γδ TCR, γδ T cells also express invariant innate receptors including pattern recognition receptors such as Toll like receptors (TLRs), and NK cell activation and inhibitory receptors. The relative importance of the γδ TCR to these innate receptors varies in a context- or population-specific manner. In subsets of γδ T cells, triggering through the γδ TCR alone, but not NKG2D alone, induces cytotoxicity via Vav1-dependent phospholipase C-γ1 signalling. Nonetheless, NKG2D is capable of augmenting the activation of γδ T cells as a costimulator through the same pathway. On the other hand, in human peripheral Vγ9$^+$Vδ2$^+$ cells, constitutively expressed NKG2D rather than the γδ TCR appears to be the predominant activating molecule eliciting anti-tumour functions [96].

In adult human and mice, the majority of γδ T in the peripheral tissues are present in a semi-activated state, and can be fully activated with signals 2 and/or 3 without further TCR crosslinking. For instance IL-17 producing γδ T cells (Tγδ17) in secondary lymphoid organs constitutively express IL-23R and the transcription factor RORγt. These cells can be activated via cytokines (a combination of IL-1 and IL-23), TLR-2 or dectin-1 to produce IL-17 in the absence of TCR ligation [89, 133].

Although provision of signal 1 in the absence of costimulation does not seem to induce anergy in γδ T cells, costimulatory molecules do augment the activation of γδ T cells, leading to increased proliferation and cytokine production. While sharing some of the costimulatory molecules known to play a role in αβ T cells, including CD28:B7 and CD27:CD70, there are also costimulatory ligand-receptors uniquely used by γδ T cells and their relevant APCs (Table 4.1).

Heterogeneity Among γδ T Cell Subsets

Recent studies strongly suggest that γδ T cells can be divided into an innate or natural population and an adaptive or inducible population [22, 73, 144]. γδ T cell populations that are generated in the foetal thymus typically home to peripheral sites such as the skin and the gut epithelium, where they self-renew *in situ*. These cells are pre-programmed in the thymus into distinct effector lineages, express markers indicative of partial activation, and at least a subset of them can be activated in a TCR-independent manner. Collectively, these features place them within the innate spectrum of γδ T cells. On the other end of the spectrum are γδ T cells showing more adaptive-like features, typically circulating in the blood, spleen and lymph nodes, where about half the population has a CD44$^-$CD62L$^+$ naive phenotype. There is no evidence of effector pre-programming in these cells. Cytokine production potential is plastic with more delayed kinetics relative to that of their more innate counterparts. These cells have different derivative requirements and can be generated from adult thymic and bone marrow precursors. Recall response can be elicited from these 'adaptive' γδ T cells in a number of different species [99, 127, 128].

Table 4.1 The role of costimulators in γδ T cell activation

JAML-CAR
DETC express JAML (junction adhesion molecule like protein) at low level in steady state and upregulate its expression upon activation. The binding partner of JAML, the coxsackie and adenovirus receptor (CAR), is expressed by keratinocytes. CAR-mediated JAML clustering recruits PI3K, in a similar mechanism as described for CD28-mediated costimulation [156]. PI3K mediates costimulatory function of JAML through the same binding motif found on B7 family members CD28 and ICOS. This leads to proliferation and production of IFN-γ, IL-2 and TNF-α by DETC. The inhibition of this interaction results in reduced γδ T activation and delayed wound healing in the skin. Based on the expression pattern of JAML and CAR in the intestine, their interaction could also play a role in activation of γδ IEL in this organ.
CD100-plexin B2
DETC express CD100/semaphorin 4D (Sema4D), a member of the semaphorin family of molecules with a known role in axonal guidance. CD100 on DETC engages plexin B2 on keratinocytes, and *in vitro* ligation of CD100 leads to activation of cofilin and ERK activation and the rounding of DETC. DETC from CD100 deficient mice show delayed rounding, which correlates with a wound healing defect in these mice [157]. In the intestine, all IEL express CD100 and epithelial cells express plexin B2. CD100-deficient mice show exacerbated inflammation and tissue damage in the DSS-colitis model. CD100 deficiency renders γδ IEL unable to produce KGF-1, and KGF-1 administration ameliorates intestinal tissue damage in these mice [93]. Collectively these data indicate the importance of CD100 in mediating tissue homeostasis and repair by DETC.
Aryl hydrocarbon receptor (AhR)
The aryl hydrocarbon receptor (AhR) is a member of the basic helix-loop-helix (HLH)/Per-Arnt-Sim (PAS) superfamily known for their roles in sensing of environmental factors. It is a ligand-activatable transcription factor, and regulates several xenobiotic-metabolizing enzymes. Cell-intrinsic expression of AhR is important for the maintenance of DETC in the skin. AhR-deficient DETC have altered morphology and do not extend dendrites to contact neighbouring cells. Although AhR deficiency does not impair thymic generation or export of these cells to the skin, their numbers in the epidermis decline over time [71]. Recent studies found a similar role for AhR in the maintenance of γδ IEL in the gut [83].
CD27
CD27 is a member of the TNF superfamily and its binding partner CD70 is constitutively expressed on thymic epithelial cells. In the thymus, a $CD25^+CD27^+$ DN population contains the precursors that subsequently diverge into the $CD27^-$ $ROR\gamma^+$ IL-17 producing lineage and the $CD27^+$ IFN-γ producing lineage. This divergence is stable and largely not interconvertible even in the face of infection in the periphery [114]. $CD27^{-/-}$ mice contain less IFN-γ producing γδ T cells, indicating that CD27 is not only a marker but also a regulator of effector cell fate determination of γδ T cells.
WC1 (Workshop Cluster 1)
WC1 are germline-encoded coreceptors of the scavenger receptor cysteine-rich (SRCR) family of transmembrane glycoprotein, consisting of 11 extracellular SRCR domains. WC1 is related to the CD163 family, with closest homology to CD163c-alpha/CD163L1 or SCART) [56]. WC1 is uniquely expressed by γδ T cells in cattle, camelids and pigs. Gene orthologues have been described in mice and human but no functional gene product has been found. The cytoplasmic domain of WC1 contains ITAMs. Specific tyrosine moieties are constitutively phosphorylated and associate with Src family tyrosine kinases. Phosphorylation of the second tyrosine residue is required for the role of WC1 in potentiating γδ TCR-mediated proliferation *in vitro*, an observation supporting the role of WC1 as a costimulatory molecules [150]. Bovine γδ T cells are serologically defined based on available antibodies into $WC1.1^+$, $WC1.2^+$ and $WC1^-$ subsets. WC1 are not merely markers but define functional subsets of bovine γδ T cells with distinct age-dependent turnover kinetics [151]; [118]; [119]. $WC1.1^+$ proliferate more and produce more IFN-γ in allogeneic MLR *in vitro* compared to $WC1.2^+$ γδ T cells [118]; [119]. Intranasal BCG vaccination induces higher expansion or recruitment of the $WC1.1^+$ subset into the lung, as well as eliciting higher production of IFN-γ from these cells [110]; [49]. Virus infection induces differential cytokine and chemokine production in the subsets, with $WC1.1^+$ and $WC1^-$ cells producing MIP-1α and GM-CSF while $WC1.2^+$ cells producing IL-10 and TGF-β [90].
SCART
SCART, another member of the SCRC superfamily, shares significant homology with WC1 but is not its gene orthologue. The expression of SCART1 and SCART2 are largely identical. In the thymus, SCART2 upregulation is first detected at the DN2 stage and does not require a TCR signal. However, its expression is downregulated by strong TCR ligation. In the adult periphery, SCART2 positivity defines a population of thymic-derived IL-17-producing γδ T cells enriched for Vγ4 reactivity residing in the skin dermis and skin-draining LN [74].
NKG2D
NKG2D interacts with various stress-inducible molecules including MICA, MICB, ULBP, H60, Rae1 and MULT. In γδ T cells, the co-ligation of NKG2D and γδ TCR potentiates γδ T cell activation, supporting a costimulotary role for this molecule. However, NKG2D is also capable of TCR-independent activation of γδ T cells in other conditions.
BTLA (B- and T- Lymphocyte Attenuator)
BTLA, an inhibitory costimulatory molecule of the B7 superfamily, has recently been described to play a role in the homeostasis and regulation of γδ T cells [6]. RORγt represses BTLA while IL-7 signalling increases its surface expression. BTLA expression limits the responsiveness of γδ T cells to IL-7 mediated proliferation thereby regulating its homeostatic number at steady state. BTLA also inhibits the production of IL-17 and TNF from $CD27^-$ γδ T cells *in vitro*. In a γδ T cell-dependent model of dermatitis, BTLA deficiency exacerbates, and BTLA ligation ameliorates disease.
Other costimulators
γδ T cells and αβ T cells share many common costimulatory molecules. However, while costimulators have a qualitative role determining the outcome of αβ T cell response between activation and anergy, the effect of costimulation in γδ T cells appears to be quantitative. For example, CD28 ligation does enhance *in vitro* response of γδ T cells to TCR crosslinking and to allogeneic DC. However, the expression of CD28 was found to be variable and its importance in the activation of γδ T cells unresolved [54]. In the presence of γδ TCR crosslinking, TNF SF family member CD40L is known to costimulate the proliferation and cytolytic function of thymic γδ T cells [113]. Persistent upregulation of CD30, another TNF SF member, can be induced upon *in vitro* activation of γδ T cells. CD30 engagement leads to enhanced cytokine and chemokine production [7].

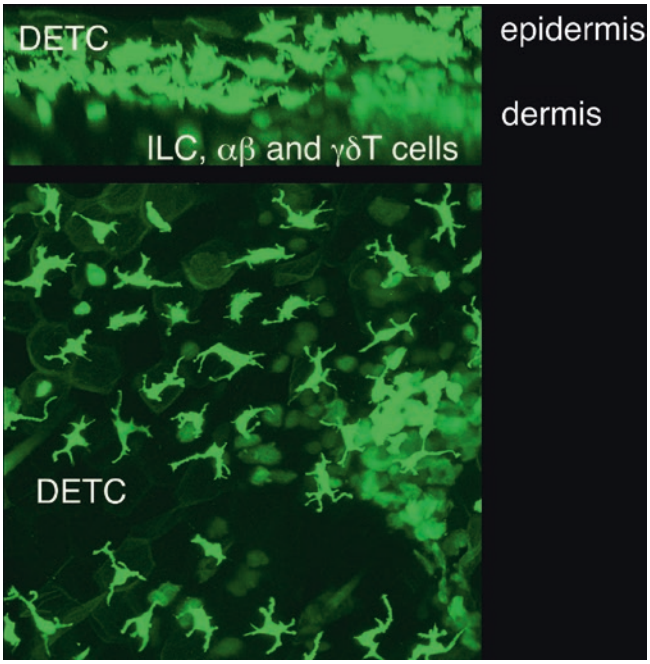

Fig. 4.1 Dendritic epidermal T cells (*DETC*) and dermal lymphoid cells in the skin of Cxcr6$^{gfp/+}$ mice. The non-migratory DETC reside in the epidermis, where their cell processes are anchored at squamous keratinocyte tight junctions, giving the cells their characteristic dendritic morphology. Dermal lymphoid cells, which include αβ and γδ T cells as well as innate lymphoid cells, are more amoeboid in morphology and actively migrate throughout the dermis. The image is a z-projection through a volume of 82 μm of ear skin, including epidermis and dermis

An Example of Microanatomical Specialisation: Dermal γδ T Cells Versus DETC

Several recent studies have highlighted the microanatomical and functional segregation of two populations of γδ T cells in the mouse skin. Using intravital multiphoton imaging of fluorescently tagged mice (CXCR6-GFP knock-in), two groups have identified a novel population of γδ T cells residing in the dermis [47, 132]. In the epidermis, DETC are sessile and constantly extend and retract their dendritic projections, while dermal γδ T cells show a different morphology and migrate in the dermis at a speed of 2–4 μm/min (Fig. 4.1). A subset of these cells also makes contact with MHC-II$^+$ cells, presumably antigen presenting cells, in the dermis. These behaviours suggest an active role for these cells in immune-surveillance of the skin. While DETC are uniformly Vγ5$^+$, dermal γδ T cells are relatively heterogeneous, expressing Vγ5, Vγ4 or other TCRs [47, 132]. In addition, the two populations also show differential expression of γδ TCR levels, CD25, CD43, CCR6 and NK1.1. Both populations are generated perinatally and homeostatically maintained by self-renewal *in situ* in an IL-7 dependent manner. In addition, DETC but not dermal γδ T cells are IL-15 dependent [29, 132]. While DETC are thymically pre-programmed by skint1 ligation to produce IFN-γ [114, 138], dermal γδ T cells constitutively express RORγt and IL-23R, and rapidly produce IL-17 following exposure to IL-1β plus IL-23 [16, 47]. In an intradermal model of BCG infection, dermal γδ T cells are the earliest population showing rapid IL-17 production, which mediates recruitment of neutrophils to the site of antigen deposit. In *Tcrd*$^{-/-}$ mice, the recruitment of neutrophils to the infected ear skin is diminished, and the downstream adaptive response of antigen-specific conventional CD4$^+$ T cells reduced [132]. Nonetheless, these two anatomically segregated of γδ T cells may have functional overlap in certain scenarios, as a recently described subset of DETC is capable of rapidly producing IL-17 in response to wounding and UV irradiation [87, 88].

Interaction Between γδ T Cells and Other Cell Types

Interaction with Other T Cell Subsets

Mature TCR γδ$^+$ thymocytes are reduced in numbers in *Tcrβ*-deficient and *pTα*-deficient, but not *Tcrα*-deficient mice, indicating a role for the CD4$^+$CD8$^+$ DP αβ T precursors on the development of γδ T cells in the thymus. DP cells are capable of conditioning γδ T precursors via lymphotoxin (LT)-mediated RelA and RelB pathways, regulating the expression of transcription factors RORγt and RORα4 to direct their differentiation into Tγδ17 cells [109, 129]. In *Tcrd*$^{-/-}$ mice hyperproliferation of the αβ T cell compartment is often seen, suggesting that γδ T cells may compete with αβ T cells for homeostatic cytokines, such as IL-7. During infection, early cytokine production from γδ T cells may directly or indirectly polarise delayed adaptive responses downstream and impact on the efficacy of pathogen clearance. For instance, infection with *Listeria monocytogenes* or *Nippostrongylus brasiliensis* elicits rapid production of IFN-γ and IL-4, respectively, from γδ T cells of the peritoneal cavity [35].

In models of autoimmune-mediated inflammation, γδ T cells may exacerbate disease. Tγδ17 that are activated by IL-23 during MOG/CFA-induced experimental autoimmune encephalomyelitis (EAE) inhibit the *de novo* induction of regulatory T cells (Treg) from conventional T cells and confer resistance of antigen-specific effector T cells towards Treg-mediated suppression [108]. Early cytokine production from resident mucosal γδ T cells aggravates colitis induced by adoptive transfer of effector CD4$^+$ T cells in lymphopenic hosts, which can be inhibited by adoptive transfer of Tregs [159]. Treg and Tγδ17 are also likely to be engaged in dynamic interactions during the steady state, as the reduction in number and function of CD4$^+$CD25$^+$ Treg in Pdk1-deficient mice allows the expansion of pathogenic Tγδ17 cells that drive chronic intestinal inflammation [103].

Interaction with B Cells

Human Vγ9$^+$Vδ2$^+$ cells are the majority population of γδ T cells in the peripheral blood. A subset of these cells has a CCR7$^+$CD62L$^+$ central memory (TCM) phenotype, expresses the B cell follicle-homing chemokine receptor CXCR5 and the costimulatory molecules CD40L and ICOS, and is capable of producing IL-2, IL-4 and IL-10. *In vitro*, these cells are capable of helper T cell function to drive antibody production and isotype class switching [13]. In patients with genetic lymphopenia, γδ cells remain functional and are capable of providing B cell help in place of CD4$^+$ T cells, leading to the formation of small germinal centres. These patients often show hyperimmunoglobulinemia of IgE, indicative that γδ T cells are capable of driving Ig class switching *in vivo* [34, 95].

γδ T Cells and Antigen Presenting Cells (APC)

The interactions between γδ T cells and antigen presenting cells (APC) in the thymus and the periphery are crucial for their generation, maintenance and function. In the thymus, Vγ5$^+$ precursors and medullary thymic epithelial cells (mTEC) are mutually dependent. LTi (lymphoid tissue inducer) cells as well as Vγ5$^+$ γδ precursor cells provide RANK ligand signal driving the maturation and expression of Aire in mTEC [116]. While Aire expression *per se* has no role in the generation of Vγ5$^+$ DETC, mature mTEC express skint1, which is crucial for the programming of effector functions in these cells.

Intravital imaging revealed that γδ T cells at peripheral sites constantly make contacts with resident antigen presenting cells (APCs) [24]. Examples include contact between DETC and Langerhans cells (LC) in the epidermis, and between dermal γδ T cells and MHC-II$^+$ cells in the dermis. While the depletion of LCs does not affect maintenance of DETCs [134], DETCs are producers of XCL1/lymphotactin, a chemokine known to attract DC [8]. While the activation of naïve αβ T cells strictly requires interaction with mature professional APC ie dendritic cells, immature DC have been shown to be able to activate γδ T cells. Vγ9$^+$ T cells engage in reciprocal interactions with DCs, and are capable of potentiating DC maturation via production of cytokines, as well as relieving inhibitory signals that block DC maturation [62, 104, 149].

γδ T cells may themselves play a role as antigen presenting cells (APCs) thereby bridging the early innate immunity to the delayed adaptive T cell-mediated response [12, 97]. Human Vγ9$^+$Vδ2$^+$ cells have been shown to present antigen to CD4$^+$ T cells, and cross-present antigen to CD8$^+$ T cells. Activated Vγ9$^+$ cells display several salient features that enable them to function as professional APC, including uptake of soluble antigens, phagocytosis, upregulation of CCR7 enabling homing to secondary lymphoid organs, upregulation of MHC-II and the costimulatory molecules CD80 and CD86.

Interaction with Other Myeloid Cells

γδ T cells engage with myeloid populations in a bidirectional manner. Efficient presentation of phosphoantigen to Vγ9$^+$ cells *in vitro* requires the presence of monocytes [94]. Previous studies showed defective maturation of monocytes derived from mice with a deficit in γδ cells [130]. *In vivo*, different subsets of γδ T cells have protective roles in controlling macrophage-mediated immunopathological tissue damage in Listeria infection. Vγ1$^+$ T cells mediate apoptosis of activated macrophages in a Fas:FasL dependent manner [28]. The interaction between Vγ4$^+$ cells and activated macrophages promotes cytokine and chemokine production by macrophages on one hand, while inducing IL-10 production from Vγ4$^+$ cells themselves on the other [137]. Yet both the Vγ1$^+$ and Vγ4$^+$ subsets are protective against Listeria-induced liver injury in independent adoptive transfers.

Interaction with Innate Lymphoid Cells (ILCs)

Administration of chitin elicits type 2 innate inflammation in the lungs involving ILC2-mediated recruitment of eosinophils and alternatively activated macrophages. When innate lymphoid cells are depleted, there is an enhancement of Tγδ17 activation and prolonged neutrophil influx, suggesting inter-regulation between ILC2 and Tγδ17 in determining the identity of infiltrating myeloid cells in response to this allergen [143].

Trafficking of γδ T Cells

Proper homing and localisation is of paramount importance to the generation and function of γδ T cells. The medullary localisation of Vγ5$^+$ precursors is sensitive to pertussis toxin indicating a requirement for G protein coupled protein in this process. Mice deficient for an enzyme required in synthesising E- and P- selection ligands have reduced number of DETC in the skin despite normal generation of DETC in the thymus indicating the importance of these molecules for their homing and/or maintenance in the skin [69]. In the foetal thymus, TCR-mediated upregulation of CCR10 is required for homing of DETC to the skin [70]. CCR9 deficient mice have a deficiency in gut intraepithelial αβ and γδ T lymphocytes [20], indicating that the same chemokine-receptor is used for targeting both populations of T cells to this site.

Despite tissue-specific localisation of γδ T cells of restricted TCR diversity, the individual TCR *per se* is not required to dictate their tissue homing specificity. In Vγ4Vδ5 γδ TCR transgenic mice, DETC expressing the transgenic TCR instead of the canonical Vγ5 are generated and home to the epidermis, albeit at a reduced number [10]. However, the expression of a specific TCR in a specific tissue compartment is clearly of physiological relevance. As evidence, Vγ5Vδ1 deficient mice have increased susceptibility to chemically induced carcinogenesis in the skin [131]. The Taconic strain of FVB mouse which harbours heterogeneous rather than the canonical $V\gamma5^{+}V\delta1^{+}$ DETC is more susceptible to spontaneous and induced dermatitis [82].

The activation of γδ T cells initiates modulation of chemokine receptors and acquisition of differential homing potential. Human $V\gamma9^{+}$ cells constitutively express CCR5, which is downregulated as the cells become activated [43]. Activation is associated with the upregulation of CCR6 and CCR7 [11, 14]. In the lungs, intratracheal instillation of LPS or BCG induces an early TLR dependent infiltration of γδ T cells. Infiltration of γδ T cells is dependent on CCL2:CCR2, as recruitment was diminished in CCL2 (MCP-1) knockout mice and after CCL2 neutralisation, and restored with administration of CCL2 [105]. Hepatic Tγδ17 cells have a protective role in chronic liver injury that is independent of IL-17 production but dependent on CCR6-mediated homing to the liver. In two models of chronic liver injury, $CCR6^{-/-}$ mice develop more severe fibrosis, and adoptive transfer of wildtype γδ T cells ameliorates hepatic inflammation and injury [51]. Notably CCR6-mediated homing of Tγδ17 may be associated with very different outcome depending on the target organ. In a cutaneous inflammation model, CCR6 deficiency precludes the development of inflammation and hyperplasia. CCL20:CCR6 interaction is required for the recruitment of γδ T cells to the epidermis, where these cells exacerbate inflammation via production of IL-17 and IL-22 [86].

Memory Responses in γδ T Cells

There are documented instances of rapid mobilisation and expansion of γδ T cells akin to adaptive memory, however clonal expansion is of a relatively lower magnitude compared to a classical memory response of αβ T cells. In addition, although context specificity is evident, demonstration of cognate antigen specificity is lacking, and probably impractical, given the relatively unknown antigen recognition apparatus and less stringent activation requirement of γδ T cells. Nonetheless, protective effect of γδ T cells in secondary infection is a promising venue to be explored for vaccine development.

Oral infection with *Listeria monocytogenes* elicits the expansion of a population of γδ T cells in mesenteric LN that produce both IL-17 and IFN-γ. These cells are capable of rapid response to secondary oral infection with Listeria but not the unrelated pathogen Salmonella, and to oral but not intravenous infection with *L. monocytogenes*, demonstrating context specificity in response [128]. Infection of *Mycobacterium bovis* in cattle induces rapid activation and IFN-γ production from $CD8^{+}CD45RO^{+}$ γδ T cells that respond more strongly towards *M. bovis* infected rather than BCG-infected macrophages [57]. Primary infection of macaques with BCG induces polyclonal expansion of $V\gamma9^{+}V\delta2^{+}$ cells in the blood. These cells rapidly expand upon secondary BCG infection, and expansion is associated with clearance of bactereamia in the blood. More importantly, in BCG-immune macaques these cells also expand in response to secondary infection with *M. tuberculosis* and showed protection against this usually fatal infection [127]. Within the skin, we have observed an increase in the number of dermal γδ T cells with age, suggesting that these cells may also be capable of exhibiting memory [135].

γδ T Cells in Skin Disease

γδ T Cells in Skin Infections

γδ T cells by themselves are generally insufficient for sterilising immunity. However, $Tcrb^{-/-}$ x $Tcrd^{-/-}$ mice are more susceptible to viral infection indicating that these cells do have a protective role [19, 150]. Different subsets of γδ T cells may be mobilised in temporally and geographically distinct manner for early containment of damage, or later in the response for tissue repair and wound healing [18, 19]. In various models of cutaneous infection and vaccination, γδ T cells are recruited early and produce cytokines, often before the development of an αβ T cell response [100, 125]. The protozoan Leishmania is transmitted to its mammalian host through sandfly bite, and γδ T cell numbers are elevated in the blood of patients presenting cutaneous, mucosal or visceral leishmaniasis [122]. In mice, subcutaneous *Leishmania major* infection leads to a systemic expansion of $V\delta4^{+}$ γδ T cells [121]. Antibody-mediated depletion of γδ T cells culminates in larger cutaneous lesions with higher number of parasites [120]. In $Tcr\alpha^{-/-}$ mice, γδ T cells are instrumental in limiting pathogen spread and pathogen-associated damage, as shown in mouse models of footpad and corneal infection with *Herpes simplex* virus-1 (HSV-1). Mice with double deficiency of αβ and γδ T cells have larger epithelial lesions, higher viral load and dissemination, and succumb to lethal viral encephalitis [125]. In cutaneous *Staphylococcus aureus* infection, mice with γδ T deficiency have significantly larger skin lesions, higher bacterial load, and impaired recruitment of neutrophils to the infected site [23]. The ability of DETC

to rapidly produce IL-17 in an IL-1, IL-23 and TLR2 dependent manner is critical for protection. In systemic *S. aureus* infection, a population of $CD44^{+}CD27^{-}$ $V\gamma4^{+}$ γδ T cells that persists at the infection site and in draining lymph nodes after clearance of primary infection is found to rapidly expand and produce high amount of IL-17 upon secondary infection, displaying features of memory [98].

In addition, γδ T cells may modulate and shape the downstream adaptive response in a multitude of different ways in different models of infection. Depletion of γδ T cells in calves reduces *M. bovis*-specific IgG2 and IFN-γ, and increases IL-4 production [91]. The absence of γδ T cells selectively reduces IgA but not IgG or IgM production elicited by oral immunisation with tetanus toxoid plus cholera toxin [36]. In Chagas disease patients, the presence of IL-10 producing $CD4^{-}CD8^{-}$ γδ T cells in the blood correlates positively with improved clinical parameters of cardiac function [148].

γδ T Cells in Tissue Homeostasis and Wound Healing

In the gut and the skin, intraepithelial γδ T cells do not only have a role in infection and inflammation, but are also indispensable in tissue homeostasis and repair. In the mouse epidermis, DETCs are in constant contact with adjacent keratinocytes as well as Langerhans cells. At steady state, DETC is the primary population of constitutive Insulin-Like Growth Factor-1 (IGF-1) producers supporting the survival, albeit not the proliferation, of keratinocytes [65]. Deficiency of γδ T cells is associated with increased epithelial apoptosis [126].

Wound healing involves coordinated phases of inflammation, proliferation, reepithelialisation, deposition of extracellular matrix and tissue remodelling. During this process, keratinocytes rapidly migrate to and colonise the wound border, produce antimicrobial factors to prevent microbial invasion, and proliferate to re-epithelialise the wound. It is known that γδ T cell deficient mice have a wound healing defect, which can be restored with wildtype DETC [66, 155]. A recent study identified a $ROR\gamma t^{+}$ IL-17A producing subset of DETC to have a role in wound healing [87]. IL-17 blockade delays wound closure in wildtype mice, and conversely administration of exogenous IL-17 or transfer of IL-17-sufficient γδ T cells restore wound healing in $IL\text{-}17A^{-/-}$ mice. IL-17 induces downstream production of a multitude of anti-microbial factors with barrier protective functions [79, 87].

In human skin, both αβ and γδ T cells are capable of producing IGF-1. Elevation of IGF-1 is seen in acute but not chronic wounds [136]. Intraepithelial γδ T cells of the skin and the intestine, but not intraepithelial αβ T cells nor lymphoid γδ T cells, are capable of Keratinocyte Growth Factor-1 (KGF-1) production [9]. Wound healing is delayed in the presence of a dominant negative KGF receptor mutant transgene [153]. Although there is no cutaneous wound healing defect in KGF-1 deficient mice due to functional compensation by KGF-2 in the skin, exogenous KGF-1 rescues the wound healing defect of $Tcrd^{-/-}$ skin organ culture *in vitro* [66]. In normal wound healing, DETC-derived KGF-1 induces hyaluronan production from keratinocytes, which has a role in recruiting macrophages to the site [67]. Consequentially macrophage infiltration is defective in $Tcrd^{-/-}$ mice.

In mice but not humans, wound repair is accompanied by hair follicle regeneration, a process known as wound-induced hair neogenesis (WIHN). This process is dependent on the production of FGF-9 by dermal γδ T cells [39].

γδ T Cells in Psoriasis

The role of the IL23-IL17 axis in psoriasis pathogenesis is well recognised. IL-17A, IL-17 F, IL-22 and IL-21 are found to be elevated in the skin and blood of psoriatic patients, and IL-23 is selectively elevated in psoriatic lesions compared to non-lesional skin. Intradermal injection of IL-21 or IL-23 causes epithelial hyperplasia or acanthosis, one of the hallmarks of human psoriasis. IL-17A also upregulates the expression of keratin 17, a classical psoriatic disease marker, on keratinocytes [15]. IL-23R polymorphism is implicated in the pathogenesis of psoriasis [17]. While earlier studies have focused on Th17 cells, it is now known that innate cells including γδ T cells [16] and NKT cells [26] are major producers of IL-17 in psoriatic skin lesions.

In murine models of spontaneous psoriasitic dermatitis, disease progression correlates with a loss of $V\gamma5^{+}$ DETC and infiltration of $IL\text{-}17^{+}$ dermal γδ T cells [4, 38]. There is compelling evidence indicating a pathogenic role of IL-17 producing dermal γδ T cells in various models of spontaneous and induced psoriatic dermatitis in mice [15, 16, 84, 86, 101, 140]. These models include topical application of imiquimod cream, a TLR7 agonist, or intradermal injection of IL-23 . IL-17A, IL-17 F and IL-22 deficient mice are protected from psoriatic dermatitis indicating the pathogenic role of these cytokines [101, 140]. Moreover, infiltrating dermal γδ T cells and $ROR\gamma t^{+}$ ILC, rather than Th17 cells, have been shown to be the primary IL-17 producers, and are necessary and sufficient for psoriatic pathogenesis. More recently, Gray et al. found SOX13-dependent $V\gamma4^{+}$ Tγδ17 cells to be the specific pathogenic population in their model of psoriatic dermatitis [45]. These cells proliferate in skin draining lymph nodes and home to the inflamed skin. In a $CD45.1^{+}$ C57BL/6 substrain, which carries a *Sox13* mutation, the neonatal development of these $V\gamma4^{+}$ T cells is impaired, and these mice are protected from psoriasis development.

In human psoriasis patients, dermal IL-17-producing γδ T cells are found to be increased in psoriatic lesions [16]. Specifically, a population of CLA^+CCR6^+ $V\gamma9^+V\delta2^+$ cells is reduced in the peripheral blood and increased in psoriatic skin lesions suggesting disease-associated redistribution of these cells. These cells produce IL-17A, and are capable of activating keratinocytes *in vitro* in a TNF-α and IFN-γ dependent manner [78].

There have been much recent efforts geared towards targeting the IL-23/IL-17 axis in the clinic. While targeting the p40 chain of IL-23/IL-12 is potentially risky due to its pleiotropic effect, the anti-IL-17 antibodies AIN457 (secukinumab) and LY2439821 (ixekizumab), and anti-IL-17R antibody AMG 827 (brodalumab) have shown promising efficacy in phase II clinical trials involving cases of chronic psoriatic plaques [15, 60, 81, 102].

Clinical Aspects of γδ T Cell Biology

Focus on Human $V\gamma9^+V\delta2^+$ Cells as an Example

$V\gamma9^+V\delta2^+$ cells constitute the major γδ T population in the peripheral blood of healthy humans. These cells are uniquely able to recognise self- and microbial- derived phosphoantigens in a TCR-dependent, MHC-unrestricted manner. This TCR binds isopentenyl pyrophosphate, an isoprenoid intermediate of the human mevalaonate pathway, and also the microbial isoprenoid (HMBPP), an intermediate of the 2-C-methyl-D-erythritol-4 phosphate (MEP) pathway for isoprenoid biosynthesis [96]. This pathway is shared by a broad spectrum of prokaryotic and eukaryotic pathogens. The ability of these cells to bind an evolutionarily conserved group of invariant molecules via the TCR is consistent with their purported role as early rapid effectors. It has been shown that phosphoantigen recognition requires the presence of APC but is independent of MHC, MR1 or CD1. The nature of presentation of phosphoantigen remains to be resolved. The mitochondrial protein F1 ATPase (F1 adenosine triphosphatase) is a candidate phospho-antigen presenting molecule, but its involvement remains to be proven. Recent studies provided compelling evidence for an antigen-presenting role of BTN3A1, a butyrophilin-like extended B7 family member, in the binding of phospho-antigen to the Vγ9Vδ2 TCR [123, 145].

$V\gamma9^+V\delta2^+$ T cells may have promising clinical potential especially in anti-tumour therapy [44, 96, 147, 158]. These cells are able to recognise a broad range of tumour cells, and have been demonstrated to be cytolytic towards a variety of tumour cells *in vitro*. Interestingly, transformed cells have been shown to upregulate the mevalonate pathway and accumulate IPP intracellularly, pointing to possibilities of *ex vivo* expansion of these γδ T cells and targeting a conserved pathway of tumour cell metabolism. The identification of the minimal binding moiety for γδ TCR, which is a five-carbon alkenyl chain with a pyrophosphate moiety, facilitates the mining and synthesis of phosphoantigen-based agonists for *ex vivo* manipulation and expansion of these cells.

In mouse models γδ T cells have been shown to mediate anti-tumour immunity via rapid early production of cytokines [37, 85]. In a murine sarcoma model, chemotherapy induces an early rapid infiltration of Tγδ17 cells into the tumour bed that is required for the subsequent infiltration of $CD8^+$ CTL and anti-tumour chemotherapeutic efficacy [85].

Tools for Probing γδ T Cells

The inherently complex biology of γδ T cells has proven to be challenging in efforts to elucidate their behaviour and functions. In recent years, the combination of several different tools has revealed previously unappreciated aspects of their biology. The development of tetramer-staining reagents has provided new information on the role of TCR ligation in generation of γδ T cells [68, 75]. Further structural studies are likely to yield useful novel insights on the mechanism by which γδ TCR recognise a diverse range of antigens.

The vast majority of γδ T cells in mice and humans are tissue resident cells, which pose a particular challenge to flow cytometry-based studies that require tissue disintegration and single cell isolation. Enzymatic digestion has to be sufficient for single cell isolation on one hand and preserve important yet enzyme-sensitive surface molecules on the other. The availability of genetically fluorescent tagged mice and powerful intravital imaging platforms have solved some of these issues, offering the opportunity to study the cells *in situ* in real-time [20, 32, 47, 132]. The discovery that the skin contains two segregated γδ populations with distinct biology in the epidermis and the dermis is a testimony of the power of the combination of such technologies. More recently, immunological synapses between keratinocytes and DETC have been characterised using intravital dynamics-immunosignal correlative microscopy [24].

Summary

γδ T cells have unique features that make them highly relevant to immune surveillance in the host, and not a vestigial population from the evolutionary perspective. These cells recognise self-derived stress signals as well as microbial invariant molecular patterns without the need for antigen processing or presentation in an MHC restricted manner. They are localised and self-renew at peripheral sites, thus increase the probability of detecting antigens.

Some γδ T populations express invariant or oligoclonal TCR. Although not a universal feature of γδ T cells, in combination with a restricted localization, this allows the cells to respond rapidly and at an effective magnitude without

having to clonally expand, with a TCR specificity evolutionarily selected to recognise antigens likely to be encountered at peripheral sites. γδ T cells are often present in a semi-activated state, allowing them to rapidly acquire effector function without TCR ligation. The myriad interactions between γδ T cells and other cell types allow them to polarise downstream responses to facilitate an efficacious immunological outcome.

Appendix

*There are different nomenclatures for the different γδ TCR V genes, namely the Tonegawa & Heilig, Garman and Hayday systems. For example Vγ5 in the Tonegawa's system corresponds to Vγ3 in Garman's and GV1S1 in the Hayday's system. The Heilig & Tonegawa system is used in this manuscript, and in the International Immunogenetics Information System (IMGT).

Learning Objectives

- Classification of T cells in the epidermis and dermis
- Development of epidermal and dermal γδ T cells
- Functions of epidermal and dermal γδ T cells
- Role of γδ T cells in skin infection and inflammation

Review Questions

1. What T cell receptors are expressed by epidermal and dermal γδ T cells?
2. When do skin γδ T cells develop?
3. Which cytokines are produced by γδ T cells?
4. What is the role of γδ T cells in cutaneous pathology?

Answers

1. TCR gamma and TCR delta
2. at birth
3. IL17; IFN gamma; IGF1; KGF1; FGF9
4. tissue repair and wound healing, but they produce IL17 which worsens psoriasis

Mast Cells: Sentinels of Innate Skin Immunity

5

Nicholas Mascarenhas, Zhenping Wang, and Anna Di Nardo

Abstract

Since its discovery over a century ago, the mast cell has been considered an important effector cell of the innate immune system. From mediating various allergic responses to playing a direct role in eliminating pathogens from the skin, the mast cell carries out its effects through a highly coordinated process of degranulation. Following stimulation by pathogens or other host cells, the mast cell is able to release chemical mediators from its intracellular stores, which include pro-inflammatory cytokines, peptidases, and antimicrobial peptides. These mediators serve to alter the inflammatory environment and allow for the recruitment of other immune cells; however, overactivity of the mast cell response has been shown to lead to a variety of disease processes. As the main drivers of both type 1 hypersensitivity and inflammatory disorders, like rosacea, the mast cell has been studied as a target for many disease-altering therapies. Continued research in the field of mast cell biology has the potential to further unveil the coordinated workings of the innate immune system.

Keywords

Mast cell • Degranulation • Innate immunity • SCF • IgE • c-kit • Antimicrobial peptide

History

Over a century ago, when German scientist Paul Ehrlich first identified the mast cell, the field of immunology was just beginning to emerge. Ehrlich initially described these cells as "granular cells of the connective tissue… characterized by a still undetermined chemical substance… bound to granular storages in the protoplasm [1]." He adopted the term "Mastzellen" from the Greek word meaning "breast," suggesting a nourishing function for the granules; however, he found the key identifying feature of these cells to be their high affinity for blue aniline dye, which allows for visualization of the granules and distinguishes the mast cell from other cell types [2]. As studies in the field of immunology advanced, a strong association was noted between the presence of both mast cells and histamine. Riley and West analyzed the mast cell content of various connective tissues from rodents, oxen and sheep, noting a strong positive correlation between the number of mast cells and the amount of histamine present in tissues [3]. Their preliminary work suggested histamine to be the main granular substance and mediator of mast cell effects, and further studies would confirm the mast cell as a key player in allergic hypersensitivity and anaphylactic shock [4]. Much advancement has been made since the pioneers of mast cell biology made their initial discoveries. In this chapter we will outline the role of these sentinel cells of the skin, focusing on mast cell development, common activating signaling pathways, and associated skin diseases.

Overview

As resident immune cells, mast cells are found in strategic locations, particularly in connective tissues of organs with constant environmental exposure, such as the skin, airways

and intestine. For example, concentrations of mast cells have been found to be as high as 12,000/mm^3 in the skin and 20,000/mm^3 in the gastrointestinal tract [5, 6]. Within their resident tissue, mast cells further localize around blood vessels, nerves, and lymphatic vessels in order to regulate vascular permeability and to recruit effector cells through release of their granular contents. Specifically in the skin, mast cells are localized near blood vessels, hair follicles, and sebaceous and sweat glands [7].

The morphology of the mast cell can vary depending on the cell's physiological location. Free mast cells and those near blood vessels are more round or ovular in shape than those that are attached to dermal fibers, which can be more spindle or stellate. Mast cells isolated from rat peritoneum have been shown to have an average diameter of approximately 13 μm with a relatively large, acentric nucleus ranging from 4 to 7 μm [8, 9]. Mast cells are typically identified by their cytoplasmic granules that take up aniline dyes, like toluidine blue, upon histological staining. These granules, which number approximately 1000 per mature mast cell, have been shown to contain multiple mediators of cellular activity including inflammatory cytokines, proteases, antimicrobial peptides and vasoactive mediators [10].

Historically, granular staining characteristics have been used to categorize different types of mast cells. In rodents, mast cells are divided into two types based on granular heparin content and their binding properties of different dyes. Connective tissue mast cells (CTMC), which are found in rodent skin, intestinal submucosa and serosa, contain granules with heparin, while mucosal mast cells (MMC) have granules with no heparin but abundant levels of sulfated proteoglycans [11–13]. However, this distinction may not be sufficient, as many more granular mediators have been identified, like mast cell chymases and tryptases, suggesting the need for a more adequate classification system based on mediator production and function. Human mast cells all contain histamine and exhibit no differences upon histological staining; however, the two types of human mast cells can be differentiated under electron microscopy and based on their granular protease content. Mast cells with granules containing tryptase but not chymase (MC_T) exhibit a granular structure that resembles scrolls on cross section and are typically found in mucosal layers of the intestine and lungs. Human mast cells with granules containing both tryptase and chymase (MC_{TC}) lack this scroll-like morphology and have granules with a more lattice-like structure [14]. MC_{TC}s are mostly found in the skin and intestinal submucosa, and those found in connective tissue selectively express the mast cell specific carboxypeptidase A [15].

While histamine, heparin and various peptidases represent some of the main granular contents, numerous other cellular mediators are known to be stored in mast cell granules, such as prostaglandins, leukotrienes, and antimicrobial peptides like cathelicidin [16]. Upon activation, mast cells release their granules, eliciting additional activity in themselves and in neighboring cells, but before fully developed mast cells can evoke their effector functions, they must undergo a process of differentiation that begins in the bone marrow.

Mast Cell Growth and Differentiation

Mast cells have been shown to develop from hematopoietic pluripotent stem cells expressing CD34, primarily found in the bone marrow and spleen, although these progenitor cells can be isolated from cord blood and fetal liver as well [17–20]. Mast cells develop along the myeloid lineage and share many common intermediates with developing monocytes and granulocytes. Mast cells eventually enter into circulation from the bone marrow, but what distinguishes them from the other hematopoietic granular cells, basophils, is their final stage of differentiation in the peripheral tissue [21].

One of the key growth factors that triggers mast cell development is stem cell factor (SCF), also known as kit ligand or steel factor [22]. SCF, which is produced by various stromal cells and fibroblasts, binds to the tyrosine kinase receptor c-kit (CD117) expressed on the surface of mast cell progenitors [23]. Once bound to its receptor, SCF induces homodimerization and autophosphorylation of c-kit, leading to subsequent signaling cascades along the RAS/ERK, Src kinase, and JAK/STAT pathways [24]. CD117 is an important cell surface marker for mast cell precursors, and it remains expressed throughout the lifetime of the cell, unlike basophils, which lose expression of CD117 in their differentiated state [25].

The critical role that SCF plays in mast cell differentiation is highlighted in *KitW/W-v* mice, a mouse strain with two mutant alleles for the gene encoding c-Kit. These mice have been shown to be highly mast cell deficient; however, due to SCF's role in the differentiation of other hematopoietic cells, these mice also exhibit impaired melanogenesis, anemia, and sterility [26]. Furthermore, the *KitSl/Sl-d* mouse strain is deficient in SCF expression and also exhibits mast cell deficiency in all tissues, along with the previously stated defects due to impaired hematopoiesis [27]. More recently, *KitW-sh/W-sh* mice strains have been utilized for *in vivo* mast cell deficient studies, as these mice do not exhibit the anemia and sterility of other mast cell deficient strains. The *W-sash (Wsh)* mutation associated with this strain is an inversion mutation of the transcriptional regulatory elements upstream of the c-Kit transcription start site [28]. As a result, these mice show decreased skin pigmentation and a lack of mast cells in the skin and peritoneal cavity; however, they remain fertile and show normal numbers of erythrocytes [29]. Thus, the *KitW-sh/W-sh* strain has proven ideal for *in vivo* studies of mast cell-deficient skin.

In addition to SCF, mast cell progenitors respond to a variety of cytokines derived from type 2 helper T cells. IL-3, IL-4, IL-6, IL-9 and IL-10 have all been shown to induce human and murine mast cell proliferation *in vitro* [30–32]. For example, when murine bone marrow cells are cultured with IL-3, a uniform population of mature mast cells can emerge [33]. Furthermore, culturing murine mast cell progenitors in combination with SCF and IL-4 produces a distinct population of connective tissue-type mast cells [34]. Murine mast cell proliferation has also been shown to be dependent on type 2 helper T cell-derived IL-3 and IL-4, as these cytokines play a key role in inducing an increase in mucosal mast cell numbers in response to helminth infection [35]. While murine mast cell differentiation and proliferation can be stimulated with a wide variety of cytokines, human mast cell development *in vitro* has been shown to be mostly dependent on the addition of SCF and IL-6 to CD34+ cord blood cell cultures [36]. Some researchers also feel the addition of IL-3 during the early stages of cord cell culture is necessary for mast cell development [37]. In general, the culturing of human mast cells is a tedious process, requiring nearly four months for the cells to reach full maturation [38].

After initial stages of development, mast cells must exit the bone marrow, be retrieved from circulation, and localize to their resident peripheral tissues. This migration into tissue is highly dependent on locally produced cytokines that, when bound to mast cells, can induce up or downregulation of various cell adhesion molecules, facilitating the mast cell's movement through the microvascular endothelium and into tissues.[166] Studies conducted with mouse bone marrow-derived mast cells (BMMCs) suggest a migration behavior similar to that of neutrophils. Mast cell expression of integrin $\alpha_4\beta_7$ on the cell surface is critical for localization to the gut via binding to mucosal addressin cell adhesion molecule-1 (MAdCAM-1) or vascular cell adhesion molecule-1 (VCAM-1) expressed on the endothelial cell surface [39, 40]. It has been shown that mice deficient in various types of integrins lack the presence of mature mast cells in corresponding tissues. For example, mice deficient in $\alpha_4\beta_7$ have reduced mast cell numbers in the gut, while mice deficient in $\alpha_m\beta_2$ show a reduced amount of mast cells in the peritoneum and skin [40, 41].

While cell adhesion molecules are necessary for translocation through the endothelium, chemokines are the molecules responsible for initiation of mast cell recruitment and endothelial translocation [42]. However, much of the current data regarding recruitment by chemokines is conflicting. During mast cell maturation, the only chemokine receptor that is consistently expressed on the mast cell surface is CCR3, which binds chemokines CCL11, CCL24, and CCL26 [43]. While this would suggest a key role for CCR3 in the recruitment of immature mast cells to tissue, studies with CCR3-deficient mice still show high numbers of mast cells in the skin after *Trichinella spiralis* infection [44]. Furthermore, *in vitro* mouse BMMCs express CCR3 mRNA, but protein levels remain undetectable. These cells also fail to respond chemotactically to CCL11 stimulation [45]. However, the fact that CCL11 in combination with SCF can promote an increase in mast cell progenitor numbers suggests that the mast cell response to chemokines may be intricately involved in both development and migration processes [46].

Other chemokine receptors of notable importance include CXCR2 and CCR2. CXCR2 is thought to be associated with recruitment of mast cell progenitors to the lung, and evidence shows that CXCR2 can directly increase endothelial expression of VCAM-1, leading to increased mast cell translocation via integrin $\alpha_4\beta_7$ [47]. Additionally, increased levels of CCR2 have been found in allergen-exposed lung tissue [48]. After similar allergen treatment in mice deficient in CCR2 and its ligand CCL2, mast cell numbers in the lung were highly reduced, suggesting a key role for CCR2 in mast cell recruitment to the lung and possible implications for asthma patients [48].

Mast Cell Signaling

Once localized to their resident tissues, mast cells can be activated to carry out their physiological role by either modulating granular contents or releasing granular contents via three types of exocytosis: granular exocytosis in which individual granules release their contents outside the cell by fusing with the plasma membrane, compound exocytosis in which granules fuse to the plasma membrane and to each other forming channels for maximum biological effect, and piecemeal exocytosis in which small vesicles bud off from granules and then fuse with the plasma membrane [49]. The process of mast cell activation is highly regulated by a combination of stimulatory and inhibitory signals downstream from a plethora of cell surface receptors. In this section, we will cover the classical mast cell activation pathways via the high affinity IgE receptor and toll like receptors, as well as pathways of inhibition. However, before covering these signaling pathways, an overview of the granular contents is warranted.

Mast Cell Mediators

The mast cell secretory granules contain a wide variety of preformed mediators that can be released within seconds to minutes after activation [49]. The most common of these preformed mediators is histamine, which constitutes approximately 10% of the weight of granules [50]. Histamine is produced by both MC_Ts and MC_{TC}s, and within the granule, it is bound to negatively charged proteoglycans and is

released from this complex after secretion by cation exchange [50, 51]. Furthermore, the presence of heparin in the granules serves to stabilize the multimeric complexes of histamine, proteoglycan and other proteases [52]. Because the half-life of histamine is relatively short, its effects are local and brief. While histamine can have broad, systemic effects, it is known to mediate the classic wheal and flare reaction in the skin, due to its ability to induce vasodilation and subsequent plasma extravasation. The combination of these two events leads to local erythema and swelling typical of urticarial reaction [53]. Additional effects of histamine include bronchial and intestinal smooth muscle constriction, increased mucus production in nasal cavities, and neutrophil and eosinophil chemotaxis [54, 55]. The effect of histamine on local tissues depends entirely on the expression of histamine receptors by the target cells. H_1–H_4 receptors all mediate the effects of histamine in a different way, leading to the above-mentioned reactions in different tissue types [56].

In addition to histamine, a wide variety of proteases are contained within preformed mast cell granules, mainly tryptases and chymases. Tryptase can serve as a marker of mast cell degranulation, as its half-life is significantly longer than that of histamine [57]. Furthermore, it is synthesized by all types of human mast cells and has been shown to induce the following physiological effects: inhibition of fibrinogenesis, stimulation of fibroblast proliferation, upregulation of IL-8 and ICAM-1 in bronchial epithelial cells, and recruitment of neutrophils in mice [58–61]. Chymase proteases, which include well-studied cathepsin G, are expressed only in MC_{TC}s found exclusively in the connective tissue and skin. Chymase proteases have been shown to induce conversion of angiotesin I to angiotensin II, degradation of adhesion proteins in the basement membrane zone, and inactivation of bradykinin [62–64]. Another molecule found exclusively in MC_{TC} mast cells is carboxypeptidase A. Functioning to convert angiotensin I to angiotensin II and to degrade toxins like snake venom, carboxypeptidase A has been found to be the most specific mast cell marker, as it has not even been identified in basophils [65, 66].

In addition to preformed mediators, mast cells have the capacity to synthesize newly formed mediators upon activation, primarily derived from cell membrane phospholipids that can be converted to arachadonic acid. This arachadonic acid can subsequently be used to form various eicosanoids, such as prostaglandins (PGs), leukotrienes (LTs), and platelet activating factor (PAF) [67]. While PGs and LTs are vasoactive and can mediate smooth muscle contraction, PAF has been shown to be a chemoattractant for neutrophils, monocytes and macrophages, as well as an inducer of bronchoconstriction and vascular permeability [56]. Additional newly synthesized mediators include various interleukins and TNF-α, which act in the recruitment of other immune cells [56].

Activating Receptors

The classical stimulatory pathway for granular mediator release involves the high-affinity IgE receptor, FcεRI. Upon primary exposure to an antigen, IgE antibodies can be synthesized and can subsequently bind to the mast cell FcεRI via its Fc region [68]. Binding of IgE to the FcεRI is high-affinity with a very slow dissociation, ensuring long-term antigen specificity and memory for the mast cell [69]. Activation of the mast cell requires cross-linking of the FcεRIs, which can be induced by antigen binding to the variable region of two IgE molecules already bound to FcεRIs [70]. A variety of molecules can induce cross-linking such as multivalent antigens, antibodies against IgE or antibodies against the FceRI itself. The FceRI has a tetrameric structure: one alpha chain with two extracellular domains for binding IgE, one beta chain with four transmembrane domains, and two gamma chains with cytoplasmic immunoreceptor tyrosine-based activation motifs (ITAMs) important for downstream signal transduction, which will be discussed later [71].

The IgG receptors FcγRI in humans and FcγRIII in mice have been shown to be expressed on the surface of mast cells and activate degranulation in response to binding of IgG3 [72]. Some research suggests that immune complexes may be important for activating signaling downstream of the FcγRI, as only antigen-antibody complexes have been shown to bind the receptor and not monomeric IgG [73]. Additional activating receptors include c-kit and complement receptors. While c-kit is critical for mast cell growth and development, binding of SCF via c-kit on mature mast cells has been shown to induce degranulation as well as the production of IL-10, IL-1beta and leukotrienes [74, 75]. Mast cells have also been observed to express receptors for complement peptides C3a and C5a. Studies show that when stimulated with C3a and C5a, skin mast cells release histamine in a concentration dependent manner. Effects are rapid, with complete histamine release occurring within 15 s; however, complement stimulation appears to have little effect on the generation of new mediators like prostaglandins or leukotrienes [76]. Furthermore, when human mast cells were stimulated with C5a and C3a in combination with aggregated IgG the effects of degranulation were additive, suggesting that, even though the signaling pathways of these receptors are independent, parallel pathways may work synergistically for maximal immune response [77].

Inhibitory Receptors

Mast cell degranulation must be kept in tight control by a balance of both activating and inhibitory signals. Most inhibitory receptors have been shown to be associated with

immunoreceptor tyrosine-based inhibitory motifs (ITIMS), unlike the ITAMs found associated with activating receptors [78]. One of the most well studied inhibitory receptors on the mast cell is the IgG receptor, FcγRIIB. It has been shown that when FcγRIIB is cross-linked to FcεRI via IgG-antigen complexes, the normal degranulation response via the high-affinity IgE receptor is greatly diminished [79]. Therapies have been investigated using this method. For example, when exposed to cat-allergic donors' mast cells, IgG-cat allergen complexes led to dose dependent inhibition of histamine release, suggesting a method for de-sensitization to various allergens [80]. Furthermore, evidence exists showing FcγRIIB's role in suppressing signaling from other activating receptors like c-kit [81]. Note that FcγRIIB is distinct from the IgG receptor involved in mast cell activation.

Other receptors, like CD300a (IRp60) and CD200, are expressed on the surface of many myeloid cells and have been shown to have inhibitory effects in mast cells. When ligated to the high-affinity IgE receptor, IRp60 blocked IgE-induced mast cell degranulation [82]. The same has been shown for CD200 in CD200-deficient mice, and although this receptor is not associated with an ITIM, this suggests a potential role in setting a threshold for mast cell activation [83]. Additionally, mouse studies have shown constitutive expression of gp49B1 on the mast cell surface. This protein contains two cytoplasmic ITIMs, and antibody-induced co-ligation of gp49B1 with FcεRI was shown to inhibit release of preformed mediators as well as synthesis of lipid mediators [84]. Furthermore, gp49B1 can constitutively suppress mast cell activation through binding of its ligand, integrin αv3, suggesting its independence from the adaptive immune response [85]. While various inhibitory receptors have been identified, their true physiological significance is still being investigated.

Signal Transduction

Signal transduction associated with mast cell activation involves a complex network of signaling cascades that ultimately function to increase cytokine production, synthesize new lipid mediators (eicosanoids), and to release secretory granules. The most well studied signal transduction pathway in mast cells involves cross-linking of the high-affinity IgE receptor and will be discussed here, as signal transduction for this receptor overlaps with that of other activating receptors in the mast cell. As stated previously, activating signaling begins with FcεRI cross-linking via a multivalent antigen [70]. Each FcεRI has two associated ITAMs, one on the beta chain and one on the gamma chain [71]. After cross-linking occurs, both ITAMs are immediately phosphorylated by Lyn, a protein tyrosine kinase that is constitutively associated with the beta chain ITAM [86]. Once phosphorylated, the ITAMs can serve as binding scaffolds for molecules with Src homology 2 (SH2) domains, such as additional Lyn molecules or Syk family kinases. Syk binds via its SH2 domain to the ITAM of FcεRI gamma chain and is subsequently phosphorylated by Lyn, which is constitutively bound to the beta chain [87, 88].

Activation of Syk is critical, as it is able to phosphorylate a number of proteins including linker for activation of T cells (LAT), SH2-domain-containing leukocyte protein of 76 kDa (SLP-76), and Vav, a guanindine nucleotide exchange factor [89]. Additionally, Fyn, another Src kinase that is activated independently of Lyn, can phosphorylate Grb2-associated binding protein 2 (Gab2) [90]. The association of LAT with SLP-76, Gab2, Grb2, and Vav is responsible for downstream signaling via the mitogen-associated protein kinase (MAPK), protein kinase C (PKC), and Ca^{2+} dependent pathways [89].

Upon cross-linking of FcεRIs, LAT is able to associate with the adaptor protein Grb2 and Sos [91]. This LAT/GRB2/Sos complex can subsequently stimulate the conversion of Ras-GDP to Ras-GTP, which can then activate the Ras/ERK signaling pathway. Ultimately, ERK can induce increased levels of phospholipase A_2 (PLA_2), which is responsible for production of arachidonic acid from cell membrane-derived phospholipids [92]. Arachidonic acid can subsequently be converted to the newly synthesized eicosanoid mediators that are released upon mast cell activation. LAT is also able to bind SLP-76, which can then associate with Vav. Vav can subsequently activate Rac proteins, which play a critical role in cytokine gene transcription and cytoskeleton rearrangement [93, 94]. Finally, the LAT/SLP-76/Vav complex can induce activation of phosphotidylinositol-specific phospholipase C (PLCγ1). Activated PLCγ1 can induce transformations in various cell membrane phospholipids to produce the second messengers diacylglycerol (DAG) and inositol 1,4,5 triphosphate (IP3) [95, 96]. DAG is able to activate protein kinase C (PKC), and PKC can in turn phosphorylate a variety of proteins including myosin light chain, thought to be involved in granule release, and c-fos and c-jun, which regulate genes involved in cell cycle progression and anti-apoptotic activity [97, 98]. IP3 on the other hand, plays a critical role in releasing intracellular Ca^{2+} stores from the endoplasmic reticulum [99]. The increase in intracellular Ca^{2+} is required for mast cell granule release. While IP3 mediates initial release of Ca^{2+} stores, TRPC channels expressed on the cell membrane are thought to be involved in extracellular Ca^{2+} influx for a sustained increase in cytosolic Ca^{2+} levels [100, 101].

In summary, mast cell activation is mediated by a wide array of stimulatory and inhibitory receptors, principally the high-affinity IgE receptor. Following the cross-linking of the IgE receptors, activation of LAT, SLP-76, and Vav can induce downstream signals that lead to granule release, synthesis of

eicosanoid mediators, and transcription of various cytokines and cell growth factors.

Mast Cell Response to Microbes

While previously discussed mast cell activation and degranulation mainly involves antibody intermediaries and activation of the adaptive immune response, mast cells also play a key role in innate immune processes and direct recognition of microbes that come into constant contact with the human epidermis. This section will assess the role of masts cell in innate immunity and processes critical to maintenance of the skin microbiome.

Mast cell activation in response to microbes typically occurs via toll-like receptor (TLR) signaling, as these receptors are able to engage in direct contact with microbial pathogens by recognizing structurally conserved molecules of the microbe. TLR signaling does not typically induce degranulation of the mast cell, but rather it stimulates the production of antimicrobial peptides and inflammatory cytokines that aid in the recruitment of other immune cells. Cultured human mast cells have been shown to express TLR-1, 2, 4, 5, and 6 on their cell walls, while TLR-3, 7, 8, and 9 are expressed on the surface of endosomes [102]. Each TLR binds to a distinct class of pathogen associated peptides or molecules. A summary of the most well studied TLRs and ligands is included below:

TLR	**Ligand** [102, 103]
TLR1	Lipopeptide (Pam3csk4)
TLR2	Peptidoglycan, Zymosan, LTA, Lipopeptide (Pam3csk4)
TLR3	PolyI:C (dsRNA)
TLR4	LPS, RSV protein F, *Mycobacterium tuberculosis*
TLR6	Peptidoglycan, Zymosan
TLR9	Bacterial DNA (CpG motifs)

For example, lipopeptides from various gram-positive bacteria can bind to both TLR1 and TLR2 inducing heterodimer TLR1/2 formation and subsequent downstream signaling. Similarly, peptidoglycans (PGNs) and zymosan, components of microbial cell walls, cause heterodimerization between TLR 2 and 6. Despite the wide array of stimulatory ligands and TLRs expressed on the mast cell, a common downstream signaling pathway leads to activation of the transcription factor NFkB and the MAPKs, p38 and JNK [102–104].

Mast Cell Response to Bacteria

Due to the mast cells' strategic location in the skin, they play an important role in innate immunity against bacteria through their ability to phagocytose pathogens, present bacterial antigens to T cells, recruit other phagocytic cells, release mediators and cytokines, and produce cathelicidin antimicrobial peptides [105–107].

Some of the earliest studies in mast cell responses to bacteria show that rodent mast cells are capable of phagocytosing bacteria via complement receptors [108]. Additional studies in complement C3-deficient mice demonstrate a decrease in peritoneal mast cell degranulation, production of TNFα, neutrophil infiltration and clearance of bacteria. Treating these mice with purified C3 protein reversed these defects, confirming that complement activation aids the mast cell's full functionality in innate immune defense [109]. Additional preliminary research shows that certain bacteria are able to induce mast cell degranulation. Formalin-killed bacteria such as *Escherichia coli, Enterobacter cloacae, Staphylococcus epidermidis, Proteus vulgaris* and *Klebsiella oxytoca* in addition to bacterial antigens like hemolysin all have the ability to induce histamine release in mast cells [110–112]. However, some bacteria have been shown to have the opposite effect. For example, *Helicobacter pylori*, a major cause of gastritis, peptic ulcers and gastric cancer, is able to directly inhibit histamine release, perhaps contributing to the bacteria's persistence in the gastric mucosa [113]. High doses of non-pathogenic, commensal *E. coli* have also been shown to be a direct inhibitor of degranulation in intestinal mast cells, suggesting a potential mechanism for this commensal bacteria's survival in the intestine, which could potentially be applied to other commensal bacteria in the skin [114].

Despite the varying effects that different strains of bacteria can have on mast cell degranulation, it is considered a commonality that TLR-2 and TLR-4 play important roles in the mast cell's innate immune response to most bacteria. More specifically, these receptors are required for mast cell release of cytokines and chemokines. For example, upon stimulation with LPS derived from *E. coli*, TLR-4 was shown to be necessary for release of the common inflammatory cytokines TNF-α, IL-1β, IL-6, and IL-13 from BMMCs [115]. Furthermore, mast cell-deficient mice that were reconstituted with TLR-4-mutated BMMCs showed defective neutrophil recruitment and production of inflammatory cytokines in the peritoneum, demonstrating the key role the TLR-4 receptor plays in mediating recruitment of other immune cells [115]. While LPS stimulation is mediated primarily through TLR-4, PGN from *S. aureus* stimulates mast cells in a TLR-2 dependent manner to produce TNF-α, IL-4, IL-5, IL-6, and IL-13 but not IL-1β. Additionally, intradermal injection of PGN promoted mast cell-mediated vasodilation and inflammation via TLR-2 [116]. Further evidence exists suggesting that skin-derived mast cells produce the pro-inflammatory cytokines TNF-α and IL-6, but not degranulation, in response to poly (I:C) stimulation via TLR-3, TLR-7 and TLR-9 [117].

Clearly, the mast cell response and production of cytokines depends greatly on the bacterial stimulus and TLR-mediated signaling.

In addition to cytokine production and release, mast cells are capable of releasing antimicrobial peptides, particularly cathelicidin, that can evoke direct bactericidal and anti-viral effects. Cathelicidin antimicrobial peptide was originally thought to be found only in neutrophils, but it has been identified in other cell types, including macrophages and epithelial cells in response to various microbes and 1,25-vitamin D [118]. Initial studies show that LL-37, the human cathelicidin peptide, is able to bind to high and low affinity receptors on the surface of mast cells. This binding cannot only induce degranulation but also mast cell chemotaxis, suggesting that mast cell recruitment to the site of infection is critical for innate immune responses [119]. However, more recent research shows that LL-37 is also synthesized by cultured murine and human mast cells and is necessary for efficient bacterial killing [120]. Furthermore, using mast cell- and cathelicidin-deficient mouse models, it has been demonstrated that mast cells help protect against invasive group A *Streptococcus* infection in the skin by producing cathelicidin. The LL-37 purified from mast cells has been identified as a unique 28-aa peptide by using surface-enhanced laser desorption/ionization time-of-flight mass spectrometry (SELDI-TOF-MS) analysis [121].

In conclusion, conserved bacterial elements not only have both stimulatory and inhibitory effects on mast cell degranulation, but they can also elicit recruitment of other immune cells via cytokine release through TLR signaling [122]. The mast cell's ability to directly clear bacteria through cathelicidin release also demonstrates this cells critical role in the innate immune response.

Mast Cell Response to Viruses

While extensive research has been conducted on the mast cell's role in bacterial infection, less has been studied about the mast cell response to viruses. Early work in this field shows that mast cells can be activated to both proliferate and release their granular contents [123, 124]. For example, Sendai virus can generate permeability lesions in the membranes of rat mast cells and induces release of histamine and various proteases by normal exocytotic mechanisms. [125] Although most research on mast cell interaction with viruses has been modeled in the airway connective tissue and epithelium, it is important to note that certain respiratory viruses, like respiratory syncytial virus (RSV) can induce degranulation as well as an increase in TNF-α production. However, this only occurs in co-culture with RSV-infected airway epithelial cells. Incubation of mast cells with medium from the RSV-infected epithelial cells fails to induce degranulation, suggesting a potential mechanism for crosstalk between infected cells and neighboring mast cells [126].

A similar occurrence has been noted between skin mast cells and epidermal keratinocytes infected with herpes simplex virus (HSV). Studies in mast cell-deficient mice showed increased severity of disease after transdermal injection with HSV2, and reconstitution of these mice with BMMCs reversed the high severity and mortality associated with HSV2 infection. Furthermore, TNF-α and IL-6 production in mast cells was stimulated by IL-33 derived from HSV2-infected keratinocytes [127]. Additionally, Wang et al. showed mast cell degranulation in the context of viral infection is dependent on the presence of a viral envelope, as found in vaccinia virus (VV). Lipid fusion of the VV envelope with the mast cell membrane was shown to be sufficient to induce cathelicidin release and TNF-α release, resulting in the recruitment of neutrophils and antimicrobial activity [128]. This further suggests a key role that mast cells may play in triggering inflammation after communication with virally infected cells.

While it is clear that mast cells assist in immune defense to help neighboring tissues, they have also been shown to be susceptible to direct infection by human immunodeficiency virus type 1 (HIV-1) due to their surface expression of CD4 and chemokine receptors CCR3, CCR5, and CXCR4 [129]. HIV-1 glycoprotein, gp120, can act as a viral superantigen inducing cytokine release from infected mast cells. The subsequent trafficking of infected mast cells to various tissues in combination with the mast cell's long life span may contribute to the widespread and persistent viral reservoir in AIDS patients [130, 131]. However, some studies show immunohistochemical evidence of no active HIV replication in tissue mast cells, challenging the hypothesis of the mast cell HIV reservoir [132]. Additional research is warranted to elucidate the mast cell's exact role in combating HIV.

It was previously mentioned that cathelicidin antimicrobial peptide from mast cells has the capacity to directly kill bacteria in the skin. Further research shows that release of cathelicidin by mast cells also has an effect on viral invasion by preventing vaccinia virus (VV) infection. VV is able to bind to the mast cell via its L1 viral membrane protein. Once bound, the virus is endocytosed leading to the activation of the phospholipid mediator S1P and expression of S1PR2. This S1PR2 receptor can function in an autocrine manner inducing degranulation of the mast cell. The granules released in response to VV are shown to contain cathelicidin, which is critical for maintaining low levels of infection [128]. Despite compelling evidence for the mast cell's role in innate immunity against viral infection, the specific mechanisms of viral response in the mast cell are still under investigation.

Mast Cell Response to Fungi

Fungi are one of the four major groups of microorganisms that affect the skin. While knowledge of the mast cell's role in defense against fungal infection remains extremely limited, some reports have highlighted the importance of the mast cell's capacity to kill *Candida albicans* in vitro. Di Nardo et al. showed that when compared to wild type mice, mast cell-deficient mice exhibit persistently larger skin lesions when inoculated with *C. albicans*, suggesting that mast cells play a central role in protecting the skin during fungal infection. Additional *in vitro* studies using isolated rat peritoneal mast cells show potential for mast cell phagocytosis of opsonized *C. albicans*, while exerting fungicidal effects on non-opsonized fungus outside the cell membrane [133]. These fungicidal effects are carried out by mast cell degranulation, but further studies in the field are needed to further unveil interactions between mast cells and fungal microorganisms.

Mast Cell Response to Parasites

Throughout the past decades, multiple studies have been performed showing the activation of mast cells during parasitic infection. While the majority of this research has focused on peritoneal and mucosal mast cells in rodents, it is important to note the key role that the mast cell plays in regulating the inflammatory response to parasites.

For example, daily injections of phospholipid preparations from *Ascaris suum* or from *Echinococcus granulosus* cysts are able to induce blood eosinophilia and mast cell granule lysis along with mast cell hyperplasia [134]. Infection by the nematode parasite *Trichinella spiralis* has been shown to induce increased numbers of IgE containing mast cells in the intestinal mucosa of mice [135]. In addition to the recruitment of mast cells to the site of infection, parasites like *Toxoplasma gondii* have been shown to induce mast cell degranulation, followed by an observed increase in neutrophil count at the site of infection [136]. This suggests that mast cells are critically involved in parasite-mediated inflammation and recruitment of other immune cells. It has also been shown that mast cells play a role in direct elimination of the parasite. During infection with *Schistosoma mansoni*, a pronounced hepatic mastocytosis, or an abnormally high number of mast cells, is observed in rats. The majority of these recruited hepatic mast cells contain a highly soluble granular chymase that is released systemically into the blood during the period of parasite elimination. Thus, due to these chymases, infection is terminated in the liver before egg laying commences [137].

More relevant to the skin is the mast cell's activity during *Leishmania major* infection. Cutaneous leishmaniasis is a quickly spreading, ulcerative skin disorder caused by protozoan parasitic infection [138]. While some evidence shows mast cells to be the cause of increased lesion size and intensity, this is likely due to the immediate release of mediators like beta-hexosaminidase and TNF-α upon mast cell contact with the parasite [139, 140]. Despite the mast cell's apparent contribution to the appearance of the lesion, it has also been shown that mast cell degranulation may inhibit infection. When mast cells in mice were induced to degranulate before *L. major* challenge, these mice showed lower rates of infection along with high levels of IFN-γ and reduced levels of IL-4 [141].

Despite a large amount of evidence that parasites are capable of inducing mast cell activation and degranulation, it has been repeatedly shown that infection by certain parasitic roundworms leads to inhibitory signaling via TLR-4. In contrast to the binding of TLR-4 to LPS, when bound to the ES-62 protein from roundworms, a resultant inhibition of FcεRI activation occurs. Binding of ES-62 to TLR-4 on the surface of mast cells causes sequestration of PKC, which in turn inhibits downstream signaling of the high-affinity IgE receptor [142].

In summary, the presence of mast cells is strongly associated with parasitic infection, mediating inflammation and the recruitment of other immune cells. Although many mechanisms of mast cell defense against parasites remain unknown, it is now evident that mast cells can amplify protective responses against parasites in innate immunity as well as play a conflicting role in inflammation and pathology at sites of infection.

Mast Cell-Associated Skin Diseases

Hypersensitivity Reactions

Mast cells are the primary mediators of immediate anaphylactic hypersensitivity (type 1) reactions. Tissue mast cells that are sensitized with IgE antibodies bound to the high-affinity IgE receptor can also bind to antigen, inducing receptor cross-linking and subsequent mast cell activation and mediator release, as outlined in the section on mast cell activating receptors. Release of these mediators results in increased vascular permeability, edema and smooth muscle contraction. The most common manifestations include urticarial rash, erythema and pruritus, while extreme cases can lead to anaphylaxis. This type 1 hypersensitivity reaction is associated with both food and drug allergies [143].

Mast cells have also been shown to be considerably active in delayed-type hypersensitivity (type 4) reactions (DTHRs), and most relevant to the skin, contact hypersensitivity reactions. DTHRs depend on the presence of type 1 memory T cells and their ability to produce IFN-γ. Hapten binding is

the initial step of these reactions. Low molecular weight contact allergens, called haptens, are able to penetrate the epidermal barrier and bind to various skin proteins [144]. During the initial sensitization phase of the reaction, the bound hapten can be recognized by Langerhans cells, leading to migration to the lymph nodes and clonal expansion of both CD4+ and CD8+ hapten-specific T cells [145, 146].

The following effector phase of the contact hypersensitivity reaction is less studied, but mast cells have been shown to play an important role. During the effector phase, Ig free light chains are produced by B lymphocytes, and they have been shown to be necessary for full development of contact hypersensitivity in mice [147]. Furthermore, these free light chains have been shown to be important in the sensitization of mast cells and for their activation when coming into contact with allergens [148]. While this evidence suggests that mast cells may be involved in the development of DTHRs, various other studies involving reconstitution of mast cell-deficient mice with mast cells cultured *in vitro* show that in various DTHRs, like allergic encephalitis, contact hypersensitivity and cutaneous responses to microbes, mast cells are needed for full manifestation of symptoms. [149–151] Specifically in the DTHR context, mast cells produce TNF-α for induction of dendritic cell migration, IL-3 for proliferation and activation of T cells, and they may play a role in direct antigen presentation [152]. While mast cells may not be the main mediators of contact hypersensitivity reactions, their presence proves necessary for a coordinated immune response, recruitment of other cell types, and full development of symptoms.

Rosacea

Recent studies show new evidence that demonstrates the mast cell's central role in the pathogenesis of rosacea. With approximately 16 million Americans affected, this chronic inflammatory disease can flare up due to increased temperature, spicy foods, or various other environmental triggers. The resulting, often painful, inflammation can take weeks to subside without treatment [153]. It has also been shown that rosacea is associated with elevated levels of an aberrant form of antimicrobial peptide, cathelicidin LL-37, due to overactivity of kallikrein-related peptidases (KLKs), which can generate LL-37 from its precursor peptide [154]. Studies in mast cell-deficient *KitW-sh/W-sh* mouse strains show that upon intradermal injection with LL-37, *KitW-sh/W-sh* mice fail to develop rosacea-related inflammation, whereas wild type mice exhibit the phenotypically characteristic inflammation of rosacea. Furthermore, it is now known that upon stimulation with LL-37, mast cells respond by releasing metalloproteinase 9 (MMP9), the enzyme responsible for activating KLKs, and proinflammatory IL-6, suggesting a critical role for the mast cell in rosacea inflammation. Ultimately, treatment in human rosacea subjects with 4% cromolyn sodium, a known mast cell stabilizer, significantly decreased rosacea-associated inflammation, and in mouse models, it has also been shown to reduce levels of MMP9 [155]. This data shows that the presence of mast cells in the skin is necessary for development of the rosacea phenotype. Furthermore, mast cell stabilizers may prove to be the treatment of choice for rosacea patients.

Mastocytosis

Mastocytosis is characterized by abnormally high numbers of mast cells localizing in one or multiple tissues. This rare disorder is accompanied by chronic or episodic degranulation and release of mast cell mediators into the tissue. Cutaneous mastocytosis involves only the skin, while systemic mastocytosis affects internal organs with or without involvement of the skin [156]. While pathogenesis of the disease is not fully understood, mastocytosis has been shown to be associated with mutations in the gene encoding the c-kit receptor or with increased expression of SCF. The most common c-kit mutation is a D816V mutation of exon 17. This activating mutation induces SCF-independent activation of c-kit, leading to both clonal expansion and apoptotic defects in the mast cells [157, 158]. Increased levels of free SCF have also been identified in the dermis and extracellular spaces of the epidermis in patients with cutaneous mastocytosis; however, this elevation of SCF may be variable in different patients [159]. Patients with cutaneous mastocytosis typically present with a yellow-tan to reddish-brown maculopapular skin lesion known as urticaria pigmentosa, a fixed accumulation of mast cells in the skin, which may also manifest itself in a plaque or nodular form. More rare presentation involves diffuse mastocytosis, which may present in a bullous form and involve the whole skin, or mastocytomas, which usually present in childhood [160, 161]. Mediator release from the mast cells has a presentation that mimics allergic reactions with the typical symptoms of pruritus and flushing [162]. While children with cutaneous mastocytosis typically clear the disease by adolescence, avoidance of triggers that lead to mediator release like temperature change, friction, and physical exertion is important for the disease to remain asymptomatic. Antihistamines and PUVA have proven to be effective therapies; however, treatment with corticosteroids has not been shown to diminish symptoms of the disease [162].

Conclusions

Mast cells prove to be an extremely important part of the innate immune system in the skin. From their ability to initiate recruitment of critical immune cells to their

central role in the allergic response, mast cells truly are the sentinels and directors of many coordinated immune responses. Furthermore, key therapies like imatinib and similar biologics act by blocking the effect of c-kit, and thus mast cell development, in the context of various types of malignancies. The development of medications that can directly target the mast cells further demonstrates this cell's key role in the innate immune response. While much has been discovered about the mast cell's role in the skin, there remains great potential for further study and development of therapeutics centered on mast cell function.

Questions

1. Which cytokine is critical for proper mast cell differentiation?
   A. IL1
   B. SCF
   C. IL6
   D. TNFα

2. Binding of which of the following molecules to the mast cell surface can induce degranulation?
   A. IgE
   B. IgG
   C. Complement peptides
   D. All of the above

3. Release of which of the following mast cell mediators has been shown to aid defense against microbes?
   A. Cathelicidin
   B. Histamine
   C. Leukotrienes
   D. Prostaglandins

Answers

1. B
2. D
3. A

Antimicrobial Peptides

6

Andrew J. Park, Jean-Phillip Okhovat, and Jenny Kim

Abstract

The skin is traditionally viewed as a physical barrier to environmental insults. Its role in immunity goes beyond its role as simply a barrier, as it plays a dynamic role in regulating immune responses and controlling microbial populations, notably through the use of antimicrobial peptides (AMPs). In 1987, Zasloff and colleagues were one of the first to describe the existence of potent AMPs on the skin of vertebrates. Since then, numerous AMPs have been identified and characterized in human skin. AMPs are a heterogeneous group of small proteins with a wide spectrum of antimicrobial activity against bacteria, fungi, and viruses. These peptides are almost all positively charged and amphipathic, allowing for the peptides to be soluble in an aqueous environment while still retaining an ability to bind bacterial membranes and walls. Once bound to the target membrane, the peptides kill through various mechanisms that involve both the physical perforation of pathogens and triggering of the host immune response. This chapter will focus on known AMPs present in human skin, with special focus given to defensins, cathelicidins, granulysins, S100 proteins, and ribonucleases; and their involvements in the etiology of dermatologic diseases.

Keywords

Antimicrobial peptide (AMP) • Defensin • Cathelicidin • LL-37 • Granulysin • S100 • Ribonuclease (RNase) • Psoriasin • Dermcidin • Secretory leukocyte protease inhibitor (SLPI) • Psoriasis • Atopic Dermatitis • Acne • Rosacea • Mycobacteria • Wound healing

Introduction

The skin is primarily thought of as a physical barrier to environmental insults and microbes. Yet its role extends far beyond simply a physical barrier, as the skin is also a dynamic immune organ that responds with robust defense mechanisms to microbial invaders, notably through the use of antimicrobial peptides (AMPs). AMPs in the skin are of considerable interest not only for their properties in controlling microbial populations but also for their effects on influencing inflammatory and immune responses. In 1987, Zasloff led one of the first groups to describe the existence of a potent antibacterial peptide present in the skin of the African frog *Xenopus laevis* [1]. Since then, numerous AMPs have been described in human skin and their roles in host defense have been extensively characterized.

AMPs are a heterogeneous group of small molecular weight proteins with a wide spectrum of antimicrobial activity against bacteria, fungi, and viruses. These peptides are almost all positively charged and amphipathic, having both hydrophobic and hydrophilic surfaces, allowing for solubility in aqueous environments while still retaining the ability

to bind bacterial membranes through their hydrophobic surfaces. Once bound to the target membrane, the peptides can kill the organism through various mechanisms. Furthermore, there is a growing body of evidence supporting the ability of AMPs to alter the host immune response (Table 6.1).

This chapter will focus on the main AMPs present in human skin and the relevant dermatologic conditions in which deficiency or overexpression of AMPs is thought to play an important etiologic role. (A summary of described AMPs present in the skin can be found in Table 6.2.)

Defensins

Defensins are a family of AMPs with a characteristic β-sheet fold and six disulfide bonds between highly conserved cysteine residues. There are two main defensin subfamilies, alpha- and beta-defensins, that differ mainly in the pairing of cysteine residues. Members of both subfamilies consist of a triple-stranded β-sheet with a prototypic 'defensin' fold (Fig. 6.1). There is a third defensin family, theta-defensins, that is not expressed in humans but is found in several Old World primates. Theta-defensins are thought to inhibit the fusion of HIV-1 to host cells by inhibiting bundle formation needed for fusion [2, 3].

Defensins are widely distributed in cells and tissues involved in host defense and are found in highest concentrations within phagocyte granules. Alpha-defensins, which have disulfide bridges between cysteines 1–6, 2–4, and 3–5 [4], are found predominantly in neutrophils [5], and have aptly been named human neutrophil peptides (HNPs). In humans, alpha-defensins are stored in azurophilic granules of neutrophils as fully processed mature peptides. Two alpha-defensins, human defensins (HD)-5 [6] and 6 [7], are expressed in Paneth cells of the small intestine and the epithelium of the female urogenital tract [8].

Alpha-defensins show a wide spectrum of antimicrobial activity against bacteria and fungi. They have also been shown to inactivate certain viruses, including adenovirus [9] and polyomavirus [10], and have been implicated as one of the molecules that may be important in the antiviral activity seen in $CD8^+$ T cells of HIV-non-progressors [11]. Immunologically, alpha-defensins contribute to the host inflammatory response, for example, by increasing the expression of tumor necrosis factor (TNF)-α and interleukin (IL)-1 in *S. aureus*-activated monocytes [12]. High concentrations of alpha-defensins are toxic to mammalian cells and may be important in tissue injury and necrosis during inflammation. It has been suggested that the upregulation of alpha-defensins 1–3 from T cells may be involved in the

Table 6.1 Antimicrobial and immunomodulatory properties

	Antimicrobial activity			Regulation
	Gram +	Gram −	Fungi	
α-defensin	+	+	+	Constitutive
HBD-1	±	+	−	Constitutive
HBD-2	±	+	+	Inducible via IL-1/NF-kB dependent mechanism Toll-like receptors
HBD-3	+	+	+	Inducible via TGF-α, and IGF-1
HBD-4	+	+	+	Via NF-kB independent pathways
Cathelicidin	+	+	+	Constitutive and inducible Vitamin-D Toll-like receptors
Granulysin	+	+	+	Toll-like receptors Activator protein-1 dependent pathway
Psoriasin	±	+	−	Calcium All-trans retinoic acid Inflammatory stress UV light EGFR ligands IL-1
Dermcidin	+	+	+	Constitutive
RNAse 7	+	+	+	Constitutive and inducible Inducible via UVB, IL-1β, IFN-γ, TNF-α Bacterial challenge (*S. aureus*, *P. aeruginosa*)

Table 6.2 Summary of major antimicrobial peptides present in skin

	Cell source	Other properties
α-defensins	Neutrophils	Increase (TNF)-α and interleukin (IL)-1 in *S. aureus* activated monocytes Inactivation of adenovirus and polyomavirus
β-defensins	Keratinocytes	Chemotaxis of T cells and Dendritic cells
Cathelicidin (LL-37)	Keratinocytes Ductal epithelium Eccrine glands Mast cells Nail bed	Angiogenesis Wound healing Chemotaxis of neutrophils, monocytes, T cells, and mast cells Induction of IL-1β and IL-6 secretion in keratinocytes Inhibition of IAP-2 via COX-2 Anti-biofilm effects
Granulysin	Cytotoxic T lymphocytes NK cells	Chemotaxis of T cells, monocytes, NK cells, and dendritic cells Cytotoxic to tumor cells Anti-inflammatory Graft Rejection Induction of MCP-1, MCP-3, IL-1, IL-6, IL-10, and IFN-α in monocytes Mediator of keratinocyte cell death in SJS and TEN
Psoriasin	Keratinocytes Follicular epithelium Sebocytes	Chemotaxis of CD4+ lymphocytes and neutrophils Calcium-dependent oleic acid transport and metabolism
Dermcidin	Eccrine glands	Limits bacterial colonization
RNase 7	Keratinocytes	Antimicrobial properties against Gram + and Gram – organisms Antifungal properties

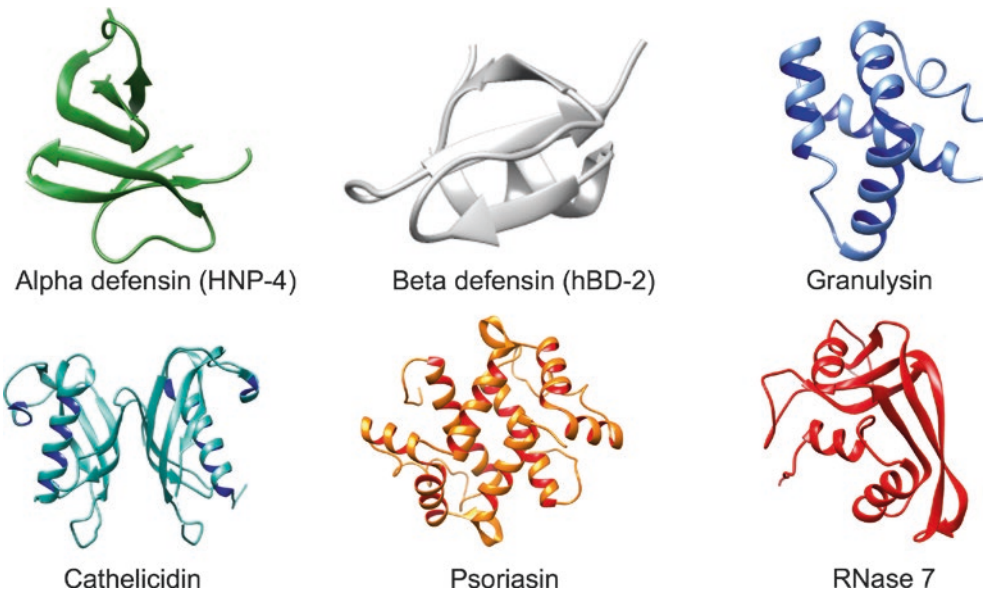

Fig. 6.1 Representative crystal structures of major antimicrobial peptides. Shown here are representative crystal structures of alpha defensin, beta defensin, granulysin, cathelicidin, psoriasin, and RNase 7. Alpha defensin, beta defensin, granulysin, and RNase 7 are shown as monomers. Cathelicidin and psoriasin are shown as dimers

etiopathology of Stevens-Johnsons Syndrome and toxic epidermal necrolysis [13].

Human beta-defensins (hBDs) are also characterized by six cysteine motifs, but are distinct from alpha-defensins through their cysteine cross-bridging. The disulfide bonds of hBDs are instead between cysteines 1–5, 2–4, and 3–6 [14]. hBDs-1, -2, -3, and -4 have been identified in many cell types, including epithelial cells, but their expression, localization, and antimicrobial specificities vary. hBD-1 is expressed predominantly in the urinary tract but is also expressed constitutively in the skin. hBD-2 is largely absent in healthy skin but is induced by bacteria through an IL-1/NF-kB dependent mechanism [15, 16]. The antibacterial spectrum of hBD-2 is broad, encompassing both Gram-negative and Gram-positive organisms. Studies found that hBD-2 is bactericidal against *Pseudomonas aeruginosa*, *Fendegoldia magna*, and *Streptococcus pyogenes*, while only bacteriostatic against *Staphylococcus aureus* [17, 18]. A synergistic effect of IL-1α and epidermal growth factor receptor (EGFR) ligands has been proposed in the induction of hBD-2 [19]. hBD-3 is also a broad spectrum antibiotic for a wide range of bacteria and fungi [20]. As with hBD-2, hBD-3 induction has also been proposed to be dependent on the transactivation of EFGR, yet with its own set of growth factors, including TGF-α and IGF-1 [21]. In addition to its bactericidal effects, hBD-3 has been shown to induce phenotypic maturation of Langerhans cell-like dendritic cells [22]. Lastly, hBD-4 induction is suggested to involve NF-kB independent pathways that have yet to be fully characterized [23].

Both alpha-and beta defensins share a common antimicrobial mechanism. The leading hypothesis proposes that the permeabilization of target membranes is the critical step in defensin-mediated cytotoxicity. In experimental models using *Escherichia coli*, membrane permeabilization resulted in the subsequent inhibition of bacterial metabolism, including RNA, DNA, and protein synthesis (Fig. 6.2) [24]. One study proposed the formation of a stable 25 Å pore, comprised of a hexamer of defensin dimers [25], allowing for small intracellular molecules to leak out of the organism resulting in a decrease in viability. This mechanism, however, only partially explains the antimicrobial activity, as evidence exists for both a transient pore formation and also intracellular sites of action, which may also be important in cell death [26]. In addition, some defensins have been found to bind to membrane glycoproteins with high affinity, giving rise to a possible explanation for antiviral activity [27]. Other proposed mechanisms of action of defensins include modifying cell migration and maturation, inducing cytokines, and triggering histamine and prostaglandin D2 release from mast cells.

Cathelicidins

Cathelicidins are a family of AMPs that contain a conserved cathelin domain, characterized by an N-terminal signal peptide, a prosequence, and a C-terminal cationic peptide [28]. Cathelicidins are expressed by cells in direct contact with the external environment. The propeptide hCAP18 (human cationic AMP, 18 kD) is first synthesized and stored in granules and lamellar bodies of keratinocytes. When hCAP18 is released into the extracellular environment, its antimicrobial C-terminus is cleaved by proteinase 3 in neutrophils and kallikrein in keratinocytes to produce the α-helical LL-37 ("LL" for two leucine residues, 37 for the number of residues present in the peptide) (Fig. 6.1) [29]. The human cathelicidin family is limited to just the one gene with a protein product hCAP18. It was initially identified in keratinocytes at the site of wound healing [30]. It was later found to be constitutively expressed in other locations and conditions, such as in nail beds, eccrine glands [31], and neonatal skin (Fig. 6.3) [32].

LL-37 has a broad antimicrobial spectrum against bacteria, fungi, and viruses. It is bactericidal against both Gram-positive and Gram-negative organisms including *Listeria monocytogenes*, *S. aureus*, *S. epidermidis*, *Salmonella typhimurium*, *E. coli*, and vancomycin-resistant *Enterococci* [33]. Unlike murine and reptilian cathelicidins, LL-37 is the only known

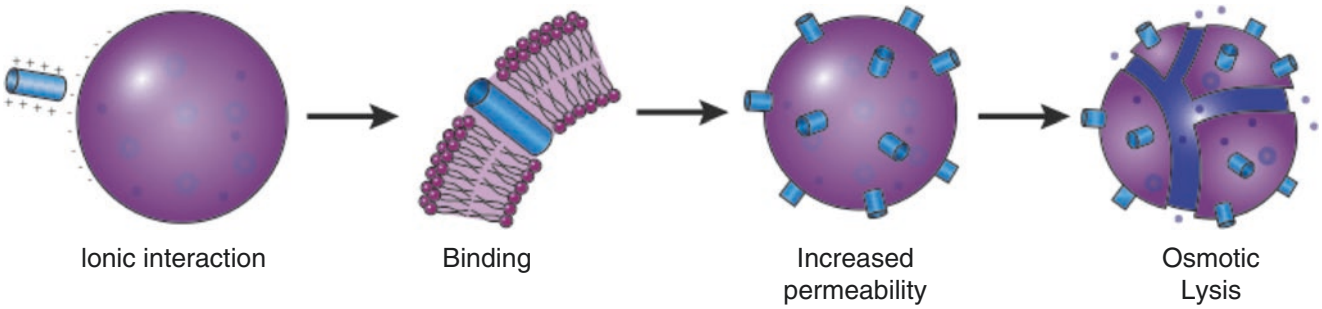

Fig. 6.2 Proposed mechanism of action of antimicrobial peptides. Cationic AMPs (e.g., granulysin) associate with the negative bacterial membranes, resulting in binding and subsequent increased permeability of the phospholipid bilayer. As a result of the increased permeability, irreversible osmotic damage results in cell death

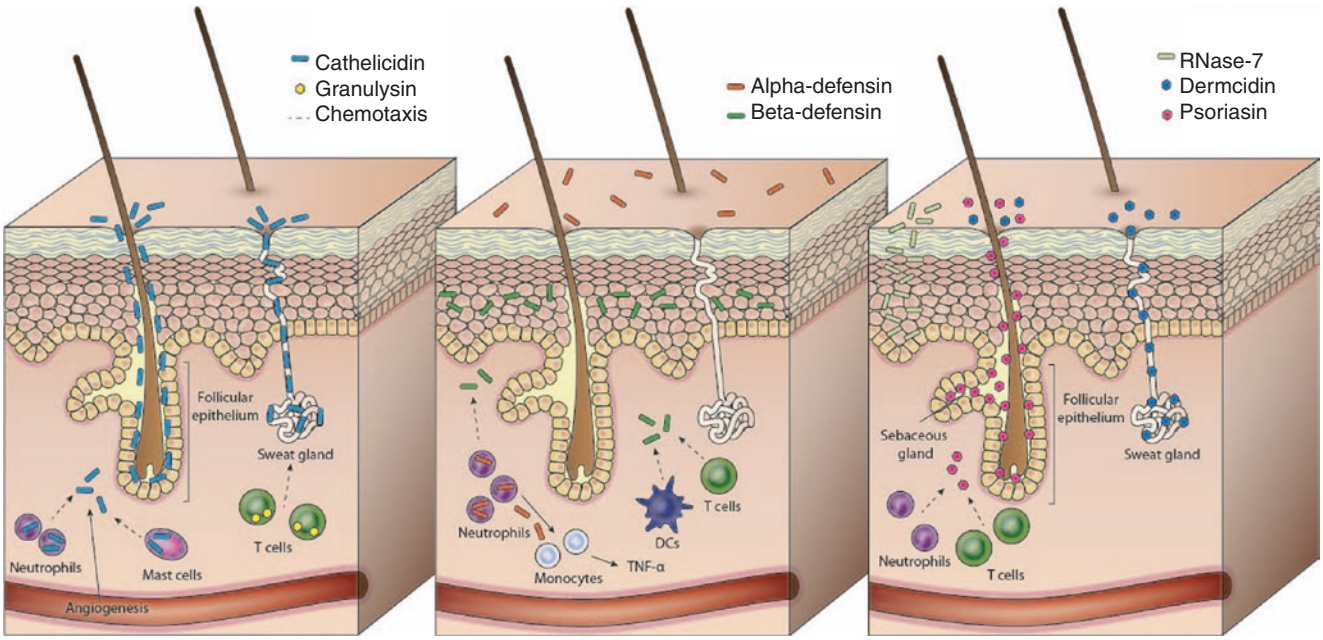

Fig. 6.3 Antimicrobial peptide expression in the skin. The expression of some AMPs by both resident skin cells and infiltrating immune cells is demonstrated in this schematic diagram

cathelicidin with anti-biofilm properties against the opportunistic human pathogens *P. aeruginosa* and *Francisella novicida* [34]. Mice with a mutation in CRAMP (the murine homologue of LL-37) are more susceptible to *Streptococcal* infections when compared to wild-type controls [35]. In humans, LL-37 is further processed into smaller peptides, such as RK-31 and KS-30, which have increasing antimicrobial activity against *Staphylococcal* species [36]. LL-37 is also active against fungal species, most notably *Candida albicans* [37], by disturbing membrane morphology to allow for a swift influx of molecules with masses up to 40 kDa [38]. Furthermore, LL-37 has a broad antiviral spectrum and has been shown to be viricidal against the vaccinia virus [39], influenza virus [40], herpes simplex 1 virus [41], adenovirus 19 [41], varicella zoster virus [42], and HIV-1 [43].

The expression of LL-37 within human skin is both constitutive and inducible. In eccrine glands and ductal cells, LL-37 is diffusely expressed in the cytoplasm of secretory glands and also the ductal epithelium [31]. Serine proteases present within sweat further cleave LL-37 into smaller peptides giving rise to enhanced antimicrobial activity against *Staphylococcal* and *Candidal* species [36]. LL-37 expression is induced in patients with cutaneous lupus erythematosus [44], and is upregulated during wound healing. Studies using a cultured keratinocyte model suggest the importance of IGF-1 in the latter scenario [45].

Vitamin D is frequently mentioned in discussions about LL-37 in the skin as an important regulator. The gene encoding LL-37 contains a vitamin D response element (VDRE) present in its promoter, which explains the dependence of LL-37 expression on vitamin D and its precursors [46]. Liu et al. [47] found that Toll-like receptor (TLR)-2-dependent microbicidal activity was dependent on the vitamin-D induced expression of LL-37 [47]. This identified a novel mechanism for TLR-induced antimicrobial activity and may represent one of the main defenses of infection for both cutaneous and systemic tuberculosis. The relationship between vitamin D and LL-37, however, remains unclear, as calicipotriol, a synthetic form of vitamin D, downregulates LL-37 in keratinocytes prestimulated with UVB, LPS, and TNF-α [48]. This dichotomous relationship poses the hypothesis that vitamin D-induction of LL-37 depends on whether or not the condition in question inflammatory or non-inflammatory.

As with other AMPs, LL-37 also has a role in modulating the host immune response. LL-37 is chemoattractant for neutrophils, monocytes, and T cells by binding formyl-peptide-receptor-like (FPRL)-1. In addition, it recruits and stimulates subsequent production of LL-37 via mast cells, creating a positive feedback loop [49]. In keratinocytes, LL-37 not only has a role in inducing IL-1β and IL-6 secretion [36], but also inhibits the expression of inhibitor of apoptosis-2 (IAP-2) via cyclooxygenase-2 (COX-2), inhibiting apoptosis [50].

Granulysin

Granulysin is an AMP derived from cytotoxic T lymphocytes and NK cells and belongs to a member of the larger saposin-like protein family. Unlike defensins and cathelicidins that are expressed in epithelial cells, granulysin is found exclusively

within the granules of cytotoxic T and NK cells recruited to sights of inflammation. Granulysin co-localizes to the cytotoxic vacuole with perforin and granzymes and acts synergistically to kill intracellular bacteria [51, 52]. Perforin forms pores in the cellular membrane allowing granulysin to access the intracellular compartment in which the pathogen resides, providing a direct mechanism of intracellular pathogen targeting (Fig. 6.3).

Granulysin is only found in humans and is synthesized as a 15 kD protein that is then cleaved to release the final 9 kD peptide [53]. The resultant 9 kD peptide is composed of 5 α-helices joined by short loops (Fig. 6.1) [54]. Granulysin is effective against a wide range of Gram-positive and Gram-negative bacteria, parasites, and fungi. Notably, it has been shown to be antimicrobial against *Mycobacterium tuberculosis* [52], *Cryptococcus neoformans* [55], *Plasmodium falciparum* [56], and *Leishmania* [57]. Granulysin also induces apoptosis of varicella-infected cells [58]. Although the structure of granulysin is significantly different from that of defensins or cathelicidin, it retains the conserved amphipathic nature. The hydrophobic surface is capable of associating closely with the target membrane, and the positively charged surface allows for association with the negatively charged bacterial membrane. In addition, studies on granulysin have shown the importance of the helix-loop-helix domain in the secondary structure. The ability of granulysin to kill *S. typhimurium* and *E. coli* has been localized to helix 2 and 3 of granulysin [57]. The amino acid residues contained within this structural component of granulysin is critical to the antimicrobial activity [59].

Similar to other AMPs, granulysin contains numerous immunomodulatory properties. Several studies show that granulysin is a chemoattractant for monocytes, NK cells, monocyte-derived dendritic cells, and a subset of T cells, including $CD45Ro^+$ memory CD4 and CD8 T cells. Granulysin also induces the expression of multiple inflammatory cytokines in monocytes including MCP-1, MCP-3, IL-1, IL-6, IL-10, and IFN-α [60].

S100 Proteins

S100 proteins belong to a multigene family of proteins with numerous functions including keratinocyte differentiation, epithelial defense, and wound healing. They were first described by Moore et al. in 1965 as nerve-specific molecules from cattle brains "soluble in 100 % ammonium sulfate," thus named S100 [61]. In general, S100 proteins are low molecular weight proteins (9–13 kD) of four conserved α-helical segments, two calcium binding regions, a central hinge, and an amino and carboxy terminal variable domain (Fig. 6.1). Interest in S100 proteins in the skin initially arose in part because many of the genes encoding for this family are located in the epidermal differentiation complex (EDC) [62], and have been implicated in epidermal defense.

In 1990, Celis et al. discovered an intense expression of low molecular weight proteins in the keratinocytes of psoriasis patients [63]. Psoriasin (S100A7) is an S100 AMP widely expressed in the human epidermis. While named after psoriasis, psoriasin is constitutively expressed on the surface of the skin and is also present in other skin diseases characterized by inflammation including lichen sclerosus and atopic dermatitis. Immunohistochemical staining has shown that psoriasin is expressed focally in keratinocytes with high expression in the stratum granulosum and stratum spinosum. As a peptide with antimicrobial properties, it is present in higher levels in areas with high bacterial colonization such as the face, axilla, and palms, and in areas with a high density of sebaceous glands and hair follicles (Fig. 6.3) [16, 64]. In addition to keratinocytes, studies have also shown staining in sebocytes, indicating secretion of psoriasin into sebum [64]. Psoriasin is thought to be preferentially active against *E. coli*, but also has some bactericidal activity against *P. aeruginosa* and *S. aureus* – albeit when psoriasin is at higher concentrations. Psoriasin is also found *in utero* and is thought to protect embryos from infection [65].

The bactericidal properties of psoriasin are attributed to the sequestration of Zn^{2+} [66]. Mutation experiments of calcium-binding and zinc-binding motifs on psoriasin confirm the importance of zinc deprivation in its killing mechanism [67]. Unlike other AMPs, the antimicrobial activity of psoriasin does not depend primarily on forming perforations in bacterial membranes. At pH values less than 6, psoriasin has been shown to permeabilize the bacterial membrane of Gram-negative *E. coli* and Gram-positive *Bacillus megaterium*; however, at neutral pH, the bacteria were killed without disrupting membrane structure in only *E. coli* and not *B. megaterium* [68].

In addition to its antimicrobial activity, psoriasin has numerous other features. Immunologically, it functions as a chemoattractant for $CD4^+$ T cells and neutrophils [69]. Various studies have shown that epidermal production of psoriasin is inducible by many factors such as a through a synergistic induction by EGFR ligands and IL-1 [19], the binding of *E. coli* flagellin to TLR5 [70], and the binding of Th17 cytokines that can be suppressed by vitamin D [71]. Furthermore, UV and all-*trans*-retinoic acid have been shown to be exogenous regulators of psoriasin expression. Psoriasin has also been suggested to have metabolic effects as it is thought to interact with epidermal fatty acid binding protein to modulate calcium-dependent oleic acid transport and metabolism [72].

Other than psoriasin, there are 20 other known S100 proteins in the skin, 11 of which are expressed in keratinocytes including psoriasin (S100A2, S100A3, S100A4, S100A6, S100A8, S100A9, S100A10, S100A12, and S100A15), 1 in Langerhans cells and melanocytes (S100B), and 1 in Meissner's corpuscles (S100P). S100A2 is localized primarily

in the basal layer of the epidermis and in hair follicles and has been shown to be an early marker of oxidative stress [73]. S100A8 and S100A9 form both homo- and heterodimers and are frequently co-expressed. They have low expression in the epidermis and are sometimes found in the granular layer. The heterodimer of S100A8 and S100A9, also known as calprotectin, has some antifungal activity against *C. albicans* [74, 75]. Increased expression of these two S100 proteins is seen in wound healing and psoriasis. S100A10 is found both in the basal and spinous layers of the epidermis [76], and forms a homodimer that binds to a pair of annexin II to form calpactin I heterotetramer [77]. It is thought to be involved in the regulation of cell membrane formation during keratinocyte differentiation. The C-terminal peptide fragment of S100A12 (calcitermin) is capable of killing Gram-negative organisms showing *in vitro* activity against *E. coli*, *L. monocytogenes*, and *C. albicans* under acidic conditions [78]. Although initially described in human airway secretions, S100A12 is also expressed in both basal and suprabasal keratinocytes and is seen in psoriatic skin [79].

Ribonuclease

The RNase A superfamily contains 6–8 conserved cysteine residues forming disulfide bridges, conserved histidines, and a lysine at the center of ribonuclease activity [80]. The human RNase A superfamily currently has 13 known genes, of which 8 genes (RNases 1–8) have been shown to be catalytically active against RNA substrates [81]. Notably, RNase-7 and RNase-5 have emerged as being especially important in acting as AMPs in the skin.

RNase-7 is a 14.5 kD protein that is found in the skin [82]. It is constitutively expressed at a relatively high level in normal skin with the highest levels of expression in the stratum corneum (Fig. 6.3). It may be important in skin disease as greater than two-fold increases of expression is seen in psoriatic skin [16, 83]. It is active against both Gram-positive and Gram-negative organisms, such as *Propionibacterium acnes*, *S. aureus*, *E. coli*, and *P. aeruginosa*; as well as fungi, such as *C. albicans* [82]. RNase-7 has also been shown to be bactericidal against multi-resistant bacteria such as methicillin-resistant *S. aureus* and vancomyin-resistant enterococci [82]. Its relationship with *S. aureus* is notable as the application of RNase-7-neutralizing antibodies to the surface of the skin increased the growth rate of *S. aureus* [84], and as RNase-7 gene expression was found to be significantly reduced in *S. aureus*-positive skin [85].

While the name RNase-7 may suggest antibacterial properties through ribonuclease activity, a study using ribonuclease-inactive recombinant RNase-7 showed no difference in killing activity against *P. aeruginosa*, *E. faecium*, and *E. coli* compared to control [86]. The exact bactericidal mechanism of RNase-7 is still being elucidated. Structurally, RNase-7 contains four disulfide bonds, similar to the defensin family and has been shown to bind and permeabilize bacterial membranes (Fig. 6.1) [87]. While RNase-7 has yet to be demonstrated to be antiviral, it is hypothesized that its ribonuclease activity may have a role against viruses, a hypothesis supported by the observation that RNase-7 expression is upregulated in keratinocytes in response to dengue virus [88]. Immunologically, RNase-7 can be induced by various stimuli including IL-1β, TNF-α, IFNγ [83] UVB [89], *S. aureus* [84], and *P. aeruginosa*. RNase-7 is found in relatively high levels of constitutive expression in normal adult skin and in lower levels in prenatal skin [90].

RNase-5 is found in abundant levels in the stratum corneum and also plays an antimicrobial role in the skin [91]. Initially, RNase-5 was named angiogenin because it was first associated with its capacity to induce angiogenesis [92], but it was later observed to share homology with the RNase A superfamily. RNase-5 has been shown to exhibit bactericidal effects against *S. pneumonia* and limited effects against *E. faecalis*, *L. monocytogenes*, MRSA, and *P. aeruginosa* [91, 93]. This limited killing spectrum compared to RNase-7 is thought to be attributed to the lack of lysine residues required for membrane permeabilization found in RNase-7. RNase-5 also exerts antifungal activity against *C. albicans*, a property attributed to the inherent ribonucleolytic properties of RNase-5.

Other members of the RNase A family have also been demonstrated to possess antimicrobial and immunological properties. RNase-2, also known as eosinophil-derived neurotoxin, attracts dendritic cells and enhances Th-2 mediated responses [94]. RNase-2 also exhibits antimicrobial activity against *S. aureus* [93]. RNase-3, also called eosinophil-cationic protein, has been demonstrated to permeabilize membranes independent of its RNA degrading properties, kill parasitic worms, and induce mast cell degranulation. RNase-3 has also been demonstrated to be antibacterial and antiviral.

Other Antimicrobial Peptides

There is growing evidence to support the presence of multiple AMPs in the human skin in addition to those discussed thus far. Discussion of all the different peptides and proteins with antimicrobial activity present within human skin is beyond the scope of this chapter. However, we would like to highlight a few additional AMPs found within the skin that have recently gained more attention. A summary of some of these AMPs is laid out in Table 6.3.

Dermcidin, a 47 amino acid peptide, is the primary AMP present in sweat, and is constitutively expressed in eccrine ducts (Fig. 6.3) [95]. It is cleaved from a 9.3 kD precursor

Table 6.3 Additional mammalian antimicrobial peptides with relevance to skin

	Cell type	Comments
Adrenomedullin	Blood Skin Mucosal secretions	Regulation of skin growth and wound repair Active against *E. coli* and *S. aureus*
α-melanocyte stimulating hormone (α-MSH)	Keratinocytes	Active against *S. aureus* and *C. albicans*; inhibits HIV-1 replication
Calgranulin A/B	Keratinocytes	Inhibits growth of *C. albicans*
Connective tissue activating peptide 3 (CTAP-3)	Platelets	Microbicidal for bacteria >fungi
Elafin	Keratinocytes	Active against *P. aeruginosa*
Fibrinopeptide A (FP-A)	Platelets	Microbicidal for bacteria >fungi
Fibrinopeptide B (FP-B)		
Lactoferrin	Keratinocytes Neutrophils	Active against Gram-negative bacteria, Decreasing IL-1, IL-2 and TNF-α Enhancing monocyte and NK cell cytotoxicity
Lysozyme	Keratinocytes	Active against Gram-positive and some Gram-negative
Neuropeptide Y	Langerhans cells	Broad spectrum
Neutrophil gelatinase-associated lipocalin (NGAL)	Infiltrating neutrophils	Bacteriostatic; mechanism of action based on iron sequestration
P-cystatin α	Keratinocytes	Inhibits growth of *S. aureus*
Perforin	T cells	Co-localized with granulysin
Platelet basic protein (PBP)	Platelets	Microbicidal for bacteria >fungi
Platelet factor 4 (PF-4)	Platelets	
Polypeptide YY	Langerhans cells	Broad spectrum
RANTES	Platelets	Microbicidal for bacteria >fungi
RNase-2	Eosinophils	Antiviral activity Chemotractant for Dendritic cells Enhances Th-2 mediated responses
RNase-3	Eosinophils	Active against *S. aureus* and *E. coli*
RNase-5	Stratum corneum	Induction of angiogenesis Active against *S. pneumonia* >*E. faecalis*, *L. monocytogenes*, MRSA, and *P. aeruginosa* Antifungal activity
S100A2	Basal layer of epidermis Hair follicles	Early marker of oxidative stress
S100A10	Basal and spinous layers of epidermis	Regulation of cell membrane formation during keratinocyte differentiation
S100A12	Basal and suprabasal keratinocytes	Active against *E. coli*, *L. monocytogenes*, *C. albicans*
Secretory leukocyte proteinase inhibitor (SLPI)	Keratinocytes Glandular epithelium Neutrophils Macrophages	Antibacterial, antifungal, antiviral properties Increased expression in psoriasis and wounds
Substance P	Macrophages Eosinophils Endothelial cells	Active against *S. aureus* Related neuropeptides Bradykinin and Neurotensin with similar, albeit weaker, antimicrobial activity
Thymosin β-4 (Tβ-4)	Platelets	Microbicidal for bacteria >fungi

molecule. *In vitro* experiments have demonstrated enhanced antibacterial activity against a variety of organisms including *E. coli*, *E. faecalis*, *and S. aureus*. In addition, there are reports of activity against *C. albicans* [96]. The function of dermcidin in sweat may be to limit bacterial colonization and protect the host from infection. Levels of dermcidin measured in the sweat of patients with atopic dermatitis compared to control saw a deficit of dermcidin in atopic dermatitis, which may partially explain the greater susceptibility of atopic dermatitis patients to cutaneous infection [97]. The tendency for superinfection in atopic dermatitis as it relates to AMPs is further discussed in the next sections.

Secretory leukocyte protease inhibitor (SLPI) is also an AMP found in keratinocytes. It was first isolated from bronchial secretions, but later found produced by mucosal surfaces, keratinocytes, neutrophils, and macrophages. SLPI is a single-chain polypeptide of 107 amino acids. It is composed of two domains, each with eight cysteine residues that form four disulfide bonds. SLPI is known to have activity against *E. coli*, *P. aeruginosa*, *S. aureus*, and *S. epidermidis*. It also has antifungal properties against *A. fumigatus* and *C. albicans* [98].

Thymic stromal lymphopoietin (TSLP) is an interleukin-7-like cytokine that is expressed in epithelial cells and may be involved in atopic eczema. TSLP was found to have antimicrobial properties particularly against Gram-negative bacteria [99]. Adrenomedullin is a hormone-like peptide of 52 amino acids first isolated from human adrenal pheochromocytoma cells [100]. Adrenomedullin is present in blood, skin, and mucosal secretions. It is also believed to play a role in skin growth, wound repair, and prevention of gastric injury. Structurally, it has a single intramolecular disulfide bond and is separated into hydrophobic and charged regions, similar to defensins. Adrenomedullin has activity against *E. coli* and *S. aureus*.

Psoriasis and Atopic Dermatitis

Human beta-defensin-2 was initially isolated from psoriatic scales, sparking numerous studies to further elucidate the role of AMPs and host defense in human skin disease. Psoriasis is often characterized as having abnormal epidermal proliferation and cellular infiltrates from neutrophils and T cells [101]. It is well-known that psoriasis, a non-infectious inflammatory condition of the skin, is relatively resistant to bacterial superinfection. However, atopic dermatitis, characterized histologically by spongiosis and inflammation, is often secondarily infected by streptococcal and staphylococcal species. One possible reason to explain the discrepancy of superinfection between these two diseases is the disparate expression of AMPs within lesional skin. Ong et al. [102] compared the expression of LL-37 and hBD-2 in psoriatic skin versus atopic dermatitis. Examination of lesional skin revealed that while patients with psoriasis up-regulate LL-37 and hBD-2, atopic dermatitis lesions are characterized by a relatively reduced or absent expression of cathelicidin, defensins, and dermcidin [97]. For unknown reasons, the inflammatory response in atopic dermatitis leads to an impairment in the upregulation of these AMPs. Several theories exist to explain the relative deficiency for LL-37, including an overexpression of IL-4 and IL-13, as well as an overexpression of the anti-inflammatory cytokine IL-10 [103]. In contrast to the relative absence of other AMPs, psoriasin is found upregulated in atopic dermatitis patients. As psoriasin is thought to have preferential killing activity against *E. coli*, this may explain why atopic dermatitis patients typically do not suffer infections of *E. coli*, despite typically experiencing the infection of other bacteria [104]. Furthermore, while RNase-7 is found upregulated in the stratum corneum of psoriasis patients, RNase-7 increased appreciably in atopic dermatitis patients [105].

In addition to bacterial infections, patients with atopic dermatitis are at increased risk for viral infections, particularly HSV and vaccinia virus (VV), implicated in eczema herpeticum and eczema vaccinatum, respectively. Atopic dermatitis patients show a relative lack of hBD-2 and LL-37 [106]. As LL-37 has been shown to have broad antiviral activities against these viruses [39, 41], this may partially account for why these patients experience higher rates of superinfection of these viruses. Moreover, cathelicidin-deficient mice exhibit reduced ability to control VV replication [107]. The local deficiency of LL-37 in atopic dermatitis may in part explain not only the increased risk of bacterial superinfection, but also viral infection in this patient population.

Acne

The pathogenesis of acne is multifactorial and includes follicular hyperkeratinization, increased sebum production, hormones, colonization with *Propionibacterium acnes*, and immunologic influences. Chronnell et al. [108] were among the first to suggest a role of AMPs in acne. They analyzed both the mRNA expression and protein expression of hBD-1 and 2 in the human pilosebaceous unit. High hBD-1 and 2 expression were present in the suprabasalar layers of the epidermis, as well as the distal outer root sheath, sebaceous glands, and the pilosebaceous duct in normal skin. However, hBD-2 expression in lesional and perilesional skin in acne biopsies were higher when compared to normal skin, suggesting a role for beta-defensins in acne vulgaris. A similar, albeit less dramatic, increase in hBD-1 was also observed.

New data has also implicated a role for *P. acnes* in the induction of AMPs. Using primary human keratinocytes, one study found that distinct clinical strains of *P. acnes* could induce the expression of hBD-2, while other strains, including common laboratory strains, did not. Moreover, the expression of hBD-2 was found to be TLR2 and TLR4 dependent [109]. The selective induction of hBD-2 by different strains of *P. acnes* could in part help explain the large clinical spectrum of the disease. Individuals colonized with certain strains of *P. acnes* may produce more hBD-2 as part of host defense and therefore have less severe clinical disease. Other studies have found that *P. acnes* induces hBD-2 production in cultured human sebocyte cell lines [110]. In addition to differential response from different *P. acnes* strains, Nakatsuji et al. demonstrated that sebum free fatty acids play a role in the induction of hBD-2 in human sebocytes [111].

Because there is evidence AMP expression in acne, researchers have aimed to use these AMPs for the treatment of acne. Given the increase in antibiotic resistant *P. acnes*, the need for novel therapeutic agents is growing. McInturff et al. [112] showed the potential use of synthetic granulysin-derived peptides to treat acne. Their work found that synthetic granulysin-derived peptides (amino acids 31–50) possessing a helix-loop-helix domain killed *P. acnes in vitro*. In addition, by substituting a tryptophan for the valine at amino acid 44, the authors were able to increase antimicrobial activity, presumably by increasing hydrophobicity, resulting in a stronger association with the bacterial surface (Fig. 6.4). Finally, using L-type amino acids, they created a peptide that was less susceptible to degradation by proteases. Clinical isolates of *P. acnes* from human microcomedones were also susceptible to the synthetic granulysin-derived peptides. In addition to its microbicidal activity, the peptides also have potential anti-inflammatory effects, as it decreased *P. acnes* induced cytokine expression [112].

Rosacea

Rosacea is an inflammatory skin and ocular disease that affects nearly 3 % of the American population above the age of 30. Rosacea in the skin is often characterized by erythema, papulopustules, and telangiectasia. Evidence indicates that abnormal production of AMPs contributes to the pathogenesis of this disease. In particular, irregularities in the production of cathelicidin in the form of LL-37 are thought to contribute to the disease, through the exacerbation of inflammation and abnormal growth of blood vessels. Rosacea patients generally show abnormally high levels of LL-37 when compared to normal skin. This abnormality has been linked to irregular activity of the stratum corneum tryptic enzyme (SCTE), also known as kallikrein 5 (KLK5), which proteolytically activates hCAP18 to LL-37 [113]. Yamasaki et al. observed that high amounts of LL-37 may also result from abnormal functioning of TLRs. TLR2, in particular, has been shown to be upregulated in rosacea and has been linked to increase protease activity of KLK5 [114].

Mycobacterial Infections

Studies of cutaneous mycobacterial infections, such as leprosy, caused by *Mycobacterium leprae*, have provided great insight into the host innate immune response and the role of AMPs in skin disease. While leprosy remains a relatively rare disease in the United States, it has sparked tremendous research interest as a model for host defense and cutaneous immunity. Leprosy varies widely in its clinical presentation, which can be correlated to the host response launched against *M. leprae*. The tuberculoid form of the disease (TL) is characterized by localized infection, granulomas, and a cytokine milieu favoring cell-mediated immunity. The lepromatous form (LL), however, is a more disseminated

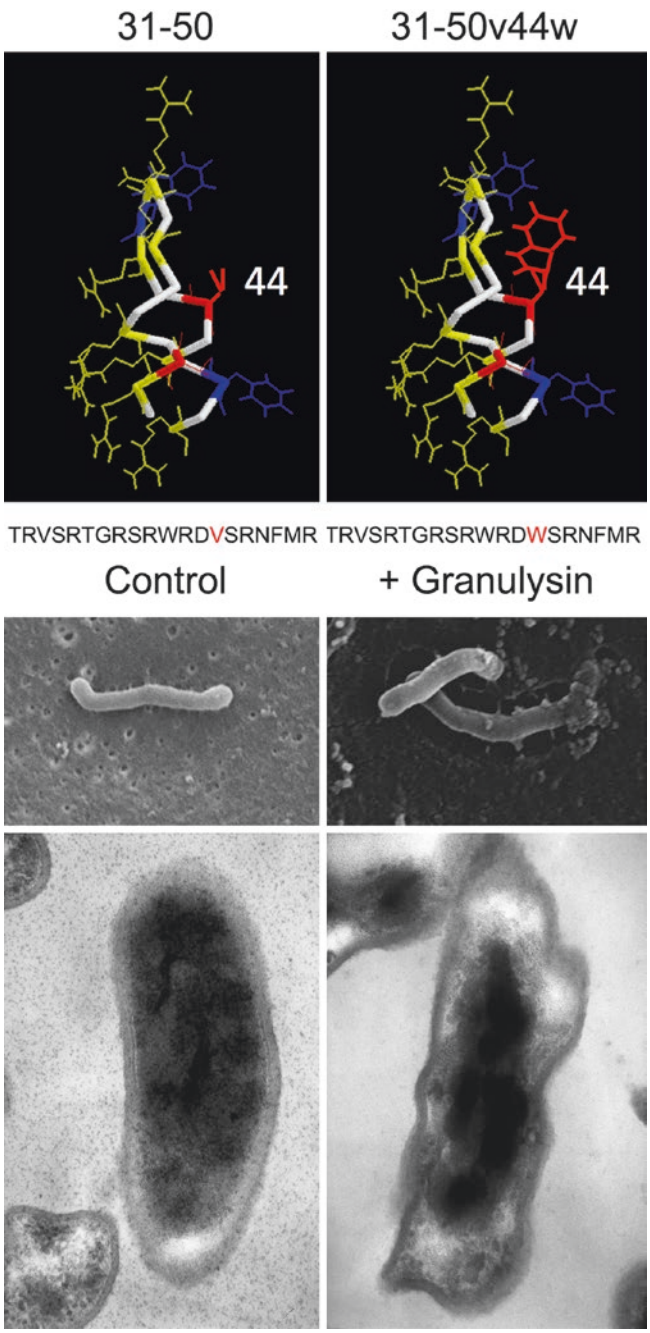

Fig. 6.4 Granulysin derived peptides are antimicrobial. Synthetic granulysin peptide containing amino acids 31–50 was altered by replacing the valine at position 44 with a tryptophan (31–50v44w) (*top panel*). The resultant peptide is more hydrophobic, and has greater efficacy in killing *P. acnes*. Scanning electron microscopy (*bottom two panels*) revealed altered surface topography (10,000X magnification, *bottom panel*) of *P. acnes*, showing decreased fimbriae and a recessed and withered surface in peptide-treated samples

infection, resulting in disfiguring nodules, and the expression of cytokines favoring humoral immunity. LL is characterized by a high organism load within affected tissues and a high level of circulating antibodies that are ineffective at controlling the infection. There also exists several intermediate states of disease, such as borderline forms, in which characteristics of both forms of the disease are present.

Ochoa et al. [115] have proposed a possible mechanism to partially explain the phenotypic mechanism seen in leprosy. Given that T cells are critical to cell-mediated immunity and cytolysis, the authors sought to characterize the level of granulysin expression, a T cell-expressed AMP with a wide antibacterial spectrum. Granulysin-expressing T cells were detected in cutaneous leprosy lesions at a six-fold greater frequency in patients with the localized tuberculoid as compared with the disseminated lepromatous form of the disease. In contrast, perforin, a cytolytic molecule that co-localizes with granulysin in cytotoxic granules, was expressed at similar levels across the spectrum of disease. Within leprosy lesions, granulysin co-localized with CD4 cells and was expressed in CD4+ T cell lines derived from skin lesions. These CD4+ T cell lines lysed targets by the granule exocytosis pathway and reduced the viability of mycobacteria in infected cells. Thus, it appears that granulysin plays a critical role in controlling mycobacterial infection and influences the spectrum of clinical disease.

Evidence has also implicated AMPs in the Toll-mediated cytotoxicity pathway in humans. Although the murine model suggests a nitrous oxide mediated mechanism for Toll-mediated cytotoxicity, evidence using primary human monocytes could not substantiate this hypothesis. However, studies demonstrate a role for LL-37 in the antimicrobial TLR response. Liu et al. [47] demonstrated that stimulation of human monocytes with TLR2 resulted in upregulation of the vitamin D receptor and the vitamin D-1-hydroxylase genes, leading to induction of LL-37 and killing of intracellular *Mycobacterium tuberculosis*. Finally, sera from African-American individuals, known to have increased susceptibility to tuberculosis, had low 25-hydroxyvitamin D and were inefficient in supporting cathelicidin messenger RNA induction. These data support a link between TLRs and vitamin D-mediated innate immunity and suggest that differences in vitamin D production may contribute to susceptibility to mycobacterial infection.

UVB Radiation

Extensive research has focused on the mechanistic links between vitamin D and cathelicidin in the skin. As the production of vitamin D is in the skin is intricately linked with ultraviolet B exposure, a discussion about AMPs would be incomplete without mention of the effects of UVB radiation. UVB has been noted for its modulatory properties on the expression and secretion of various AMPs, including increases of S100A12, S100A8/9, hBD3, RNase-7 [116], and psoriasin, which has been implicated in the recruitment of CD4+ T cells post-UVB radiation [117]. These results are mirrored in skin explants taken from donors exposed to different levels of UV [89]. Glaser et al. measured AMP expression in normal human keratinocytes both *in vivo* and *in vitro* and found after UV radiation, there was a dose-dependent increase of hBD-2, -3, RNase-7, and psoriasin [89]. In addition to improving vitamin D balance, the use of narrowband ultraviolet B as treatment has shown alterations in AMP expression in psoriatic lesions and in atopic dermatitis [118]. After six treatments of narrowband UVB exposure, the skin of psoriasis and atopic dermatitis patients both exhibited an increase in LL-37 expression. Contrastingly, narrowband UV exposure resulted in a decrease in hBD-2 expression.

Wound Healing

AMPs have been described in healing skin of mammals. For example, pig cathelicidin (PR-39) is found in the healing skin of pigs, and has pro-wound healing effects in fibroblasts. In particular, PR-39 increases the expression of certain extracellular matrix proteoglycans, which have been speculated to aid wound healing [119]. In agreement with the porcine data, LL-37 expression is enhanced in wounds [35] and has been shown *in vitro* to stimulate keratinocyte proliferation and angiogenesis. Moreover, inhibiting cathelicidins in pigs leads to increased bacterial colonization and subsequent decreased wound healing [120]. LL-37 has also been implicated in keratinocyte migration through epidermal growth factor receptor (EGFR) transactivation [121]. In addition, LL-37 and alpha-defensins induce cellular proliferation, and subsequent wound closure in airway epithelium [122, 123]. HNP-1 also decreases the expression of the collagen degrading enzymes, e.g. matrix metalloproteinase-1, while simultaneously increasing the expression of procollagen in dermal fibroblasts, suggesting one possible mechanism of action in wound healing.

In addition to LL-37 and alpha-defensins, a study has implicated the role of beta-defensins in cutaneous wound healing. Niyonsaba et al. [124] showed that hBD-2, -3, and -4 was able to stimulate the production of various pro-inflammatory cytokines and chemokines in human primary keratinocytes, including IL-6, IL-10, and monocyte chemoattractant protein-1, *in vitro*. Moreover, they found that hBDs stimulate keratinocyte migration, and that hBDs in fact serve as chemoattractants for keratinocytes. An *in vitro* wound closure assay also showed that keratinocytes incubated with optimal does of hBD-2, 3, and 4 migrated inwardly and covered a larger area of the wound, when compared with untreated or hBD-1 treated samples [124]. Keratinocyte derived growth factors and AMPs may serve as autocrine stimuli for wound healing, promoting keratinocyte migration and collagen synthesis.

In light of serious skin injuries where the structure and function of the epidermis is significantly compromised, the relative decrease in the total amount of keratinocyte derived AMPs may be in part responsible for increased risk of infection. For example, a decrease in AMP can be used to partially explain the increased risk of *Pseudomonas* infections in burn patients. Also, a deficiency in cathelicidins in mice has been reported to result in more severe and longer lasting cutaneous *S. pyogenes* infections [18]. Nonetheless, reports show that while the overall expression of AMPs in serious skin injuries remains relatively lower, individual keratinocytes express an increase in AMPs. A study profiling partial thickness burns and unburned skin tissues observed increases in LL-37, hBD1-4, dermcidin, psoriasin, and RNase-7. The authors acknowledged that this increase in AMP expression did not correlate with clinical observations of wound infections [125].

Concluding Remarks

Over the past 20 years, our knowledge of the function of skin has drastically evolved. What was once seen as simply a stagnant and physical barrier to the outside world, skin has come into light as a dynamic immune organ, capable of mounting specific and effective immune responses. The discovery of AMPs has greatly influenced the way we view the skin. From their initial discovery in invertebrate organisms, AMPs have proven to be a highly conserved and important mechanism of host defense. In addition, our ever-expanding knowledge has shown the importance of overexpression, or lack of expression, of these cationic proteins in various skin conditions. Although they vary in structure and function, the mechanism of action is generally dictated by their cationic and amphipathic nature, which is a hallmark of nearly all AMPs. It may one day be possible to develop synthetic AMPs that can be used as antibiotics and as immune modulators. Given the rapid increase in resistant bacteria, a need to add a potent antimicrobial agent to our armamentarium is imperative. With the increasing research in the field, synthetic AMPs and/or regulation of endogenous AMPs may hold promise in the future of antimicrobial therapy.

Questions

1. Describe the physical property of AMPs.

   Cationic AMPs associate with the negative bacterial membranes, resulting in binding and subsequent increased permeability of the phospholipid bilayer. As a result of the increased permeability, irreversible osmotic damage results in cell death

2. What are some known differences between alpha, beta, and theta defensins?

   Alpha defensins have wide spectrum antimicrobial activity against bacteria, fungi, and some viruses. They contribute to the host immune response by increasing the expression of TNF and IL-1, yet high concentrations are toxic to cells and may be involved in Stevens-Johnson Syndrome and toxic epidermal necrolysis

   Beta defensins differ from alpha defensins in their cysteine cross-bridging. Beta defensins also have a wide spectrum of antimicrobial activity against bacteria and fungi and are thought to have a role in cell proliferation and maturation of dendritic cells

   Theta defensins are not expressed in humans

3. What factors are thought to be important components in the induction of cathelicidin (LL-37)?

   Vitamin D and Toll-like receptor 2. The gene encoding LL-37 contains a vitamin D response element in its promoter. Recent studies show a TLR-2 dependent microbicidal activity on vitamin D-dependent induction of LL-37

4. What are the key differences of the roles of AMPs between psoriasis and atopic dermatitis?

   Psoriasis is often resistant to bacterial superinfection while atopic dermatitis often involves secondary infections. One proposed mechanism behind this phenomenon is a discrepancy of AMPs expressed in these diseases. Psoriatic lesions often upregulate the expression of cathelicidin and beta defensin, while atopic dermatitic lesions are characterized by reduced or absent cathelicidin or defensin expression. The deficiency in cathelicidin in atopic dermatitis has been linked to an impaired immune response

5. What are the roles AMPs play in wound healing?

   AMPs are implicated in keratinocyte migration (LL-37, beta defensins), cell proliferation (LL-37 and alpha-defensins), matrix metalloproteinase induction (alpha defensins), and wound-closure (beta defensins)

B Cell Biology

7

Saheli Sadanand and Mary M. Tomayko

Abstract

B cells, central players in the adaptive immune response, produce antibodies and are essential for protective immunity. This chapter provides an overview of the current understanding of B cell biology for the dermatologist and cutaneous biologist. Antibody structure and function are reviewed in detail, outlining the varied antigenic targets of antibodies, enumerating the many effector functions of antibodies and describing how these effector functions differ by antibody isotype. Additionally, an overview of the complement system is provided, highlighting its role in the immune response and mechanisms of its activation. B cell development is summarized, with a focus on generation of the antibody repertoire and establishment of tolerance to self-antigens. Current therapeutic mechanisms of targeted B cell depletion are described and biological caveats of their use are discussed. An overview of the B cell response to infection is presented, highlighting the role of B cell – T cell interactions, formation of the germinal center response and the role of regulatory B cells. Finally, the formation, function and maintenance of long-lived plasma cells and memory B cells, key components of durable immunity, are reviewed.

B lymphocyte • B cell • B cell receptor • Immunoglobulin • Antibody • Antigen • Fc receptor • Complement • Tolerance • Follicular dendritic cell • T follicular helper cell • Memory • Plasma cell • Memory B cell

Introduction

B lymphocytes, or B cells, together with T cells and NK cells, constitute the adaptive immune system. The adaptive immune system, which arose in jawless vertebrates more than 525 million years ago [1], complements the more ancient, innate immune system to provide protection during a primary infection. The hallmark of the adaptive immune response is the development of *memory*, or the ability to rapidly mount an effective and specific response to re-infection with a known or related pathogen.

B cells recognize antigen via the B cell receptor, which is membrane-bound antibody. Antibody can recognize and bind a wide variety of antigens, including proteins, polysaccharides, small chemicals, nucleic acids and lipids, and can recognize antigen in its native form. This is in contrast to T cells, which recognize processed protein fragments displayed by other host cells. While B cells are best known for their ability to differentiate into antibody-secreting plasma cells, they also play roles independent of antibody production. B cells are antigen-presenting cells for T cells and secrete cytokines that augment or dampen the immune response. Normal B cell responses are therefore crucial for protective immunity through both direct and indirect interactions with other cells in the immune system.

B Cells and Antibodies Are Critical for Effective Natural and Vaccine-Mediated Immunity to Infectious Disease

In ancient times it was recognized that prior infection, such as with smallpox, one of the most devastating diseases in human history, could prevent an individual from becoming sick again upon re-exposure. Based on these observations, people in China and the Middle East developed a technique known as variolation to generate prophylactic smallpox immunity. In variolation, pus or powder from smallpox scabs was inhaled or crudely introduced into pierced skin. Despite opposition, variolation was adopted by societies throughout the world, during the seventeenth and eighteenth centuries [2]. While often effective, duration of immunity was variable and variolation carried significant risks, including the development of full-blown smallpox. Furthermore, variolation paradoxically required a constant supply of smallpox patients.

Edward Jenner, an English countryside doctor, built upon the observation that milkmaids infected with cowpox, a virus related to but far less dangerous than smallpox, rarely became sick with smallpox itself. Such individuals were remarkable for their smooth "milkmaid's complexions," which lacked the pitted smallpox scars common amongst others. In 1796, Jenner inoculated James Phipps, the young son of his gardener, with pus from a milkmaid's cowpox scab; a few weeks later, he performed a standard smallpox variolation on the boy. Phipps did not develop mild symptoms of smallpox typical of variolation nor did he become sick after subsequent variolations, indicating that the cowpox had induced a protective immune response. Thus, Jenner proved that effective protection could be induced by immunization with a related but less virulent pathogen. The term vaccination, derived from *vacca*, Latin for cow, was coined and the procedure was adopted worldwide. In 1977, less than 200 years after Jenner inoculated Phipps, the World Health Organization declared that smallpox was eradicated.

It is now known that the induction of highly specific serum antibodies is central not only to the function of the smallpox vaccine [3], but for virtually all currently licensed vaccines [4]. A notable exception is the BCG vaccine for tuberculosis, which appears to rely primarily on the induction of T cell immunity [4]. Robust serum antibody titers correlate with reduced susceptibility to infection [5]. For many vaccine antigens, including vaccinia, measles, mumps and rubella, these titers can last decades, enduring beyond the typical human lifespan [6]. Induction of this specific, protective long-lived immunity requires highly orchestrated interactions between B cells, T cells, follicular dendritic cells and other arms of the immune system.

Improving our understanding of B cells is critical if we are to develop better vaccines and strategies to treat aberrant B cell responses in autoimmunity, allergy and B cell malignancy. This chapter will introduce the basic principles underlying antibody structure and function, B cell development, the B cell response to antigen and the long-lived products of these immune responses – memory B cells and long-lived plasma cells – that mediate protection to subsequent pathogen re-challenges.

Antibody Structure and Effector Functions

Introduction

Antibodies and antisera were first described in 1938 [7] and studies to elucidate both antibody formation and structure garnered researchers Nobel Prizes in the subsequent decades. It was not until the 1960s that B cells, the cells that produce antibodies, were described [8]. B cells display antibodies on their surface, termed B cell receptors (BCRs) and secrete them into the extracellular space. Over 10^9 different specificities can exist in a single individual. One individual B cell, however, encodes only a single specificity of BCR.

Unlike the T cell receptor (TCR), which only recognizes processed, linearized protein antigens presented on MHC Class I or MHC Class II molecules, the BCR and secreted antibodies bind antigens in their native, unprocessed, forms. Like the TCR, the BCR binds protein antigens, but unlike the TCR, it also binds polysaccharides, lipids, nucleic acids and small chemicals. Antibodies bind antigens on microbial surfaces, such as bacterial capsular or viral envelope structures, as well as soluble toxins and native antigens presented by macrophages, dendritic cells (DCs) [9] and follicular dendritic cells (FDCs) [10].

The antibody is typically depicted as a "Y"-shape (Fig. 7.1a). Each antibody molecule contains two identical antigen-binding domains and a single constant domain. The antibody molecule is comprised of two identical heavy chains (IgH) and two identical light chains (IgL), each containing a variable region and constant region. Each arm of the "Y", known as a Fab (antigen binding) fragment, contains heavy and light chain variable regions that together form the molecule's unique antigen-binding domain. The stem of the "Y" is the Fc (crystalline) region, comprised entirely of IgH constant domains. For membrane-anchored antibody, the Fc region associates with Igα and Igβ transmembrane signaling proteins to form the BCR complex, enabling triggering of an intracellular signaling cascade upon antigen binding (Fig. 7.1b). For secreted antibody, the Fc region confers other various effector properties, such as the ability to fix complement and bind Fc receptors.

As antibodies can be raised against a wide range of antigens, they are valuable reagents in clinical and research applications. Antibody molecules can be conjugated to

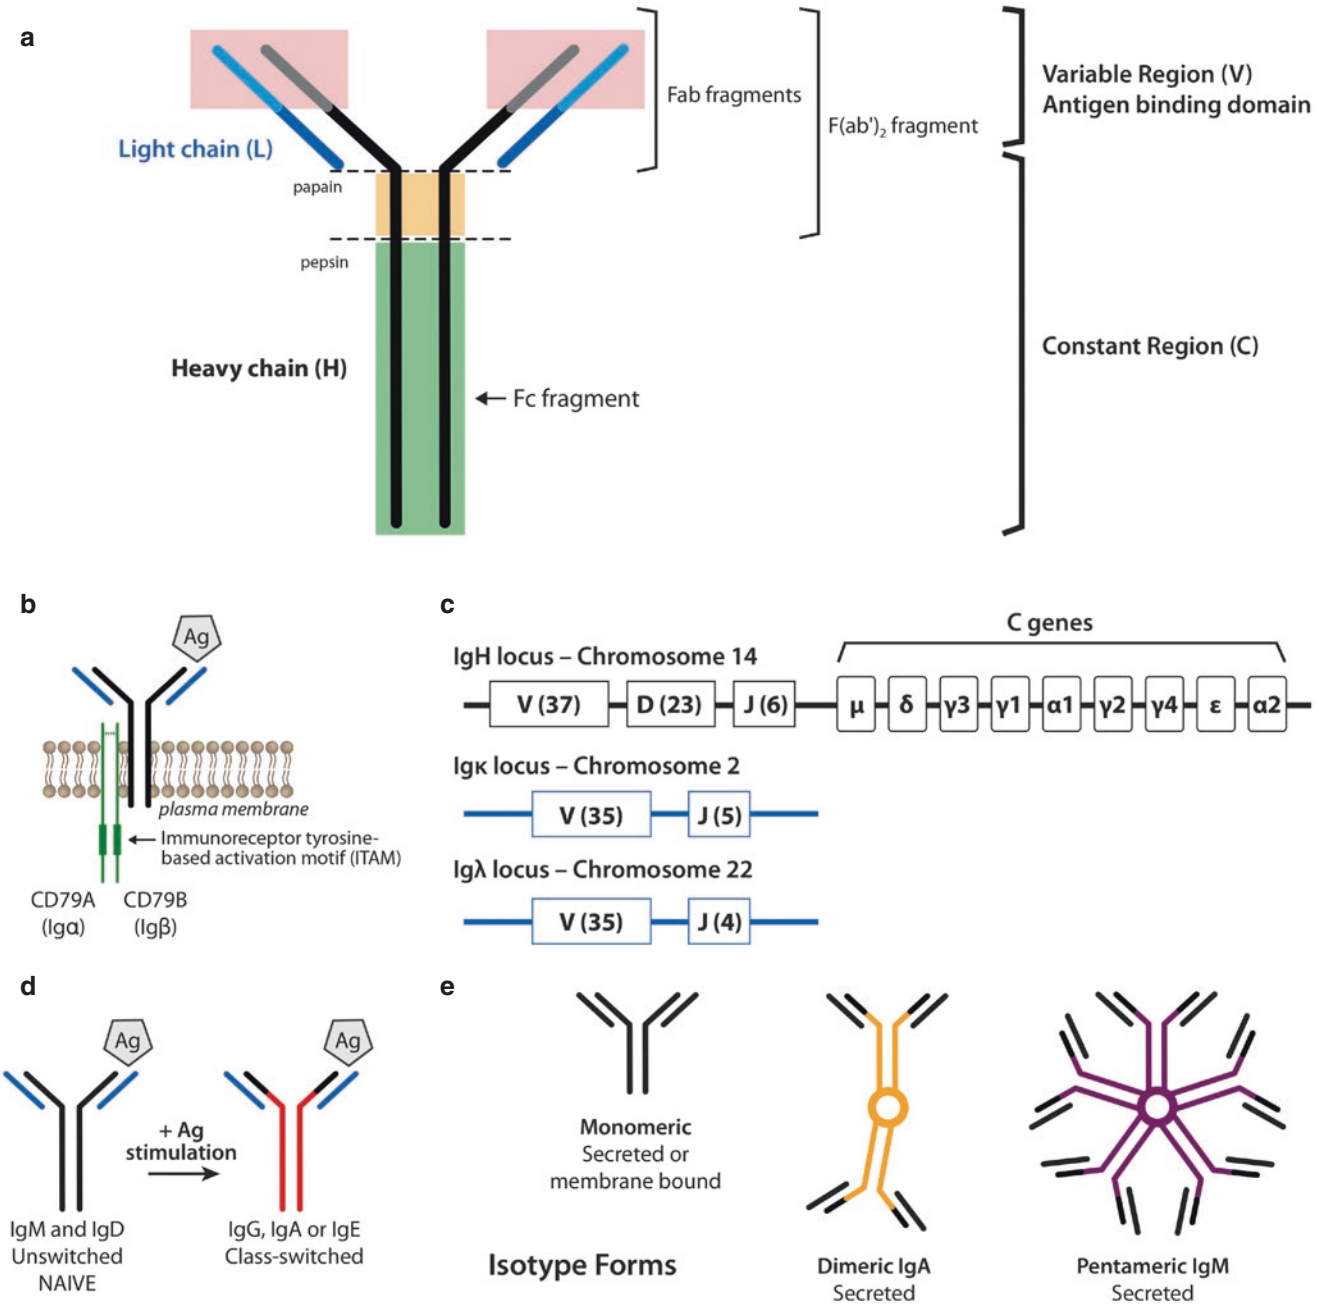

Fig. 7.1 Antibody structure and immunoglobulin locus organization. (**a**) Structure of an individual antibody molecule. Highlighted are the immunoglobulin light chains (IgL, *blue*) and heavy chains (IgH, *black*), the disulfide hinge (*yellow*), two identical antigen binding variable regions (Fab, *pink*) and the crystalline region (Fc, *green*). Cleavage sites for the generation of Fab, F(ab′)2 and Fc fragments, with papain and pepsin, respectively, are indicated. (**b**) The B cell receptor (BCR) signaling complex is comprised of membrane anchored immunoglobulin and a CD79A/B (Ig α/β) heterodimer. Following antigen (Ag) binding to the antigen binding variable region of the BCR, signaling is triggered via the CD79A/B immunoreceptor tyrosine-based activation motifs (ITAMs). (**c**) Key components of the human germline IgH locus and IgL (both k and λ) loci [11–13]. Numbers of estimated functional gene segments are indicated in parentheses following gene segment type. IgH constant (C) genes encode constant regions and dictate isotype. μ = IgM, δ = IgD, γ = IgG (IgG1, IgG2, IgG3, IgG4), α = IgA (IgA1, IgA2) and ε = IgE. (**d**) Antigenic (Ag) stimulation initiates class-switch recombination (CSR). Mature, antigenically-naïve B cells express both IgM and IgD; following Ag stimulation and class switch, they express IgG, IgA or IgE. (**e**) Secreted antibodies can exist in three forms: monomeric, dimeric (IgA only) or pentameric (IgM only) that have implications for avidity and for downstream antibody-mediated effector function

flurochromes, enzymes, toxins and chemical isotopes or used directly (ustekinumab, adalimumab**,** belimumab) to target specific antigens for the treatment of malignancies or autoimmune diseases or for flow cytometric or histologic analysis. To develop reagents that lack background binding from the Fc region, it is often useful to separate antigen-binding domains from effector domains using proteases that cleave the disulfide bonds between Fab and Fc fragments. Digestion with papain yields two identical, but separated Fab fragments (each with a single antigen-binding domain) and digestion with pepsin yields a single $F(ab')_2$ fragment with two antigen-binding domains (Fig. 7.1a). These fragments can also be labeled with fluorochromes and enzymes, etc., as described above. Using genetic approaches, the DNA encoding the variable region can be ligated to alternate Fc regions to create chimeric human-mouse monoclonal antibodies (infliximab, rituximab), which are less immunogenic than complete mouse antibodies, or antibodies with enhanced Fc-mediated functions (obinutuzumab, omalizumab). Additionally, Fc regions can be linked to receptors in order to target ligands of interest (etanercept, abatacept).

Diversity in the Antigen-Binding Variable Region Is Generated via Gene Segment Recombination and Use of Editing Enzymes

The enormous diversity in BCR specificity is generated via several mechanisms. Prior to antigen exposure, diversity in the BCR repertoire results from the recombination of a seemingly limited number of gene segments encoding the heavy (IgH) and light (IgL) variable regions and from variations in the junctional regions between these segments (Fig. 7.1c). This process is analogous to the generation of the TCR repertoire. The IgH locus, located on human chromosome 14, is comprised of three gene segments – Variable (V), Diversity (D) and Joining (J). IgL loci, found on chromosomes 2 (kappa) and 22 (lambda), contain only V and J gene segments. The IgH locus contains an estimated 37 V_H gene segments, 23 D_H gene segments and 6 J_H gene segments [11–13]. There are also approximately 35 Vk gene segments, 5 Jk gene segments, 35 Vλ gene segments and 4 Jλ gene segments [12]. A rearranged IgH will contain a single V, D and J gene segment while a rearranged IgL will contain a single V and J gene segment from either the kappa or lambda locus. Thus, combinatorial diversity yields roughly 10^6 possible IgH and IgL pairings [12].

Recombination of IgH and IgL segments proceeds in an orderly fashion mediated by the V(D)J recombinase enzyme complex, which includes two proteins encoded by genes uniquely expressed in B cells and T cells: recombination activating gene-1 (RAG-1) and recombination activating gene-2 (RAG-2). Recombinases bind signaling sequences flanking the gene segments and then bind to each other to bring the segments together for joining. Mice deficient in the RAG proteins lack mature B cells and T cells and thus have no viable adaptive immune system. Some humans with severe combined immunodeficiency (SCID) have mutations in one or both of the RAG genes, resulting in little to no V(D)J recombination [14]. Additionally junctional diversity/generates more sequences than would be present through mere recombination of the germline genes. Junctional diversity is introduced by exonuclease, which removes nucleotides at the sites of V(D)J recombination, and terminal deoxynucleotidyl transferase (TdT), which catalyzes the addition of random nucleotides.

While the above mechanics generate diversity in the pre-immune antibody repertoire, further diversification in the BCR occurs after antigen exposure and can result in the formation of B cell clones that bind pathogens and immunogens with a much higher affinity than the original clone. This process of somatic hypermutation occurs in the germinal center reaction as a result of T-dependent B cell activation. It is catalyzed by activation-dependent (cytokine) deaminase (AID) and results in the selection of point mutations focused in hotspot hypervariable regions important for binding antigen.

The Heavy Chain Constant Region Dictates Antibody Isotype and Effector Function

The effector function of an antibody is distinct from its antigen binding specificity and is dictated by the class of its heavy chain. There are five antibody isotypes – IgM, IgD, IgA, IgG and IgE – that are each encoded by a distinct constant region (C) gene. The C gene cluster follows the J gene segments on the IgH locus. All mature naïve B cells co-express transmembrane IgM and transmembrane IgD of identical specificities. Other isotypes are expressed only when the B cell is activated by antigen, after an irreversible process known as class-switch recombination (CSR) (Fig. 7.1d). Class-switch recombination does not affect the rearranged V(D)J nor does it use the RAG enzymes. Therefore, a single variable region can elicit a number of different effector functions depending on the C gene with which it is associated.

Functional properties of the various isotypes are summarized in Table 7.1. Secreted IgM is unique amongst the isotypes in that it can pentamerize, which is advantageous in binding repetitive antigen sites, such as those found on encapsulated bacteria and gut flora, and in increasing antibody avidity (binding strength) (Fig. 7.1e). IgD, initially expressed by all naïve B cells, is poorly defined in effector function. IgG is the most abundant isotype in the serum and

Table 7.1 Isotype-specific functions of antibodies

Isotype	Complement fixation	Major functions and unique properties
IgM	+++	Antigen receptor of naïve B cells
		Pentameric secreted IgM
		Fcα/μR binding
IgD	No	Antigen receptor of naïve B cells
IgG1, IgG3	++/+++	FcγR binding – all
IgG2	+	FcγR binding – all except FcγRI, FcγRIIB and FcγRIIIB
IgG4	No	FcγR binding – all except FcγRIIIB
IgA1, IgA2	No (Lectin but not classical pathway)	Mucosal immunity
		FcαR, Fcα/μR binding
IgE	No	Helminth response
		Allergic response
		FcεR1, FcεRII binding

also has the longest half-life. In humans, there are four subclasses of IgG – IgG_1 (the most abundant IgG subclass), IgG_2, IgG_3, and IgG_4. Maternal IgG can cross the placenta, providing protection to the fetus. IgA is produced primarily at mucosal surfaces such as the respiratory and gastrointestinal tracts and, when secreted, can dimerize and cross the epithelium (Fig. 7.1e). Finally, IgE plays an important role in immunity to parasites, in type I hypersensitivity and in common allergic responses. It is unique amongst antibody isotypes in that it can be bound to its high affinity Fc receptor prior to antigen binding.

Class-switch is heavily influenced by the cytokine milieu surrounding the B cell. Cytokines may be produced by $CD4^+$ T cells, macrophages or dendritic cells and can promote, inhibit or augment class-switch to specific isotypes. For example, in mice, IL-4 promotes class-switch to IgG_1 and IgE but blocks class-switch to IgG_{2a} and IgG_3. Conversely, IFN-γ induces class-switch to IgG_3 and IgG_{2a}, but blocks class-switch to IgG_1 and IgE. Along with IL-5, IL-6 and TGF-β, IL-4 and IFN-γ play important roles in influencing B cell effector function.

Effector Functions of Antibodies

Neutralization

Some antibodies function by binding to and directly neutralizing their antigens, a role that does not require the help of other immune cells or immune cell products. Neutralizing antibodies are effective against bacterial toxins, viruses and adhesion factors expressed on bacteria that facilitate host entry. Thus, B cells (through antibodies) are capable of blocking infection before it occurs. Neutralizing antibodies are central to the protective effects of the tetanus toxoid, pneumococcal, hepatitis A and B and HPV vaccines. Development of effective vaccination strategies to induce neutralizing antibodies against human immunodeficiency virus (HIV) and influenza virus have been more challenging, in large part because these viruses have intrinsic mechanisms to mutate or mask vulnerable surface epitopes.

Complement Activation

Most antibodies do not neutralize their targets, but instead initiate a protective response by recruiting other components of the immune system, such as the innate complement system. The complement system is a collection of circulating and cell membrane proteins that play critical roles in host defense against microbes and in tissue injury. The complement system can be activated by pathogens directly or by antibodies, thus linking the adaptive and innate immune systems. Ability to activate the complement pathway varies widely amongst antibody isotypes; IgM and most IgG isotypes are robust at activating the complement cascade while IgE and IgA are not (Table 7.1).

The complement pathway is a series of controlled proteolytic cleavage reactions that ultimately lead to microbe or host cell destruction, neutrophil recruitment and inflammation. There are three complement pathways – classical, mannan-binding lectin and alternative – which all converge on a common intermediate protease, C3 convertase. This convertase is in turn cleaved with its products eliciting various effector functions.

Activation of the classical pathway is initiated by binding of the first complement component, C1q, to the Fc portion of an antibody:antigen complex, known as an immune complex. This binding triggers a series of proteolytic reactions, leading to C3 cleavage and activation. Activated C3b fragments can opsonize (coat) microbes and these fragments in turn bind to specific complement receptors on phagocytes, ultimately leading to microbe phagocytosis. When binding to microbes such as Neisseria, C3b fragments initiate formation of the membrane-attack complex, which creates pores in the pathogen membrane, leading to its lysis. Lastly, C3 activation and subsequent reactions stimulates release of inflammatory

mediators, enhances vascular permeability and triggers neutrophil recruitment and activation.

There are six complement receptors (CR) that vary in cell expression and in effector function. Red blood cells (RBCs) express the most CRs, binding immune complexes for later removal in the spleen. CRs can be found on macrophages, endothelial cells, mast cells, dendritic cells, FDCs and even B cells themselves.

Complement activation can stimulate and enhance the humoral response via binding of B cell-expressed CR1/CD35 and CR2/CD21. CR2 functions as a BCR auxiliary receptor, as recognition of C3 coated pathogens by the BCR and CR2 simultaneously triggers a stronger net signal than BCR alone. Additionally, complement receptors on FDCs bind antigens coated with complement proteins, presenting them to B cells in the germinal center reaction, thus facilitating B cell activation and selection during the immune response.

The complement system is tightly regulated and dysregulation of or deficiencies within the complement cascade can lead to poor pathogen clearance and immune complex-driven disease. Complement opsonization is a primary clearance mechanism for polysaccharide encapsulated bacteria, so individuals with complement deficiencies can have serious Hemophilus, Streptococcal and Neisseria infections [15]. Binding of antigen:antibody immune complexes to complement receptors on red blood cells is critical to their clearance in the spleen and liver. Thus, in systemic lupus erythematosus (SLE), deficiencies in CR1/CD35 on red blood cells and C1q, C2 and C4 contribute to immune complex deposition and subsequent sequelae in the skin and kidney. Conversely, complement activation promotes tissue damage in many autoimmune situations, such as in bullous pemphigoid [16, 17]. Complement measurement is therefore a useful clinical disease metric in both autoimmune and infectious contexts.

Fc Receptor-Mediated Cell Activation

In addition to antigen neutralization and complement activation, antibodies activate other arms of the immune system via binding to specific Fc receptors (FcR) on the surfaces of immune cells. All known human FcRs and their expression patterns and functions are outlined in Table 7.2. Specific FcR-mediated effector functions are described below.

FcR-Mediated Opsonization and Phagocytosis In addition to recognizing antigens opsonized with complement proteins, phagocytes bind immune complexes directly via binding of phagocyte FcR to Fc portions of immune complexes. Macrophages, dendritic cells and neutrophils bind and phagocytose pathogens opsonized with antibody, then degrade the pathogens within phagolysosomes. Antibody-mediated phagocytosis is the major form of defense against encapsulated bacteria such as pneumococcus.

FcR-Mediated Antibody-Dependent Cellular Cytotoxicity FcγIIIA is expressed on natural killer (NK) cells and binds to multiple IgG subclasses. Binding initiates a process known as classical antibody-dependent cell-mediated cytotoxicity (ADCC), in which the opsonized cell is brought into close proximity to the NK cell, which then discharges granules to lyse the cell. ADCC is one mechanism by which therapeutic antibodies deplete target cells in autoimmune disease and cancer.

FcR-Mediated Eosinophil and Mast Cell Degranulation IgE:FcεRI ligation can trigger degranulation by eosinophils or basophils. Parasites such as helminthes evade phagocytosis because of their large size. When opsonized with IgE, they can bind to FcεR1 on eosinophils which then destroy them by degranulation. IgE:FcεRI-induced eosinophil and mast cell degranulation also play important roles in tissue damage in asthma, urticaria and other allergic disease.

FcR-Mediated Antibody Recycling and Transport The neonatal FcR, FcRn, is expressed in the placenta, neonatal intestinal epithelium and adult vascular endothelial cells [18]. It binds maternal IgG in blood or milk and transports it across the placenta or intestinal lumen, providing short-term passive immunity to the fetus and neonate. It also plays a homeostatic role by recycling serum IgG and protecting it from catabolism. In a therapeutic context, it has been hypothesized that high dose intravenous immunoglobulin (pooled IgG from donors) competes with pathogenic auto-antibody for binding to FcRn, resulting in more rapid degradation of pathogenic IgG antibodies [19].

FcR-Mediated Downmodulation of the Immune Response FcR activity is not exclusively activating. FcγRIIB binds all IgG subclasses with low affinity and this binding can mediate endocytosis of immune complexes as well as triggering of negative signaling cascades that dampen the immune response. FcγRIIB is expressed on B cells and tranduces downregulating signals via immunoreceptor tyrosine-based inhibition motifs (ITIMs). FcγRIIB influences peripheral tolerance by binding low-affinity, autoreactive IgG^+ B cells and blocking clonal expansion [20] and, in the context of a productive immune response can negatively regulate B cell activation [20]. FcγRIIB, is also involved in plasma cell survival [21].

Factors That Modulate Antibody: FcR Interactions Antibody glycosylation can affect binding to FcRs and thus can also affect antibody effector function. Additionally, FcγR

Table 7.2 Fc receptors and their functions

Fc Receptor	Ig Ligand (Avidity)	Cell expression pattern	Downstream effector function
FcγRI (CD64)	IgG_1,IgG_3, IgG_4 (high to very high)	Macrophages	Phagocytosis
		Monocytes	Endocytosis
		Neutrophils	Antigen presentation
		Eosinophils	Respiratory burst

polymorphisms can affect binding of the receptor to IgG and this in turn can lead to increased susceptibility to autoimmune diseases and infections. Several FcγR alleles have been associated with increased risk for developing systemic lupus erythematosus, rheumatoid arthritis and Wegener's granulomatosis, amongst other autoimmune diseases [22]. In a murine model of bullous pemphigoid, mice deficient in activating FcγRs, but not in the inhibitory FcγRIIB, have a reduced disease phenotype [23]. Thus, dysregulated or deficient expression of FcγRs can have a variety of effects as these receptors both promote and negatively regulate the immune response.

Summary

Antibodies contain two identical antigen binding domains (Fab domains) and a single effector domain (Fc region). Antigen binding diversity in the mature naïve B cell repertoire results from somatic recombination of assorted Variable, Diversity and Junctional (V, D, and J) gene segments and editing at gene segment junctions during the recombination process. Upon activation, some B cells undergo class-switch recombination, resulting in antibodies with the identical antigen specificity but different heavy chain isotypes (IgG, IgA, IgE), each with specialized effector functions. One role of antibodies is to directly neutralize pathogens. Via complement activation or engagement of Fc receptors on a variety of immune cells, antibodies can also trigger effector processes that result in pathogen destruction. Such effector functions include phagocytosis, degranulation and antibody-dependent cell-mediated cytotoxicity and require the recruitment of arms of the innate immune system including NK cells, neutrophils, eosinophils, mast cells and macrophages. Lastly, antibodies play immunomodulatory functions. Antibody binding to Fc receptors on B cells provides feedback inhibition to activated B cells. Binding to Fc receptors on epithelia and endothelia regulates protective antibody levels in the blood and tissues.

B Cell Development and Tolerance

Introduction

In 1965, Max Cooper formally identified the cells that give rise to antibodies and the humoral response [8]. Dr. Cooper was working with chickens, where the cells are derived from the Bursa of Fabricius, and thus the term "B" cell was coined. In mammals, B cell lymphopoiesis occurs primarily in the bone marrow. B cells are continually produced throughout life, though generation slows with advanced age [24].

B cells, T cells and NK cells originate from a common lymphoid progenitor cell, which is in turn derived from a pluripotent hematopoietic stem cell (Fig. 7.2). B cell development can broadly be divided by geography – initial stages (pro-, pre- and immature) occur "centrally" in the bone marrow. The last two developmental stages (transitional and mature) occur in the periphery, which includes secondary lymphoid organs such as the spleen and lymph nodes. B cell developmental stages are defined by the expression of markers that are turned on and off and by rearrangement of the IgH and IgL loci. Developing B cells, like T cells, pass through both positive and negative selection checkpoints. The BCR must bind ligand to be positively selected; however, strong binding to self-antigen will generally trigger negative selection. The vast majority of developing B cells will die or be rendered unresponsive due to unsuitable and/or autoreactive BCRs.

In this section, we will review the basic steps in B cell lymphopoiesis and highlight two monoclonal antibodies that selectively deplete B cells at specific developmental stages. We will also describe B cell-intrinsic and B cell-extrinsic mechanisms – in both the bone marrow and in the periphery – that prevent the proliferation of autoreactive B cells in healthy individuals.

Developing B Cells Must Productively Rearrange Both the Immunoglobulin Heavy and Light Chain Loci to Exit the Bone Marrow

The first cell in the B cell development assembly line is known as a pro-B cell, which differentiates from the common lymphoid progenitor cell. The pro-B cell undergoes rearrangement at the IgH locus (first D to J and then V to DJ). If rearrangement on the first allele results in an in-frame V(D)J, the IgH locus on the other allele is turned off in a process known as allelic exclusion, ensuring that the B cell expresses an IgH of a single specificity. Should the first allele have a nonproductive V(D)J rearrangement (a sequence that cannot result in a properly folded, functional IgH molecule), the IgH locus on the second allele undergoes rearrangement. Nonproductive V(D)J rearrangements on both alleles results in death of the pro-B cell.

Productive IgH rearrangement allows the pro-B cell to progress to the pre-B cell stage. At this stage the IgH protein pairs with a surrogate IgL to form a pre-BCR. Meanwhile, the pre-B cell undergoes rearrangement at the IgL locus (first the kappa (k) light chain genes, then, if they fail, the lambda (λ) light chain genes). Again, the principle of allelic exclusion applies: an in-frame VJ IgL rearrangement on one allele results in the remaining IgL locus on the other allele being turned off. Without productive rearrangement on any allele, the pre-B cell dies. If

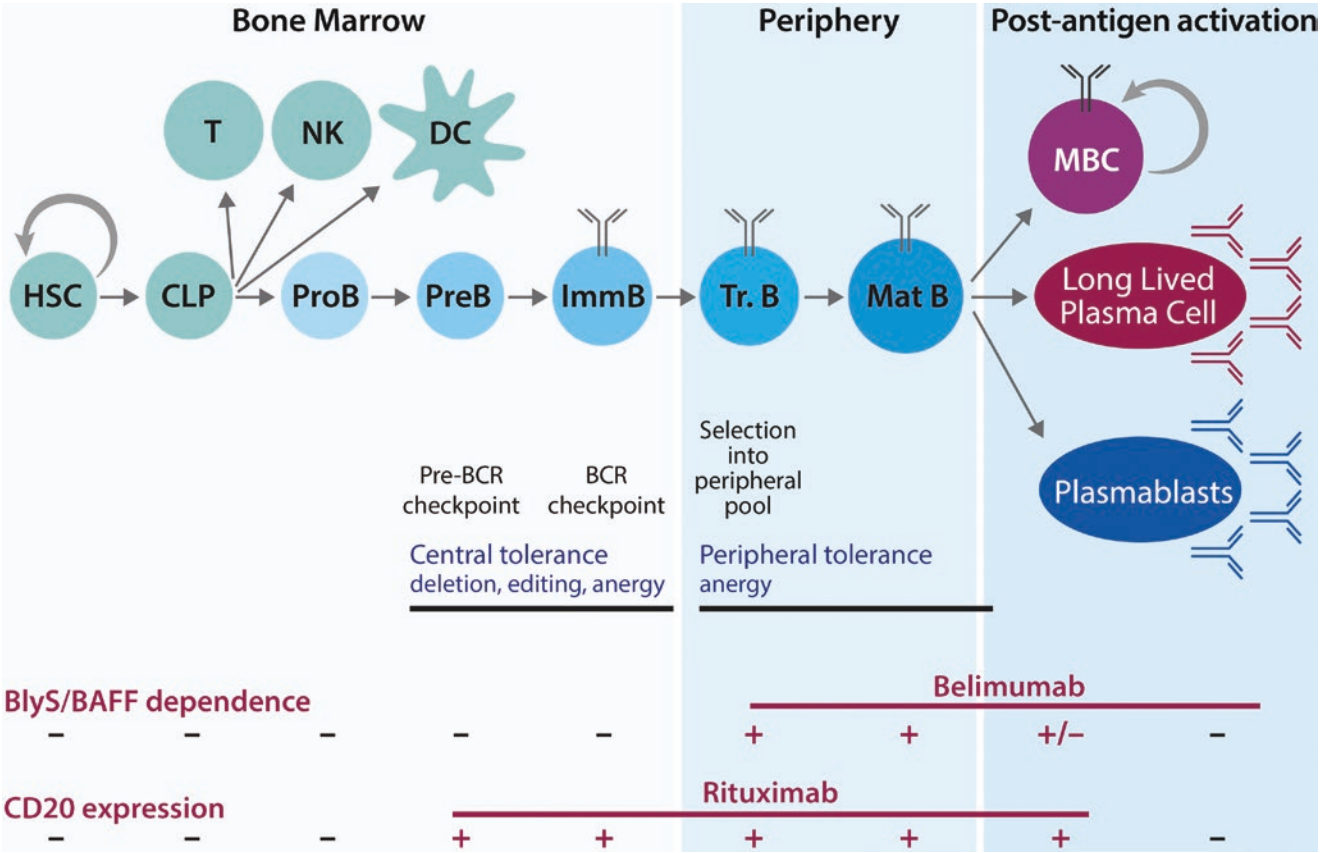

Fig. 7.2 B cells develop in an ordered maturation process that includes central and peripheral tolerance checkpoints and is characterized by distinct marker expression and survival factor dependence. Development stages include the hematopoietic stem cell (HSC), common lymphoid precursor (CLP), pro-B, pre-B, immature (Imm) B cell, transitional (Tr) B cell and the mature (Mat) B cell. Timing of B cell receptor (BCR) checkpoints and tolerance mechanisms are depicted. Following antigen stimulation, mature B cells can differentiate into memory B cells (MBC) or antibody-secreting plasmablasts (short-lived) or long-lived plasma cells. MBCs and long-lived plasma cells constitute humoral memory. Therapeutically, specific developmental populations of B cells can be deleted via the monoclonal antibody, belibumab, which blocks the soluble survival factor, BLyS/BAFF or rituximab, a chimeric antibody which targets $CD20^{+}$ B cells

productive IgH and IgL rearrangements are achieved, the pre-B cell is termed an immature B cell.

Immature B Cells Are Evaluated for Strong Self-Antigen Binding

Immature B cells express a true surface BCR of the IgM isotype and express the co-receptors required for signaling. Via this BCR complex, immature B cells sample antigens within their environment. If there is little to no antigen recognition – indicating low autoreactivity – they shut off the recombinase activating gene (RAG) enzymes, preventing further rearrangement, and exit the bone marrow. If the BCR binds antigen more tightly – indicating potential autoreactivity – they die or undergo receptor editing, described below.

B cells exit the marrow as immature cells and undergo final stages of maturation in the periphery, termed the transitional B cell stage [25, 26]. Early transitional cells that bind tightly to antigen die via apoptosis in another critical checkpoint for potential autoreactivity, and later transitional cells appear to undergo positive selection events into the mature B cell pool [27]. Transitional B cells require stimulation with B cell activating factor (BAFF) to survive, and without it die before transitioning to maturity [28–30]. The half-life of transitional B cells is only a few days and in a healthy adult most cells die without entering the mature pool.

A mature B cell expresses its BCR in both the IgM and IgD isotypes and expresses markers that distinguish it from its precursors. Mature B cells continually recirculate via the blood and lymphatics through the spleen, lymph nodes, tonsils, bone marrow, mucosa and other tissues. These "naïve" (non-antigen activated) mature B cells sample the environment for cognate antigen to bind. Mature B cells do not self-renew and turn over every 2–4 months [31, 32]. They rely on stimulation with BAFF and ligand-independent tonic non-BCR signals for survival. When a naïve mature B cell binds

cognate antigen via its BCR, the cell is activated and an immune response is initiated, as detailed later.

Tolerance Mechanisms Limit the Expansion of Autoreactive Lymphocytes

Given the incredible antigen-binding diversity in the naïve B cell repertoire, it may seem surprising that autoimmune diseases are not more common. In healthy humans there are two major check points where autoreactive B cells are managed: central (during early development in the marrow) and peripheral (during later stages of maturation outside of the marrow) (Fig. 7.2). Central tolerance mechanisms help manage immature B cells. It is estimated that approximately 75 % of the human immature B cell repertoire is self-reactive [33]. If an immature B cell binds antigen strongly, it can undergo receptor editing whereby RAG genes are re-expressed and mediate further recombination of light chain genes in an attempt to generate antibody of an alternate specificity [34]. Immature B cells that continue to bind antigen strongly die by apoptosis (negative selection).

As not all self-antigens localize to the bone marrow, autoreactive lymphocytes must be managed in the periphery as well. Peripheral tolerance is a collection of mechanisms that prevent transitional or mature self-reactive B cells from becoming activated. Peripheral tolerance mechanisms include deletion by apoptosis, functional inactivation by anergy or regulatory cells and physical sequestration of self-antigen. When peripheral tolerance is broken, pathogenic autoreactive responses can be initiated.

Deletion Autoreactive B cells in the periphery can die by apoptosis when they encounter antigen in the absence of co-stimulatory signals. This can occur because cognate helper T cells were themselves deleted thorough negative selection or rendered anergic or because the self-antigens lack innate activating signals characteristic of pathogens.

Anergy and Hyporesponsiveness After encounter with self-antigen, some B cells become functionally unresponsive, or anergic, to further simulation. Such cells express low levels of surface BCR and have an inhibited capacity to be activated. For example, anergic B cells upregulate SHIP1 [35], a phosphatase that negatively regulates BCR signaling [36]. Additionally, self-reactive B cells may be more dependent on BAFF stimulation for survival; in competition with non-reactive cells, many self-reactive B cells are disadvantaged [37–39], although this scenario does not necessarily apply to all self-reactive B cells [40]. Generally, anergic B cells have a reduced lifespan relative to other, non-autoreactive mature B cells [41].

Regulatory Cells Specialized regulatory cells also play a role in the maintenance of peripheral tolerance. These cells are discussed later in the section on the immune response.

Mechanisms of Targeted B Cell Depletion

Unique surface marker 'fingerprints' for B cells at different developmental stages can be used to develop therapeutic strategies to selectively deplete B cell subpopulations. One such marker is CD20 (Fig. 7.2), a B cell-specific transmembrane protein with no defined function or ligand to date [42]. CD20, commonly used as a B cell identification marker, is expressed on pre-, immature-, mature and memory B cells, but is down-regulated on plasmablasts and long-lived plasma cells. Rituximab is an anti-human CD20 chimeric monoclonal antibody that depletes CD20-expressing B cells via a combination of antibody-dependent cellular cytotoxicity, complement-mediated cellular toxicity and directly inducing apoptosis [43]. Rituximab treatment depletes most B cell precursors, mature and memory B cells, but spares lymphoid and pro-B precursors and long-lived plasma cells in the marrow. Thus, following rituximab-mediated B cell depletion, the B cell pool will slowly reconstitute itself. Furthermore, vaccine-induced and naturally acquired standing antibody titers to pathogens are spared. Rituximab is approved by the U.S. Food and Drug Administration for the treatment of B cell lymphoma, rheumatoid arthritis and ANCA-associated vasculitis and is used off-label to treat systemic lupus erythematosus and immunobullous disorders [44].

Another approach to B cell depletion is to target soluble factors required for their survival. One successful target is B cell activating factor (BAFF; also known as BLyS). BAFF is a TNF superfamily ligand that binds BAFF-receptor (BAFF-R) on transitional and mature B cells and is required for their survival [28, 45, 46]. Memory B cell survival as a whole is independent of BAFF [47], although subsets differ in their dependence [48]. While plasma cells utilize BAFF signals to survive, they are not absolutely dependent on BAFF. APRIL, a ligand related to BAFF, can compensate for BAFF loss. BAFF is an appealing therapeutic target in B cell mediated autoimmunity because some autoreactive B cells may be more BAFF-dependent than non-autoreactive populations [49, 50]. Belimumab is a human monoclonal antibody that targets BAFF, thus inhibiting receptor binding. Belimumab treatment depletes immature and mature B cells but spares plasma cells and the majority of memory B cells. As with CD20-targeted depletion, the B cell pool can reconstitute as precursor populations in the bone marrow are spared. In 2011, the U.S. Food and Drug Administration approved belimumab for the treatment of systemic lupus erythematosus (SLE), the first drug approved for the treatment of SLE since hydroxychloroquine in 1955 and aspirin in 1948 [51, 52]. Related drugs are in development, including

ones that block BAFF via alternate mechanisms or that block BAFF and APRIL simultaneously.

Summary

B cell development is an ordered maturation process that starts from a pluripotent hematopoietic stem cell in the bone marrow and concludes with a mature B cell in the periphery. The goal of early stages of development is the formation of a B cell precursor bearing a fully functional B cell receptor of a single antigen specificity. Next, developing B cells are evaluated for autoreactivity (central tolerance). Immature B cells with strongly reactive B cell receptors can be deleted directly or can undergo receptor editing, in an attempt to generate receptor of a different specificity. Next, newly generated transitional B cells exit the bone marrow and undergo final stages of maturation and selection in the periphery. This population includes cells with weak autoreactivity, which can be managed though deletion or other mechanisms that suppress their activity (peripheral tolerance). Finally, a minority of transitional B cells are positively selected into the mature B cell pool. This mature B cell pool is comprised of B cells of diverse antigenic specificities. Mature B cells continually recirculate through the spleen, lymph nodes, marrow and peripheral tissues via the blood and lymphatics, surveilling for infection.

Breaks in central and/or peripheral B cell tolerance underlie autoimmune disorders such as systemic lupus erythematosus, rheumatoid arthritis and immunobullous skin disease. Malignant proliferation of B cell populations results in lymphoma. Targeted monoclonal antibodies that deplete B cells can be effective therapies for B cell malignancies and B cell-mediated autoimmune disease. Such drugs include rituximab and belimumab, which target CD20 or BAFF-R expressing B cell subpopulations.

B Cells in the Immune Response

Introduction

Upon binding to its cognate antigen, a B cell becomes activated. B cell receptor activation is intrinsically regulated – positively and negatively – through accessory surface proteins. Different types of antigens and the involvement of $CD4^+$ T cells shape the B cell response. A primary goal of the B cell response is to produce antibody, which binds the pathogen or pathogen-produced toxins, mediating a variety of effector functions as described above (Antibody Structure and Function). $CD4^+$ T cell help enables another, more temporally distant goal – that of achieving long-term immunity (memory) to the pathogen.

This section will describe B cell signaling and B cell participation in the immune response. The focus is the T cell-dependent immune response, although the T-independent B cell response is reviewed as well. Specific interactions between T cells and B cells that profoundly influence B cell fate are highlighted.

Activation of the B Cell Receptor Signaling Complex Triggers a Protein Kinase Signaling Cascade

B cell activation begins with ligation of antigen to the BCR complex which triggers an intricate and highly regulated signaling cascade [53]. The BCR does not on its own trigger downstream signaling following antigen binding, but rather, it requires invariant transmembrane proteins Igα (CD79a) and Igβ (CD79b) – which each have immunoreceptor tyrosine-based activation motifs (ITAMs) – to initiate a protein kinase signaling cascade. These proteins associate with a portion of the immunoglobulin heavy chain constant region and are phosphorylated by associated kinases. The phosphorylation cascade culminates in the activation of phospholipase C-γ (PLC-γ) and guanine-nucleotide exchange factors (GEFs). PLC-γ cleaves a membrane phospholipid, resulting in an increase in intracellular Ca^{++} levels. This in turn leads to the activation of two transcription factors: NF-kB and NFAT. Guanine-nucleotide exchange factors activate a MAP kinase cascade that leads to the activation of another transcription factor, AP-1. Together, these three transcription factors turn on genes important for proliferation, differentiation, antigen presentation and cytokine production.

BCR signaling is tightly regulated. At the initiation stage, crosslinking of two or more BCRs with antigen is required for triggering the downstream signaling cascade (Fig. 7.3). Subsequently signaling can be both positively and negatively modulated. The B cell coreceptor complex – CD19, CD21/CR2 and CD81 – is activated by antigens opsonized with complement and augments BCR signaling by recruiting one of the guanine-nucleotide exchange factors. BCR signaling can be negatively regulated by several B cell-intrinsic proteins, such as CD22 and FcγRIIB, that contain immunoreceptor tyrosine-based inhibitory motifs (ITIMs) in their cytoplasmic tails. ITIMs recruit the phosphatases SHIP1 and SHP1, which dephosphorylate and thus deactivate kinases involved in the BCR signaling cascade. SHIP1 and SHP1 are upregulated in germinal center B cells and may be involved in their selection by increasing the minimum threshold for BCR signaling, thus favoring higher-affinity B cells [36]. Anergic B cells – B cells that are unresponsive to antigen stimulation – have chronic activation of SHIP1 [35].

In addition to recognizing antigen via the BCR, B cells engage antigen or modified antigen via surface receptors,

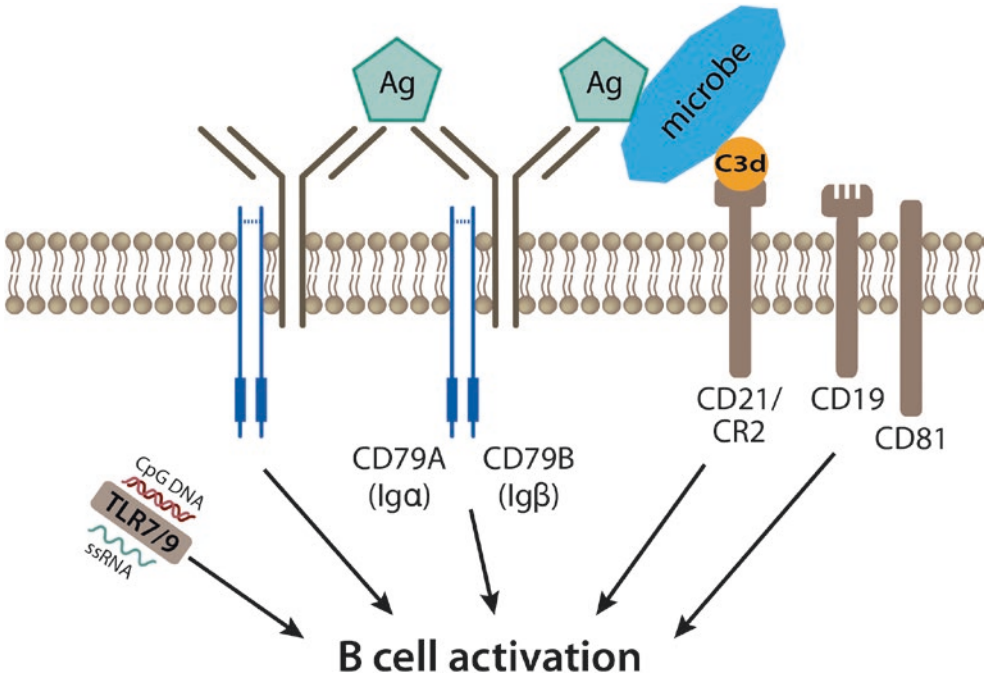

Fig. 7.3 B cell activation requires B cell receptor (BCR) cross-linking and is augmented by additional signals. B cell activation is initiated by antigen (Ag) binding induced BCR cross-linking. Additionally, the BCR co-receptor complex – CD21/CR2, CD19 and CD81 – can further enhance signaling. CD21/CR2 binds complement-coated microbes and activates CD19. Toll-like receptors (TLRs) recognize motifs unique to different classes of pathogens and further activate B cells, thus linking the innate and adaptive immune systems

particularly Toll-like receptors (TLRs), CD21/CR2 and FcγRIIB. The latter two proteins manipulate the BCR signaling cascade by binding complement-bound antigen or IgG-bound antigen respectively. TLR activation can exquisitely tune B cell antigen presentation, differentiation and class-switch during the B cell immune response [54].

B Cells Responses to Lipid and Polysaccharide Antigens Do Not Require T Cells

Humoral responses are the principal defense against polysaccharide and lipid antigens, and T cells are not required to mount these "T-independent" (TI) responses. In TI responses, antigen binding induces B cell activation, proliferation, expansion and differentiation into antibody-secreting plasma cells. Resultant antibodies are typically IgM and low affinity, identical to those produced by their naïve precursors. There are two forms of T independent responses, classified by antigen type. Type I responses involve pathogens that engage B cell Toll-like receptors (TLRs) as well as the BCR. Type II responses involve polysaccharide antigens that exclusively activate the BCR and induce strong cross-linking because of their repeating antigenic epitopes. T-independent type II antigens can elicit both memory B cells and a long-lasting antibody response [55–57], although antibody titers are not boosted upon repeat immunization [58]. Polysaccharide-based vaccines include Pneumovax and Menomune, which provide protection against pneumococcus bacteria and bacterial meningitis, respectively.

B Cell Responses to Protein Antigens Require Cognate B-T Interactions

An effective humoral responses against protein antigens requires both B and T cells is and is termed a "T-dependent" (TD) response. B cell responses primarily occur in secondary lymphoid organs such as the spleen or lymph node. B cell activation occurs when a naïve B cell binds cognate antigen, triggering intracellular signaling and receptor-mediated endocytosis of antigen. Antigen is processed and the resultant peptide fragments presented on MHC class II molecules for display to $CD4^+$ T cells.

B and T cells are located in separate areas of the spleen and lymph node, so during early activation they must be brought into close proximity. Activated B cells alter expression of chemokine receptors, downregulating receptors for chemokines expressed in the B cell follicle and upregulating receptors for chemokines expressed in T cell zones. Thus, activated B cells migrate toward T cells and, similarly, dendritic cell-activated T cells migrate towards B cells. When B and T cells specific for the same antigen meet and have a cognate MHC Class II:TCR interaction, the T-dependent response is initiated. Additional direct interactions between B cells and T cells further stabilize the conjugate.

The B cell response to T-dependent antigen is highly orchestrated and occurs in overlapping stages (Fig. 7.4). The early "extrafollicular" response, so called as it occurs outside of the B cell follicle at the T cell zone – follicle border, is characterized by B cell proliferation and differentiation into short-lived plasmablasts that secrete copious amounts of low affinity

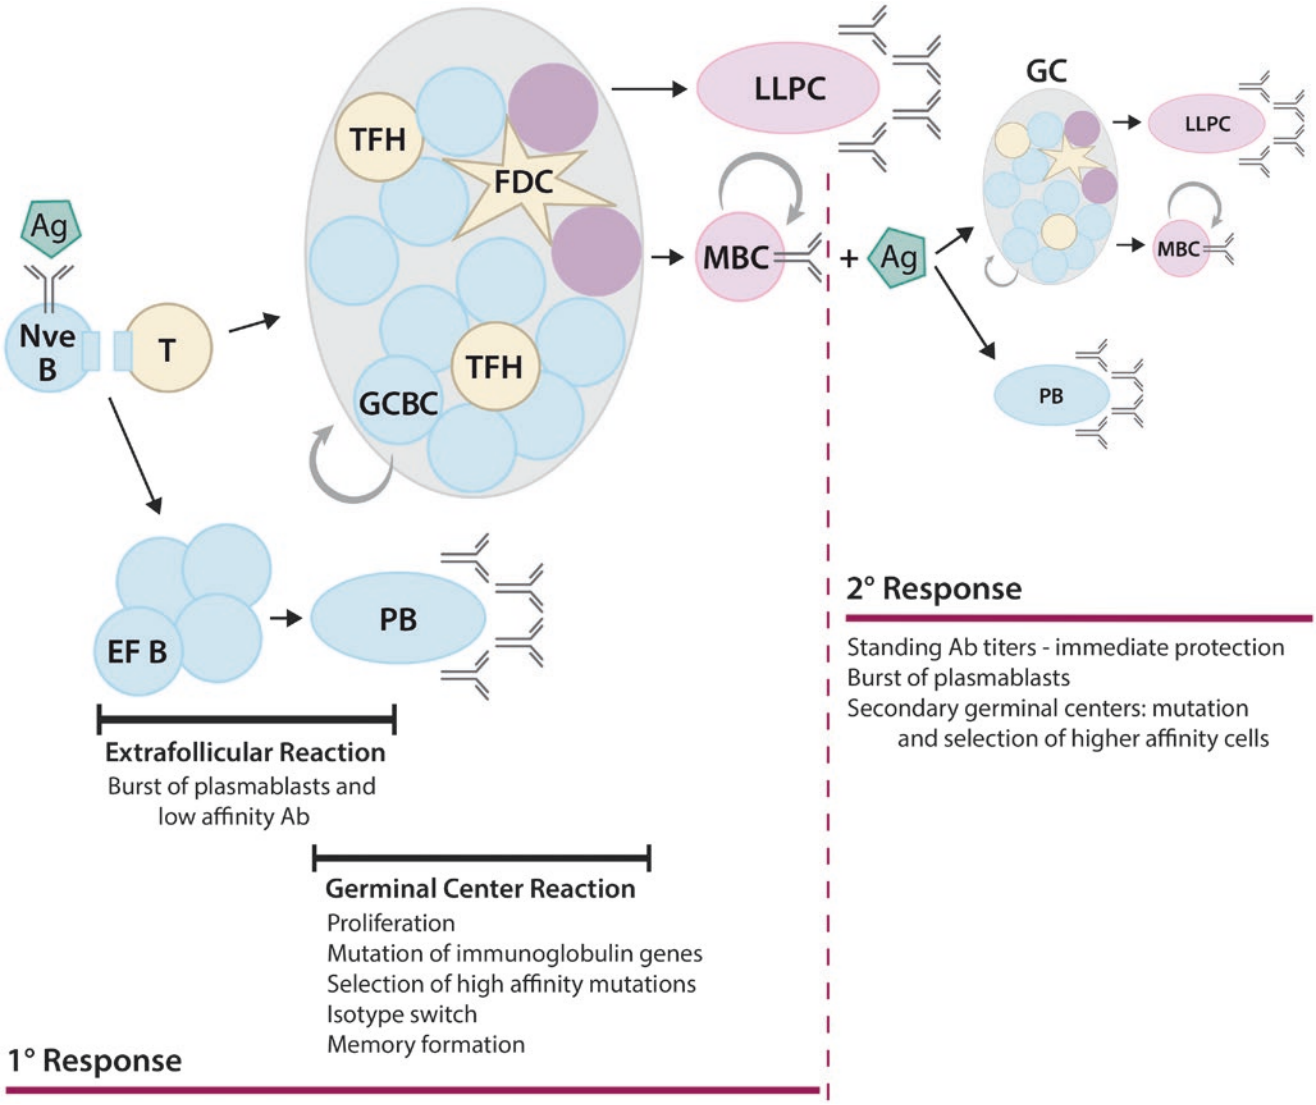

Fig. 7.4 B cells in the immune response. Following binding to its cognate antigen (Ag), the naïve B cell (Nve B) presents antigen-derived peptide to an activated CD4+ T cell and is itself activated. Rapid proliferation results in the formation of an extrafollicular focus of B cells (EF B), which is characterized by rapid differentiation into short-lived plasmablasts (*PB*) that produce a large burst protective low-affinity IgM antibody (Ab). With time, some B and T cells can seed a germinal center (*GC*). Germinal center B cells (*GCBC*) proliferate rapidly and interact with follicular dendritic cells (*FDC*) and T follicular helper cells (*TFH*). Somatic hypermutation, competition between B cell clones and affinity maturation yield B cells with higher affinity for antigen. Class-switch recombination produces clones with switched immunoglobulin isotypes. Ultimately, the germinal center produces long-lived plasma cells (*LLPC*), terminally differentiated cells that exclusively produce antibody, and memory B cells (*MBC*). Upon antigen re-stimulation in a secondary (2°) response, MBC rapidly differentiate into plasmablasts or form new germinal centers and undergo further affinity maturation

antibody. This early extrafollicular response is important for gaining rapid control of a new infection, and in the case of persistent self-antigen, can contribute to autoimmunity [59, 60]. Some memory B cells are formed during this time, but are typically unmutated and of low-affinity compared with those that are generated later in the response [61, 62].

After several days, some interacting B and T cells begin to express the master transcriptional regulator Bcl-6 and migrate into the follicle where they continue to proliferate and form nascent germinal centers (GC). The germinal center is a site of intense B cell proliferation, BCR mutation and ultimately B cell differentiation into memory B cells and plasma cells. Germinal center B cells (GCBC) can undergo somatic hypermutation, potentially altering the structure and affinity of the antigen-binding region of the BCR. They can also undergo class switch recombination, resulting in permanent switch away from IgM and IgD heavy chains to IgG, IgA or IgE. Both somatic hypermutation and class switch recombination are dependent on B cell-intrinsic expression of the DNA-editing deaminase, activation-induced cytidine deaminase (AID). GCBC divide on average every 6 h, with one precursor producing as many as 5000 progeny in a week [63]. There is

intense competition between B cells for critical interactions with cognate T cells, follicular dendritic cells and survival signals, and this competition results in the death of the vast majority of germinal center B cells. Those that survive and continue to propagate tend to be of higher affinity, a process referred to as affinity maturation. Ultimately, a germinal center B cell can undergo one of three fates: death, division (with retention in the germinal center), or positive selection and differentiation into the memory B cell or long-lived plasma cell pools (with exit out of the germinal center).

B cell participation in the germinal center comes at a cost, as germinal center B cells do not immediately contribute to pathogen clearance. Germinal center kinetics differ based on tissue and antigen accessibility. For example, murine influenza virus studies have shown that germinal center B cell frequency peaks later in the lungs than in the lymph nodes or spleen [64], suggesting that rapid production of antibody by plasmablasts (and thus more rapid influenza virus clearance) is prioritized over germinal center participation amongst lung B cells. While the germinal center reaction may be less immediately relevant to pathogen clearance when compared to extrafollicular plasmablast production, its products (memory B cells and long-lived plasma cells) play a vital role in the response to re-infection. Thus, the germinal center is an investment in the immunological future of the host.

Follicular Dendritic Cells Shape the Geography of the Germinal Center

Germinal center B cells (GCBC), T follicular helper cells (T_{FH}) and follicular dendritic cells (FDC) are the critical cellular components of the germinal center. Importantly, FDCs are not professional antigen-presenting dendritic cells. Rather, they capture and retain immune complexes on their surfaces via complement receptors and Fc receptors. FDCs present unprocessed, native antigen to GCBC and help mediate their survival [65]. They also produce chemokines that regulate lymphocyte migration and germinal center architecture. FDC density is varied within the germinal center, providing a structural framework for GCBC migration and division.

T Follicular Helper Cells Interact with Germinal Center B Cells to Promote B Cell Selection, Proliferation, Class-Switch and Differentiation

T cell help to B cells is fundamental to the adaptive immune response and the generation of immunological memory. In the context of a germinal center reaction, this help is provided by T follicular helper cells (T_{FH}), specialized CD4 T cells located in the follicle and defined in part by their high expression of CXCR5, PD-1 and IL-21 [66, 67]. T_{FH} provide critical signals driving B cell proliferation, survival, immunoglobulin isotype class-switch and differentiation into long-lived plasma cells and memory B cells. Both GCBC and T_{FH} express the transcriptional repressor and master regulator Bcl6, which is crucial to their identities and distinguishes them from other B cell and T cell subsets. T_{FH} require two direct signals for optimal activation. The first is provided by the antigen-derived peptide presented by MHC Class II on the surface of the B cell. The second signal, a costimulatory signal, can be provided by a variety of receptor interactions and can further hone the 'help' provided by the T_{FH} cell.

Positive selection of germinal center B cells was long thought to exclusively depend on BCR signaling strength, with the assumption that GCBC with higher affinity BCRs would have stronger downstream signaling. However, it has recently been demonstrated that BCR signaling in GCBC is actually attenuated [36], so BCR signaling cannot be the sole determining factor in selection. Instead, antigen presentation signals appear to dictate GCBC selection. High affinity BCRs effectively capture more antigen and ergo present more antigen to T cells [68]. The resulting enhanced T cell-B cell interaction leads to more B cell division and more somatic hypermutation. Thus, T cell help via peptide-loaded MHC Class II molecules plays a crucial role in deciding GCBC fate. The mechanisms determining when a GCBC will differentiate into a plasma cell or memory B cell and exit the germinal center, rather than divide and remain in the germinal center, however, are not understood and are under active investigation.

B:T Interactions in the Immune Response

B cells express a number of proteins that bind partner proteins expressed on the surface of T follicular helper cells. Figure 7.5 depicts some of the primary T cell-B cell interactions that take place. T cells influence numerous aspects of germinal center B cell fate including maintenance, differentiation, proliferation and class-switch. This complex web of interactions also has consequences for the T cell. Expression of some of these proteins (on both B cells and/or T cells) is dictated by the activation state of the cell as well as pre-existing expression of other proteins.

Direct Interactions Between B Cells and T_{FH} Promote Germinal Center Formation and Germinal Center B Cell Survival

Specific receptor-ligand interactions between B cells and T_{FH} are necessary for germinal center formation. CD40 is constitutively expressed on B cells and binds CD40L, expressed on activated T cells. This interaction is absolutely required for

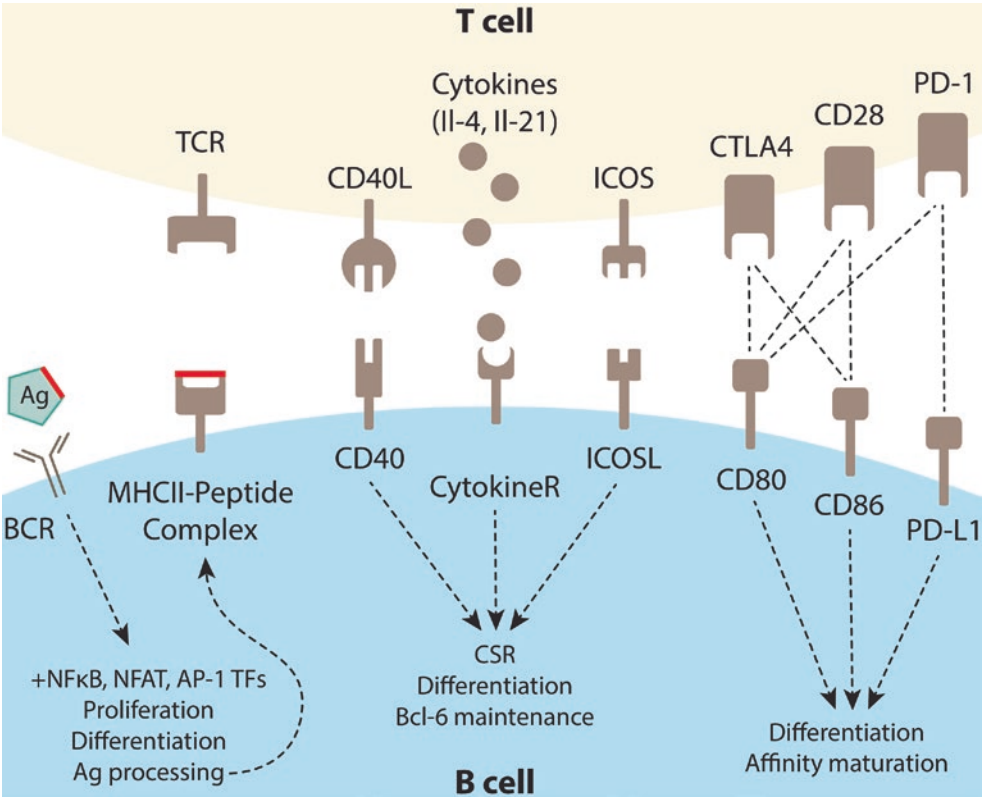

Fig. 7.5 Key interactions between activated B cells and T follicular helper cells (T_{FH}). Following antigen (Ag) binding to the B cell receptor (*BCR*), B cells process antigen and present peptides on MHC Class II to T cells. T cell receptor (*TCR*)-MHC Class II binding is further modulated by CD40/CD40L, ICOSL/ICOS interactions and by T cell-produced cytokines. B7 family interactions modulate the response further [72]. While effects on B cells are highlighted, these B cell-T_{FH} interactions have functional consequences for the T cell as well

germinal center formation. In the absence of CD40L, T_{FH} are reduced [69–71]. Similarly, ICOS and ICOSL – expression of which are induced following T cell and B cell activation respectively – also interact to promote germinal center formation, notably through T cell production of IL-4 [70].

Other direct T_{FH}-B cell interactions may not be absolutely required for germinal center formation, but do influence GCBC survival and selection. One example of this type of signaling involves the B7 family of proteins, which includes CD80, CD86, PD-L1, PD-L2 as well as the receptors CD28 and PD-1 [72]. GCBC upregulate first CD86 and then CD80, both of which can bind CD28, an activating receptor expressed by T cells, and CTLA-4, an inhibitory receptor expressed by T cells. CD80 can further bind PD-1, an inhibitory receptor that is highly expressed on T_{FH} and crucial for T cell secretion of IL-4 and IL-21. Finally, PD-L1 and PD-L2 – additional ligands for PD-1 – are also upregulated on murine GCBC. Murine studies have revealed that the B7 family has an important role in T cell-dependent immune responses with the varied types of interactions having similar, but not always completely redundant, effects. CD80 expression on B cells not only promotes normal T_{FH} development, but also GCBC survival and selection of high-affinity plasma cells [73]. Similarly, interactions between PD-1 on T_{FH} and PD-L1 or PD-L2 on GCBC influence GCBC survival and long-lived plasma cell formation, with fewer but higher-affinity long-lived plasma cells surviving in the absence of PD-1 and PD ligand signaling [74]. Thus, in addition to the binding of the peptide-loaded MHC Class II to the TCR, other direct interactions between GCBC and T_{FH} can influence the GCBC selection process.

T_{FH} Produce Cytokines That Indirectly Influence Germinal Center B Cell Maintenance, Class-Switch and Differentiation

In addition to direct protein-protein receptor binding, T_{FH} produce several cytokines that influence GCBC fate. Most prominently, they secrete IL-21, which binds IL-21R on B cells. In conjunction with IL-6, IL-21 is also reciprocally important for T_{FH} formation. IL-21 promotes the expression of Bcl6 in GCBC. In its absence, there is no quantitative effect on the T_{FH} population but there is reduced GCBC proliferation and a decrease in long-lived plasma cell production [75]. In conjunction with the B7 family interactions described above, this further demonstrates the requirement for functional T_{FH} in long-lived plasma cell output and affinity maturation. Memory B cell output is generally not significantly affected by the absence of B7 family members, but interestingly, there is an increased frequency of memory B cells in the absence of IL-21, suggesting that sustained T cell interactions are not required for GCBC to differentiate into memory B cells. In addition to IL-21, T_{FH} can secrete IL-4, which promotes class-switch to IgG_4 and IgE as well as GCBC proliferation.

A diverse range of direct and indirect stimuli guides the formation, maintenance and ultimate output of the germinal center. While some proteins may be absolutely necessary for germinal center formation, it is likely that differential signaling and variable participation of most ligands, receptors and cytokines finely tune individual germinal centers. This tuning can go awry: T_{FH} can also promote expansion and differentiation of autoreactive B cells. Current research is directed towards better understanding the range of interactions between T_{FH} and GCBC, including the sequence of ligand, receptor and cytokine upregulation as the germinal center reaction matures. Such knowledge will help develop targeted therapies to constrict autoreactive or malignant GCBC proliferation and differentiation and conversely to expand and fine tune the germinal center response to vaccination.

Regulatory T Cells and B Cells Dampen the Immune Response

The immune system exists as a delicate balance – while a healthy individual should mount a vigorous protective response to an invading pathogen, an overly vigorous response could be dangerous. Sometimes, dampening of the immune response is absolutely necessary. Successful reproduction in placental mammals depends upon repression of the maternal immune response to prevent rejection of the fetus. In addition to T_{FH}, other $CD4^+$ T cell subtypes can be involved in regulating the B cell response. Regulatory T cells (Tregs) are generally characterized by expression of the transcription factor Foxp3, the IL-2 receptor CD25 and production of IL-10. They are capable of directly suppressing autoreactive B cells in many situations, including in systemic lupus erythematosus [76]. Effective suppression of autoimmunity requires functional Tregs to be present in adequate numbers in the correct location.

In addition to their roles as antibody-producing cells and antigen-presenting cells, B cells secrete regulatory cytokines. B cells can be subdivided based on cytokine production in a manner similar to $CD4^+$ T cell subtypes. Regulatory B cells (Bregs), like Tregs, are characterized by production of IL-10 or TGF-β [77–79]. In mice, Breg is a catchall term that applies to B cells from different lineages and anatomic niches. In humans, they have been characterized using combinations of surface markers, including markers associated with memory B cells [80]. Like Tregs, they may be involved in suppressing the maternal anti-fetal T cell response in pregnant women [81]. In murine models of autoimmune disease, Bregs have been shown to protect against disease progression. In systemic lupus erythematosus and pemphigus, B cell depletion therapy has been suggested to work in part by increasing the relative amount of tolerogenic B cells.

Summary

B cell activation is initiated when antigen binds the B cell receptor, triggering an intracellular signaling cascade. Responses to polysaccharide and lipid antigens do not require T cell help and are termed T-independent reactions. Responses to proteins do require T cell help and are termed T-dependent reactions. For T-dependent reactions, after B cell receptor ligation, the antigen is endocytosed, processed and presented on MHC class II to $CD4^+$ T cells. When a B and T cell specific for the same antigen make contact, the B cell proliferates. First an extra-follicular focus is formed wherein there is extensive differentiation to short-lived plasmablasts that secrete large amounts of low affinity antibody to provide immediate protection against the infection. Next, a germinal center reaction is formed. Here, B cells interact with T follicular helper cells and follicular dendritic cells and undergo massive clonal expansion. Some germinal center B cells undergo class-switch to IgG, IgA or IgE isotype and some undergo somatic mutation of the B cell receptor, thus generating new clones of differing affinity for antigen. Germinal center B cells compete with one another for access to necessary survival signals and clones with higher affinity are selected, a process termed affinity maturation. The goal of the germinal center reaction is the production of long-lived plasma cells and memory B cells. In the next section, we will discuss describe these cells and their significance.

Long Lived Plasma Cells and Memory B Cells

Introduction

Immunologic memory, the basis of durable immunity to vaccination and natural infection, is the hallmark of the adaptive immune system. Memory is comprised of durable antibody titers and the bone-marrow resident long-lived plasma cells that produce them and antigen-specific memory B and T cells. Long-lived plasma cells and memory B cells differentiate from the germinal center reaction through critical but poorly understood mechanisms, after undergoing multiple rounds of proliferation, somatic hypermutation and selection. Long-lived plasma cells are terminally differentiated cells that continually produce and secrete antibody. In contrast, memory B cells are not terminally differentiated and upon antigen re-stimulation can either differentiate into plasmablasts or can generate or re-enter a new germinal center. In this section, we will review basic properties of both long-lived plasma cells and memory B cells and consider new ways in which optimization of the germinal center reaction could be used to improve vaccine design.

Long-Lived Plasma Cells Exclusively Secrete Antibodies and Lose the Ability to Proliferate or Present Antigen to T Cells

Terminal differentiation of germinal center B cells to long-lived plasma cells (LLPC) requires initiation of a unique transcriptional program and the concomitant blockade of the germinal center B cell transcriptional program [82, 83]. The plasma cell differentiation program relies on increased expression of three transcription factors – Xbp1, Prdm1 (encoding BLIMP1) and Irf4. Together, these expand the size of the burgeoning plasma cell, stop cell cycle progression, downregulate MHC Class II expression and enhance protein manufacturing and secretion. The requirement for these transcription factors in LLPC development and function has been validated in elegant studies utilizing mouse models with gene-specific deletions.

The exact signals required to induce the development of LLPC are unclear, but signals delivered through the BCR and cytokines in the milieu are clearly important. Long-lived plasma cells emerge from the germinal center late in the immune response, in contrast to memory B cells, which tend to arise earlier [84]. The primary and best-characterized niche for LLPC is the bone marrow. Thus, LLPC must egress from the site of formation in germinal centers in the spleen, lymph node or other secondary lymphoid organs and migrate to the marrow. An early step in their development is the downregulation of CXCR5, a chemokine receptor that retains B cells in the follicle. Egress also requires signals delivered through β-integrins [85] and CD138/syndecan. Migration to the marrow is directed in part by the upregulation of CXCR4, the receptor for the chemokine CXCL12, which is produced by bone marrow stromal cells.

The BM-resident plasma cell compartment is long-lived, with plasma cells estimated to survive in mice for their lifespan (at least 1 year) [86]. The lifespan of LLPC in humans is unclear, but antibody titers can be durable over a lifetime. As plasma cells are terminally differentiated, non-dividing cells, longevity of an individual plasma cell is likely quite long. Bone marrow stromal cells provide several key survival factors, including IL-6, IL-21 and BAFF and APRIL. In mice, survival or retention signals are also provided by eosinophils and basophils [87, 88].

IL-21 is a master regulator of B cell differentiation that, among other effects, promotes plasma cell development [89]. IL-21 is produced by T follicular helper cells and regulates B cell expression of Bcl6, Prdm1/Blimp-1 and Aicda/AID. It has myriad effects, resulting from combinatorial signaling provided by other direct and indirect cues, which orient B cell fate. Humans with homozygous loss-of-function mutations in the IL-21R gene have, amongst other problems, reduced serum IgG levels and impaired responses to T-dependent antigen-based vaccines. Additionally, IL-21 and IL-21R gene polymorphisms that result in aberrant production of IL-21 have been associated with several autoimmune diseases [90].

Long-Lived Plasma Cells Utilize Several Mechanisms to Cope with High Protein Output Stress

Ex vivo and without additional stimulation, human bone marrow-derived plasma cells produce 10^7–10^8 Ig molecules/cell/hour [91]. Thus, long-lived plasma cells are highly stressed cells and require several mechanisms to adapt [92]. The unfolded protein response and the ubiquitin proteasome system are part of this transformation. Increased stress from misfolded protein accumulation renders long-lived plasma cells more sensitive to death induced by proteasome inhibitors such as bortezomib [93]. This finding has been applied to treatment of multiple myeloma and proteasome inhibitors may also have a role in the treatment of autoimmune disease.

In addition to modifications in the protein folding and degradation process, murine plasmablasts and plasma cells rely on autophagy. Autophagy is a self-recycling process that rids cells of damaged proteins and organelles while maintaining metabolism under nutrient-poor conditions. Mice whose B cells conditionally lacked a component of autophagy participated normally in germinal centers, but had lower antibody titers and fewer bone marrow-resident LLPC than wild-type mice [94]. While the role of autophagy in supporting human LLPC survival has not yet been studied, it is likely important.

Because plasma cells differ from their B cell precursors in expression of cell surface molecules and in their dependence on survival factors, they often respond differently than other B cell populations to medications used to treat autoimmune diseases and malignancies. Importantly, rituximab, which targets CD20-expressing cells, is effective at depleting naïve and memory B cells but leaves CD20-negative plasma cells and plasmablasts intact. Belimumab, a monoclonal antibody that binds and blocks BAFF activity, depletes transitional and mature B cell populations, but is relatively sparing of certain memory B cell compartments and plasma cells. Therapeutic strategies that directly target signals and proteins important for long-lived plasma cell survival and maintenance may therefore be more effective in the treatment of some autoimmune diseases and multiple myeloma. These signals can include both external survival factors such as BAFF or APRIL as well as internal plasma cell components needed for the unfolded protein response or autophagy.

Memory B Cells Can, Upon Re-activation, Differentiate into Plasmablasts or Reenter the Germinal Center

Like long-lived plasma cells, memory B cells (MBC) are effectively elicited after vaccination and infection and are clonally long-lived [95]. They too are produced in the germinal center and are critical for long-term immunity. Unlike long-lived plasma cells, MBC are not terminally differentiated, and thus are poised to respond dynamically to reinfection with either known or new-but-related antigen. Upon challenge, MBC can rapidly differentiate into antibody-secreting plasmablasts, contributing immediately to short-term protection, or form new germinal centers and undergo further affinity maturation. Successful elicitation of a robust MBC population is likely required for effective vaccination strategies for chronic and/or rapidly evolving pathogens such as HIV and influenza virus, and pathogenic autoreactive MBC may underlie autoimmune disease. Therefore, the study of MBC biology is a dynamic area of investigation.

Memory B Cells Can Be Divided into Phenotypic and Functional Subsets

Phenotypically, MBC resemble naïve B cells and until recently, understanding of MBC biology was severely limited due to a lack of reliable markers to distinguish true, antigen-specific memory cells from their naïve precursors. Historically, the presence of class-switch isotype (IgG) was used as a marker for MBC, however, this definition excludes the significant proportion of MBC that are IgM-bearing [96] while encompassing recently activated but not true memory cells. Recently, we have identified several markers of MBC in mice, including CD80, PD-L2 and CD73, which together define distinct MBC subsets [97, 98]. Some of these markers, such as the B7 family members CD80 and CD86, are also upregulated on human MBC [99, 100] and B cell-intrinsic CD73 plays a role in class-switch recombination [101]. Importantly, CD80 and PD-L2 define subsets of MBC, independent of isotype, that differ functionally from one another [102]. Together with work illustrating differential functionality of MBC subsets defined by isotype [103] and tissue distribution [64], these data demonstrate that the MBC population is heterogeneous both phenotypically and functionally.

In humans, CD27, a member of the TNF receptor superfamily, is upregulated on most MBC [104, 105]. As in mice, MBC are not exclusively class-switched or somatically hypermutated and marker expression can vary across subsets [106, 107]. In addition to CD27, other MBC markers have been identified, including CD21/CR2 [108], FcRH4/FcRL4 [109, 110] and CD148 [111]. Thus, human MBC are also heterogeneous [106]. Intriguingly, additional memory B cell subsets have been described in individuals with HIV infection [108] and systemic lupus erythematosus [112]. These include activated memory B cells ($CD27^{hi}CD21^{low}$), which are a source of plasmablasts and more vulnerable to apoptosis, and tissue-like memory B cells ($CD27^{low}CD21^{low}$), which harbor exhausted B cells enriched in HIV-specificity [108]. Further characterization of these subsets could suggest new vaccine and therapeutic strategies for HIV and other chronic diseases.

MBC are generated from antigen responding B cells in the germinal center reaction. MBC are formed biphasically in the early germinal center, while long-lived plasma cells are formed in the late germinal center [84], suggesting that the germinal center milieu changes with maturation and that MBC generation may be less dependent on prolonged T cell help than LLPC generation. Ultimately, relatively few MBC and LLPC are generated in spite of the high number of germinal center B cells at the peak of the reaction. The mechanism(s) that underlie germinal center B cell differentiation into MBC or LLPC remain poorly understood.

Memory B Cells Respond Quickly and Robustly to Antigenic Stimulation

Compared with naïve B cells in the primary response, MBC mount a secondary response more quickly and robustly, and this response tends to be of higher affinity and more enriched in class-switched antibodies (Fig. 7.4). The mechanisms enabling the rapid and robust memory response are not entirely elucidated, but MBC may have a lower threshold for activation than naïve B cells. They are more responsive to cytokines such as IL-21 and IL-10, which can promote plasmablast differentiation [113]. Moreover, memory, but not naïve, B cells constitutively express proteins such as CD80 and CD86 that enable direct interaction with $CD4^+$ T and upregulate survival factors in response to Toll-like receptor (TLR) stimulation more readily [100]. Upon activation, MBC can either rapidly differentiate into short-lived antibody-secreting plasmablasts, thus providing a burst of antibody for immediate protection, or rapidly form new germinal centers, wherein they undergo further affinity maturation and produce new MBC and long-lived plasma cells that produce antibody with improved affinities for the pathogen. The former fate is critical for protection to known pathogens, while the latter is likely key for protection against new but related pathogens, such as rapidly mutating viruses. Recent studies in mice indicate that these functions are provided by distinct subsets of MBC [102] suggesting the same may be true for human MBC.

Memory B Cells Are Clonally Long-Lived and Self-Renew

A defining characteristic of the MBC compartment is its longevity [95]. MBC longevity is in stark contrast with the

relatively short lifespan of their direct naïve precursors. In part, this longevity can be explained by the fact that MBC survival is relatively independent of BLyS/BAFF signals compared with naïve B cells [114], but the magnitude of independence differs between subsets [48], indicating that other factors are important as well. Interestingly, T cell help does not appear to be required for MBC survival [115]. Furthermore MBC and long-lived plasma cell compartments appear to be maintained independently [6, 116].

Longevity also depends on MBC self-renewal. Homeostatic self-renewal has been observed in careful long-term kinetic studies [117, 118]. In this respect, MBC are more similar to their early hematopoietic stem cells precursors, which self-renew, than their direct mature precursors, which cannot, suggesting a process of neoteny wherein MBC, or a subset of MBC, acquire stem cell-like properties. Genetic evidence for this concept comes from microarray comparisons between murine MBC, memory T cells and hematopoietic stem cells that indicate that memory lymphocytes share an expression signature with hematopoietic stem cells [119]. Furthermore, human MBC and memory T cells (both $CD4^+$ and $CD8^+$) have been shown to share a common genetic signature, which includes some genes important for quiescence [120]. Elucidating the mechanism(s) underlying MBC durability could lead to improved vaccine design strategies and is a focus of active research.

Summary

Long-lived plasma cells and memory B cells are independent B cell populations that emerge from the germinal center and provide protection against re-infection. Plasma cells are antibody-producing factories that maintain durable standing antibody titers for immediate protection to re-exposure to pathogen. Plasma cells have a highly specialized transcriptional program with mechanisms in place to handle the high stress of enormous protein output. Memory B cells resemble naïve B cells in many respects, retaining the ability to enter the germinal center as well as to differentiate into plasmablasts upon re-stimulation. Unlike their naïve precursors, memory B cells are frequently class-switched and often bear mutated, high affinity B cell receptors. Critically, they have a lower threshold for activation and are thus better positioned to adapt to pathogen re-challenge. Unlike their precursors, memory B cells are long-lived and self-renew.

Conclusions

B cells are key components of the adaptive immune system. They produce antibodies, act as antigen-presenting cells for T cells and secrete cytokines that modulate other arms of the immune system. A hallmark of the B cell response is the development of memory, comprised of protective standing antibody titers, long-lived antibody-secreting plasma cells and memory B cells. B lymphocyte responses are thus critical for effective and durable immunity to pathogens but can drive and promote pathology in autoimmune, allergic and malignant disease.

In summary, this chapter broadly reviewed the current field of B lymphocyte biology, providing a conceptual framework for the dermatologist and cutaneous biologist. Significant redundan emphasis was devoted to reviewing antibody structure, isotype variation and effector function, in part because antibodies are critical tools for dermatologists and biologists given their exquisite specificity against protein, small molecule, lipid and carbohydrate molecules. The field of B cell development was reviewed briefly, introducing the fundamental mechanisms by which current and emerging B cell depletion therapies work. The dynamics of the B cell response, central to the pathogenesis of cutaneous autoimmune disease such as immunobullous disease, vasculitis and systemic lupus erythematous, was broadly outlined. The final subsection was devoted to a discussion of B cell memory, laying a foundation for understanding the mechanisms by which vaccination, plasmapheresis and intravenous immunoglobulin therapy function.

Questions

1. Which of the following is true of class-switch recombination?
   A. It affects the rearranged V(D)J
   B. It uses the RAG enzymes
   C. It is an irreversible process
   D. A single variable region cannot elicit a number of different effector functions

2. Which is the only secreted immunoglobulin isotype that can pentamerize?
   A. IgA
   B. IgD
   C. IgE
   D. IgG
   E. IgM

3. Which immunoglobulin isotype has the longest half life?
   A. IgA
   B. IgD
   C. IgE
   D. IgG
   E. IgM

4. All three complement pathways converge on which common intermediate protease?
   A. C3 convertase
   B. alpha/beta hydrolase
   C. alkaline phosphatase
   D. serine protease
   E. GTPase

5. Which of the following is not a characteristic of regulatory T cells (Tregs)?
   A. expression of Foxp3
   B. expression of CD25
   C. production of IL10
   D. expression of the IL-2 receptor
   E. expression of CD80

T Cell Immune Responses in Skin

8

Sherrie J. Divito and Thomas S. Kupper

Abstract

The adaptive immune system is historically divided into cell-mediated immunity and humoral immunity, which were considered to provide defense against intracellular and extracellular pathogens, respectively. As the complexity of each element of the adaptive immune system is revealed, it is now clear that extracellular pathogens can also be targeted by cell-mediated immunity, and intracellular viruses by humoral immunity. The two main effector cell types mediating adaptive immunity are T and B lymphocytes (more commonly called T and B cells). Both cell types are characterized by a nearly infinite variety of unique antigen receptors, so that at the genomic level no two naive T cells or naive B cells are alike. There are two hallmarks of the adaptive immune system, specificity and memory, and lymphocytes are the only immune cells capable of both. Naïve lymphocytes are antigen inexperienced, meaning they have not previously recognized and responded to antigen. Their response upon first exposure is termed the primary response. The primary response is characterized by rapid but transient clonal expansion, and this ultimately generates a limited number of long-lived antigen specific lymphocytes, termed memory cells, which upon re-exposure to their cognate antigen produce a more rapid and effective immune response, termed the secondary response. Engineered generation of memory T and B cells to specific pathogens is the basis for vaccination. Specificity to structurally distinct antigen is produced by a combination of genetic events and selection process that allows lymphocytes to recognize and react predominantly to foreign, and much less frequently to self, antigen. The loss of inhibition of recognition of self results in autoimmune disease, and there are a number of mechanisms in place to prevent this from occurring.

This chapter will review development and selection, antigen recognition, effector and regulatory functions, and memory responses of T cells, with special focus on recently described skin resident memory T cells, and with clinical correlations to dermatologic disease and therapeutics.

T Cell Development and Thymic Selection

The T cell receptor (TCR) on the surface of all T cells allows for the detection of a diverse array of closely related chemical structures termed antigens (Ag). Peptide antigens are expressed by MHC molecules on the surface of antigen

presenting cells [94]. For an effective immune response, a T cell must be able to recognize a foreign antigen presented by self-MHC [70, 126, 161]. Antigen receptors (TCR and B cell receptors) are clonally distributed, meaning, that each naive lymphocyte has a particular sequence in the antigen recognition part of its receptor known as CDR3 sequence that is unique to that T cell. For memory T cells, a clone consists of a parent cell and all its progeny which express the same TCR. The vast majority of T cells express a TCR made up of one alpha chain and one beta chain. A smaller number of T cells express a TCR made up of one gamma chain and one delta chain [38]. All four chains contain a variable region (V) which recognizes the antigen, and a constant region (C) which is conserved amongst all chains. Within the V region, there are three hypervariable regions (also called complementarity determining regions, CDR) which is the actual part of the TCR that binds the MHC:Ag complex [37, 48]. Associated with the TCR are intracytoplasmic signaling proteins that together make up the TCR complex. When two or more adjacent TCRs bind antigen, the complexes cross-link which allows downstream signaling proteins to come into close proximity and initiate an enzyme cascade that ultimately results in T cell activation [15, 37]. The lymphocyte repertoire refers to the total collection of lymphocyte TCR specificities. The number of potential viable TCR recombinations is estimated to be over 10^{20} [157]. Estimates of the size of the actual T cell repertoire pool are much lower, for example Artsila et al estimated that there are approximately 2.5×10^7 diverse T cell clones in human blood (with 10^6 unique TCRβ chains paired with 25 different α chains) [1], and Robins et al calculated there to be $3–4 \times 10^6$ unique TCRβ CDR3 sequences in peripheral blood [116].

CD4 and CD8 are coreceptor molecules that enhance the binding of the TCR to MHC molecules and resultant signaling [156]. A mature T cell expresses either CD4 or CD8. The TCR on the surface of CD8 T cells recognizes Ag presented in the context of MHC class I, and the TCR on the surface of CD4 T cells recognizes Ag presented in the context of MHC class II. The genes that code for each chain of the TCR (i.e., α, β, γ, δ) undergo gene rearrangement which generates tremendous diversity of the T cell repertoire.

T cells are so-called because they develop in the thymus (reviewed in [74, 124, 153]). Pre-thymocytes are T cell precursors that develop in the fetal liver and bone marrow where they undergo initial TCR rearrangement. They express neither CD4 nor CD8 on their cell surface. The pre-thymocytes migrate to the thymus where they undergo a series of further TCR gene rearrangements and maturation. Within the thymus, as T cells develop, they express neither CD4 nor CD8 (double negative), and rearrange and express the TCR β or γ chain. They then express both CD4 and CD8 (double positive) and rearrange and express the TCR α or δ chain. These double positive T cells expressing complete TCRs on their surface then undergo thymic selection. Even in αβ TCR T cells, the TCR γ gene locus undergoes rearrangement [125] although the γ chain protein is not expressed.

While in the thymus, immature T cells contact thymic epithelial cells that express self MHC: self Ag complex. If the immature T cells recognize the self MHC they are selected to continue on with maturation, termed 'positive selection'. If the TCR does not recognize the MHC, the T cells fail to receive a life-saving signal and undergo apoptosis, a process termed 'death by neglect' [74], (a T cell that cannot recognize self-MHC is of no use to the immune system). If the bond between TCR and MHC is too strong though, this could result in autoimmunity, so the immature T cell is destroyed, termed 'negative selection'. Medullary thymic epithelial cells express the Autoimmune Regulator (*AIRE*) gene (reviewed in [79]). Aire protein acts as a master regulator controlling expression of tissue-specific self-Ags by thymic epithelial cells and leading to negative selection of self-reactive thymocytes (reviewed in [79]). Deficiency of Aire results in APECED – Autoimmune-Polyendrocrinopathy-Candidiasis-Ectodermal Dystrophy syndrome [105]. APECED is characterized by hypoparathyroidism, adrenal insufficiency and mucocutaneous candidiasis. In addition to mucocutaneous candidiasis, dermatologic manifestations include alopecia, vitiligo, keratoconjunctivitis, dental enamel hypoplasia and nail pits [73].

As T cells proceed through thymic selection, they lose expression of either CD4 or CD8. Only ~5 % of immature T cells will survive thymic selection to be released as mature T cells into the peripheral circulation [153]. Of these mature single positive T cells, ~95 % express TCR αβ, the remaining ~5 % express TCR γδ [38]. There are more CD4 T cells in the periphery than CD8 T cells at roughly a 2:1 ratio. Thymic selection is imperfect, and there are T cells in the periphery capable of responding to self antigen in the context of MHC. T regulatory cells (discussed below) are important for the control of these potentially autoreactive T cells.

Activation of Naïve T Cells

Mature T cells released into the periphery are antigen inexperienced, or naïve T cells. Naïve T cells express CD45RA on their cell surface, a useful marker in determining naïve vs memory T cells in humans (human memory T cells express CD45RO) [41]. Naïve T cells circulate between blood and lymph nodes, entering through specialized high endothelial venules and exiting through efferent lymphatics. As they migrate to the T cell rich areas of lymph nodes, they constantly sample MHC:Ag complexes on the surface of antigen presenting cells (APC), looking for their cognate MHC:Ag [98]. These APC are typically dendritic cells (DC) that have processed and are presenting peptides from proteins found in the tissue drained by the lymph node.

Initiation of a skin adaptive immune response occurs when skin DC capture antigen introduced into the skin, and travel to draining lymph nodes. As DC migrate to draining LN, they mature and up-regulate surface expression of MHC:Ag complex, co-stimulatory molecules CD80, CD86 and CD40, and adhesion molecules that facilitate binding to T cells [7]. Antigen can also be captured by DC resident in LN. Within draining lymph nodes, the mature (or activated) DC interact with naïve T cells searching for cognate MHC:Ag complex. Activation and clonal proliferation, termed priming, of a naïve T cell requires sufficient signaling via TCR bound to MHC:Ag complex, termed signal 1, and signaling via CD28 on the surface of the T cell via binding to CD80 or CD86 on the surface of the APC, termed signal 2 (Fig. 8.1). The combination of robust signal 1 and signal 2 results in an enzymatic cascade that induces production of Interleukin (IL) – 2 and IL-2 receptor by the T cell [27, 66]. IL-2 functions in an autocrine and paracrine manner to promote T cell proliferation (Fig. 8.1). Further, DC secrete cytokines (signal 3) that influence T cell differentiation. The interaction between DC and T cell is not unilateral however. CD4 T cells express on their cell surface CD40L which induces signaling via CD40 on the DC surface that in turn promotes upregulation of CD80 and CD86 and secretion of cytokines by the DC (Fig. 8.1) [7, 50], further amplifying T cell stimulation and proliferation. The robust proliferation of clonal T cells is termed expansion. An activated T cell divides 20 times to expand 10,000 fold in 1 week in response to antigen (reviewed in [35]). Of clinical note, the calcineurin inhibitors cyclosporine, tacrolimus, and pimecrolimus inhibit IL-2 production [66] and therefore T cell proliferation, and are used to quell inflammation in dermatologic conditions [52, 90].

As T cells proliferate, they decrease surface expression of CD28 and up-regulate expression of CTLA-4, an inhibitory molecule, that also binds CD80 and CD86 on the surface of antigen presenting cells [149]. CTLA-4 binds CD80/86 more avidly than CD28 [82]. This serves to limit the T cell proliferative response, and prevent immune-mediated tissue

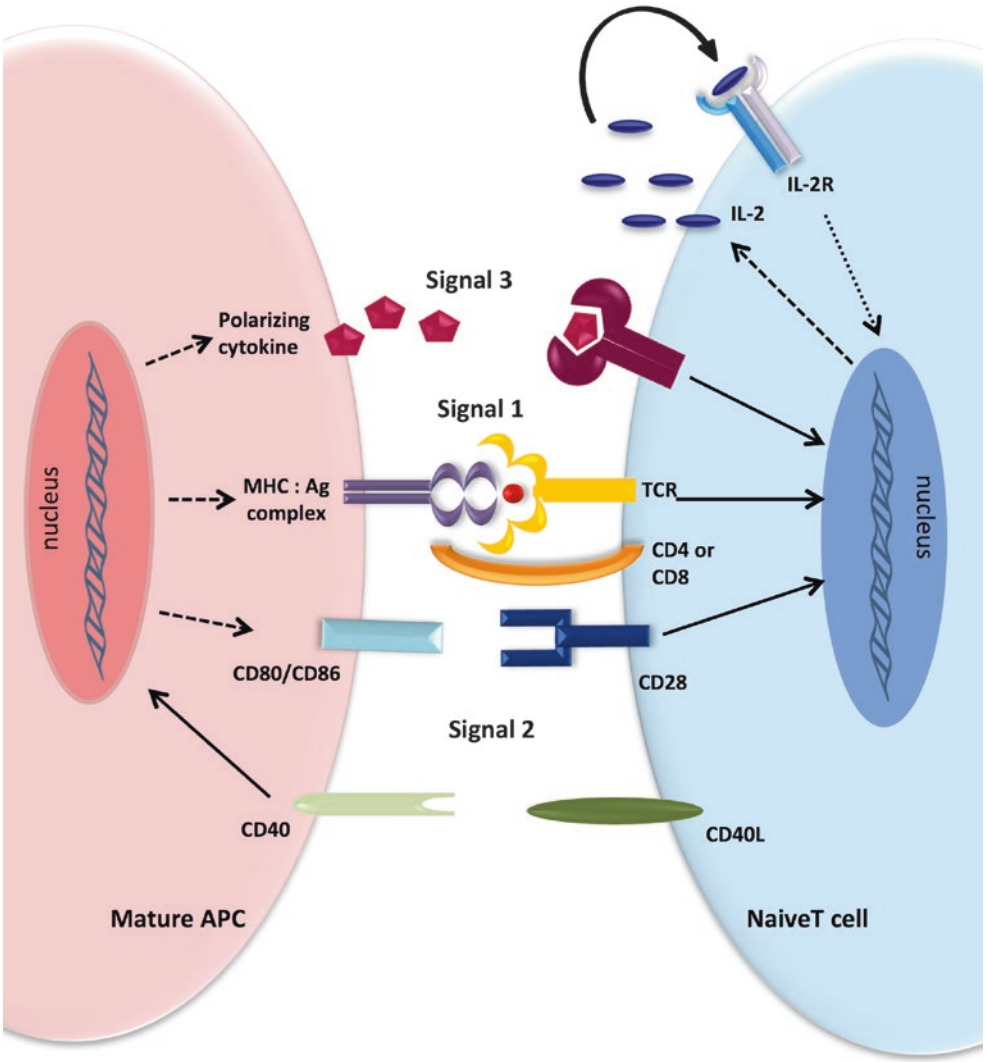

Fig. 8.1 T cell priming by APC. TCR binds cognate Ag presented in the context of MHC on the surface of mature APC to trigger TCR signaling (signal 1). Mature APC also express high levels of the co-stimulatory molecules CD80 and CD86 which bind CD28 on the T cell surface (signal 2). Signaling via TCR and CD28 results in production of IL-2 which acts both in a paracrine and autocrine fashion to stimulate T cell proliferation. Mature APC also express CD40 on their surface that binds CD40L on the T cell surface. CD40 binding of CD40L results in further APC activation. Finally, APC release polarizing cytokines (signal 3) which guide differentiation of T cells

Table 8.1 Notable co-stimulatory and co-inhibitory receptor/ligand pairs on T cells and APC

	T cell	APC
Co-stimulatory	CD28	CD80, CD86
	CD40L	CD40
	ICOS	ICOSL
	OX40	OX40L
	4-1BB	4-1BBL
	CD137	CD137L
Co-inhibitory	CTLA-4	CD80, CD86
	PD1	PDL1, PDL2
	TIM-3	Galectin 9

damage. In metastatic melanoma, the CTLA-4, blocking antibody ipilimumab is employed to block CTLA-4 induced T cell inhibition and therefore promote T cell responses against the tumor [59].

There are several additional co-stimulatory and co-inhibitory molecules expressed on the surface of T cells to promote or inhibit, respectively, T cell stimulation (Table 8.1). Similar to the use of ipilimumab in metastatic melanoma, antibody blockade of the inhibitory molecules PD-1 or its ligands are currently used in melanoma and other solid tumors [39, 55, 89], and one therapeutic antibody targeting PD-1, pembrolizumab, is approved by the FDA for advanced melanoma. Likewise, adhesion molecules expressed on T cells, APC, and endothelium enhance T cell binding and are also potential clinical targets to alter immune responses [13, 62].

If a T cell receives insufficient signal 1 and/or signal 2, the T cell can become 'tolerized' to that antigen, meaning it either undergoes deletion (apoptosis), becomes anergic (refractory to activation), or becomes a regulatory T cell [122, 131]. The result of this T cell inactivation is known as 'peripheral tolerance' [131]. In steady state conditions, APC are constantly sampling self Ag in the human body and presenting this self Ag to cognate naïve T cells in lymph nodes [131]. Since these APC are not activated, i.e. they are immature (express low levels of MHC:Ag complex and low levels of CD80/CD86) [131], T cells that are specific for self Ag undergo this 'tolerization' process rather than becoming activated to self.

T Cell Differentiation and Function

CD4 T Cells

Upon antigen stimulation, T cells not only proliferate, but also differentiate into effector T cells with specialized functions. CD4 effector T cells are termed 'helper' T cells because they function to (i) promote phagocytosis of microbes by macrophages, (ii) promote antibody production by B cells, and (iii) enhance CD8 T cell cytotoxicity (reviewed in [160]). This is achieved via two mechanisms. First, as introduced above, CD4 T cells express on their cell surface CD40L which binds to and stimulates CD40 on the surface of APC [50] (Fig. 8.1). This signaling enhances APC activation and function. Second, CD4 helper T cells produce various cytokines and chemokines that further influence the immune response. The specific cytokines produced depend on their differentiation, or polarization. T helper cell differentiation is guided by the strength of TCR signaling, co-stimulatory molecules and cytokines provided by APC, and inflammatory signals in the surrounding microenvironment, including autocrine signals produced by the CD4 T cells themselves (reviewed in [160]). Teleologically, CD4 helper T cell differentiation evolved to provide ideal effector function to clear the provoking infection.

Historically, CD4 T cells were thought to polarize toward one of two phenotypes, T helper type 1, Th1, cells, and T helper type 2, Th2, cells [103]. However, the past decade has witnessed discoveries of additional phenotypes and functions suggesting additional T cell subsets, identified as Th9, Th17, Th22 and follicular helper T cells, Tfh, on the effector side, and nTregs, iTregs and Tr1 cells on the regulatory side. Each subset will be described below, however it is important for the reader to know that many of these cell types appear to be quite plastic, and may be capable of converting to another phenotype/function given the appropriate stimulation. Figure 8.2 reviews T helper cell differentiation.

Th1

Th1 cells promote macrophage and DC maturation that in turn increases stimulation of CD8 cytotoxic T cells and induces macrophages to destroy phagocytosed microbes. These two responses enhance clearance of intracellular pathogens. Th1 cells produce the pro-inflammatory cytokines IL-2, IFN-γ, and TNF (reviewed in [160]), which further bolster macrophage activation and CD8 cytotoxic T cell responses. Th1 cells also produce chemokines that attract macrophages to sites of infection (reviewed in [65]). The mechanism of Th1 polarization is well-elucidated (reviewed

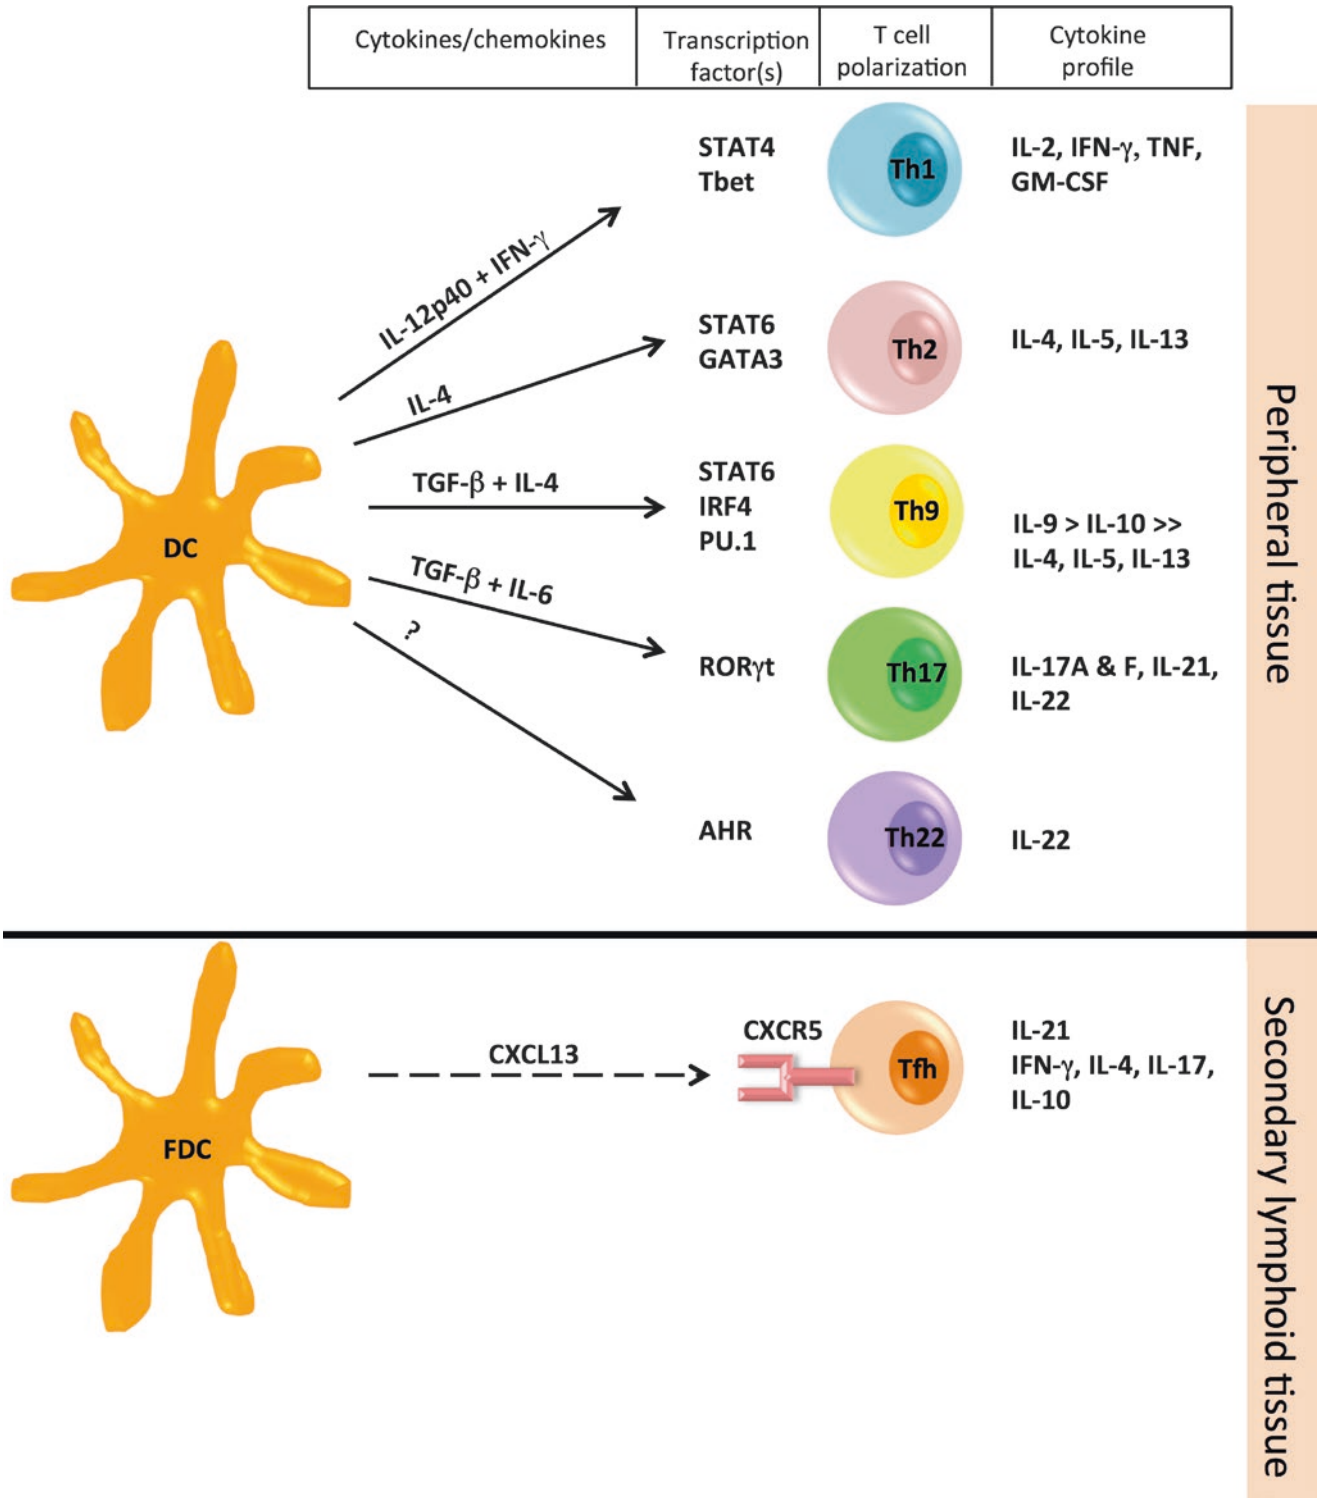

Fig. 8.2 T helper (Th) cell polarization. DC in peripheral tissues produce various cytokines that guide T helper cell polarization via specific transcription factor activation. Polarized T cells in turn release cytokines specific to their differentiation. Follicular (F)DC produce the chemokine CXCL13 which attracts T follicular helper (Tfh) T cells. TFh can produce various cytokines in a similar fashion to polarized Th cells. *AHR* aryl hydrocarbon receptor, *FDC* follicular DC

in [65]). IFN-γ binds to its receptor on the surface of activated T cells and induces the transcription factor T-bet via STAT 1 signaling. Tbet in turn transactivates IFN-γ and IL-12Rβ2. The cytokine IL-12p70 is then capable of binding

to the IL-12 Receptor (a heterodimer consisting of IL-12Rβ1 and IL-12Rβ2) on the T cell surface and induces signaling via STAT4 which further promotes Th1 activity. IFN-γ is the hallmark cytokine for Th1 cells.

Th2

Th2 cells activate naïve Ag-specific B cells to produce antibody which targets extracellular pathogens, particularly parasites and helminths, and they also stimulate eosinophil and IgE responses (reviewed in [65]). Th2 cells secrete the pro-inflammatory cytokines IL-4, IL-5, and IL-13 (reviewed in [160]). Th2 polarization (reviewed in [65]) is induced via TCR and IL-4 receptor signaling, which induces STAT6. Phosphorylated STAT6 in turn induces the transcription factor GATA-3 which transactivates IL-4, IL-5 and IL-13, while down-regulating STAT4 and IL-12Rβ2.

Polarization of T helper cell responses toward Th1 or Th2 is important for skin disease. For example, the bacterium *Mycobacterium leprae* grows inside macrophages, so Th1 responses that trigger macrophages to kill intracellular pathogens limits extent of clinical disease to tuberculid leprosy [102]. Comparatively, Th2 differentiation is largely ineffective against intracellular pathogens and so there is a higher burden of *M. leprae* in patients with a Th2 response resulting clinically in lepromatous leprosy [102]. This is likewise true for the intracellular pathogen Leishmania; Th1 responses are more effective at controlling infection than Th2 responses [151]. The dichotomy of Th1 versus Th2 extends beyond pathogen control to autoimmune disease. Polarization toward Th1 is observed in psoriasis (although Th17 cells appeared to be more pathogenic) [88], while polarization toward Th2 is seen in acute atopic dermatitis [56]. This helps explain why the anti-TNF agents etanercept, adalimumab and infliximab are effective in psoriasis and psoriatic arthritis [14], while anti-IL-5 antibody, mepolizumab, and anti-IL-4Receptor antibody, dupilumab, are therapeutic agents for atopic dermatitis [56].

Th17

Th17 cells secrete the pro-inflammatory cytokines IL-17A and IL-17F, which belong to the same cytokine family and have overlapping functions. Receptors for IL-17A and F are expressed on both hematopoietic and non-hematopoietic cells and receptor binding induces production of IL-6, IL-1, TNF, and IL-22, as well as chemokines that promote inflammation and neutrophil recruitment [11]. Th17 cells function in host defense to help clear bacterial and fungal infections when Th1 and Th2 responses are insufficient [11]. Th17 cells are generated by TGF-β and IL-6, which together induce the transcription factor RORγt, which drives production of IL-17, IL-21 and IL-23Receptor (R) [10, 64, 96, 143]. IL-21 functions in an autocrine manner to amplify differentiation [77, 108] and IL-23 produced by APC and non-hematopoietic cells such as skin keratinocytes binds the IL-23R on the surface of Th17 cells, and signals via STAT3, to further promote expansion and survival [2, 80, 100].

Notably, IL-23 receptor is a heterodimer consisting of IL-23R bound to IL-12Rβ1 [111]. Increasing IL-23R surface expression effectively impairs Th1 differentiation by limiting the ability of IL-12Rβ1 to bind to IL-12Rβ2. Further, both IL-12 and IL-23 share a common p40 subunit. IL-12 (officially called IL-12p70) is a heterodimer consisting of IL-12p40 and IL-12p35, while IL-23 heterodimer consists of IL-12p40 and IL-23p19 [110]. Ustekinumab is a monoclonal antibody developed to block the p40 subunit of IL-12 and is effective clinically in psoriasis patients [54, 83]. Although initially thought to function by decreasing Th1 responses via blocking IL-12, the reality that IL-23 is also blocked by an anti-IL-12p40 antibody implicates Th17 cells in psoriasis pathogenesis. Indeed, IL-23 induces Th17 cells to produce the cytokine IL-22 [84, 159] which has been demonstrated to induce human keratinocyte proliferation and acanthosis, consistent with psoriasis pathogenesis [117]. IL-22 also helps elicit innate immune responses via β-defensins [84] which are upregulated in psoriasis [19]. There are now several antibodies specifically against IL-23 and IL-17 and its receptor for psoriasis [47], and this appears to be the central cytokine pathway for this disease.

Th22

There are CD4 helper T cells that produce IL-22, but not IL-17, IL-4 or IFN-γ. These CD4 helper T cells have been termed Th22 cells, but it is unclear whether they are a distinct helper T cell subset. The master transcription factor for Th22 cells has been identified as aryl hydrocarbon receptor which has been shown to inhibit IL-17 production [115, 142]. Th22 cells reside in normal skin but are increased in lesional skin in psoriasis and atopic dermatitis, and these cells express skin homing markers such as CCR4 and CCR10 [40]. The IL-22 receptor, consisting of IL-22R1 and IL-10R2, is only expressed on non-hematopoietic cells, including epithelial cells such as keratinocytes [46]. In addition to increasing keratinocyte proliferation and epidermal hyperplasia as seen in psoriasis [16, 107], IL-22 has been shown in vitro to decrease filaggrin, loricrin and involucrin [16, 53, 107], suggesting that it contributes to impaired epidermal barrier function as is seen in atopic dermatitis. IL-22 is reduced in psoriasis after treatment [46], and patients with chronic atopic dermatitis treated with narrow-band UVB have reduced IL-22 in their skin [139]. A role for Th22 has also been suggested in allergic contact dermatitis, scleroderma and CTCL [46].

Th9

Th9 cells are a recently described CD4 helper T cell representing a unique T cell subset. Th9 cells are generated via the combination of TGF-β and IL-4 [36, 144]. IL-4 induces

STAT6 and the transcription factor IRF4 and TGF-β activates the transcription factor PU.1 while suppressing the transcription factors Tbet and GATA-3, ultimately inducing production of the pro-inflammatory cytokine IL-9 [158]. Th9 cells also secrete to a lesser extent the anti-inflammatory cytokine IL-10, and only a small amount of IL-4, IL-5 and IL-13 [65]. These latter cytokines parallel those seen in Th2 cells. Th9 cells are pleiotropic, i.e. depending on the environmental milieu, they are also capable of producing Th1 and Th17 cytokines. In fact, in human T cells stimulated via CD3/CD2/CD28, blocking IL-9 limits production of IFN-γ, IL-13 and IL-17 [121]. The IL-9 receptor is expressed on the surface of many immune cell types including T and B cells, mast cells, macrophages and DC, and also on non-hematopoietic cells [44, 65, 87]. Th9 cells seem to play a role in helminth infections [42], asthma and allergy [130].

In regards to skin, Th9 cells were shown to be skin-tropic in humans, with a high frequency of specificity for *Candida albicans*, suggesting a role in protection against extracellular pathogens [121]. Interestingly though, Th9 cells were also increased in number in lesional skin in psoriatic patients suggesting a contribution to inflammatory skin disease [121]. In keeping with this, Th9 T cells were demonstrated in skin biopsies of allergic contact dermatitis [85] and the percentage of Th9 cells in peripheral circulation was increased in patients with atopic dermatitis [91]. Our lab has shown that the pro-inflammatory functions of Th9 cells can be harnessed in tumor immunity, via adoptive transfer of Th9 cells into B16F10 melanoma tumor bearing mice, in which Th9 cells impaired tumor growth [114].

Tfh

Th1, Th2, Th9, Th17 and Th22 cells all function in the periphery to guide and promote immune responses. Conversely, there is a CD4 helper T cell subset that remains in the lymph node follicle, appropriately termed follicular helper T cells, or Tfh. Tfh cells are recognized by their location in germinal centers and by surface expression of CXCR5, ICOS and PD-1 (reviewed in [134, 136]). CXCR5 is a surface receptor that binds CXCL13, a chemokine produced by follicular dendritic cells in the germinal center, thereby attracting $CXCR5^+$ Tfh to that locale (reviewed in [136]). Tfh cells are required for the germinal center reaction in lymph nodes to occur, by which B cells are activated to undergo class switching and produce abundant antibody (reviewed in [134]). They generate the cytokine IL-21, which is a potent growth and differentiation factor for B cells, but also IFN-γ, IL-4, IL-17 and IL-10, suggesting that their cytokine production helps guide antibody class switching (reviewed in [134, 136]). The role of Tfh in skin disease has not been directly studied, however Tfh have been implicated in autoimmune diseases where antibody production is pathogenic. For example, there are increased numbers of $CD4^+CXCR5^+ICOS^{hi}PD1^{hi}$ T cells in circulation of some patients with SLE and Sjogren's syndrome, and this increased number correlates with disease severity [43, 127, 138]. Further, the frequency of $CD4^+CXCR5^+$ T cells was reduced in SLE patients following treatment with steroids [43]. The study of Tfh in human disease is in its infancy, and it is likely that further involvement in cutaneous disease will be unearthed going forward.

CD4 Regulatory T Cells

Immunologic tolerance refers to a state of unresponsiveness to substances or tissues that would otherwise have the ability to stimulate an immune response. We have already seen above one mechanism by which tolerance is induced centrally, by thymic selection, and one by which peripheral tolerance is maintained, by sub-threshold stimulation of naïve T cells. The immune system is more complex still, producing multiple cell types with regulatory function. Here we will review regulatory CD4 T cells, or Tregs.

Like other CD4 T cells, Tregs have been divided into different classifications. Tregs produced in the thymus are referred to as naturally occurring Tregs, nTregs, while Tregs induced in the periphery are termed inducible Tregs, iTregs [112]. iTregs are further divided into two populations, Tr1 cells which are induced by IL-10, and Th3 Treg, which are induced by TGF-β [112], (recall from above that effector Th17 cells are generated by the combination of TGF-β and IL-6, while Th9 cells are generated by the combination of TGF-β and IL-4). Both nTregs and Th3 cells express the transcription factor Forkhead box P3, Foxp3, and are largely phenotypically indistinguishable, while Tr1 Treg do not express Foxp3 [112]. The importance of Foxp3 function is demonstrated by the X-linked genetic disorder IPEX, in which a mutation in the *Foxp3* gene results in multi-organ inflammatory disease, including type 1 diabetes, psoriasis-like dermatitis and enlarged secondary lymphoid organs [8]. The thymic transcription factor, Aire, discussed above, also plays a role in nTreg development (reviewed in [79]), (recall that a mutation in its gene, *AIRE*, results in the APECED).

Tregs maintain tolerance to self-antigens (the body's own tissue) and to harmless or commensal organisms. They function by releasing regulatory cytokines, most notably IL-10 and/or TGF-β, by expressing on their cell surface co-inhibitory molecules such as PD-1, and by cytotoxicity [112]. They also consume IL-2, thereby limiting its availability to effector T cells [112]. They suppress T effector cells that have received low to medium strength TCR signaling, but not high avidity TCR signaling [6] and the ratio of Tregs to Teffector cells seems to be important for suppression of T effector cell responses [20].

Tregs have been heralded as a potential cellular therapeutic against a number of autoimmune diseases and transplant

rejection. Significant time and effort have been spent researching *in vitro* and *ex vivo* expansion, generation and manipulation of Tregs for this purpose. However, Tregs have been shown repeatedly to be particularly plastic, meaning that under different environmental conditions, Tregs gain pro-inflammatory functions, raising concerns about their clinical safety. With that said, clinical studies treating chronic Graft versus Host Disease with low dose IL-2, which promotes Treg responses *in vivo*, has shown initial promising results [76].

CD8 T Cells

Cytotoxicity

CD8 effector T cells recognize intracellular pathogen-derived Ag presented in the context of MHC class I on the surface of an infected cell. In some cases, CD8 T cells may require CD4 effector T cell help to become activated [26]. The main effector function of CD8 T cells is direct target cell killing, or cytotoxicity. They are thus referred to as cytotoxic T lymphocytes (CTLs). When CTLs recognize their cognate Ag presented by MHC on a target cell, the CD8 T cell can employ one of two main mechanisms to induce target cell killing (reviewed in [57]). Firstly, CD8 T cells release granules containing perforins and granzymes. Perforins bind the target cell surface, integrate into the cell membrane, and as the name suggests, induce tiny pores in the surface through which granzymes can enter the target cell cytoplasm. Granzymes are proteases that induce both caspase-dependent and –independent target cell apoptosis. Secondly, CTLs also express on the cell surface Fas ligand (FasL), which binds to Fas on target cells. Binding of Fas on target cells also induces target cell apoptosis.

In regards to skin disease, CTLs have long been suspected in the pathogenesis of toxic epidermal necrolysis (TEN), although their role is controversial [140]. CD8 T cells have been observed infiltrating lesional TEN skin and in TEN blister fluid [34, 81, 106], and granulysin, a cytotoxic mediator of CD8 T cells has been demonstrated in TEN blister fluid [28]. The ability of CD8 T cells to express FasL and keratinocyte Fas, has long been one basis for the [controversial] use of IVIg in TEN, as it is hypothesized that IVIg blocks Fas:FasL binding and downstream keratinocyte apoptosis [145]. Also of interest, is the role of CD8 T cells in alopecia areata (AA), an autoimmune mediated non-scarring form of alopecia. A well-conceived study by Xing et al. demonstrated in both human samples and a mouse model the mechanism by which pathogenic CD8 T cells mediate AA [152]. Defective cytotoxic killing activity is observed in Griscelli syndrome, a rare autosomal recessive genodermatosis with pigmentary defect and immunodeficiency [51].

Cytokine Production

In addition to direct cytotoxicity, CD8 effector T cells directed against intracellular pathogens secrete the pro-inflammatory cytokines IFN-γ and TNF-α, consistent with Th1 cell cytokine pattern, and are therefore referred to as Tc1 (reviewed in [101]). More recently, alternative CD8 T cell subsets have been identified, similar to CD4 T cells. Tc2 cells produce IL-5 and IL-13, Tc9 cells produce IL9, IL-10 and low levels of granzyme B, and Tc17 cells produce IL-17 and IL-21 [101]. Further, suppressor CD8 T cells exist and have been termed CD8 Tregs [101]. The study of these CD8 T cell subsets in skin disease is a burgeoning field.

γδ T Cells

In addition to conventional CD8αβ T cells, as described above there is a second type of CD8 T cell, consisting of one γ and one δ TCR chain, or γδ CD8 T cells. Complicating matters, there are γδ T cells that do not express the CD8 coreceptor (reviewed in [69]). Unlike conventional CD8αβ T cells, γδ T cells do not bind MHC I, but rather recognize and respond to a number of stress-inducible proteins expressed on malignant or stressed cells via activating receptors on the γδ T cell surface (reviewed in [69]). As such, they are classically considered a component of the innate immune system.

γδ T cells exist at low levels in the peripheral blood but are enriched at mucosal interfaces, and in mice, constitute a significant fraction of T cells in the epidermis (where they are called dendritic epidermal T cells-DETCs). DETCs depend on IL-15 for survival. A separate γδ T cell population exists in the mouse dermis [133]. While DETCs express mostly Vγ5 TCR, the dermal γδ T cells are largely Vγ5 negative [133] all activated by IL-23 and produced IL-17. γδ T cells also produce cytokines such as IFN-γ, IL-2 and IL-13 and chemokines such as CCL3, CCL4, CCL5 and XCL1 (reviewed in [58]) and appear in mice to play a role in homeostasis, infection, tumor surveillance, and wound healing (reviewed in [75]). Comparatively, γδ T cells compose only a small fraction of T cells in human epidermis [141], but do appear to play a role in wound healing [141].

T Cell Migration to Skin

Migration of differentiating effector T cells to sites of inflammation is determined by derivation of cognate antigen. T cells express CLA and CCR4 if they encountered antigen first in skin draining LN [21, 23]. CLA binds to E-selectin which is expressed on the surface of post-capillary venules in skin, and up-regulated during inflammation [9, 45, 78, 113]. Skin migrating T cells also express CD44 and CD43 which help facilitate binding to E-selectin [3, 99]. CCR4 binds to two chemokines, CCL17 and 22 [155], which are produced at the site of infection and help attract T cells

[25]. In addition to CCR4, the chemokine receptors CCR6, CCR8 and CCR10 have also been implicated in T cell homing to skin [61, 63, 92]. Modification of selectin ligands on T cells requires α(1,3)fucosyltransferses IV and VII [60, 95, 129] and mice lacking these enzymes are used to study the role of T cells in skin disease [71, 95, 101]. Preferential differentiation toward skin-homing T cells is further promoted by skin itself; skin fibroblasts produce prostaglandin E2 which inhibits DC production of retinal dehydrogenase, thereby impairing gut-homing differentiation [132].

Memory T Cells

Development of a memory response that is capable of more rapid Ag specific immunity upon Ag re-exposure is a major hallmark of the adaptive immune response. How memory T cells are generated in vivo is an avid area of investigation in immunology. It is known that upon primary antigen exposure, naïve T cells expand into an effector cell population that functions to clear an infection. As the infection wanes, the majority of effector cells (90–95 %) die off in a process termed contraction, leaving behind a small population of memory T cells [104] (Fig. 8.3). It is suggested that memory cell generation may be related to the strength of TCR stimulation [128, 135], with higher levels of inflammation and antigen favoring generation of effector cells rather than memory cells [5, 68, 109]. Development of memory cells may also be linked to naïve T cell precursor frequency [4, 97]. Regardless, it is known that distinct subsets of memory T cells exist. Memory T cells are traditionally divided into two categories based on effector function, proliferative capacity and migration potential [119], and are termed central memory T cells, Tcm, and effector memory T cells, Tem. Tcm express the lymphoid organ homing receptors L-selectin (CD62L) and CCR7, but not peripheral tissue homing molecules, and so are confined to secondary lymphoid organs [104, 118]. At baseline, these cells exist in low numbers and can produce IL-2 but not IFN-γ, but upon re-exposure to Ag, vigorously proliferate, migrate to sites of infection, and develop effector functions [104, 118]. Comparatively, Tem express tissue homing molecules but not lymphoid homing molecules, and so remain migrating between peripheral tissues and blood. They produce IFN-γ but have less proliferative capacity. Upon Ag re-exposure, these cells rapidly migrate to peripheral tissue where they provide an early Ag-specific defense against a pathogen [93, 150], while Tcm cells in secondary lymphoid organs are mobilized. A useful marker for memory cells is CD45RO [41]. Therefore CD45RO$^+$ L-selectin$^+$ CCR7$^+$ denotes Tcm while CD45RO L$^-$selectin$^-$ CCR7$^-$ denotes Tem.

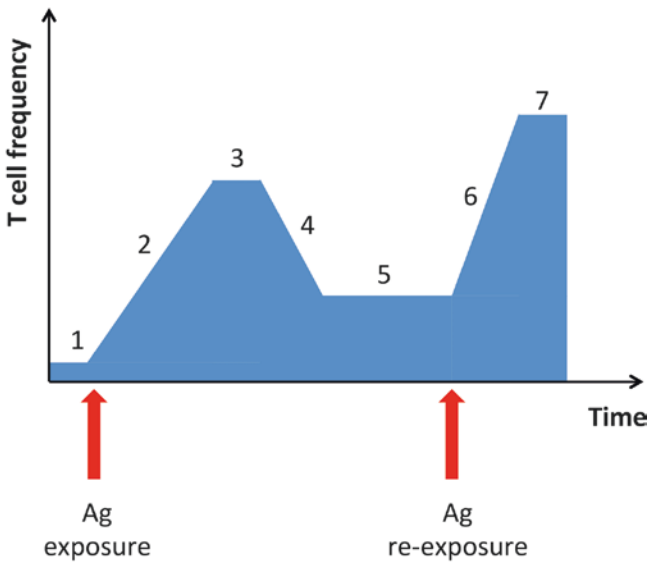

Fig. 8.3 T cell frequency as a function of Ag exposure (infection). (*1*) Naïve precursor T cell pool (*2*) Expansion of Ag-specific T cells (*3*) Ag-specific T effector cells control infection (*4*) Contraction of T effector cell population (*5*) Ag-specific memory T cells remain at a higher frequency than their naïve precursors (*6*) Upon Ag re-exposure, memory T cells require less stimulation, so more rapidly expand and acquire function to control re-infection (*7*) Repeat infection is controlled

Skin-Resident Memory T Cells

In 2006, a method of isolating T cells from human skin via tissue explant cultures allowed for the first time enumeration of T cells in normal human skin [30]. Surprisingly, calculations determined that there are approximately 1 million T cells/cm^2 of skin [29], and based on the average adult total body surface area roughly 20 billion T cells in an adult human's skin [29]. Notably, this is more than is present in an adult's entire blood supply. Further, >95 % of T cells in normal skin are CD45RO memory T cells and the majority express CLA and CCR4, while <5 % are naïve T cells [17, 24, 61, 120]. The majority of these cells also lack expression of the lymphoid homing molecules CCR7 and L-selectin, supporting their categorization as effector memory T cells. The discovery that the vast majority of these CLA$^+$ memory T cells are present in skin under resting conditions (non-inflamed skin), rather than in circulation [29], suggested that this effector memory T cell population is actually resident in skin, and so have been aptly named skin-resident memory T cells. There is also a smaller population of T cells in skin expressing both CLA and CCR4, and CCR7 and L-selectin [29], suggesting an intermediate phenotype population also exists. CD8 resident memory T cells exist primarily in the epidermis, while CD4 resident memory T cells are found primarily in the dermis [93, 154]. A population of T cells that express CLA, CCR4 and CCR7 but not L-selectin

have been recently identified. These migratory memory cells, or Tmm, can recirculate out of skin [162].

The purpose of resident memory T cells is likely to provide a rapid response to antigenic re-challenge (i.e. re-infection). For example, following skin HSV infection in mice, CD8 T cells accumulate in high numbers in skin at the site of infection, are long-lived, and are protective against virus infection [49]. Re-infection of skin with HSV results in a transient population of non-specific T cells recruited from circulation, but also in local proliferation of antigen-specific skin resident CD8 T cells that accumulate in skin [148]. Results were similar in BCG vaccinated humans challenged with the Mantoux skin test, where memory CD4 T cells proliferated locally in skin and were long-lived [147]. Using a vaccinia virus infection model in mice, our lab observed high numbers of protective resident memory T cells at the site of infection, but also noted these cells throughout uninfected skin [67]. Further, skin resident memory T cells were sufficient to clear vaccinia virus in the absence of central memory T cells [67, 86], and utilizing a parabiotic mouse model, Trm were demonstrated to be superior to Tcm in clearing virus [67]. This realization, that a large number of skin resident memory T cells can be generated by skin infection not only at the site of infection, but throughout the skin, and that these cells are poised to act upon re-challenge has heralded great promise in the study of vaccination. Currently, most vaccinations are given intramuscularly or subcutaneously and generate primarily antibody responses which are highly effective against extracellular pathogens and toxins, but less so against viral pathogens. Comparatively, vaccinia vaccination against smallpox, which is performed through skin scarification, prompts a robust and long-lived skin resident memory T cell response [86].

The elucidation of the existence of a skin resident memory T cell population has shed light on the pathophysiology of a number of immune-mediated skin disorders. For example, in psoriasis, the fact that effector memory T cells are present in non-inflamed human skin explains why blockade of T cell entry into skin in a patient with preexisting psoriasis is ineffective at treating disease [12]. This also explains the finding that grafting of 'uninvolved' skin from psoriasis patients to immunocompromised mice results in graft psoriasis despite the absence of human T cells in circulation [18]. In fixed drug eruption (FDE), a skin lesion occurs following ingestion of a causative drug, resolves once the drug is discontinued, then recurs at the same site up to decades later when the same drug is again ingested. FDE is CD8 T cell mediated and following resolution of the FDE, CD8 T cells remain in the epidermis of clinically resolved FDE lesions [137].

Perhaps the best example of the role of skin resident T cells in human skin disease is that of cutaneous T cell lymphoma. In stage IA mycosis fungoides, malignant T cells are confined to stable patches and plaques on the skin [72]. In Sezary syndrome, malignant T cells migrate throughout the entire skin surface, blood and lymph nodes [72]. Interestingly, our group has shown that the malignant T cells in mycosis fungoides are skin resident Trm, while the malignant T cells in Sezary syndrome are consistent with Tcm [22]. Based on the clinical observation that patients with mycosis fungoides treated with alemtuzumab, a monoclonal antibody against CD52, do not have increased susceptibility to cutaneous infections, we have shown that treatment with alemtuzumab is effective in Sezary syndrome, but not mycosis fungoides, as alemtuzumab depletes circulating but not skin resident T cells [33].

Skin Resident Regulatory T Cells (Tcm, Tem)

Approximately 5–10% of skin resident T cells in normal human skin are Foxp3$^+$ Tregs [31] and under inflammatory conditions, these cells can proliferate [32]. Increased numbers of Tregs have been observed in skin injected with PPD and of resolved fixed drug eruptions [137, 146]. Interestingly, it has been shown that Tregs are necessary to control inflammation in non-challenged skin [71, 101] and must actually be present in skin to exert their suppressive effects [71, 101]. Langerhans cells, a type of DC found in epidermis promote skin resident memory Treg proliferation via MHC II:Ag – TCR interaction under both resting and inflammatory conditions [123]. The role of skin resident Treg remains an active area of research and it is likely that these cells will turn out to play a significant role in dermatologic disease and therapeutics.

Conclusions

T cells are clearly a complicated yet essential component not only of the systemic immune system at large but of the skin immune system as well. Their involvement in skin span from protecting against cutaneous pathogens in an otherwise healthy host, to their pathologic targeting of self-Ag leading to cutaneous autoimmune disease, to their own deregulation leading to cutaneous T cell malignancy. As hinted at above, the unique features of these cells are only partially explored. As also suggested in this chapter, understanding of their phenotype and function has led to significant breakthroughs in the treatment of human disease. Taken together, these realizations raise the hope that further investigation of these fascinating cells will continue to impact clinical care of patients with skin disease.

Questions

1. Which of the following binding partners is incorrect?
   A. MHC I : CD8
   B. CD28 : CD80

C. CTLA-4 : CD80
D. MHC I : CD4
E. CLA : E-selectin

2. The genodermatosis APECED results from a defect in which gene:
   A. FoxP3
   B. Calcineurin
   C. CTLA-4
   D. Aire
   E. SPINK5

3. Calcineurin inhibitors (Cyclosporine and Tacrolimus) function by?
   A. Inhibiting production of the effector cytokine IL-17
   B. Promoting IL-2 production thereby decreasing T cell proliferation
   C. Inhibiting IL-2 production thereby decreasing T cell proliferation
   D. Increasing IL-10 production thereby decreasing T cell function
   E. Increasing IL-12 production thereby increasing T cell function

4. Which surface molecules expressed on resident memory T cells allow their migration to the skin?
   A. CD45RO and CCR4
   B. CD4 and CLA
   C. CD28 and CD45RO
   D. CLA and CCR4
   E. Granzyme B and CD8

Answers

Cutaneous Dendritic Cells in Health and Disease

9

Sakeen W. Kashem and Daniel H. Kaplan

Abstract

Dendritic cells (DCs) are a heterogeneous cell type found in lymphatic and peripheral tissues. They function as professional antigen-presenting cells (APCs), specialized to acquire antigen from their environment that they process and present to T cells. In addition, DC participate in the generation of local inflammation and suppression of inappropriate immune responses. Thus, they play a critical role in the initiation, propagation and suppression of immune responses that promote health and autoimmune disease. The skin of humans and mice contain several distinct subsets of DC (epidermal Langerhans cells are the most well-known) that are speculated to have varied and versatile functions. In this chapter, we discuss dendritic cells as important players of the innate and adaptive immune system. We will cover their roles in acquiring antigen, inducing T cell responses, and characterizing the functional differences between distinct skin DC subsets. Finally, we will relate DC in relation to human health including their contribution to diseases such as allergic contact dermatitis and psoriasis and their ability to serve as therapeutic targets in vaccinations.

Keywords

Dendtrict cells • DC • Lymphatic tissue • Peripheral tissue • APC • Antigen-presenting cells • Autoimmune disease • Skin disease • Psoriasis • T cell • Allergic Contact Dermatitis • ACD • Langerhans Cells

Historical Perspectives

In 1868, German physician Paul Langerhans observed a network of cells with a dendritic morphology throughout the epidermis [1]. These eponymously named cells were thought to be part of nervous system in the skin. At roughly the same time, Metchnikoff introduced the concept of phagocytosis by macrophages which was later recognized with a Nobel Prize in 1908 [2]. Although Langerhans cells (LC) are related to macrophages, it took more than 100 years for the function of LC to be understood. In 2011, Ralph Steinman received the Nobel Prize for his recognition in 1973 of a novel cell type in murine spleen with an appearance distinct from macrophages that he termed dendritic cells (DC) [3]. He found that DCs were not as apt at endocytosis as macrophages but expressed high levels of major histocompatibility (MHC) molecules and were potent inducers of the mixed leukocyte reaction in mice [4]. Balfour characterized cells resembling LC in the skin draining afferent lymph that were critical for promoting lymphocyte activation [5]. Katz and Frelinger demonstrated mouse LC to be bone marrow derived and, therefore, part of the hematopoietic system [6, 7]. Finally in 1985, Austrian dermatologist Schuler in the Steinman laboratory defined LC as members of the DC family thereby demonstrating the presence of dendritic cells in the skin [8]. In recent years, there has been an explosion of research examining the phenotype and function of dendritic cells.

Dendritic Cell Paradigm

Dendritic cells that reside in both peripheral and lymphoid tissues (e.g. lymph nodes and spleen) exist in what is termed an immature or unactivated state under normal conditions. They are able to efficiently acquire extracellular material from their environment through a variety of mechanisms. In the case of skin DC, these antigens include self proteins expressed in the skin, products of skin commensal organisms as well as invading skin pathogens. DC in the spleen and lymph node acquire antigens from the circulation or from draining lymphatics, respectively. Immature DC acquire soluble antigens via endocytosis or fluid phase macropinocytosis allowing them to accumulate antigens that are extensively diluted in their environment [9, 10]. DC ingest particulate antigen by phagocytosis. DC also express a variety of antigen-uptake receptors. These include Fc receptors (recognition of Fc domains of immunoglobulin), complement receptors, and many different C-type lectin receptors that recognize microbial carbohydrates [11].

DC activation occurs in response to a large variety of pathogen associated molecular patterns (PAMPs) (e.g. TLR receptors) that are discussed in detail in Chap. 2. Once activated, DC undergo a series of cellular changes that result in mature dendritic cells. As part of the maturation process, DC increase expression of the chemokine receptor CCR7 that is the receptor for the ligands CCL19 and CCL21 [12]. These chemokines are expressed by lymphatic endothelium and direct the migration of antigen-bearing DC from the periphery via afferent lymphatics into the T cell area of regional lymph nodes. Within the lymph node, DC express CCL19 that attracts T cells though the interaction of CCR7 that is also expressed by naïve T cells [13].

Immature DC retain the bulk of the antigen they acquire in an unprocessed form within intracellular endosomes. Activated DC shunt this antigen into intracellular pathways that results in processing and surface presentation of antigen in the context of MHC-II for recognition by CD4+ T cells [14]. Specific DC subsets also have the capacity to present antigen acquired from their environment in the context of MHC-I for recognition by CD8+ T cells, a process termed cross-presentation. In addition, some DC present lipid antigens on nonpolymorphic CD1 molecules to both classic αβ T cells as well as non-classical T cells such as invariant NKT cells [15–17]. Ligation of the T cell receptor (TCR) by antigen-MHC complexes on the surface of DC (or other APC) results in the first signal of T cell activation.

As part of the DC maturation process, activated DC increase surface expression of adhesion molecules that are required for efficient formation of the immunological synapse with the T cell [8, 10, 18, 19]. TCR ligation alone, however, in the absence of co-stimulation results in antigen-specific unresponsiveness, termed anergy, rendering the T cell unable to respond to subsequent antigen encounters (Fig. 9.1a) [20]. DC have a higher capacity to provide co-stimulation compared to other APCs [19]. Surface expression of CD80 (B7.1) or CD86 (B7.2) that bind CD28 on T cells is greatly increased by DC activation. Other co-stimulatory molecules of the B7 family (ICOS ligand, PD-L1, PD-L2, etc.) and TNFR family (CD40L, CD70, OX40L, 4-1BBL, GITRL) are also expressed at high levels by DC and serve significant and diverse roles in inducing and regulating immunity [21, 22].

In addition to TCR ligation and co-stimulation, DC-derived cytokines determine the specific phenotype of T cells that respond (Fig. 9.1b). For instance, DC-derived IL-12 is required for the development of cytotoxic function in CD8+ T cells. In the absence of IL-12, peripheral tolerance is evident in CD8+ T cells and they have reduced ability to kill target cells and to produce IFNγ [23]. Similarly, IL-12 and its homolog IL-27, also have been shown to be important for CD4+ T cell commitment to the Th1 lineage and for the secretion of IFNγ that facilitates immune responses against intracellular pathogens such as viruses, certain bacteria and neoplasia [24–26]. DCs also produce IL-1β, IL-6 and IL-23 that induce Th17 cells. Th17 cells secrete IL-17A that recruits and activates neutrophils as well as IL-22 that signals on keratinocytes to stimulate proliferation and production of antimicrobial peptides [27–32]. Th17 cells are crucial for protection against extracellular skin bacteria and fungi such as *S. aureus* or *C. albicans* (see Chap. 16) [33]. Conversely, over-activity of Th17 is associated with autoimmune conditions such as psoriasis (Chap. 21) [34]. DC are also critical for generation of Th2 responses, which protect against parasites and are also a key cell type involved in atopic dermatitis (Chap. 22) [35–37]. It is important to note that the specific cytokines that DC elaborate and thus the ultimate composition of the T cells response depends both on the specific DC subset and on the nature of the pathogen encountered. The function of individual DC subsets in response to specific pathogens is discussed below.

Steady-State DC Paradigm

The DC paradigm described above was defined based on work with DC that had been activated by inflammatory stimuli. Under steady-state conditions, DC that reside in LN and spleen present self antigens acquired locally as well as filtered from the lymph and blood in the absence of inflammatory stimuli. Antigen that is experimentally targeted to DC in the absence of adjuvant results in transient activation and proliferation of CD4+ and CD8+ T cells, followed by deletion of these cells and the establishment of antigen specific tolerance [38, 39]. Similarly, a genetic approach to limit antigen expression to immature DC resulted in transient activation and proliferation of CD4+ and CD8+ T cells, followed

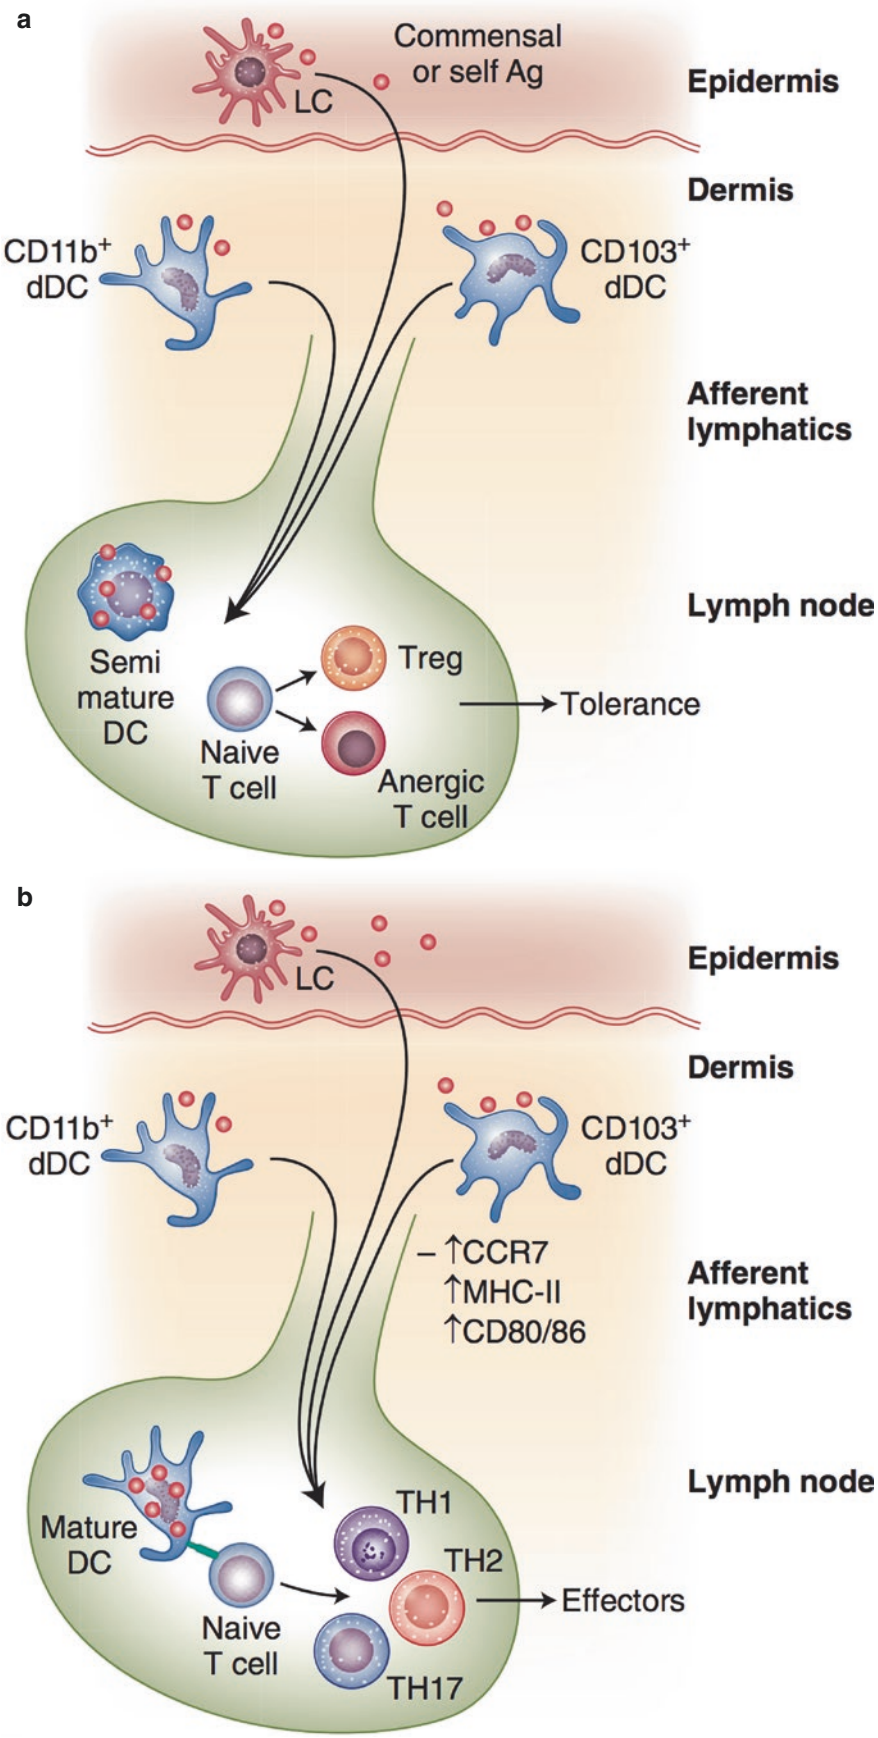

Fig. 9.1 Dendritic cell paradigm during steady state and activation. Cutaneous dendritic cells (DC) include Langerhans cells (LC) in the epidermis and CD11b + and CD103+ dermal dendritic cells (dDC) in the dermis. In the steady state (**a**), cutaneous DC patrol and survey the skin for commensal and self-antigens. Semi-mature DC migrate to the lymph node to present antigen to CD4+ and CD8+ T cells to induce tolerance via the differentiation of regulatory (Treg) and anergic T cells. During inflammation (**b**), DC sample danger and pathogen associated molecular patterns, take up the causative agents, become activated and upregulate CCR7, MHC-II and CD80/86. DC migrate to the lymph nodes, where they present peptides, provide co-stimulation and secrete cytokines to drive the differentiation of effector CD4+ and CD8+ T cells

by deletion of these cells and the establishment of antigen specific tolerance. This was mediated by increased expression of the inhibitory molecules PD-1 and CTLA-4 on T cells and required Treg cells [40–42]. Peripheral DC also migrate in the absence of exogenously added stimuli. These DC, termed "semi-mature", present antigens to T cells that are derived from self proteins and possibly from products of commensal organisms as well. DC that are activated through disruption of E-cadherin mediated DC-DC interaction or by genetic manipulation of β-catenin take on this "semi-mature" phenotype and induce tolerance [43, 44]

In addition to inducing T cell deletion or unresponsiveness, DC have the capacity to induce the formation of Treg cells through the elaboration of specific factors such as transforming growth factor-β (TGFβ) and retinoic acid [45–47]. Interestingly, the number of Tregs in unmanipulated mice correlated with the number of DC [48]. In addition, mice in which peripheral DC are prevented from migrating have reduced number of Treg and develop autoimmunity, implicating peripheral DC in maintaining tolerance [49]. The role of individual DC subsets in Treg induction and maintaining tolerance will be discussed below.

Dendritic Cell Subsets

A major barrier for the study of dendritic cells is their relative rarity and the existence of several distinct subsets of these cells. Initially, DC were distinguished from other leukocytes based on a shared set of characteristics including morphology, distribution, and function. DC have elongated processes termed dendrites that project outward and sample the environment. An irregular shape allows DC to have a large surface area and, while they account of a small population of all cell present, they are able to interact with many neighboring cells. Unlike cells such as T and B cells, there is no single antigenic marker that uniquely identifies DCs. All DCs, regardless of subset, constitutively express the hematopoietic markers CD45, MHC-II, as well as CD11c. They also lack T cell, natural killer (NK) cell, B cell, granulocyte, and erythrocyte lineage markers. CD11c is the classic marker associated with DC but is not unique and is also expressed by several macrophage populations—particularly lung and intestinal macrophages—but also on cDC precursors and other leukocytes [50–52]. The addition of other surface markers in combination with CD11c and MHC-II allows for reliable classification of DC subsets (Table 9.1). To make sense of the complexity of DC subsets, it is easiest to examine them based on their ontogeny and tissue of origin (i.e. peripheral tissues such as skin vs. LN/spleen resident).

Classical DC

Classical DCs (cDC) are a broad category of LN/spleen resident DC that have a high turnover and are constantly replaced by blood-derived precursors. cDCs develop from a hematopoietic lineage distinct from other leukocytes requiring the transcription factor zbtb46 and the cytokine Flt3L [53–56]. Importantly, cDC can be divided into two groups that were

initially demarcated as "lymphoid" and "myeloid" DC lineages but are now best described as IRF8 dependent and IRF4 dependent cDC. **IRF8 cDC** require the transcriptional factor Basic leucine zipper transcription factor ATF-like (BATF3), interferon regulatory factor 8 (IRF8), and inhibitor of DNA protein 2 (ID2) (Table 9.2) [57–59]. They express high levels of Flt3, proliferate after administration of Flt3L and are nearly absent in Flt3L−/− mice [55, 60]. They can be best identified based on the expression of CD8α but not CD8β and are often referred to as CD8+ cDC. They also express no or low levels of integrin CD11b as well as other macrophage defining markers [61] and represent 20–40 % of the secondary lymphoid organ resident DC [62, 63]. **IRF4 cDC** similarly proliferate in response to Flt3L and are reduced in Flt3- and Flt3L-deficient mice, but to lower levels in comparison to IRF8 cDC [55, 60]. They depend on transcriptional factor IRF4 and zbtb46, but not on BATF3, IRF8 or ID2 for their development [57, 58, 64]. They can be identified based on their expression of integrin CD11b+and the absence of CD8α.

Dermal DC

The best defined DC subsets in the dermis can be classified as **CD103+ dermal DC** (dDC) or **CD11b+dDC**. CD103+ dDC are homologues of the IRF8/CD8+ cDC. They express the integrin CD103 that binds e-cadherin expressed by epithelial cells but lack expression of CD8a [58]. CD103+ cDC lack the macrophage markers CD11b, CD115, CD172a, F4/80, and CX3CR1 [65]. They also depend on BATF3, IRF8 and ID2 [57–59]. In addition to Flt3L, CD103+ cDC also require Csf-2 for their development [66, 67]. This DC subset is fairly infrequent in the dermis but they migrate and are replenished from bone marrow precursors at a high rate [68].

CD11b+dDC comprise the majority of DC in the dermis but are less well studied than CD103+ dDC [68]. They are homologous to IRF4 cDC and can be identified based on expression of CD11b and the absence of CD103. They require cytokine Csf-1, IRF4 and Flt-3 for development [51, 66, 69]. Importantly, these dDC are often confused with macrophages that are also abundant in the dermis and express CD11c, MHC-II and CD11b. CD11b+dDC can be distinguished based on the absence of FcγRI (CD64) and MerTK expression [70].

Langerhans Cells

Langerhans cells constitute the sole APC population in the epidermis under steady-state conditions. Murine LCs are uniformly CD11b+F4/80+ and lack CX3CR1 expression [51]. They express the C-type lectin Langerin (CD207), which is involved in the formation of Birbeck's granules, a pathognomonic marker for LC [71]. LC account for 3–5 % of epidermal cells and stand apart from the other DC subsets through their unique ontogeny and homeostatic properties [72]. During ontogeny, LC precursors seed the epidermis first from hematopoetic precursors in the yolk-sac and then from the fetal liver [73, 74]. In contrast to most classical DC, LC develop independently of Flt3 and Flt3L and require keratinocyte-derived IL-34 signaling on Csf-1R for their development. CSF1R signaling is also required for macrophage development suggesting that LC may be more closely related to macrophages than other DC subsets [75–78]. In addition, LC require Runx3, PU.1, ID2 and BMP7 for their differentiation and autocrine TGF-β for their epidermal maintenance and homeostasis [79–84]. In the adult, LC form a self renewing population that can be replenished from

Table 9.2 Human APC subsets

blood derived monocytes after strong inflammatory stimuli such as UV light [85–90]. LC precursors emigrate into the epidermis via the hair follicle [91]. In the absence of strong inflammatory stimuli, LC will remain of host origin after bone marrow transplantation

Human Skin DC Subsets

The use of flow cytometric and gene profiling methods have allowed for refined characterization of DC in the human skin (Table 9.2). This is an active area of research but the current data suggests that human DC subsets are homologous to mice DC subsets but express a different set of identifying markers. DC in humans are defined as lacking lineage markers CD3, CD19, CD14, CD20, CD56 and glycophorin A [92]. Conventional human DC also express MHC-II and CD11c, but do not express markers such as CD303 (BDCA-2) and CD304 (BDCA-4) that are exhibited on plasmacytoid DC. Circulating pre-DC differentiate into conventional DC in peripheral tissue in mice while human skin CD1c+(BDCA-1) and CD141+ (BDCA-3) are found and arise in circulating blood. CD1c+DC represent the major APC population in the human dermis as well as circulation and are similar to the mouse CD11b+conventional DC [93, 94]. CD141+ DC are the only DC to express XCR1 and make up a small population, representing the same lineages as the mouse IRF8 and cD103+ DC [94]. The human dermis also contains CD14+ monocyte derived DC and macrophages. Langerhans cells are the only APC population in the human epidermis, expressing CD1a, and E-Cadherin. In contrast to the mice DC subsets in which LC and IRF8 DC both express Langerin, human LC are the only skin DC to express Langerin [95].

Cutaneous DC Function

Cross Presentation of Exogenous Antigen to CD8 T Cells

An important function of DC is the acquisition of foreign antigen that is then processed and cross-presented in the context of MHC-I in order to activate CD8+ cytotoxic killers (CTL). CD8+ CTLs provide immunity to viral and intracellular bacteria as well as many varieties of neoplasia. Identifying which DC subsets cross-present antigen is of particular importance for designing effective vaccines. Numerous *in vivo* experiments in mice have identified the IRF8 cDC and CD103+ dDC and the primary DC subset responsible for cross-presenation [96–99]. Mice with a selective deficiency of these subsets (i.e. Batf3$^{-/-}$ mice) are unable to mount CD8+ T cell response against subcutaneous infection with West Nile virus, epicutaneous infection with *C. albicans,* and are unable to reject fibrosarcomas [57, 100, 101]. In addition, CD103+ dDC cross present keratinocyte derived antigens to CD8+ T cells that could be important in promoting cross-tolerance [68]. IRF8 cDC and CD103+ dDCs express MHC-I related genes [102, 103] and are a source of IL-12 and IL-15, cytokines that drive differentiation of cytotoxic CD8+ T cells [104]. Moreover, these DC uniquely express the chemokine receptor XCR1. XCL1, the ligand for XCR1, is rapidly produced by CD8+ T cells upon antigen presentation and promotes CTL differentiation [105].

Other DC subsets may also have the capacity to cross-present antigen. CD11b+dDC can present antigen to CD8+ T cells. Whether this occurs in only specific circumstances and whether this is presentation of antigen expressed by the DC itself or represents true cross-presentation is unclear [106–109]. LC grown *in vitro* or isolated from human or mouse skin explants efficiently cross-present antigen to CD8 T cells *in vitro*. In contrast, LC were unable to generate CD8+ T cell expansion in response to skin infection with HSV-1 or *C. albicans in vivo* [101, 110]. It is unclear whether these conflicting results represent disparate functions of human vs. mouse LC, derive from differences in experimental technique, or reflect differences in DC isolated from skin vs lymph node [111]. Interestingly, all DC subsets isolated from human skin explants can prime CD8+ T cells to some extent *in vitro* but CD141+ DC, the human homolog of IRF8+ and CD103+ dDC, are significantly more efficient than other subsets [94, 100, 112, 113].

Allergic Contact Dermatitis

A key event in allergic contact dermatitis (ACD) is the priming of hapten-specific naïve CD4+ and CD8+ T cells in the regional lymph node (see Chap. 23) [114]. Although haptens can drain to the lymph node via lymphatic flow this does not lead to a productive T cell response [115, 116]. Instead, antigen presentation in the lymph node by migratory DCs is absolutely essential for the generation of responses to peripheral antigen [115–118]. Most studies examining the contribution of individual DC subsets have been performed in mice with selective ablations of individual DC subsets using contact hypersensitivity (CHS) assays to small haptens such as DNFB. In one series of studies, mice in which LC are selectively ablated develop enhanced contact hypersensitivity responses to various contact allergens suggesting that LC suppress the development of CHS. The suppressive function of LC occurs during the initial priming step and the absence of LC during the effector phase does not affect CHS [119–121]. LC suppression of CHS responses depends on cognate interaction with CD4+ T cells and LC derived IL-10 [121]. LC have been also demonstrated to suppress CHS by tolerizing

CD8+ T cells and activating regulatory T cells [122]. CD103+ dDC appear to participate in the development of CHS since some mice with a conditional depletion of CD103+ dDC have reduced CHS [123, 124]. This suggests that CD103+ dermal DC, rather than Langerhans cells, promote the development of contact hypersensitivity. Other data, however, particularly using low doses of hapten find that LC are required for the development of CHS [125–127]. Moreover, mice constitutively lacking C103+ dDC and IRF8 cDC develop CHS responses normally [114]. In addition, transplant of hapten primed CD11b+dermal DC can transfer CHS *in vivo* [128]. Thus, the relative importance of individual DC subsets for the induction of CHS remains unresolved. Untangling the functions of skin-resident DC during CHS is hindered by the intrinsic experimental variability of the assay and the difficulty in analyzing hapten specific T cells responses.

Skin Infection

In the setting of skin infection, distinct skin resident DC subsets have diverging functions in mounting T cell differentiation. In the setting of *C. albicans* skin infection, CD103+ dDC are required for the development of CD8+ T cell and Th1 responses through a mechanism that likely involves CD103+ dDC-derived IL-12 [101]. In contrast, Langerhans cells are specialized to drive Th17 differentiation in the setting of an epicutaneous *C. albicans* infection and produce significant amounts of Th17 differentiating cytokines such as TGF-β, IL-1β and IL-6. The function of skin DC may vary with the pathogen used since mice lacking CD103+ dDC and IRF8+ DC are able to mount protective responses to West Nile Virus and cutaneous *Leishmania major* infection [57]. In the setting of *N. brasiliensis* helminth infection, CD11b+and IRF4+ DC are important in inducing Th2 immunity [35, 36]. Similarly, dermal immunization with papain and epicutaneous immunization with FITC promote Th2 responses that required CD11b+dDC [36, 128]. Th2 induction by CD11b+dDC likely involves DC-derived thymic stromal lymphopoetin (TSLP) [129, 130]. LC also express the receptor for TSLP and been shown to initiate epicutaneous sensitization with protein antigens and induce Th2-type immune responses via TSLP signaling [129, 131].

Tolerance

Immunological tolerance describes a state of T cell unresponsiveness. A failure of tolerance to self antigens results in autoimmune disease. As discussed above, "semi-matured" DC present self antigen and participate in tolerance to self antigen. Dendritic cells that are "semi-matured" by repeated injections of TNFα suppress autoimmunity [132]. Few but not all pan-DC depletion models demonstrate the generation of spontaneous autoimmunity [133–135]. It is important to note that while the role of individual DC subsets have been shown to be important in peripheral tolerance, no single constitutive DC subset deficiency models have been demonstrated to lead to autoimmunity [55, 57, 58, 91]. Individual DC subsets do suppress inflammatory responses. LC suppress irritant responses in hapten challenge settings and in mouse model of acrodermatitis entropathica [119, 136]. In addition, LC have been shown to suppress immune responses to *L. major* via the activation of regulatory T cells and promote tolerance to minor-mismatched skin grafts [137, 138]. Receptor activator of NF-kB ligand (RANKL) expression on keratinocytes mediates LC directed Treg activation and regulates UV induced immunosuppression [139]. In addition, CD11b+dDCs are thought to have a superior ability in inducing peripheral Treg differentiation due to their unique expression of aldehyde dehydrogenase (ALDH), an enzyme that metabolizes exogenous vitamin A into retinoic acid that helps regulatory T cell differentiation [140–143]. Steady state targeting of antigens to LC and CD103+ dDC can induce Treg cells [38, 39, 144] demonstrating that most DC are capable of inducing Tregs *in vivo*. Thus, it appears likely, that the ability to suppress effector responses is not limited to an individual "suppressive" DC subset.

Antibody Responses

DC have been shown to be important for B cell mediated antibody responses. Langerhans cells project their dendrites through the epidermis and capture antigens, leading to production of significant IgG1 production [145]. Steady state antigen targeting to DC to various antigen uptake receptors have shown the induction of robust humoral immunity. Specifically, targeting antigen to IRF8+ and CD103+ DC induce the differentiation of antigen specific T follicular helper cells and germinal center B cells [146, 147]. DC induction of antibody response is likely an important contribution to skin autoimmune disease such as pemphigus vulgaris as well as for vaccine therapeutics.

Monocyte, Macrophage and Recruited DC

Macrophages

In addition to subsets of dendritic cells, other subsets of MHC-II antigen presenting cells are present or can be recruited into the skin. Dermal macrophages do not migrate to the draining lymph nodes in mice and form a self renewing population similar to Langerhans cells [148]. Dermal macrophages have a lower capacity to present antigen compared to dermal DC

and function in scavenging and killing microorganisms [148]. They also likely participate in presentation of antigen to T cells that are recruited into the skin [93]. In stark contrast to dermal DC, macrophages as well as monocyte derived DC in the human and mouse dermis express high levels of IL-10 transcript, suggesting a possible anti-inflammatory role [70]. Some dermal macrophages express CD4 and surround post-capillary venules and produce chemokines that promote extravasation of neutrophils into the infected dermis [149].

Monocyte Derived DC

In healthy mouse skin, dDC and monocyte-derived DC have a fast turnover whereas dermal macrophages have a slower turnover and a longer life. Most tissues macrophages are thought to be derived from blood LY6Chi monocytes while some macrophages are established prenatally, and derive from self replicating yolk sac progenitors [73, 150, 151]. In addition, there is a small population of blood derived CD16-expressing monocytes that display an advanced stage of differentiation with effector functions related to antigen processing and presentation [152, 153]. They arise in inflammatory conditions and represent the main producers of inflammatory cytokines such as TNFα and have a high capacity to stimulate antigen-independent T-cell responses. Monocyte derived DC can be further subdivided into 6-sulfo LacNAc (slan) -positive and -negative monocytes that both produce pro-inflammatory cytokines. The expression of slan was initially identified on an inflammatory human DC subset found in the blood and skin [154]. In steady-state, murine classical monocytes continuously extravasate and transport tissue antigens to the LN without differentiating into DC or macrophages [155]. Despite high levels of antigen capture and expression of MHC-II, monocyte derived DC are relatively poor antigen presenters [156, 157]. Alternative mechanisms such as cytokine production or antigen transfer with productive DC and APC may be their role in adaptive immunity.

Inflammatory DC

Inflammatory DCs refer to populations of DCs that are transiently formed in response to various inflammatory stimuli and disappear when the stimuli is resolved. Inflammatory DC development and function remain poorly understood, with the lack of surface markers to identify them. The phenotype of inflammatory DCs is influenced by kinetics and the nature of the stimuli. Inflammatory DCs that accumulate in the LN in response to lipopolysaccharide (LPS) administration express DC-specific transcription factor zbtb46 and fail to accumulate in Flt3L−/− mice, validating them as DC [53, 56]. Another subset of inflammatory DCs identified in mice infected with *L. monocytogenes* was termed TNF-α/iNOS-producing DCs (TipDC) because of their ability to produce high levels of TNF-α and iNOS. TipDC are also found abundantly in psoriatic skin and are believed to be a key effector population [158]. However, in contrast to LPS-induced DC, TipDCs lack zbtb46, suggesting that they are distinct from true DC [53, 56]. The full understanding of inflammatory DC function is lacking, as are subset specific depletion models.

Plasmacytoid DC

Plasmacytoid DCs (pDCs) represent a small subset of DCs that share a similar origin to DC but a distinct life cycle. They circulate in blood and lymphoid tissues and can be found in the skin and other peripheral tissues under inflammatory conditions. They express lower levels of MHC-II and costimulatory molecules in the steady state and display a narrow range of PRRs that include Toll-like receptors 7 and 9. Upon recognition of pathogenic nucleic acids, they produce massive amounts of type I IFNs that are important for resistance to viral infections but also participate in the development of autoimmune conditions such as psoriasis and systemic lupus erythematosus [159–163].

DC and Disease

Syndromes with DC Defects

There are three known genetic DC deficiencies in humans. DCML deficiency syndrome is caused by a mutations of GATA-binding factor 2 (GATA2) and demonstrates a complete absence of blood DCs, pDCs, tissue cDCs, circulating monocytes, B cells and NK lymphoid cells [164]. IRF8 null mutations are found in humans and lead to the absence of monocytes, pDC, cDCs, and dermal DCs and defective IL-12 production and intact epidermal LC, resembling the mice knockout of IRF8 [165]. Mutation of adenylate kinase 2, a phosphotransferase required for nucleotide homeostasis causes a form of severe combined immunodeficiency known as reticular dysgenesis. It is associated with impaired formation of all nucleated blood cells, including neutrophils, lymphocytes, monocytes, and cDCs as well as LCs [166]. Patients with these defects all have increased risk of infections, but it is difficult to pinpoint the specific function of individual DC since the defects affect a broad range of cell types.

Psoriasis

Psoriasis is also another condition in which DC are implicated for pathogenesis. Repeated application of the TLR7 ligand imiquimod to murine skin induces an inflammatory response that recapitulates some similarities to that of human psoriasis, including hyperproliferation and differentiation of keratinocytes and thickening of the epidermis [167, 168].

Infiltrates of neutrophils in the epidermis and DC, macrophages and T cells in the dermis is found after imiquimod induced psoriasis an other genetic mouse models of psoriasis. In the imiquimod model of psoriasis, IL-23 production by DC elicits dermal gamma delta T cells to secrete IL-17 and IL-22 which recruit neutrophils and drive the proliferation of keratinocytes, respectively [169–173]. TLR signaling in DC seems to be necessary and sufficient for the formation of IL-23 mediated psoriasis [174]. While pDC are found in the skin of psoriatic patients and mouse models of psoriasis, conditional ablation of pDC does not lead to attenuation of disease [174]. More recently, it has been suggested that sensory nociception leads to the activation of DC to produce IL-23 after the application of imiquimod and cutaneous denervation leads to attenuation of disease in transgenic mice models of psoriasis [175, 176]. However, which DC or monocyte or macrophage subset is responsible for IL-23 secretion remains controversial [172, 174].

Vaccination

Efficient vaccination requires acquisition of antigen by DC. The density and easy access to DC in the skin makes them an attractive target for vaccination strategies.

Interestingly, the smallpox vaccine, which was the first vaccine developed, is administered intradermally and remains one of the most effective vaccines developed [55, 74, 119, 177]. The density of skin DC is thought to explain the increased efficiency of skin immunization compared with the intramuscular route [93]. Most vaccines, however, bypass the APC rich epidermis and the dermis and target the connective and adipose tissue rich hypodermis. More recently, newly developed delivery systems are becoming more common in order to target the more superficial layers of the skin. For example, microneedle vaccination has been used to introduce encapsulated influenza virus vaccine into the dermis leading to robust cellular and humoral immune responses [178]. Laser-generated micropores have been used for intradermal immunizations to induce potent immune responses [179]. Combinations of novel delivery systems with epitopes coupled to antibodies that specifically target cell surface endocytic receptors (e.g. DEC-205 or Langerin) expressed by APC populations are becoming more popular for researchers to study DC functions as well as for vaccination trials against cancers and pathogens [180, 181]. For example, targeting vaccine antigens directed against receptor Clec9A to CD103+ or CD8+ cDC enables robust cross-presentation and CD8+ T cell response [135, 146, 147]. In addition, antibody responses are generated via the production of T follicular helper cells [147]. Given the potential for DC specific differences in function, it is plausible that specific DC may be targeted for a tailored cellular immune response, such as tolerance in the setting of autoimmunity [38, 39, 144].

Review Questions

1. Identify the two major subsets of dendritic cells found throughout the secondary lymphoid tissues (select all correct answers).
   a. IRF8 DC
   b. Langerhans Cells
   c. CD103+ dDC
   d. IRF4 DC
   e. CD11b + dDC

Correct answer: a and d. Classical DCs (broad category of LN/splenic resident DCs) can be broadly categorized into two distinct subsets by the expression of transcriptional factors IRF4 and IRF8. IRF8 cDCs express CD8, XCR1 and Clec9a while IRF4 cDCs express CD11b and CD172. These 2 DC types are found in lymph node, spleen and have closely related counterparts in most peripheral tissues. Skin DCs can be categorized into three broad categories: Langerhans cells, CD11b+ dDCs, and CD103+ dDCs

2. How are dendritic cells activated (select all correct answers)?
   a. PAMPS
   b. Cytokines
   c. Stochastically
   d. Antigen
   e. B-catenin

Correct answer: a and b. Skin DCs get activated through their pattern recognition receptors (e.g. TLR) as well as by inflammatory cytokines. This results in expression of CCR7 that facilitiates migration into LN and increased expression of MHC-II and co-stimulatory molecules (e.g. B7) that allow for efficient activation of cognate CD4+ and CD8+ T cells

3. What is the function of skin dendritic cells under steady-state conditions (select all correct answers)?
   a. T cell activation
   b. Clean-up necrotic debris
   c. B cell activation
   d. Inhibition of Mast cell activation
   e. T cell tolerance

Correct answer: e. Steady state DCs mediate tolerance to self antigens through a mechanism involving b-catenin as well as other likely mechanisms

4. What role do dendritic cells play during allergic contact dermatitis, Psoriasis and during infection (select all correct answers)?
   a. Activate T cells specific for foreign antigens
   b. Secrete IL-23
   c. Secrete IL-15
   d. Induce Th17 responses
   e. Induce Th2 responses

Correct answer: a,b,c,d,e. The precise role of individual DC subsets during allergic contact dermatitis remains

unclear. Some studies demonstrate that LCs suppress CHS and DTH while others show that LCs induce CHS and DTH responses. Similarly, the data is also controversial for CD103+ and CD11b+ dDCs. For Psoriasis, mice in which DCs are conditionally depleted have less response in imiquimod induced psoriasis inflammation model. TLR signaling on CD11b+ dDCs have recently been demonstrated to be sufficient in inducing IL-23 in response to imiquimod to drive psoriasis like inflammation in mice. Fo infection, In response to *C. albicans, L. major* and West Nile virus infections, CD103+ dDCs mediate Th1 responses. LCs mediate Th17 responses in response to epicutaneous *C. albicans* infection. Finally, CD11b+ dDCs induce Th2 responses to *N. brasiliensis* infection

Photoimmunology

10

Jake E. Turrentine and Ponciano D. Cruz Jr.

Abstract

Photoimmunology is the study of the effects of non-ionizing electromagnetic radiation (principally ultraviolet light) on the immune system. Ultraviolet (UV) light represents the spectrum of electromagnetic radiation between the wavelengths of 100 and 400 nm. Through its actions on the immune system, UV radiation promotes the development of skin cancers, modulates the development of allergic contact dermatitis, and triggers several specific photosensitivity disorders collectively known as the immunologically-mediated photodermatoses. These disorders include polymorphic light eruption, actinic prurigo, solar urticaria, hydro vacciniforme, and chronic actinic dermatitis. In addition to discussing the molecular underpinnings of UV-induced carcinogenesis and the effects of UV radiation on contact hypersensitivy responses, this chapter reviews the clinical features, epidemiology, pathophysiology and treatment of the immunologically-mediated photodermatoses. Additionally, this chapter highlights the key immunologic mechanisms by which UV radiation is used therapeutically to treat dermatologic diseases, especially T-cell mediated skin disorders.

Keywords

Photoimmunology • Ultraviolet light • Ultraviolet radiation • Photoimmunosuppression • Actinic prurigo • Polymorphic light eruption • Solar urticaria • Hydroa vacciniforme • Chronic actinic dermatitis • Phototherapy

Photoimmunology is the study of effects of ultraviolet (UV) light/radiation (photons) on the immune system. UV light occupies a narrow portion (100–400 nm) of the sun's electromagnetic radiation, which spans ionizing wavelengths (<100 nm) on one extreme and radio- and microwaves (>10,000 nm) on the other. Despite its reported diminution, our stratospheric ozone layer continues to filter solar radiation by blocking all ionizing and UVC radiation and the vast majority of UVB radiation from reaching the earth's surface. What natural exposure to sunlight delivers is some UVB, much UVA and visible light, and considerable infrared radiation (>800 nm) (Fig. 10.1).

The UV spectrum is subdivided into UVC (100–290 nm), UVB (290–320 nm), and UVA (320–400 nm) radiation. The ability of these wavelengths to penetrate the skin depends in great part on their absorption by different chromophores or photoreceptors (Fig. 10.2). UVC and UVB are readily absorbed by DNA within living cells, and thus almost all of these shorter wavelengths are absorbed as they pass through the epidermis, with little to none reaching the dermis. By contrast, UVA and visible light penetrate deeper into the dermis where these wavelengths are absorbed principally by

aromatic amino acids on cell membrane proteins, and by collagen, elastin, and ground substance [1]. As will be discussed later, the development of high-energy light sources that emit 340–400 nm (UVA1) exclusively and their use as a therapeutic modality that is safer than PUVA (psoralens plus UVA) has led to its distinction from UVA2 (320–340 nm), which more closely resembles UVB. UVA1 has features intermediate between UVB and visible light. UVC and UVB are absorbed primarily by DNA, and are mutagenic. Indeed, UVC (germicidal) lamps are used to kill microbes. Of the solar radiation reaching the earth's surface, UVB is the most carcinogenic. UVB is also the most erythemogenic and is responsible for producing sunburn and immediate tanning. By contrast, UVA is considerably less erythemogenic, but more effective in producing a longer lasting tan.

Photocarcinogenesis

Human epidemiologic and laboratory animal studies overwhelmingly support the concept of UV exposure as the major environmental risk factor for non-melanoma skin cancer (NMSC) [2–5]. In this respect and as cited previously, UVB is most carcinogenic [6], although large doses of UVA also have been shown experimentally to cause non-melanoma skin cancer [7]. A causative role for UV radiation in melanoma is also supported by scientific evidence, albeit at a level less substantial than for NMSC [8–10]. Both UVA and UVB may be involved in the pathogenesis of melanoma [11], but the two types of UV radiation likely act by different mechanisms. Experimentally, UVA-induced melanoma requires the presence of melanin pigment and the DNA damage is caused indirectly by reactive oxygen species, whereas UVB-induced melanoma develops in a melanin-independent manner and is due directly to UV-mediated DNA-damage [12].

UVB causes a variety of DNA mutations, most commonly cyclobutane pyrimidine dimers that have been linked to the genesis of sunburn, tanning, and skin cancer. The biologic consequences of UVB-induced mutations depend on the ability of the host to repair DNA defects and on the specific gene mutations left unrepaired. Mutations that activate oncogenes (e.g., ras) or deactivate tumor suppressor genes (e.g., p53 for squamous cell cancer; PATCHED for basal cell cancer) set the stage for carcinogenesis [13]. It is assumed that people with competent DNA repair mechanisms are able to correct UV-induced mutations. These protective mechanisms may deteriorate with age, allowing some mutations to escape repair, thereby leading to actinic keratoses, squamous cell cancers, and basal cell cancers. Xeroderma pigmentosa, a congenital disorder of absent or deficient DNA repair enzymes, provides a dramatic illustration of the foregoing concepts since afflicted individuals suffer from multiple skin cancers as early as childhood.

UV-Induced Immunosuppression

In addition to its carcinogenic effects, UV radiation promotes cancer growth by suppressing a second host defense mechanism – the ability of the immune system to kill UV-induced skin cancers. That UVB radiation leads to suppressor T-cell activation has been demonstrated not only for UVB-induced carcinogenesis but also for UVB-induced suppression of delayed-type (DTH) and contact hypersensitivity (CH) [14, 15]. The immunosuppression generated is not a generalized one, but specific for the antigen to which the host is being sensitized at the time of UV exposure [14]. Several overlapping pathways have been shown to lead to UV-induced immunosuppression (Fig. 10.3). There is overwhelming scientific evidence supporting the ability of UVB to induce immunosuppression, yet recent evidence has also suggested that UVA wavelengths from 364 to 385 nm may also be immunosuppressive [16], though the immunomodulatory effects of UVA have a complex dose–response relationship [17].

UVB light can induce keratinocytes to secrete soluble factors, of which tumor necrosis factor-α (TNF-α) [18, 19] and interleukin-10 (IL-10) [20, 21] are most critical to UVB immunosuppression; TNF-α regulates Langerhans cells' emigration out of the epidermis into draining lymph nodes, and IL-10 shifts T-cell responses from T-helper-1 (Th1) to Th2 phenotype [20]. UV light can also trigger lipid peroxidation on cell membranes leading to secretion of platelet aggregation factor (PAF), which in turn stimulates prostaglandin E2 (PGE2) production, which in turn prompts IL-4 secretion, and also IL-10 production [21, 22]. UV-induced oxidation reactions can also produce PAF analogs such as 1-alkyl-2-(butanoyl and butenoyl)-sn-glycero-3-phosphocholine that can stimulate the PAF receptor [23]. Trans-urocanic acid, a by-product of histidine metabolism, accumulates in the stratum corneum; UV non-enzymatically transforms trans-urocanic acid into the cis isomer, which contributes to immunosuppression via effects on antigen-presenting cells (APCs) [24, 25]. Immunosuppressive effects of cis-urocanic acid were shown to be mediated through binding to the serotonin (5-HT) receptor [26]. Finally, UVB radiation can trigger release of calcitonin gene related peptide (CGRP) from cutaneous nerve endings, leading to mast cell release of TNFα, which dampens CH responses [27].

UV can directly alter the function of epidermal Langerhans cells (LC) and other APCs. Depending on the UV dose and the manner in which it is administered, UV may induce these APCs to undergo apoptosis, shift their function from stimulators of Th1 (cellular) to Th2 (humoral) responses, or cause them to activate "suppressor" T cells [28–30]. Previously, as LC were regarded as the most important APCs in the skin, it was thought that such antigen tolerance was due to epidermal LC depletion by UV light. [31] Now dermal dendritic cells

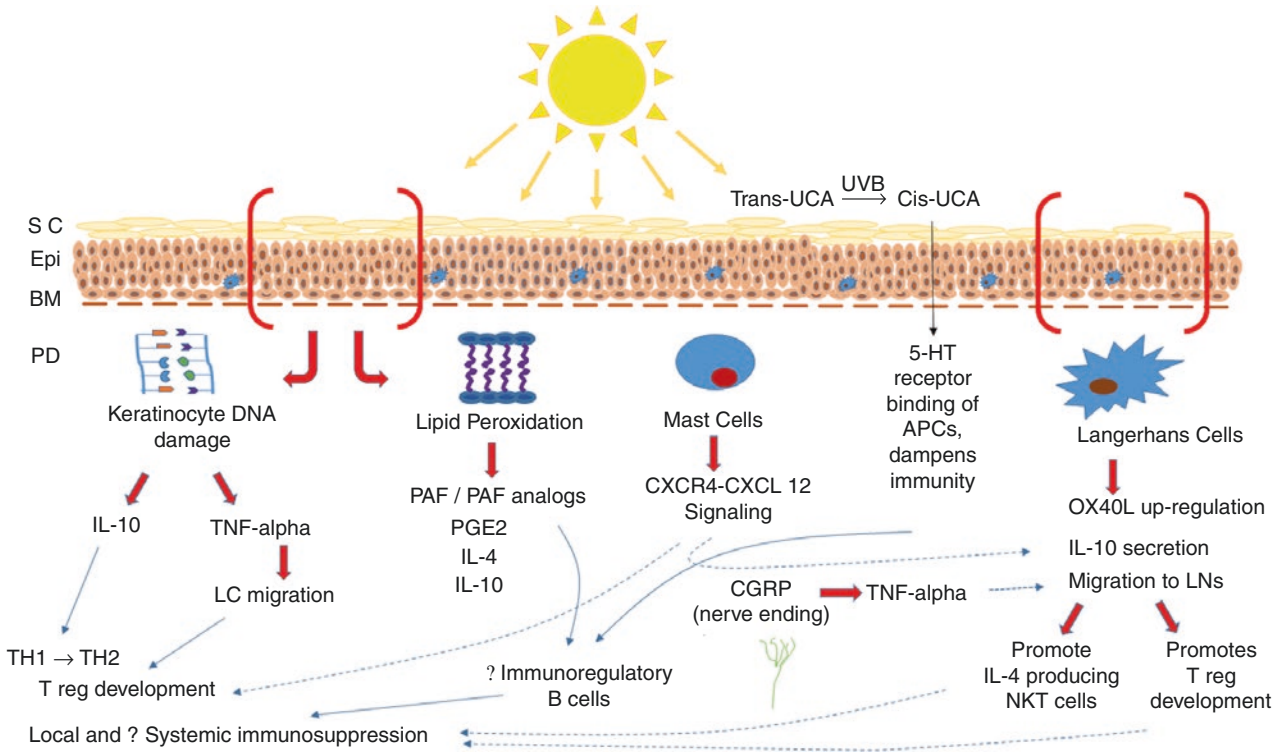

Fig. 10.3 Overlapping pathways accounting for the effects of ultraviolet radiation on the immune system. *5-HT* serotonin, *APC* antigen presenting cell, *BM* basement membrane, *CGRP* calcitonin gene related peptide, *CXCL* CXC chemokine ligand, *CXCR* CXC chemokine receptor, *Epi* epidermis, *IL* interleukin, *LC* Langerhans cell, *LNs* lymph nodes, *NKT* natural killer T, *OX40L* ligand for CD134, also known as CD252, *PAF* platelet activating factor, *PD* papillary dermis, *PGE* prostaglandin E, *SC* stratum corneum, *TH* T-helper, *UV* ultraviolet, *TNF* tumor necrosis factor, *T reg* T regulatory cell, *UCA* urocanic acid

(FITC+, CD11c+, Langerin−) are thought to be critical for antigen presentation and immune stimulation (even in the setting of UV light) [32, 33]. By contrast, LC play a significant role in UV-mediated immunosuppression. UVB radiation leads to LC maturation, up-regulation of surface marker OX40L, and production of IL-10, which upon migration to lymph nodes, supports the development of regulatory T cells [34]. Regulatory T cells express CD4, CD25, and CTLA-4 markers, secrete copious amounts of IL-10, bind dectin-2, and dampen immune responses [35, 36]. LC migrating to the lymph nodes may also mediate immunosuppression by activating a population of natural killer T (NKT) cells to secrete IL-4 [37]. Interestingly, topically applied low-dose green tea extract (3 %) has recently been shown to reduce UV-mediated depletion of LC [38].

Additionally, mast cells and complement activation via the C3 pathway have been shown to participate in UVB-induced immunosuppression [39–42], and evidence continues to mount in support of an integral role for mast cells in UV-induced immunosuppression [43]. Dermal mast cells have been shown to critically mediate UV-induced immunosuppression through the CXCR4-CXCL12 signaling pathway. In fact, blockade of mast cell trafficking with the CXCR4 antagonist AMD3100 prevented UV-induced immunosuppression and reduced the number of cutaneous squamous cell carcinomas in mice, presumably by reducing mast cell migration into local lymph nodes and the tumors themselves [44, 45]. Interestingly, studies have shown an increased mast cell density in buttock skin of patients with basal cell carcinoma and melanoma compared to controls [46, 47].

UV light also leads to the development of a suppressive population of B cells that express high levels of major histocompatibility complex II (MHC II) and B220 but low levels of co-stimulatory molecules. When dendritic cells and B cells isolated from UV-radiated mice were conjugated to antigen ex vivo and injected into naïve hosts, this subset of B cells suppressed dendritic cell activation of immunity (which occurred in the absence of these B cells) [48]. Both platelet activating factor (PAF) and serotonin were shown to promote development of these so-called "immunoregulatory B cells" (FITC+, IL-10-secreting, CD19+, B220+) capable of inducing tolerance to antigens following UV exposure [49].

In addition to attenuation of CH and skin cancer immunosurveillance, UV light has been shown to serve as an immunomodulator for systemic autoimmune diseases, including multiple sclerosis, type I diabetes, and rheumatoid arthritis [50]. Much of the evidence is epidemiologic: the latitude

gradient in these diseases suggests an inverse relationship between disease incidence and UV exposure. However, in a murine model of multiple sclerosis (experimental autoimmune encephalitis or EAE), UVB radiation was shown to induce tolerogenic dendritic cells that circulated systemically and promoted development of regulatory T cells in several organs, including the CNS [51].

UVB Radiation and Vitamin D

UVB causes the non-enzymatic conversion of 7-dehydrocholesterol to cholecalciferol (vitamin D3) in skin. Although vitamin D is well-known for its effects on mineral metabolism and bone health, it has also become apparent that cholecalciferol modulates immune responses in skin and, perhaps, systemically. Vitamin D can modulate UVB-mediated damage to keratinocytes, although the effect is lost at higher doses of UVB irradiation, which may explain increased skin cancer risk associated with chronic, high dose UV exposure [52]. Several laboratory studies have suggested a protective role of vitamin D against basal cell and squamous cell carcinoma as well as melanoma, although further human studies need to be performed. Toll-like receptors (TLRs) activated in response to intracellular bacteria can upregulate vitamin D receptors on macrophages, leading to the induction of canthelicidin and intracellular killing of Mycobacterium tuberculosis [53]. In addition, sera from African Americans, a population known to be more susceptible to tuberculosis, were found to have lower levels of 25-hydroxyvitamin D compared to controls. Vitamin D may also stimulates phagocytosis by monocytes and macrophages [54].

While these examples support an immunostimulatory role for vitamin D, there is also data suggesting that vitamin D may be immunosuppressive. Cholecalciferol may inhibit the production of Th1 type cytokines, suppress activation of Th1 cells, and enhance the function of regulatory T cells [50]. These actions may play be protective or preventative of autoimmunity. Life-long vitamin D supplementation in NOD mice prevented development of diabetes mellitus whereas induced vitamin D deficiency from birth led to early development of type I diabetes mellitus [55]. A promising role for UVB radiation in multiple sclerosis is related to elevated levels of vitamin D in patients treated with UV light. [51] The exact role of vitamin D in skin and systemic immunity remains to be fully elucidated. UVB as the primary external stimulant of vitamin D production has the potential to mediate vitamin D- dependent immunity.

Immunologically-Mediated (Idiopathic) Photodermatoses

The immunologically mediated photodermatoses (IMPs), also known as idiopathic photosensitive skin disorders, are a heterogeneous group of conditions for which exact etiopathologic mechanisms remain elusive though each manifests immunologic underpinnings (Table 10.1). Our focus will be on polymorphic light eruption, actinic prurigo, solar urticaria, hydroa vacciniforme, and chronic actinic dermatitis.

Polymorphic (Polymorphous) Light Eruption

Polymorphic light eruption (PMLE) is the most common photosensitivity disorder, with estimates of prevalence as high as 20% of the general population [56, 57]. PMLE has a

Table 10.1 Photosensitivity disorders

Immunologically-mediated (idiopathic) photodermatoses	Polymorphic light eruption (including juvenile spring eruption)
	Actinic prurigo
	Solar urticaria
	Hydroa vacciniforme
	Chronic actinic dermatitis
Defective DNA repair	Xeroderma pigmentosa
	Trichothiodystrophy

Drug-induced	Phototoxic reaction
	Photoallergic dermatitis
	Pseudoporphryia
Porphyrias	Porphyria cutanea tarda
	Erythropoietic porphyria

predilection for women, an age of onset in the teenage and young adult years, and a tendency to affect people living in temperate climates. Recurrent outbreaks typically occur in spring, with clinical onset occurring several hours following UV exposure. The eruption develops over sun-exposed skin, is usually pruritic, and may take several morphologic patterns (i.e., polymorphic): small to large papules, vesicles, plaques, and even erythema multiforme-like eruptions [56]. Despite the wide variety of morphologic patterns, individual patients tend to present with the same morphologic feature in a recurrent manner [58]. Outbreaks typically last 1–2 weeks, and the eruption frequently improves in the summer (termed hardening). Photoprovocation studies have implicated different wavelengths spanning UVB, UVA, and even visible light ranges [59, 60]. Juvenile spring eruption (JSE) is considered a localized variant of PMLE that tends to occur on the ears of young boys. Outbreaks most commonly occur during the spring after exposure to bright sunlight in cold weather, with body sites lacking hair (e.g., protuberant ears) as favored locations [61].

Pathogenesis is believed to be a delayed cellular hypersensitivity reaction to an endogenous cutaneous antigen possibly generated by the action of UV radiation [62, 63]. Although the identity of the chromophore/antigen remains unknown, studies have shown patients to be relatively incapable of manifesting UVB-induced suppression of immune responses like induction (but not elicitation) of contact hypersensitivity [64], a defect ascribed to inability of UVB to induce emigration of Langerhans cells from the epidermis to draining lymph nodes [65, 66]. Lesions of PMLE have demonstrated an altered immunoregulatory network, with reduced epidermal or dermal expression of TGF-beta-1, IL-10 and RANKL, and a relatively low number of Tregs [67]. This reduced ability of UVB to suppress immune responses leads to an enhanced immune response to cutaneous neoantigens generated from UV exposure. Repeated UV exposure in these patients eventually suppresses immunity, explaining the natural improvement (hardening) during summer months as well as the therapeutic role of prophylactic NB-UVB or PUVA therapy [58].

Most cases of polymorphic light eruption are mild and can be managed by photoprotection plus topical corticosteroids for symptomatic relief. Occasionally in young, otherwise healthy patients, a short course of systemic corticosteroids (0.6 mg–1 mg/kg per day for 1 week) can help control symptoms. For patients with severe, recurrent disease, NB-UVB or PUVA therapy in late winter can prevent seasonal flares during spring [58].

Actinic Prurigo

Actinic prurigo is an immune-mediated photodermatosis most commonly seen in the indigenous Indian and mestizo populations of Central and South America, especially individuals living at high altitudes, although Caucasian and Asian populations are also affected [58]. The disorder is thought to be caused by transformation of an epidermal antigen upon exposure to UV light, leading to an abnormal immune response [68]. Although both UVA and UVB have been implicated in actinic prurigo, the eruption is most often linked to UVA radiation [58, 68]. Typically, actinic prurigo presents in children younger than 10 years (often 4–5 years) with intensely itchy papules, plaques and nodules as well as excoriations and scarring on sun exposed areas. The face, neck, extensor forearms, dorsal hands, and upper chest are usually affected, but involvement of the back and buttocks may occur. Conjunctivitis and cheilitis (lower > upper lip) are characteristically present. Pruritus tends to last throughout the entire year, with exacerbations in the spring and summer.

While actinic prurigo may share with polymorphic light eruption a similar immunologic mechanism, lesion morphology, and delayed-onset relative to sun exposure, there are several clinical differences between the two disorders. As outlined above, actinic prurigo is more likely to affect both exposed and covered sites, can occur in the winter, tends to persist beyond 4 weeks, often exhibits lip or conjunctival involvement, and frequently presents with excoriation and scarring [69]. Furthermore, actinic prurigo has been linked to human leukocyte antigen (HLA) subtypes. Originally HLA subtypes A24 and Cw4 were linked to actinic prurigo in patients of Cree ancestry [70], but subsequent studies in both European and Central American populations demonstrated strongest association with the DR4 allele, with the specific allele HLA-DR4/DRB1*0407 being most common, found in 60–70 % of affected individuals [58, 68, 69, 71].

Unlike polymorphic light eruption, management of actinic prurigo tends to be more challenging. Photoprotection is the most important measure, including use of protective clothing, sunscreens, lip balms, and sunglasses. Multiple therapies may reduce pruritus, including topical corticosteroids, emollients, and oral antihistamines. Occasionally NB-UVB and PUVA are also used, although the level of evidence for their efficacy is lower than for polymorphic light eruption [58]. In actinic prurigo, the most consistently effective form of therapy is thalidomide, although its use is limited by adverse effects including teratogenicity, peripheral neuropathy, and venous thromboembolism [58, 68, 72].

Solar Urticaria

Solar urticaria is a rare form of physical urticarial provoked by exposure to UV light. Most studies support an action spectrum between 300 and 500 nm, although the exact action spectrum tends to vary between studies and individuals. Rare cases due to infrared light have also been reported [73, 74]. Solar urticaria affects about 0.8 % of patients with urticarial

eruptions, and up to 7 % of patients with photodermatoses. The disorder has a variable age of onset, although most patients present in young adulthood. Women tend to be affected more commonly than men. There does not seem to be a racial or ethnic predilection [73].

Unlike polymorphic light eruption and actinic prurigo, solar urticaria typically develops within minutes of exposure to sunshine and manifests as itching, burning, erythema, and wheals [75]. The eruption tends to affect "classic" photodistributed areas such as the V-shaped area of the upper chest and the arms, but urticarial lesions may spare areas regularly exposed to sunlight like the face and hands. Systemic symptoms including headache, nausea, wheezing, dizziness and rarely anaphylactic shock [73].

Solar urticaria is an immediate type of photoallergic reaction caused by immunoglobulin E (IgE) autoantibodies. There are two subtypes of solar urticaria based on our most current understanding of these autoantibodies. In Type 1 solar urticaria, affected individuals have an abnormal chromophore within the skin to which IgE antibodies develop, leading to urticarial lesions. In these cases, passive transfer of serum to a normal individual will variably produce lesions of solar urticaria upon light exposure if the abnormal chromophore is also contained in the serum. By contrast, in Type 2 solar urticaria, affected individuals have IgE antibodies to a normal chromophore in the skin. In these cases, passive transfer of serum to a normal individual will always lead to urticaria upon subsequent light exposure [73]. While this distinction is useful for understanding underlying mechanisms of solar urticaria, passive transfer experiments are not routinely performed for ethical reasons, so the distinction between these subtypes is generally not made in clinical practice.

Treatment of solar urticaria is aimed at strict photoprotection. As in other types of urticaria, symptom relief can be achieved with topical corticosteroids or oral antihistamines. Although phototherapy should be approached with caution due to potential flaring of the disease, both NB-UVB (only to areas of skin that are regularly sun exposed, to produce "hardening") and PUVA have been used effectively in select cases. There is limited evidence supporting the use of beta-carotene, antimalarial medications, plasmapheresis, systemic immunosuppressives, and intravenous immunoglobulin [58, 62].

Hydroa Vacciniforme

Hydroa vacciniforme is a rare photosensitivity disorder found almost exclusively in children, with a mean age of onset around 8 years. Boys are affected more often than girls [58, 76]. Most patients are sensitive to UVA radiation, which causes recurrent crops of 2- to 3-mm erythematous macules that evolve into blisters within a few hours to days. The lesions then become umbilicated with crusting within a few days, often mimicking impetigo or impetiginized herpes simplex virus infection. These lesions heal with pitted varioliform scarring. The face and hands are the most commonly affected sites.

Epstein-Barr Virus (EBV) infection has been linked to hydroa vacciniforme. One case report of EBV-associated hydroa vacciniforme suggested that plasmacytoid monocytes (CD68+ and CD123+) may play a crucial role in the pathogenesis based on immunohistochemistry from the patient's biopsy demonstrating a predominance of this cell type [77]. More recently, a case series evaluating biopsies and peripheral blood of patients with hydroa vacciniforme found an increase in EBV-infected γ/δ T cells in affected patients which was not present in controls with hypersensitivity reactions to mosquito bites [78]. However, the exact pathophysiology to explain the relationship between the viral infection and UVA light is yet to be elucidated.

No treatments for hydroa vacciniforme are consistently successful, so photoprotection remains a critical aspect of management. Occasionally anti-malarials, beta-carotene, PUVA, systemic immunosuppressives, and thalidomide have been used successfully [62]. In severe cases, systemic corticosteroids can be used [58].

Chronic Actinic Dermatitis

Chronic actinic dermatitis is an umbrella term for several forms of chronic photosensitivity disorders including photosensitive eczema, persistent light reaction, chronic photosensitive dermatitis, and actinic reticuloid. It often begins insidiously as nonspecific eczematous lesions in sun-exposed areas that become more persistent, in the absence of known topical or systemic photosensitizers [62]. Eczematous lesions are by far the most common, though papular lesions and pseudolymphomatous "reticuloid" lesions may also occur [79]. It is more common in men and tends to occur in later adult years, although it may occur earlier in patients with a strong history of atopic dermatitis [56, 80]. UV-B, UV-A, and visible light, either alone or in combination with each other, have been implicated in chronic actinic dermatitis [81].

Although the exact etiology is uncertain, the cause appears to be a form of delayed type hypersensitivity to a normal skin constituent that becomes altered by UV light and becomes antigenic in the absence of "normal" UVB-induced immunosuppression [80–82]. In many cases, there is a strong association with allergic contact dermatitis, though it remains unclear whether ACD is directly involved in the pathogenesis of chronic actinic dermatitis or whether allergy develops secondary to abnormal barrier function in the setting of a susceptible cutaneous microenvironment. Sesquiterpene lactone has a well-known association with

chronic actinic dermatitis and remains an important allergen even in recent studies. Other studies have shown a significant increase in patch test positivity to non-fragrance consumer allergens in affected individuals, particularly para-phenylenediamine [83]. Up to 75 % of patients react on patch testing or photopatch testing to allergens suspected to be involved in chronic actinic dermatitis; it is unclear whether the remaining patients have underlying allergy to an untested hapten or develop chronic actinic dermatitis in the absence of allergic contact dermatitis [80, 83].

With appropriate treatment, including avoidance of sunlight, regular use of sunscreen and skin-protective clothing, and avoidance of known allergen(s), chronic actinic dermatitis tends to improve or resolve over the course of many years, with approximately 55 % of patients experiencing improvement and 35 % experiencing resolution over 15 years in one study [84]. Aside from these basic measures, many other therapeutic options may be tried, including emollients, topical corticosteroids, topical tacrolimus, systemic corticosteroids, azathioprine, cyclosporine, methotrexate, hydroxyurea, retinoids, antimalarials, and phototherapy. Azathioprine tends to be quite effective for severe forms of this disorder, and systemic corticosteroids may be beneficial in acute exacerbations. Phototherapy tends to be poorly tolerated, but has been useful in some patients [79].

Phototesting and Photopatch Testing

Both phototesting and photopatch testing may be diagnostically useful in the evaluation of immunologically-mediated photodermatoses. Sensitivity to UV is usually assessed by measuring the minimal erythema dose (MED), which is the amount of UV radiation that will produce minimal erythema. MED can be tested with either UVB or UVA wavelengths but tends to be more reliable for evaluating photosensitivity to UVB. In PMLE, most patients have normal MEDs to UVB and UVA, although some patients have decreased MEDs to UVB and/or UVA. However, photoprovocation testing (repeated exposures to sub-erythemogenic doses of UV radiation for 3–4 days) often reproduces the eruption [58]. Although not necessary for diagnosis, phototesting may be useful in the evaluation of other immunologically-mediated photodermatoses (Table 10.2). Photopatch testing is a procedure in which a typical patch test is performed with addition of UV exposure (usually UVA) upon removal of patches. In addition to evaluation of photo-allergic contact dermatitis, photopatch testing can be useful in the diagnosis of chronic actinic dermatitis [81].

Phototherapy

Along with Mohs micrographic surgery for the treatment of skin cancer and patch testing for the diagnosis of allergic contact dermatitis, phototherapy is among the most quintessential of dermatologic procedures (rarely performed by other medical specialists). Phototherapy refers to the use of artificial UV light to treat skin (and potentially systemic) disorders, a domain that for several decades was based largely on empirical evidence but over time has developed a stronger foundation in the scientific literature.

The major mechanisms of phototherapy in most inflammatory skin disorders, such as psoriasis and atopic dermatitis, are: (1) diminishing effector T cell responses, (2) promoting the development of regulatory immune cells, and (3) restoring normal barrier function, especially in atopic dermatitis [85]. Increasing knowledge and insight derived from photoimmunology have provided cellular and molecular mechanisms that account for phototherapy's beneficial effects (Table 10.3). Both UVB and UVA1 can induce

Table 10.2 Evaluation of photosensitivity disorders

	Phototesting		Photopatch testing	
Disorder	Useful?	Result?	Useful?	Result?
Polymorphic light eruption	Yes	Normal (usually) or decreased MEDs to UVB/UVA	No	N/A
Actinic prurigo	Yes	Low or normal MEDs to UVA > UVB	No	N/A
Solar urticaria	Yes[a]	Broad spectrum sensitivity (hives) to visible and UV light	No	N/A
Hydroa vacciniforme	Yes	Vesiculation/scarring following UVA exposure	No	N/A
Chronic actinic dermatitis	Yes	Delayed dermatitis or pseudolymphomatous response to UVB, UVA and visible light	Yes	Delayed dermatitis, often to sunscreen allergens, topical medicines and Compositae

MED minimal erythema dose

[a]Phototesting in solar urticaria should be performed with caution, by experienced clinicians and only on very small areas, due to the risk of anaphylaxis

apoptosis, and the threshold for causing programmed cell death is much lower for lymphocytes than for other cells. Apoptosis by UVB may be achieved via mutations or activation of death receptors (e.g., Fas/Fas ligand, TNF receptor, TRAIL [TNF-Related Apoptosis Inducing Ligand] receptor) [86]. By contrast, apoptosis by UVA may be mediated through reactive oxygen species, differential killing of Th1 over Th2 cells, or lysis of mast cells [86]. As cited previously, UVB light can induce secretion of cytokines including IL-1, IL-4, IL-6, IL-8, IL-10, and TNF-α, with the last two deemed responsible for immunosuppression [18–22]. UV light also leads to down-regulation of major histocompatibility complex (MHC) and co-stimulatory molecules on antigen presenting cells (APCs) in the skin, making these cells functionally impaired in their ability to stimulate T cell effector function [85]. As cited previously, ultraviolet B also generates regulatory immune cells, the most well-characterized being regulatory T cells which are critical to phototherapy-mediated immunosuppression [34–36]. Regulatory T cells are FoxP3+ and CD4+, and they secrete IL-10 and TGF-beta, which dampen effector T cell and APC function. By contrast, UVA (but not UVB) can inhibit collagen synthesis and metalloproteinase activity, leading to changes in extracellular matrix which makes UVA therapy useful in sclerotic skin diseases [86].

In general, UVB, UVA, and PUVA are useful for treating T cell–mediated inflammatory skin diseases because of the aforementioned mechanisms. PUVA tends to be the most effective but is also the most toxic since it is very mutagenic and thus a risk factor for both melanoma and nonmelanoma skin cancer. Indeed patients treated with PUVA for more than 250 sessions remain at risk for melanoma long after the photochemotherapy has ceased [87]. The commercial availability of light sources emitting high-energy, narrower-range wavelengths (i.e., UVA1 and narrow-band UVB) has led to phototherapy protocols that are less toxic and better matched to treat specific skin diseases. Thus the older modalities of broadband UVB and PUVA have given way to shorter-timed, more efficient narrow-band UVB and safer UVA1 treatments. With respect to HIV infection, there is no compelling proof that UVB or PUVA leads to systemic effects in seropositive patients, although UV has been shown to activate HIV gene expression in vitro [88, 89]. Clinically, NB-UVB and PUVA do not affect HIV viral loads, CD4 count, or risk of infection/malignancy and, therefore, phototherapy is recommended as a first line treatment for psoriasis in patients with moderate to severe HIV infection [90].

Specific therapeutic indications correlate with depth of penetration, which in turn is based on the nature of the absorbing chromophores (Table 10.4). Thus, UVB is most useful for eczematous disorders that primarily involve the epidermis and superficial dermis, such as psoriasis, atopic dermatitis, patch-stage cutaneous T-cell lymphoma, vitiligo, and pruritus due to various causes. For these diseases, narrow-band UVB is the phototherapy of choice since it

Table 10.3 Mechanisms of phototherapy

	UVB	UVA1
Apoptosis	Yes	Yes
Cytokine secretion	Yes	Probably
Regulatory T cell induction	Yes	?
Altered APC function	Yes	?
Extracellular matrix remodeling	?	Yes

Table 10.4 Selected therapeutic indications

NB-UVB	UVA (PUVA and/or UVA1)
Atopic dermatitis	Atopic dermatitis
Psoriasis	Localized cutaneous scleroderma
Vitiligo	Urticaria pigmentosa
Patch-stage cutaneous T-cell lymphoma	Plaque-stage cutaneous T-cell lymphoma
Polymorphic light eruption	Follicular mucinosis
Actinic prurigo	Polymorphic light eruption
Erythropoietic porphyria	Actinic Prurigo
Pityriasis lichenoides	Dyshidrotic eczema
Generalized pruritus	Disseminated granuloma annulare
	Pityriasis lichenoides
	Systemic lupus erythematosus

NB narrow band, *UV* ultraviolet, *PUVA* psoralens plus UVA

Table 10.5 Risks of phototherapy

Risks	UVB	PUVA
Skin aging	Yes	Yes
Skin cancer		
Melanoma	Probably	Probably (>200 sessions)
Non-melanoma	Yes	Yes
Drug photo-sensitivity	Rare	Yes
Ocular damage		
Cataracts	No	Yes
Keratitis	Yes	No
Immunosuppression	Yes	Yes
Internal malignancy	No	No

PUVA psoralens plus UVA

approximates, if not equals, the efficacy of PUVA, while avoiding the latter's risks of greater mutagenicity/carcinogenicity and cataracts (Table 10.5). The principal limitation to UVB-based protocols is erythema, which peaks a day after exposure; for this reason, UVB phototherapy is delivered on an every-other-day basis to avoid causing burns.

Unlike UVB, UVA-based protocols allow penetration deeper into the dermis, and thus are useful for treating diseases characterized by fibrosis (e.g., scleroderma and/or morphea, at least during the early inflammatory phase). Counterintuitively, despite the importance of lupus patients avoiding sunlight exposure, UVA1 phototherapy has also been found to have Level A data (randomized controlled trials and/or meta-analysis) supporting its efficacy in systemic lupus erythematosus, probably by reducing interferon production by Th1 cells and antibody production by pathogenic B cells [91]. UVA therapy has also been used for diseases for which UVB is indicated (Table 10.4). In this respect, PUVA may be more efficacious than UVA1, but the latter comes close enough to PUVA's efficacy while avoiding its toxicity. Erythema is generally not a problem with UVA1 treatment so it can be used to treat patients with erythroderma and acute flares of atopic dermatitis. The principal limitations to UVA1 are cost of the equipment and its installation (currently available in only a few centers in the United States) and hyperpigmentation. The risks of phototherapy are dose related, so the greatest frequency of adverse events is associated with high-exposure doses of treatment. Risks are similar to those resulting from chronic exposure to sunlight and are augmented by additional exposure to sunlight. Patients should be selected appropriately and counseled on both the benefits and risks of this treatment modality.

Aside from traditional phototherapy regimens described above, there are several other important light-based treatment modalities which are thought to work based on their effects on the immune system. One particularly important modality in dermatology is extracorporeal photopheresis (ECP), in which blood is cycled through a circuit outside the body and treated with ultraviolet light to induce apoptosis of malignant lymphocytes [92]. This technique is most often used in dermatology to treat erythrodermic cutaneous T cell lymphoma, but it has recently found use in some other disorders as well, including chronic graft versus host disease [93]. Photodynamic therapy (PDT), a commonly used method for treatment of actinic keratoses and some non-melanoma skin cancers, involves the application of a photosensitizer to the skin followed by exposure to light designed to target the photosensitizer. While there are many proposed mechanisms of PDT, its action may in part be related to induction of tumor immunity [94]. Finally, several lasers are being used in treatment of inflammatory skin disease, including the excimer laser (308 nm, within the UVB spectrum) to target recalcitrant lesions of psoriasis or vitiligo [92], and pulsed dye laser (PDL, 585 or 595 nm) to treat conditions such as acne and psoriasis [95].

Conclusion

Ultraviolet light is a major environmental factor that can have both acute and chronic effects on the skin. The study of the effects of UV light on the skin and its associated immune system has resulted in a better understanding of the effects of this physical modality on the skin. Ultraviolet light has an important pathogenic role in skin cancer development (by means of both photocarcinogenesis and photoimmunosuppression) and immune-mediated photosensitivity diseases. However, UV light can also be utilized as an effective therapy in the treatment of certain skin diseases, such as psoriasis and atopic dermatitis, and it shows promise for the treatment of some systemic autoimmune diseases.

Acknowledgement We would like to thank the previous authors of this chapter, Christopher Hansen, Justin J. Leitenberger, and Heidi T. Jacobe, whose contributions established a strong foundation and formed the basis for the organization of this update.

Questions

1. Which of the following wavelengths of light correctly describes the UVA1 spectrum?
   A. 200–290 nm
   B. 290–320 nm
   C. 320–340 nm
   D. 340–400 nm
   E. 400–800 nm

2. Which of the following cytokines is critical to UV-induced immunosuppression?
   A. IL-1
   B. IL-5
   C. IL-10
   D. TGF-beta
   E. Interferon-alpha

3. Phototesting of patients with polymorphic light eruption is most likely to demonstrate which of the following findings?
   A. Decreased MED-A and decreased MED-B
   B. Decreased MED-A and normal MED-B
   C. Normal MED-A and decreased MED-B
   D. Normal MED-A and normal MED-B
   E. Vesiculation and scarring in response to UVA exposure

4. Patch test positivity to para-pheylenediamene (PPD) is most likely in patients with which of the following immunologically medicated photodermatoses?
   A. Actinic Prurigo
   B. Chronic Actinic Dermatitis
   C. Hydroa Vacciniforme
   D. Polymorphic Light Eruption
   E. Solar Urticaria

5. Which of the following presentations is characteristic of actinic prurigo?
   A. A 5 year old boy with itchy papules and excoriations on the face and neck, conjunctivitis, and cheilitis lasting throughout the year
   B. An 8 year old boy with recurrent vesicles on the cheeks that umbilicate and heal with pox-like scars
   C. A 10 year old boy with itchy papules on the ears for 1–2 weeks every spring
   D. A 24 year old woman with itchy papules on the forearms for 1–2 weeks every spring
   E. A 60 year old man with itchy lichenified plaques on the hands, face, and neck

Answers

1. D
2. C
3. D
4. B
5. A

Angiogenesis for the Clinician

11

Michael Y. Bonner and Jack L. Arbiser

Abstract

Angiogenesis, the development of a microvasculature to a neoplastic, inflammatory, or infectious disease process, is a promising therapeutic target that has not been fully exploited. Virtually all processes of therapy impinge on cutaneous angiogenesis. A proper understanding of cutaneous pathophysiology, with respect to angiogenesis, will lead to a more effective use of current therapies for dermatologic diseases, as well as development of novel therapies. With this knowledge, the clinician can make educated guesses on the effect of therapy on a process. The primary disorders of the skin are infectious, inflammatory, and neoplastic. All of these categories are capable of inducing angiogenesis through a limited and overlapping subset of mechanisms, and these mechanisms can be understood by the practicing dermatologist. This chapter discusses the primary mediators of angiogenesis and examples of common skin disorders in which they occur. Antiangiogenic therapy is also discussed. Factors that directly impact endothelium are called direct angiogenesis stimulators or inhibitors, while factors that stimulate nonendothelial cells to make stimulators or inhibitors are called indirect angiogenesis stimulators and inhibitors.

Clinical Angiogenesis

Angiogenesis, the development of a microvasculature to a neoplastic, inflammatory, or infectious disease process, is a promising therapeutic target that has not been fully exploited [1]. Virtually all processes of therapy impinge on cutaneous angiogenesis. A proper understanding of cutaneous pathophysiology, with respect to angiogenesis, will lead to a more effective use of current therapies for dermatologic diseases, as well as development of novel therapies. With this knowledge, the clinician can make educated guesses on the effect of therapy on a process. The primary disorders of the skin are infectious, inflammatory, and neoplastic. All of these categories are capable of inducing angiogenesis through a limited and overlapping subset of mechanisms, and these mechanisms can be understood by the practicing dermatologist. This chapter discusses the primary mediators of angiogenesis and examples of common skin disorders in which they occur. Antiangiogenic therapy is also discussed. Factors that

Key Points

- Angiogenesis is the development of microvasculature in response to an infectious, neoplastic, or inflammatory agent.
- Angiogenesis contributes to the pathogenesis of many common skin disorders, such as acne, psoriasis, photoaging, common warts, and a variety of precancers and skin cancers (basal cell carcinoma, squamous cell carcinoma, actinic keratosis, and melanomas), and wound healing.
- Angiogenesis in the skin is accomplished by recruitment of mesenchymal cells locally and by recruitment of the bone marrow–derived stem cells that can differentiate into endothelial cells.
- Important growth factors for endothelial cells include vascular endothelial growth factor, basic fibroblast growth factor, platelet-derived growth factor, cyclooxygenase-2, and prostaglandin E_2.
- There are a number of angiogenesis inhibitors, many of which are experimental. These agents have great potential as therapeutic interventions for a number of skin diseases.

directly impact endothelium are called direct angiogenesis stimulators or inhibitors, while factors that stimulate non-endothelial cells to make stimulators or inhibitors are called indirect angiogenesis stimulators and inhibitors (Table 11.1).

Infectious Processes

Neither acute nor chronic infections have traditionally been considered angiogenic processes, but the resolution of an acute infection and the maintenance of a chronic infection require an intact angiogenic system. Colonization and invasion of the skin by both gram-positive and gram-negative organisms activates the innate immune system, which results in the production of antimicrobial peptides, some of which also impact endothelial cells. While the activation of the innate immune system is sufficient to control and eliminate many bacterial colonizations and invasions, it is not sufficient to control high inocula of infection or particularly virulent bacterial or viral infections. Therefore, danger signals are transmitted systemically, which allow for cellular reinforcements. The arrival of cellular reinforcements requires an intact vascular system, which can respond to infection by activation of endothelial adhesion molecules (vascular cell adhesion molecule [VCAM], intercellular adhesion molecule [ICAM], E-selectin), allowing neutrophils, lymphocytes, and macrophages to proceed to the site of infection with selectivity (Fig. 11.1).

One of the most graphic demonstrations of the importance of this system is the genetic deficiency of CD11, a neutrophil adhesion molecule that is required for the exit of neutrophils from blood vessels. Patients lacking CD11 develop neutrophilia due to inflammatory stimuli, but these neutrophils are unable to leave the blood vessel, leading to "cold" staphylococcal abscesses and high neutrophil counts due to the inability of these neutrophils to reach the site of infection. In the absence of bone marrow transplantations, these patients succumb to staphylococcal sepsis. Acute infections like colonization of atopic dermatitis by gram-positive organisms e.g. Staphylococcus and Streptococcus cause exacerbation of Th2 type of inflammation. A major player in the vascular permeability of gram-positive infections is angiopoietin-2 (Ang2). Recently we described elevated levels of Ang2 in superinfected atopic dermatitis and demonstrated that the NADPH oxidase inhibitor, gentian violet, is useful in the treatment of atopic dermatitis, due to both downregulation of host Ang-2 and killing of gram-positive organisms [14].

Chronic infections are usually the result of bacteria capable of intracellular colonization (treponemes, mycobacterium, *Bartonella*), viral infections that are capable of latency, or viral oncogenes (human papillomavirus [HPV], herpes virus). Bacterial infections often colonize cells of endothelial or monocyte/macrophage origin, and in retrospect, this should not be surprising. These cells share a common precursor cell in the hemangioblast. As opposed to most extracellular bacteria, chronic bacterial infections of the skin often manifest after a systemic infection, perhaps due to infection of the hemangioblast, with preferential colonization of the infected endothelial cell or monocyte in the dermis. Of note, there are two major receptors for VEGF, the major chemotactic angiogenic factor, and these are differentially expressed in the descendants of the hemangioblasts. Endothelial cells express primarily VEGFR2, while monocytes/macrophages express VEGFR1. Blockade of each of these receptors with specific antibodies impairs angiogenesis, thus demonstrating a role of both endothelial cells and hematopoietic cells in angiogenesis. These blockades likely results in the highly impaired wound healing in patients who are neutropenic.

Recently, tissue hypoxia has been shown to be a factor favoring the persistence of intracellular organisms such as Leishmania. This may also hold true of cutaneous tuberculosis, in which tissue hypoxia may prevent access of bactericidal nitric oxide [21].

Outside of embryonic cells, angiogenesis is affected primarily by the endothelial cell in two ways: through recruitment of endothelial cells from local mesenchymal cells, and

Table 11.1 Description of angiogenesis inhibitors and stimulators

Angiogenesis inhibitors	
Angiostatin	Naturally occurring protein found in some animal species. Angiostatin is known to be cleaved by MMPs [2]. Angiostatin binds to endothelial cell surface adenosine triphosphate (ATP) synthase and angiomotin.
Bevacizumab	A humanized monoclonal antibody. The first commercially available angiogenesis inhibitor. Inhibits the actions of VEGF by binding directly to VEGF-A. Used primarily for colorectal cancer [3]. Usually used along with combination drug chemotherapy.
Celecoxib	A nonsteroidal anti-inflammatory drug (NSAID). Highly selective COX-2 inhibitor. This selectivity helps reduce stomach ulcers.
Curcumin	Anti-inflammatory properties are due to inhibition of eicosanoid biosynthesis. Interferes with the activity of the transcription factor NF-kB, which has been linked to a number of inflammatory diseases and tumor survival [4, 5].
Epigallocatechin gallate	A flavanoid class molecule that acts as a powerful antioxidant and protects against oxidative stress and free radical damage.
Endostatin	A C-terminal fragment derived from type 18 collagen. It is a broad-spectrum angiogenesis inhibitor that interferes with the proangiogenic action of growth factors, bFGF and VEGF.
Imatinib mesylate	Acts by inhibiting particular tyrosine kinase (TK) enzymes, instead of nonspecifically inhibiting rapidly dividing cells. It occupies the TK active site, leading to a decrease in bcr-abl transformation. Imatinib mesylate is especially useful in that it is one of the few tyrosine kinase inhibitors with appropriate selectivity and limited toxicity. Studies show that imatinib may be also useful in treating smallpox [6].
Honokiol	Melanoma therapy under development. Relevant in that IFN-α, the only widely prescribed adjuvant therapy for melanoma, has marked side effects. A biphenolic ring with an ortho-allyl moiety, honokiol induced caspase-dependent cell death in B-CLL cells [7] and a variety of melanoma cell lines. Mechanism of action is likely direct inhibition of GRP78 and activation of Sirt3 [8].
Silymarin	Silymarin consists of a family of flavonoids commonly found in the dried fruit of the milk thistle plant. Extensive research has shown that silymarin can suppress the proliferation of a variety of tumor cells. This is accomplished by inhibition of cell-survival kinases (AKT and MAPK) and inhibition of inflammatory transcription factors (NF-kβ). It can also downregulate gene products involved in the proliferation of tumor cells (COX-2), invasion (MMP-9), angiogenesis (VEGF), and metastasis [9].
Thalidomide	Thalidomide inhibits the release of TNF-α from monocytes and modulates other cytokine action. Thalidomide may act to heal aphthous ulcers by inhibiting angiogenesis and promoting reepithelialization [10]. Thalidomide is also useful in the treatment of multiple myelomas, autoimmune diseases, and leprosy [11].
Gentian violet	Occupies the chemical class of triphenylmethane dyes. Once used as a topical antiseptic, gentian violet is experiencing a reawakening as a nox4 inhibitor. Potentially useful in the treatment of melanoma, eczema, psoriasis, and verruca vulgaris [12–14].
Solenopsin	Alkaloidal component of fire-ant venom. Inhibitor of phosphatidylinositol-3–kinase signaling and angiogenesis [15–17].
Rapamycin	Macrocyclic triene antibiotic, also known as sirolimus, possessing immunosuppressant and antiproliferative properties. Works through inhibition of mTOR, leading to interruption of IL-2 signaling and a cell cycle arrest at G1–S [18]. In preliminary trials for treatment of angiomyolipomas and brain tumors associated with tuberous sclerosis [19]. Used in the treatment of Kaposi's sarcoma in patients receiving renal transplants [20].
Angiogenesis stimulators	
Vascular endothelial growth factor (VEGF)	The upregulation of VEGF is the main operator in the physiologic response during exercise. Muscle contraction increases the blood flow to the affected areas. This increased flow causes an increase in the mRNA production of VEGF receptors 1 and 2. This increase in receptors increases the signaling cascades related to angiogenesis.
Basic fibroblast growth factor (bFGF)	Basic fibroblast growth factor is a member of the fibroblast growth factor family. In normal tissue, basic fibroblast growth factor is present in basement membranes and in the subendothelial extracellular matrix of blood vessels. bFGF stays membrane-bound as long as there is no signal peptide. During both wound healing of normal tissues and tumor development, the action of heparan sulfate–degrading enzymes activates bFGF, thus mediating the formation of new blood vessels (angiogenesis).
Matrix metalloproteinase (MMP)	MMPs help degrade the proteins that keep the vessel walls solid. This proteolysis allows the endothelial cells to escape into the interstitial matrix as seen in sprouting angiogenesis. These enzymes are highly regulated during the vessel formation process because this destruction of the extracellular matrix would destroy the integrity of the microvasculature. MMP2 and MMP9 are the two proteinases linked to angiogenesis.
Cyclooxygenase-2 (COX2)– prostaglandin E_2 (PGE_2)	COX-2 inhibitors are a class of nonsteroidal anti-inflammatory drugs (NSAIDs) that selectively block the COX-2 enzyme. This action impedes the production of the chemical messengers (prostaglandins) that cause the pain and swelling of arthritis inflammation. Being that COX-2 inhibitors selectively block the COX-2 enzyme and not the COX-1 enzyme, these drugs are uniquely different from traditional NSAIDs.
Platelet-derived Growth factor (PDGF)	PDGF is a dimer that activates its signaling pathway by a ligand-induced receptor dimerization and autophosphorylation. PDGF has provided a market for protein receptor antagonists to treat disease. These antagonists include specific antibodies that target the molecule of interest.

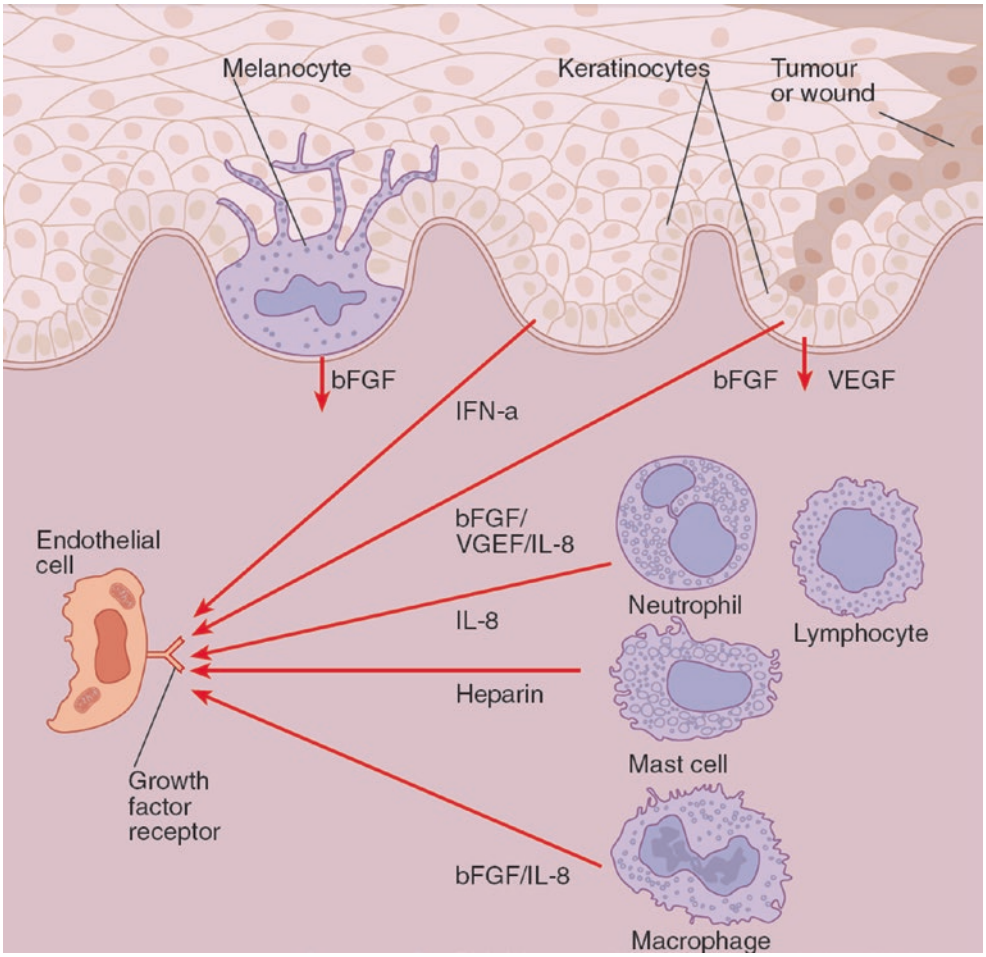

Fig. 11.1 Basement membrane-reservoir of acidic fibroblast growth factor (aFGF) and basic fibroblast growth factor (*bFGF*) bound to heparan sulfate proteoglycan leads to the disruption of basement membrane which leads to release of growth factor. Keratinocyte-derived interferon-α (IFN-α) directly inhibits endothelial growth. Upon activation of a growth factor receptor by a growth factor, the endothelial cell is stimulated to proliferate, produce proteases that migrate toward the source of growth factors, and form tubes, the precursors of capillaries

through recruitment and trans-differentiation of bone marrow-derived stem cells into endothelial cells. As cells may be derived from either of these sources, the efficacy of an antiangiogenic treatment is dependent on the source of cells in a particular lesion. For instance, in advanced malignancy, tumor cells can form vascular channels and phenotypically resemble endothelial cells; this process is known as vascular mimicry. Thus, for the development of an efficacious angiogenesis inhibitor, and for a proper understanding of the dynamic and unique nature of a lesion, the mechanisms of angiogenesis must be understood.

One of the cornerstones in the development of angiogenesis inhibitors is the angiogenic "switch." In a given cell, there is a balance between pro- and antiangiogenic signals. As cells become more malignant, a threshold is crossed as the balance shifts toward the proangiogenic state. It follows that cells produce angiogenesis stimulators and direct or indirect inhibitors. The direct inhibitors diminish endothelial cells' development of neovasculature. Indirect inhibitors block the angiogenic stimulatory pathway through inhibition of growth factors such as VEGF or the basic fibroblast growth factor (bFGF), or through blockade of releasing factors such as the corticotropin-releasing factor [22]. All of this functions, in the end, to impair cells' ability to promote angiogenesis.

The regulation of angiogenic growth factors is often complex, but the best elucidated is the regulatory pathways surrounding VEGF. Several stimuli regulate VEGF; on a transcriptional level there are AP1 and Sp1, and on a translational level there are hypoxia-inducible factor 2α (HIF-2α) and mitogen-activated protein kinase (MAPK) (Fig. 11.2). Though much research has focused on inhibition of HIF-1, selective HIF-2α inhibition is emerging as a more vital protein in VEGF transcription, or the inhibition thereof. The fact that HIF1-deficient cells are capable of forming aggressive tumors implicates HIF1-independent processes in VEGF upregulation. Though many specific and selective inhibitors of HIF, akt, and a variety of other VEGF signaling molecules are under development, it must be understood that, like many biologic systems, tumors are dynamic and capable of switching signaling pathways, for example from HIF1-dependence to HIF1-independence.

The major angiogenesis stimulators in the skin are VEGF and bFGF, and the major inhibitor is interferon-α (IFN-α), the latter being a widely prescribed adjuvant therapy for

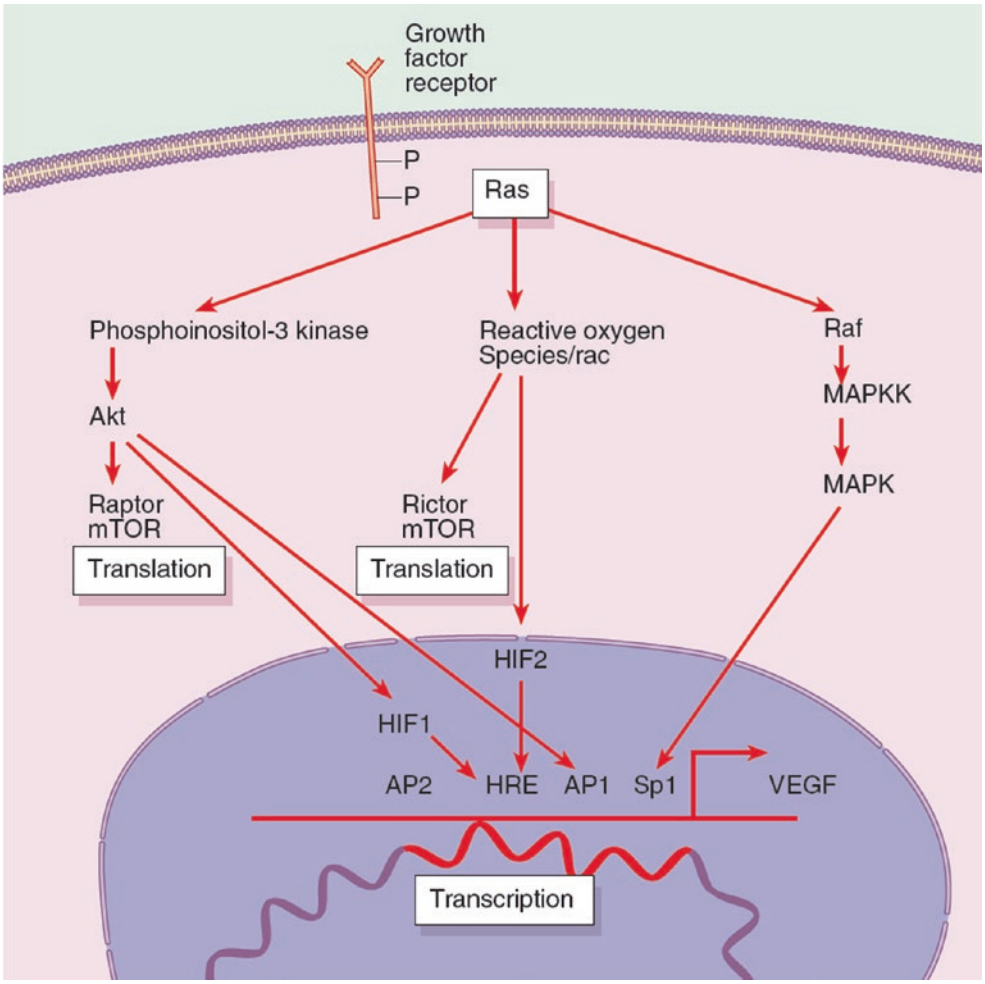

Fig. 11.2 Summary of molecular pathways that lead to vascular endothelial growth factor (*VEGF*) gene expression. As indicated, there are a number of signaling pathways that can activate *VEGF* transcriptions. *HIF*, hypoxia-inducible factor; *MAPK*, mitogen-activated protein kinase; *MAPKK*, mitogen-activated protein kinase kinase; mTOR, mammalian target of rapamycin; *P*, phosphate

melanoma. Both the major stimulants and inhibitors are produced by keratinocytes, helping to provide a barrier between vasculature and the epidermis. When there is contact between the two (barrier disruption), VEGF is increased; when there is occlusion, VEGF is decreased. This lends credence to occlusional therapies.

The Importance of Stem Cell Recruitment in Angiogenesis

The reservoir of endothelial cells for neovascular development is of two sources: local recruitment of endothelial cells, and differentiation of quiescent mesenchymal cells. Exposure of cells to cytokines and other stimuli leads to upregulation of adhesion molecules, which bind immune effector cells; such cells can migrate to sites of infection and inflammation. Withdrawal of the stimulus will lead to apoptosis of the neovasculature. Persistent endothelial stimulation, either through angiogenic growth factors, loss of endogenous factors, or mutations, will cause cells to resist physiologic apoptosis. Recall that mutations involve activation of the phosphoinositol-3-kinase (PI3K)/akt pathway; such activation accounts for neovascular formation in humans.

The recruitment of bone marrow cells is imperative for the success of vascular formation. This notion explains some observations in cancer therapy. A large group of natural products, known as chemo-preventive agents, prevent cancer development but have little effect on advanced neoplasms. Xenograft models can help select for angiogenesis inhibitors that block mesenchymal recruitment, though tumors persist in recruiting local endothelial cells. While an effective treatment may require inhibition of both pathways, recognition of the tumor's dynamic ability to switch signaling pathways may even render recruitment-inhibiting therapies ineffective.

The ligands responsible for endothelial stem cell recruitment in ischemic tissues and tumors likely start with high expression of stromal cell-derived factor 1 (SFD-1). CXCR4 (also known as fusin is a CXC chemokine receptor 4) is the SDF1 receptor, and blockade of CXCR4 is a promising new

course of therapy that has been shown to block revascularization of ischemic tissue. Matrix metalloproteinase 9 (MMP-9) mobilizes the small kit ligand (sKITL). Mobilization of sKITL could be clinically useful in the treatment of acute myocardial infarction.

Recognition by the clinician and pathologist of certain signaling markers could be vital in the early detection of aberrant cells. Angiopoietin-1 (ang1) and angiopoietin-2 (ang2) have antagonistic effects: the former binds Tie-2 to inhibit vascular permeability, while the latter binds Tie-2 to stimulate vascular permeability. Hemangiomas of infancy and the hemangioma-like verruga peruana both show elevated levels of ang2. Work by Arbiser et al. suggests that hemangiomas arise from an unknown event, causing rapid stem cell recruitment from bone marrow (Fig. 11.3). A similar situation likely exists in high-malignancy tumors. Thus early detection of alterations in ang2 expression could be developed as a diagnostic tool for early detection of tumors.

Hemangiomas exhibit a characteristic natural involution after several years. This is likely due to a decreased VEGF expression leading to apoptosis. This parallels the apoptosis observed in endothelial cells during menstruation upon lessening of estrogen signaling. This fate of the hemangioma illustrates the potent response toward removal of proangiogenic, specifically VEGF, signaling.

The beta blocker propranolol was accidently discovered to cause hemangioma regression, and has become the treatment of choice for large hemangiomas of infancy [12, 23–25]. Thus, it is possible that hemangiomas can be inhibited by beta blocker independent modes of action, and that beta blockade per se is not essential to the activity of propranolol for hemangiomas.

Inflammatory Angiogenesis

Inflammatory skin conditions can be separated into two categories. Those expressing a predominance of interferon gamma (IFN-γ), interleukin-12 (IL-12), and interferon-inducible protein 12 (IP-12) are classified as Th1. Psoriasis is considered Th17+, with IL-17 being a mainstay of inflammation. Those expressing predominantly IL-4, -5, -6, and -10 are classified as Th2, such as systemic inflammatory

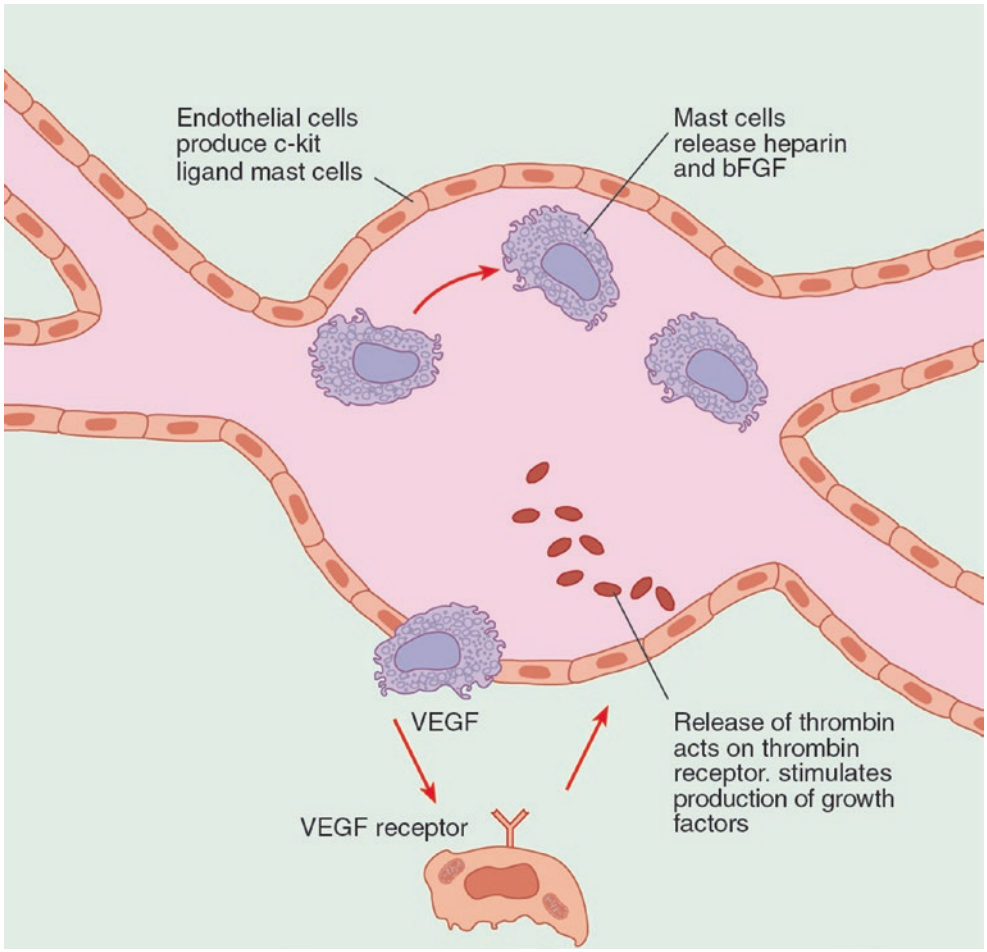

Fig. 11.3 A model for angiogenesis in hemangiomas. This model demonstrates interaction between endothelial cells. Most cells and stem cells that are recruited from bone marrow are induced to differentiate into endothelial cells

infiltrates of lymphocytes, mast cells, granulocytes, and macrophages. Both conditions show excess angiogenesis (despite the presence of antiangiogenic IL-12 in Th1 disorders), showing the potential utility of angiogenesis inhibitors for treatment, not merely of malignant neoplasms, but also in a wide range of dermatologic disorders.

The Role of Angiogenesis in Major Skin Disorders

Acne Vulgaris

Acne is the most common cutaneous disorder in the United States. This disorder accounts for over 10% of all patient encounters with a primary care physician. While the number of cases of acne vulgaris in adolescents has remained relatively stable over the past decade, the number of cases of adult-onset acne is increasing. The majority of debilitating effects of acne are psychological, with embarrassment and anxiety being among the top reported symptoms. Scarring is not uncommon and contributes to the lifelong effects of a moderate to severe case.

The role of MMPs in acne has been somewhat unclear in recent work, though it appears that they are involved in acne progression. The source of MMPs in acne appears to be keratinocytes [26] or neutrophils.

Treatment of acne includes both topical and systemic therapies. For treatment of noninflammatory comedones, topical retinoids such as tretinoin, adapalene, and tazarotene are often prescribed. Salicylic acid also has proven comedolytic activity. The most prominent therapy, both over-the-counter and prescription-based, is topical benzoyl peroxide. Some patients experience increased inflammation due to the presence of *Propionibacterium acnes* in sebaceous follicles. Treatment of such cases usually involves topical antibiotics such as clindamycin or erythromycin. It should be noted that to lessen the opportunities for the generation of antibiotic-resistant bacteria, treatments should be coupled with benzoyl peroxide [27, 28]. In severe cases of inflammatory acne, patients can be prescribed system isotretinoin. There are prescribing restrictions for this drug that are left to the discretion of the physician. Blue light and laser therapy are expensive and unproven treatments for acne should be avoided pending further data.

Psoriasis

Psoriasis is a common cutaneous disorder characterized by erythematous papules and silvery-scaled plaques. Though not entirely understood, the pathophysiology of clinical psoriasis tends to result from hyperproliferation and abnormal differentiation of epidermal keratinocytes, accompanied by inflammatory cell infiltration and vascularization. This remodeling resembles a prolonged wound response, with many reparative and remodeling processes being utilized [28] (Fig. 11.4).

To follow the wound healing analogy presented by Nickoloff, et al. [28], tumor necrosis factor (TNF), VEGF, IL-23, and transforming growth factor (TGF) are present in high levels in psoriatic tissue. Though these cytokines are

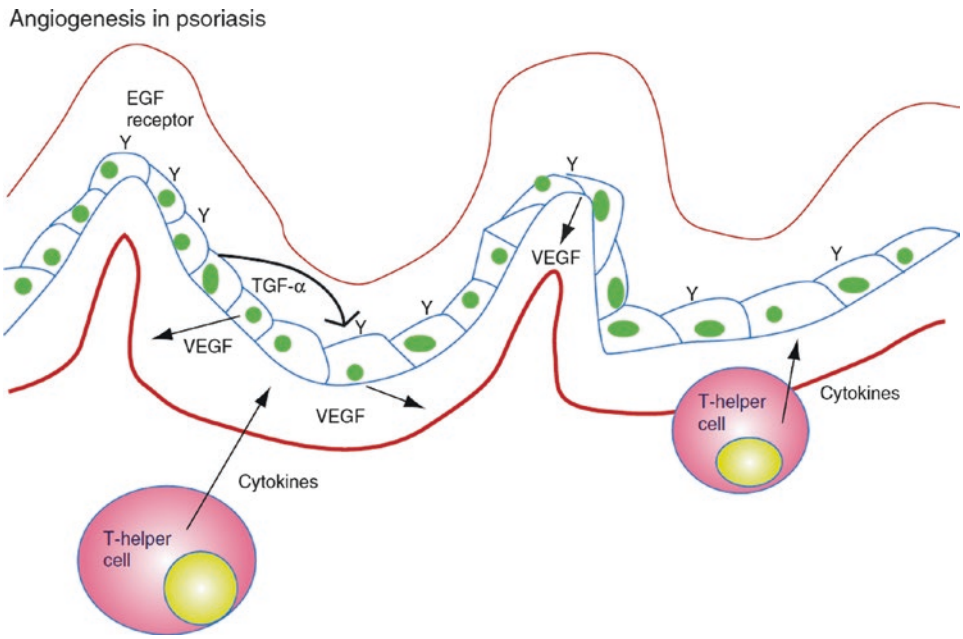

Fig. 11.4 Psoriasis is an example of chronic inflammation that drives excessive angiogenesis. It is a result of T cells and keratinocyte interactions, resulting in *VEGF* production, which then impacts endothelial cells

present in healthy skin, the exaggerated angiogenic response and epidermal thickening draws a definite line between healthy epidermal/dermal signaling and pathologic psoriatic skin. Genetic susceptibility plays a major role, as evidenced in the Koebner phenomenon, which describes an outbreak of psoriatic lesions on genetically susceptible patients upon mild trauma applied to the skin. Expression of TGF is a relevant early event in the formation of psoriatic lesions. Such expression leads to upregulation of VEGF, which promotes angiogenesis and changes in blood vessel morphology. In fact, elevated levels of VEGF are noted in lesional keratinocytes in psoriasis [29]. Accordingly, the angiopoietin (Ang)-Tie signaling pathway is activated in psoriasis, leading to vascular remodeling, formation, and invasion. To view the whole picture, VEGF expression leads to increased vascular permeability and capillary diameter. Once this angiogenic "switch" is turned, alterations in ang1/ang2 expression allow for increased vascular proliferation. Tumor necrosis factor provides differential direct regulation of the Tie2 signaling pathway. Tumor necrosis factor and ang1/ang2 allow for vascular survival and maintenance during this proliferative phase [30].

The increased angiogenesis in the early phases of psoriasis formation allows for the proinflammatory response that will follow. It is important to note that psoriasis is not simply an epithelial hyperplasia growth along the lines of carcinoma, but rather a metaplastic exaggerated wound response.

More recently, additional cytokines such as IL-17, IL-22, and IL-23 have been implicated in the pathogenesis of psoriasis. Based upon the involvement of IL-23 in psoriasis, ustekinumab a monoclonal antibody to the common p40 subunit of IL12- and IL-23 has been used extensively for psoriasis [31].

Treatments of psoriasis are varied, and include topical and systemic corticosteroids, immunomodulators such as cyclosporine and methotrexate, TNF blockers, and topical therapies such as calcipotriene. A long-trusted treatment has been topical coal tar treatment, and it is supposed by Arbiser that carbazole is the active ingredient in coal tar–mediated psoriasis treatment [32].

Ultraviolet light is one of the more popular therapeutic methods. Experimental treatments include topical applications of gentian violet, a triphenylmethane dye once used as a topical antiseptic that selectively kills gram-positive bacteria.

Warts (Verruca Vulgaris)

Verrucae are a common clinical manifestation of an HPV infection of epithelial tissue. The common wart or verruca vulgaris, derived from HPV-2, is a benign proliferative lesion manifesting as a raised hyperkeratotic papillomous lesion. There are many HPV subtypes, some seemingly more site-specific than others. Though all humans are susceptible, infections are more common in children and young adults. Infection occurs through skin-to-skin contact, with macerated sites predisposing one to infection. Human papillomavirus infections from HPV-16 or HPV-18 are considered high risk as HPV-16 and HPV-18 are carcinogenic. Accordingly, there exist in all HPV infections proangiogenic signaling. There is no consensus on which cytokines actually stimulate the angiogenesis and vasodilation seen in HPV^+ skin, as VEGF is commonly found in healthy uninfected human skin as well [33]. It is known that HPV-2 DNA is correlated with increases in angiogenesis [34], but it is not confirmed whether or not VEGF is responsible for verruca angiogenesis. However, VEGF is implicated in the angiogenesis of HPV-induced cervical tumors. Though it is unconfirmed at this time, VEGF overexpression is the likely initiator of wart microvascularization in the common HPV-2 infection (Fig. 11.5).

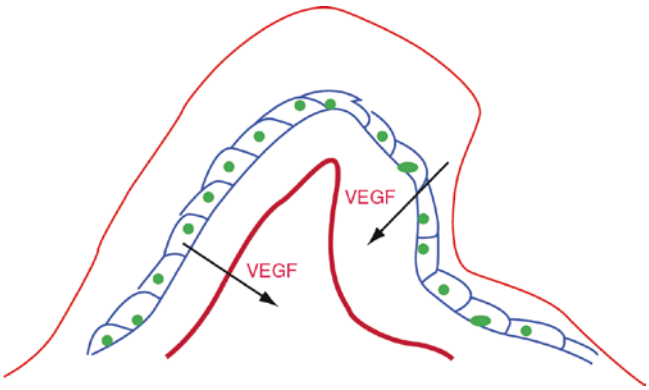

Fig. 11.5 Angiogenesis in common warts is the result of overproduction of *VEGF* by hyperproliferating epidermal keratinocytes

Current therapies for cutaneous nongenital warts include debridement accompanied by freezing with liquid nitrogen, treatment with salicylic acid, bichloracetic acid, or cantharidin. Flat warts are treated with cryotherapy, 5-fluorouracil, or tretinoin, while filiform warts are generally treated with a snip excision. Imiquimod is a common topical treatment for anogenital warts, working through local cytokine induction (including the antiangiogenic cytokine interferon-α). Currently, we combine debulking plus the combination of gentian violet and imiquimod for the treatment of warts. Debulking allows decreased tissue hypoxia, which is in itself immunosuppressive [13]. Gentian violet, which is used to inhibit angiogenesis, may promote dendritic cell maturation and effective presentation of viral antigen, while imiquimod promotes interferon alpha production through TLR7 agonism.

Basal Cell Carcinoma

Basal cell carcinomas (BCCs) occupy a classification of skin cancers known as the nonmelanoma skin cancers (NMSC). This classification extends to squamous cell carcinomas (SCCs) and BCCs almost exclusively. The causes of BCCs vary, but are largely attributed to overexposure to ultraviolet (UV) light, genetic predisposition (illustrated in an extreme case by xeroderma pigmentosum), and possibly HPV infection.

The main effector of angiogenesis in BCCs appears to be the basic fibroblast growth factor (bFGF), which occupies a small family of peptides including the acidic fibroblast growth factor (aFGF) and the Kaposi fibroblast growth factor (kFGF). The fibroblast growth factors (FGFs) are small molecules, ranging from 18 to 21 kd. These molecules bind heparin and interact with a family of four receptors [22]. In mice that were irradiated with UV light, upregulation of bFGF rather than VEGF was noted. Considering that UV overexposure is considered one of the primary causes of BCCs in humans, this finding may underlie the cutaneous angiogenesis behind UV-induced tumors. An introduction of signaling peptides that convert bFGF into an oncogene with the capability of malignant transformation. Basic FGF shows baseline limited expressivity in normal epidermis. However, studies have found diffuse and strong bFGF immunoreactivity in BCCs. It is known that SCCs produce a FGF-binding protein that localizes bFGF, and BCCs could work along a similar pathway.

Therapy and treatment modalities for BCCs vary, but surgical excision still remains the most reliable treatment for a primary or recurrent tumors. Among the surgeries, the most prevalent methods are cryosurgery, curettage and electrodissection, and Mohs' micrographic surgery (MMS). The latter has some marked advantages, especially in that it affords a much higher confidence in a clear border. Studies have shown that MMS does not provide significantly lower rates of recurrence, but the cosmetic sensitivity of MMS often tips the scales. It is most useful on tumors of the face, neck, head, and hands. As with all surgeries, the cosmetic and practical outcome of the procedure is largely influenced by the skill of the surgeon. Adjuvant therapy for BCCs includes radiation therapy (RT), or topical treatment with imiquimod or 5-fluorouracil.

Small molecules of sonic hedgehog have entered the clinic, including vismodegib, an antagonist of the receptor smoothened. Vismodegib has been used in both inoperable/metastatic BCC and for basal cell nevus syndrome [35].

Regression of both of these have been seen, although resistance is common in large BCCs, likely due to both intrinsic (mutant smoothened) and acquired resistance. A major side effect is altered taste (dysgusia), which may reflect a requirement for active sonic hedgehog signaling for taste bud activity [36].

Squamous Cell Carcinoma

Squamous cell carcinomas are the second member of the class of NMSCs, and they result from malignant proliferation of keratinocytes in the epidermis. The tumors present as a hyperkeratotic nodule, papule, or plaque, closely resembling actinic keratoses. The angiogenic pathophysiology of an SCC involves dual signaling for neovascularization, blood vessel permeability, and vasodilation by both VEGF and bFGF [1]. It is theorized that the NMSCs are the result of UVB radiation, while melanomas result from mostly UVA radiation. Despite the fact that SCCs overexpress both VEGF and bFGF, they are predominantly locally invasive. The most effective treatments are surgery, with reasonable effectiveness following a topical treatment with imiquimod of 5-fluorouracil. Patients must be given careful follow-up exams to ensure complete resection of all tumor tissue.

Photoaging

Photoaging is the overall process of skin aging due to UV exposure. It is characterized by wrinkle formation, blistering, and reduced recoil capacity. The cause of photoaging is likely matrix degradation or remodeling due to overexposure to UV light. The most common source of matrix degradation or remodeling in most people is chronic sun exposure. Matrix metalloproteinases secreted by dermal fibroblasts and keratinocytes are generally considered responsible for the matrix remodeling. The MMPs are zinc-dependent endopeptidases in a subclass of the metzincin superfamily of proteins. The effects of MMP can be inhibited by the tissue inhibitor of MMP (TIMP-1). Another effector of cutaneous photoaging is the serine protease granzyme B (GrB) [37]. Keratinocytes irradiated with UVA simultaneously produced GrB and MMP1. The result of this finding elucidates the complementary actions of MMPs and GrB in matrix remodeling upon prolonged UV irradiation. Therapy and treatment for photoaging is limited.

Actinic Keratosis

Actinic keratosis (AK) is a premalignant lesion occurring on sun-damaged skin. Over many years AKs can progress to SCCs, exemplifying tumorigenesis through loss of tumor suppressor genes. These tumors display increased angiogenesis as the tumor progresses [38]. Angiogenesis inhibitor thrombospondin-1 (TSP-1) is strongly expressed in most AKs [39]. It has been reported that patients treated with sorafenib resulted in inflammation of AK, which in some cases progressed to invasive squamous cell carcinoma [40].

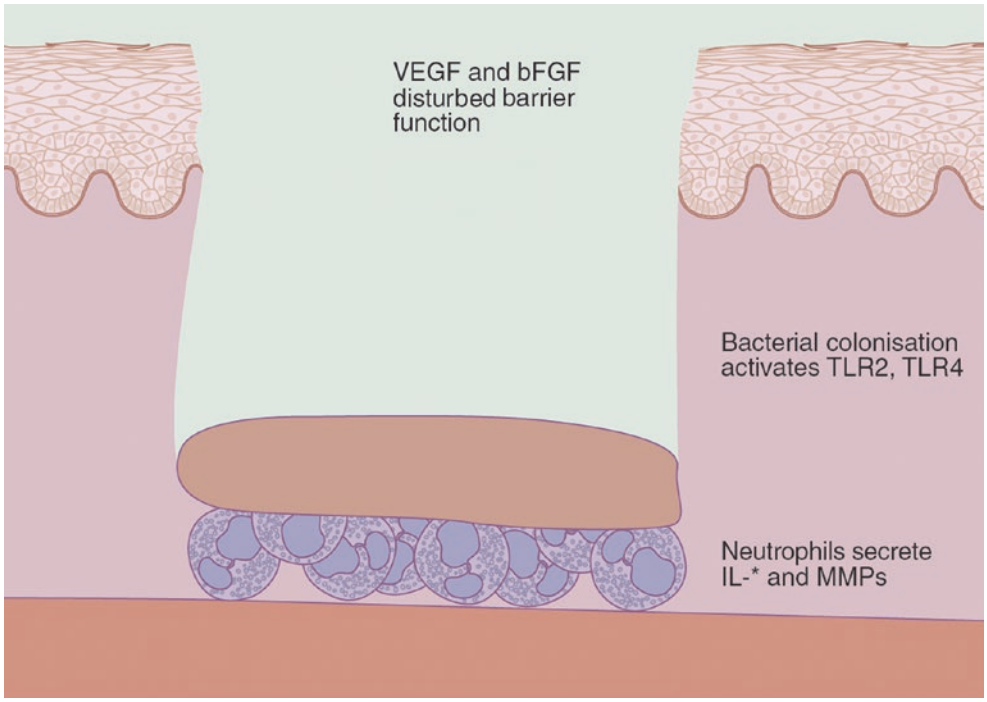

Fig. 11.6 A model for angiogenesis in venous ulcers. In chronic wounds, there is a proinflammatory process that drives angiogenesis. There is also imbalanced collagen production/degradation by fibroblasts, with the result being a chronic wound

The treatment for AK is cryotherapy and, in some cases, a topical treatment with imiquimod or 5-fluorouracil. Physicians should be vigilant in follow-up exams, because these lesions are a risk factor for NMSC.

Ulcers

Chronic skin ulcers occur in approximately 1 million people in the United States. Little is known about the pathways leading to degeneration of tissue and ulcer formation, though common theories connect degeneration to inadequate circulation and ischemia—elements in most dermal ulcers. Collagen is the primary component of mechanical strength in most tissues. Collagen stability is dependent on adequate oxygen supply. In ischemic skin, biochemical mechanisms of tissue repair are activated, with increases in lactate, TGF-β, VEGF, collagen synthesis, and MMP-1 and -2. The upregulation of VEGF and MMP (primary angiogenesis stimulators) are known to signal increased angiogenesis to the location. In some cases unstable collagen molecules are synthesized together with upregulated MMPs, resulting in collagen denaturation, defective angiogenesis, weaker skin, and predisposition to ulceration [41].

In chronic ulcers, slow and abnormal healing occurs due to biochemical and physiologic defects of the local tissue. The inflammatory phase may be prolonged, possibly with decreases in collagen synthesis by fibroblasts and increased levels of MMPs (Fig. 11.6). Epithelial cells and fibroblasts are senescent at the wound edges, and do not respond to growth factor signals such as platelet-derived growth factor (PDGF) or TGF-β. Nonhealing ulcers including diabetic, venous stasis, and pressure ulcers, can be characterized by inadequate wound granulation, and thus inadequate angiogenesis. In diabetic ulcers, glucose is antiproliferative, which causes loss of angiogenic stimulators, such as PDGF-BB, TGF-β, and ang-1. In pressure ulcers, tissue compression and vasoconstriction result in poor tissue perfusion. In venous stasis ulcers, fibrin cuffs around capillaries cause local hypoperfusion and also may sequester growth factors.

Ulcers are commonly treated through mechanical and compression therapy. Topical treatments vary, but include occlusive therapy, topical debriding agents, PDGF, and topical antibiotics. Gentian violet can be used topically to decrease inflammation in skin ulcers (JLA, 2010). In some cases, surgery (skin grafting or transposition skin) may be necessary. However, preventative care remains the best way to avoid development or exacerbation of skin ulcers.

Melanoma

Melanoma is the sixth most common cancer in the United States, with rates of occurrence increasing faster than those of any other cancer. Some risk factors for melanoma include overexposure to UVA radiation, sensitive skin type, immunosuppression, family history of melanoma, dysplastic mole syndrome, multiple common or atypical nevi, and exposure to positive mutagens.

Melanoma is infamous for its poor prognosis and resistance to treatment. Melanoma tends to metastasize via the lymphatic vessels to the areas surrounding the tumor and to draining lymph nodes. Overexpression of angiogenesis factors such as VEGF-A, FGF-2, IL-8, PDGF, and ang2 have been observed in human melanoma. VEGFA-transfected melanomas are

characterized by increased angiogenesis and tumor growth. Importantly, several receptors previously thought to be exclusively expressed on endothelial cells such as VEGFR-1, VEGFR-2, and Tie-2 are also expressed in different tumor cells. Recent experiments implicate the Tie-2 signaling pathway as an important angiogenesis modulator in melanoma. Ang1/ang2 are ligands that (de)activate the Tie-2 pathway. Dominant Ang-2 expression against ang-1 through Tie2 receptor in the presence of VEGF plays a critical role in initiating early neovascularization [42]. Akt/PI3K has emerged as a critical pathway downstream of Tie2 that is necessary for cell survival effects as well as for chemotaxis, activation of endothelial nitric oxide synthase, and perhaps for anti-inflammatory effects of Tie2 activation. Mitogen-activated protein kinase (MAPK) activation has also emerged as a pathway that may be responsible for the morphogenetic effects of Tie2 on endothelial cells.

Several experimental approaches to treat melanoma using angiogenesis inhibitors have been reported. Besides the surgical modalities for the removal of melanoma, the common medical treatment modalities include adjuvant therapy with IFN. However, due to the marked side effects of IFN, many patients do not complete the full course. Cheaper, more effective, and safer methods under study include endogenous inhibitors of TSP-1, TSP-1 fragments, TRAIL, TSP-2, IL-12, angiostatin, endostatin, and other compounds such as TNP-470, thalidomide, SU6668, SR25989, solenopsin, honokiol, and batimastat. Triphenylmethane dyes are suspected to suppress Ang2 via nox4 inhibition, and are promising medical therapies for melanoma [13].

Approximately 60 % of melanomas carry mutations in the Braf oncogene. Based upon this, Braf inhibitors and combination Braf/MEK inhibition have been used in the treatment of metastatic melanoma. The use of vermurafenib alone led to increased survival, albeit, with the presence of keratinocyte neoplasia, some with Hras mutations. The combination of dabrafenib and the MEK inhibitor trametinib showed superior results with decreased development of keratinocyte neoplasia [43]. However, blockade of ERK/BRaf does not address additional signaling mechanisms in melanoma, such as reactive oxygen/NFkB signaling. Perhaps combinations of reactive oxygen signaling inhibitors and Braf/MEK inhibitors may lead to enhanced survival and cure of melanoma. Reactive oxygen inhibition also leads to suppression of notch signaling, which may be of additional benefit in melanoma [44].

Conclusion

Angiogenesis, or the formation of microvasculature is a fundamental process responsible for tissue homeostasis, and is also a part of many disease processes. Angiogenesis can be manipulated by resetting the balance of pro- and antiangiogenic factors in endothelial cells. Because angiogenesis plays an important role in a number of common skin diseases, experimental agents (mostly angiogenesis inhibitors), have great potential as therapeutic agents.

Questions

1. Which of the following is not an important growth factor for endothelial cells?
   A. angiopoietin-2
   B. basic fibroblast growth factor
   C. cyclooxygenase-2
   D. platelet-derived growth factor
   E. prostaglandin E-2

2. Which signaling pathway does not active vascular endothelial growth factor (VEGF)?
   A. hypoxia-inducible factor (HIF)
   B. interferon (IFN) alpha
   C. mammalian target of rapamycin (mTOR)
   D. mitogen-activated protein kinase (MAPK)
   E. mitogen-activated protein kinase kinase (MAPKK)

3. Overexpression of which of the following angiogenesis factors is not involved in melanoma progression?
   A. Ang-2
   B. FGF-2
   C. IL-8
   D. TRAIL
   E. VEGF-A

4. Mutations involving activation of which pathway accounts for most neovascular formation in humans?
   A. bFGF
   B. IFN alpha
   C. PI3K/akt
   D. reactive oxygen species/rac
   E. Raf

5. Which of the following is true of angiopoietin (ang)-1?
   A. it has antagonistic activity to ang-2
   B. it binds Tie-2 to stimulate vascular permeability
   C. it is stimulated by carbazole therapy
   D. it is stimulated by ultraviolet light therapy
   E. it is stimulated by methotrexate

Answers

1. A
2. B
3. D
4. C
5. A

Cutaneous Neuroimmunology

12

Sarah J. Coates, Erica H. Lee, and Richard D. Granstein

Abstract

Many observations suggest a functional relationship between the nervous system and cutaneous immunology. Experimental work has demonstrated the presence of receptors for nerve-derived factors on epidermal and dermal cells as well as an anatomic relationship between peripheral nerves and both immune and non-immune cells within the skin. The skin contains an extensive network of nerve fibers that both transmit afferent sensory signals to the central nervous system and are also capable of secreting various mediators in the periphery. These mediators include both peptide and non-peptide factors that regulate a variety of processes including blood flow, sensation, temperature regulation as well as other homeostatic processes. There is a large body of evidence that products of nerves regulate, in part, immunity, inflammation and wound healing. In support of a role for products of nerves in the pathophysiology of skin disease, much evidence exists showing a key role for innervation in psoriasis and there is some data indicating a role for nervous system influences in other inflammatory skin disorders. An improved understanding of the relationship between the nervous system and cutaneous immunity may have important therapeutic implications for inflammatory skin diseases including atopic dermatitis, psoriasis, rosacea, acne vulgaris and, perhaps, neoplastic and other disorders.

Keywords

Neuropeptide • Neurogenic inflammation • Cutaneous Immunity • Cutaneous Nerves • Substance P

Introduction

Human skin contains a sophisticated network of nerve fibers and specialized sensory structures that serve to transduce sensations of touch, vibration, temperature and pain. Nerve fibers have dual functions: to transmit afferent sensory impulses to the central nervous system and to secrete mediators into the local environment. While many of these mediators are polypeptides (called neuropeptides), others are non-peptide factors. These factors affect various biological processes including inflammation, immunity, wound healing and perhaps even aging.

Cutaneous neurobiology is an expanding field of research with increasingly appreciated clinical relevance. The presence of neuropeptide receptors on epidermal and dermal cells and the close anatomic relationship of nerve fibers with immune and non-immune cells demonstrate the link between the nervous system and the skin.

Core Messages

- The skin is a complex organ system containing a sophisticated network of nerve fibers and specialized sensory structures.
- Cutaneous nerves release neuropeptides and neurohormones into the local milieu in response to internal and external stimuli. Many appear to serve an immunoregulatory role.
- Neuropeptides play a role in the pathophysiology of common skin diseases such as atopic dermatitis and psoriasis.
- Substance P and calcitonin gene-related peptide are among the most prevalent and multifunctional neuropeptides in the skin.

Background

The classic "triple response" of sensory nerves was demonstrated by Lewis in 1927 [1]. This is seen after the skin is stroked, with production of local erythema (capillary dilatation), followed by the axon-reflex flare to produce erythema (arteriolar dilatation) and a wheal (transudation of fluid). Vasodilatation has been shown to occur following dorsal nerve root stimulation and is inhibited by depleting sensory nerves of neuropeptides with capsaicin, demonstrating the role of nerves in cutaneous inflammation [2]. Furthermore, Bayliss and Bruce noted that patients with defective cutaneous sensory systems could not mount normal inflammatory responses to cutaneously applied inflammatory agents [3, 4]. Similarly, observations that patients with sensory disorders such as postherpetic neuralgia have defective responses to inflammatory stimuli suggest that the cutaneous nervous system modulates inflammation [5].

Anatomy

Highly specialized afferent sensory and efferent autonomic nerve branches innervate the skin [5–7]. The nervous system is split into two main divisions – the central and peripheral nervous systems. The peripheral nervous system (PNS) includes peripheral nerves, sensory nerves and the autonomic nervous system (ANS). The ANS is further divided into the sympathetic, parasympathetic and enteric nervous systems [8].

The sensory component of the peripheral nervous system conveys mechanical and chemical activity to the central nervous system (CNS). Stimuli include external and internal physiologic and mechanical triggers. Afferent unmyelinated C or myelinated Aδ fibers from the dorsal root ganglia innervate the epidermis as fine nerve fibers with free endings that converge in the dermis [5]. Sensory receptors include encapsulated structures such as Pacini, Rufini and Meissner's corpuscles, and nerve fibers with "free-ends." Free nerve endings are in contact with hair follicles, pilosebaceous units, glandular structures and the epidermis. The trunk, extremities, neck and posterior scalp are supplied by nerves derived from the dorsal root ganglia, whereas the upper anterior neck, face and the majority of the scalp are innervated by the trigeminal nerve [9].

Sensory fibers are generally classified into three groups based on their size and conduction velocity. C-fibers are unmyelinated, thin afferent fibers consisting of pain receptors called nociceptors and mechanoreceptors. A subpopulation termed C-polymodal nociceptors represent 70 % of all cutaneous C-fibers and participate in the release of neuropeptides [10]. Aδ-fibers are small, myelinated fibers that innervate the skin although to a much smaller extent than C-fibers. Autonomic nerves represent a minority of the cutaneous fibers. These nerves predominantly generate neurotransmitters such as acetylcholine and catecholamines; however, they also produce neuropeptides including neuropeptide Y (NPY), calcitonin gene related peptide (CGRP), vasoactive intestinal peptide (VIP) and atrial natriuretic peptide (ANP) [2].

Neuropeptides

Neuropeptides (NPs) are a heterogeneous group of polypeptides ranging from 2 to greater than 40 amino acids in size. There are over 50 identified NPs, 11 of which are found in human skin [11]. NPs are released in response to a range of stimuli including pain, temperature and irritation, in order to mediate diverse biologic processes related to injury, inflammation, infection and wound healing. NPs are synthesized in the nerve cell bodies. Their precursors are produced in the endoplasmic reticulum, and then processed and packaged in the Golgi apparatus for eventual transport to the nerve endings. The most abundant NPs in the skin include substance P (SP), CGRP, neurokinin A (NKA), neurotensin, pituitary adenylate cyclase activating polypeptide (PACAP), VIP, NPY, β-endorphin, enkelphalin, somatostatin, galanin, dynorphin, ANP, α or γ-melanocyte stimulating hormone (MSH), parathyroid hormone-related protein (PTHrp), urocortin and corticotrophin-releasing hormone (CRH) [2]. NPs are released predominantly from nerve fibers; however, evidence exists that epidermal and dermal cells also produce neuropeptides and neurohormones. These cells include fibroblasts, keratinocytes, Langerhans cells, macrophages, mast cells, melanocytes, endothelial cells, Merkel cells and leukocytes [2, 12]. Table 12.1 summarizes some of the well-characterized neuromediators found in the skin.

Table 12.1 Neuromediators in the skin

Neuromediator	Source	Receptor	Primary function
Substance P	Sensory nerve fibers Meissner corpuscles Perivascular nerves Mast cells Monocytes Eosinophils	Tachykinin (neurokinin) receptor	Mediates erythema and edema Increases histamine and TNF-α release from mast cells Upregulates cell adhesion molecule expression in dermal endothelial cells Stimulates release of proinflammatory cytokines from keratinocytes
VIP	Sensory nerve fibers Sweat glands Merkel cells PMNs	VPAC1 and VPAC2 receptors	Vasodilation Increases sweat secretion Histamine release from mast cells Keratinocyte proliferation and migration Inhibits Langerhans cell antigen presentation for Th1 responses while augmenting Th2 and Th17 responses
PACAP	Sensory nerve fibers Autonomic nerves Lymphocytes Endothelial cells	VPAC1 and VPAC2 receptors	Vasodilation Down-regulates proinflammatory cytokines in T cells Modulates mast cells Inhibits NF-κB Inhibits Langerhans cell antigen presentation for Th1 responses while augmenting Th2 and Th17 responses
CGRP	Sensory nerve fibers Perivascular nerves Meissner corpuscles	CGRP receptors	Vasodilation Keratinocyte proliferation Histamine release (mast cells) Inhibits NF-κB Inhibits Langerhans cell antigen presentation for Th1 responses while augmenting Th2 responses
POMC peptides	Keratinocytes Melanocytes Langerhans cells Fibroblasts Mast cells Monocytes Macrophages Endothelial cells PMNs Sensory nerves	Melanocortin receptors	Immunomodulation (upregulates IL-10 and antagonizes effects of proinflammatory cytokines) Inhibits NF-κB Melanogenesis
Catecholamines	Autonomic adrenergic nerves Keratinocytes Melanocytes	Adrenergic receptors	Inhibit keratinocyte migration Regulates natural killer and monocyte activity Inhibits Langerhans cell antigen presentation for Th1 responses
NPY	Perivascular nerves Langerhans cells	G protein-coupled Y1-Y5 rhodopsin-type receptors	Vasoconstriction Eccrine sweat production Antimicrobial properties
ATP	Numerous sources with intracellular and/or extracellular activity Keratinocytes Sympathetic nerve fibers	Ligand-gated purinergic P2X receptors G protein-coupled purinergic P2Y receptors	Regulation of cell growth and differentiation Immunomodulation [promotes dermal microvascular endothelial cell production of IL-6, GRO-α (CXCL1) and IL-8 (CXCL8), MCP-1 (CCL2) production; IL-1 release by macrophages] Enhance Langerhans cell antigen presentation

The activities of various neuromediators in the skin account for the ways in which nerves influence cutaneous immunology

Abbreviations: *CGRP* calcitonin gene-related peptide, *IL* interleukin, *PACAP* pituitary adenylate cyclase activating polypeptide, *NF-κB* nuclear factor κB, *POMC* pro-opiomelanocortin, *TNF-α* tumor necrosis factor-alpha, *VIP* vasoactive intestinal peptide, *NPY* neuropeptide Y, *ATP* adenosine triphosphate

The distribution of NPs varies depending on the body site. High levels of SP, NKA and CGRP are found in areas with the greatest tactile sensation. Intermediate levels are found in the neck and face, whereas the lowest levels are present in the groin, arm and thigh [16]. Levels of VIP and peptide histidine methionine (PHM) are also highest in axillary skin, suggesting their role in axillary eccrine sweat production. The location of NPs also varies based upon the layer of the skin in question. SP, NKA and CGRP are found in nerves penetrating the epidermis and the neuropeptides SP, CGRP, VIP and NKA are in nerves innervating dermal structures [9]. NPs bind to specific receptors on nerves and other cell types and, in turn, activate intracellular signaling cascades. NPs are then inactivated by peptidases such as neutral endopeptidase or angiotensin-converting enzyme (ACE) [17, 18].

Delineating the myriad functions of neuropeptides and neurohormones has led to the emergence and explosive growth of a field investigating the intimate relationship between the nervous, immune and endocrine systems and the skin. Terms such as the neuro-immune-cutaneous system are used to imply a relationship between immune and non-immune cells in the skin and between the immune system and the nervous system within the skin [19].

The skin is an ideal organ in which to investigate these relationships due to its location, size and function. As the interface between the external and internal environments the skin has a unique role in modulating and transmitting outside stimuli while maintaining internal homeostasis. As a result, there is increasing attention and focus on the skin as a site for unraveling these connections, applying them to other organ systems and ultimately, using them as a model for therapeutic interventions in several disease states. In this chapter we highlight several NPs and other neural signals, discuss their functions and describe their role in clinical skin disorders (Table 12.1).

Receptors

There are numerous neuropeptide receptors. For example, SP has three receptors, NK_1, NK_2, NK_3. Two receptors have been identified for CGRP (1,2) and NPY has receptors referred to as $Y_{1,2,3,4,5}$ [20]. Most cutaneous cells express several receptor types; to discuss each in detail is beyond the scope of this chapter, and more comprehensive reviews are available [9]. Rather, the receptors most relevant to the skin will be discussed. These include NK_1, preferentially expressed on human keratinocytes [2], VPAC-1R (vasoactive intestinal polypeptide/pituitary adenylate cyclase activating polypeptide 1 receptor) on dermal endothelial cells and Langerhans cells [21], VPAC-2R on keratinocytes and Langerhans cells [21] and melanocortin 1 receptor (MC-1R) on melanocytes, keratinocytes, monocytes, fibroblasts and Langerhans cells [9]. Additionally, CGRP has effects on many cellular components of skin that can be blocked by competitive inhibitors of the type I CGRP receptor (see below) suggesting the presence of CGRP receptors on various cell types within the skin.

Substance P (SP)

SP is the best-characterized neuropeptide. An undecapeptide, it is a member of the tachykinin family along with NKA and neurokinin B (NKB). SP is released from sensory nerves that are in contact with endothelial cells, mast cells, hair follicles and epidermal cells [22]. Its biological effects in the skin are mediated predominantly by the NK_1 receptor. SP receptor-binding leads to activation of phospholipase C, an increase in intracellular calcium and subsequent activation of nuclear factor-kappa B (NF-kB) [23].

SP is a potent vasodilator, accounting for its role in the wheal and flare response in neurogenic inflammation. SP directly acts on vascular smooth muscle and indirectly on the endothelium to enhance the production of nitric oxide, which contributes to vasodilatation and increased vascular permeability [24]. In human skin, SP is also released by free nerve endings in the dermal papilla and epidermis of human fingers, in Meissner corpuscles, and near sweat gland ducts and blood vessels [12]. Receptors for SP are found on mast cells, lymphocytes, leukocytes and macrophages. SP-stimulated macrophages generate prostaglandin E2, thromboxane B2 and superoxide ion, and SP-stimulated keratinocytes release proinflammatory cytokines IL-1α, IL-1β and IL-8 [2]. Furthermore, SP induces histamine release from mast cells, lymphocyte proliferation and chemotaxis, immunoglobulin production and the release of cytokines IL-1, IL-6 and TNF-α [25]. An increase in SP-expressing nerve fibers is seen in inflammatory skin diseases such as atopic dermatitis [26]. SP increases the release of proinflammatory cytokines from keratinocytes and TNF-α, histamine, leukotriene B4 and prostaglandin D2 from mast cells. SP also upregulates IL-2 production to promote T-cell proliferation and induces the expression of the adhesion molecules P-selectin, intercellular adhesion molecule (ICAM) 1 and vascular cell adhesion molecule (VCAM) 1 [2, 26]. Recent evidence suggests that SP also plays a role in regulating cutaneous microflora [27]. SP-treated bacteria populations including *B. cereus* were found to have increased biofilm formation activity. Furthermore, SP enhanced *B. cereus*-induced cytotoxic activity against keratinocytes, evidenced by increased caspase 1 production and morphological changes characteristic of necrosis [27]. The effect of SP on the cutaneous microbiome may influence a variety of skin disorders [27].

Pituitary Adenylate Cyclase Activating Polypeptide (PACAP) and Vasoactive Intestinal Peptide (VIP)

PACAP exists in two forms, PACAP-38 and a truncated form, PACAP-27 [28]. PACAP belongs to the glucagon-secretin family that includes VIP and growth hormone-releasing hormone. PACAP binds to two types of receptors. PAC1 binds PACAP to activate adenylate cyclase and phospholipase C, whereas a second type of receptors, VPAC1 and VPAC2, bind both PACAP and VIP to activate adenylate cyclase [14]. PACAP has the highest immunoreactivity around blood vessels, hair follicles and sweat glands, and has been shown to modulate inflammatory responses in the skin [2].

VIP is a 28-amino-acid peptide that is localized in the deeper dermis in nerve fibers situated around eccrine sweat glands, superficial and deep vascular plexuses and hair follicles [24]. VIP is a potent vasodilator that contributes to the development of pruritus, erythema and edema. VIP also plays a role in the regulation of cutaneous blood flow, the promotion of nitric oxide synthesis, keratinocyte proliferation and sweat production. VPAC-1R (vasoactive intestinal polypeptide/pituitary adenylate cyclase activating polypeptide 1 receptor) is the dominant receptor on human dermal endothelial cells, whereas VPAC-2R is expressed on keratinocytes [2]. Both receptor types are found on Langerhans cells [21].

In a murine model, intradermal administration of PACAP suppressed the induction of contact hypersensitivity (CHS) at the injected site and *in vitro* treatment of epidermal antigen presenting cells inhibits their ability to present antigen for elicitation of delayed-type hypersensitivity (DTH) in previously immunized mice [14]. PACAP also inhibited the ability of Langerhans cells to present antigen in wholly *in vitro* assay systems for a Th1 response [14] . *In vitro* studies suggest this may be due to PACAP-induced suppression of IL-1β release and augmentation of IL-10 production [14]. In a mouse model, VIP also inhibited the ability of epidermal cells enriched for Langerhans cell content to present antigen for elicitation of delayed-type hypersensitivity in previously immunized mice [13]. Furthermore, VIP inhibited Langerhans cell antigen presenting capability in *in vitro* assays of antigen presentation for Th1 responses [13].

The inhibitory effects of PACAP, VIP and CGRP on antigen presentation may occur through suppression of NF-kB, which is known to be involved in regulating transcription of the TNF-α gene [29], as well as CD86 and other pro-inflammatory cytokines [14].

While VIP and PACAP inhibit Langerhans cell antigen presentation for Th1 immune responses, these NPs enhance antigen presentation to generate Th2 cells [30]. *In vivo* promotion of Th2 responses by VIP and PACAP signaling has also been demonstrated through manipulation of VPAC2 expression in a transgenic murine model; overexpression of VPAC2 in $CD4^+$ T cells biased toward Th2 immunity, whereas mice deficient in VPAC2 demonstrated predominance of the Th1 response [31].

Th17 cells are a subset of $CD4^+$ T cells that produce a variety of cytokines of the IL-17 family, as well as IL-21 and IL-22. IL-21 production may lead to further differentiation of more Th17 cells, while IL-22 plays a role in keratinocyte proliferation and epidermal hyperplasia [32]. Some Th17 cells produce IL-17A but only very little IL-22 [33].

Th22 cells are $CD4^+$ T cells that produce IL-22 but not IL-17A. IL-22 is known to act on epithelial cells such as keratinocytes to trigger antimicrobial peptide production [30]. VIP and PACAP have been shown *in vitro* to bias Langerhans cell antigen presentation toward Th17, in addition to Th2 immune responses. Exposure of Langerhans cells to PACAP or VIP followed by antigen presentation to $CD4^+$ T cells led to enhanced production of IL-17A and IL-4 by $CD4^+$ T cells with suppressed production of IL-22 and IFN-γ [30]. Furthermore, after antigen presentation the $CD4^+$ T cell population had enhanced number of cells expressing intracellular IL-17A or IL-4 with decreased numbers of cells expressing IFNγ [30]. In accordance with these findings, the Th17 cell-associated transcription factor RORγT and the Th2-associated transcription factor GATA3 were elevated while T-bet (Th1-associated) was decreased [30].

In vivo studies in which PACAP was applied topically to human skin revealed that PACAP induces marked edema in a concentration-dependent manner [34]. Investigators also injected PACAP intravenously and observed a concentration-dependent vascular response (flushing, erythema and edema) as well as a 2.7 °C rise in body temperature [34]. Together, this evidence suggests a role for PACAP in the vasoactive component of neurogenic inflammation found in skin disorders such as rosacea, urticaria and atopic dermatitis [34].

Recent experiments demonstrated that human keratinocytes significantly upregulated vascular endothelial growth factor (VEGF) production in response to VIP stimulation in a dose- and time-dependent manner [35]. Maximum enhancement of VEGF production was observed with the combination of VIP and IFN-γ stimulation [35]. This mechanism might underlie the angiogenesis and vasodilatation characteristic of lesional psoriasis skin [35].

Calcitonin Gene Related Peptide (CGRP)

CGRP is a 37-amino-acid neuropeptide discovered in 1982 [36]. There are two forms, CGRP-α, or CGRP-1, and CGRP-β, or CGRP-2. In human skin, CGRP is co-localized with SP in nerves in the dermal papillae and free nerve endings of glabrous skin; however, when co-localized with somatostatin, it is found in nerve fibers associated with the

epidermis and perivascular space [24]. CGRP is among the most prevalent cutaneous NPs and is found in association with mast cells, melanocytes, keratinocytes, Langerhans cells and Merkel cells [2, 22].

CGRP inhibits antigen presentation by macrophages [37] and blood-derived dendritic cells [38, 39] and upregulates melanocyte proliferation, dendricity and melanogenesis [19]. Early observations of CGRP-containing unmyelinated nerve fibers in direct contact with the surface of epidermal Langerhans cells suggested an intimate relationship [40] (Fig. 12.1). While CGRP inhibits Langerhans cell antigen presentation in Th1 responses [40], it enhances Langerhans cell antigen presentation for Th2 responses, as evidenced by increased IL-4 production [41]. It also stimulates Langerhans cell production of the Th2 chemokines CXCL17 and CXCL22 while inhibiting the stimulated production of the Th1 chemokines CXCL9 and CXCL10 [40]. CGRP effects on LC antigen presentation for Th1 responses can be inhibited by $CGRP_{8–37}$, a competitive inhibitor of the type I CGRP receptor [42]. Recent *in vivo* studies have corroborated CGRP as a mediator of Th2-type immune responses [43]. The significance of CGRP's role in shifting toward a Th2 immune response is not fully understood.

CGRP is a mediator of neurogenic vasodilatation and a modulator of keratinocyte proliferation and cytokine production [2]. Human primary dermal microvascular endothelial cells (pDMECs) express mRNA for CGRP and adrenomedullin receptors, and recent investigations found that CGRP inhibits lipopolysaccharide-induced production of various chemokines, including IL-8, MCP-1 and GRO-α by pDMECs, as well as by human microvascular endothelial 1 cells (HMEC-1) [44]. These cells were found to express all components of the CGRP receptors at the mRNA level and the effects on chemokine release could be blocked by the type I CGRP receptor antagonist $CGRP_{8–37}$ [44]. CGRP inhibits NF-kB activation in the HMEC-1 cell line [44], and inhibition of NF-kB signaling was found to suppress the production of these chemokines [44]. Accordingly, CGRP treatment also suppresses neutrophil and monocyte chemoattraction by LPS-stimulated HMEC-1 cells [44]. These experiments suggest a role for CGRP in endogenous anti-inflammatory pathways, in addition to its effects on the adaptive immune response [31]. There is also some *in vitro* and *in vivo* experimental evidence that CGRP inhibits inflammation via a pathway that involves rapid upregulation of the inducible cAMP early repressor (ICER) [45]. ICER is a repressor protein that, in dendritic cells, suppresses LPS-induced transcription of genes encoding the inflammatory molecules TNF-α and CCL4, both of which share the quality of having a CRE-kB promoter element [45]. CGRP did not attenuate the expression of genes such as the one that encodes CXCL1 that lack this element [45]. These findings were found to occur in the absence of IL-10, a well-known suppressor of inflammation, suggesting that CGRP suppresses immune responses by cAMP-induced activation of intracellular kinases such as protein kinase A (PKA), providing an alternative to the NF-kB and MAPK pathways as a route by which interference with the downstream effects of toll-like receptor (TLR) signaling ultimately attenuates inflammation [45].

CGRP is involved in ultraviolet radiation (UVR)-induced immunosuppression. In the low dose model of UVB-induced immunosuppression (sensitization to a hapten is impaired at the irradiated site) UVR releases CGRP from sensory neurons to locally impair contact hypersensitivity responses [46]. The release of CGRP after UVR may be triggering mast cells to release stored TNF-α, which in turn downregulates Langerhans cell density and function to impair CH induction [47]. CGRP also contributes to the high-dose or systemic model of UVR-induced immunosuppression (sensitization at a non-irradiated site is impaired) as suppression of CHS responses are inhibited when mice are pretreated with CGRP antagonists [48].

Proopiomelanocortin Peptides

The skin is a source of neuroendocrine hormones of the proopiomelanocortin (POMC) family, termed melanocortins (MCs). POMC hormones include α, β, and γ-melanocyte stimulating hormone (MSH). These are derived from POMC along with adrenocorticotrophic hormone (ACTH) and endorphins. POMC is predominantly synthesized in the pituitary gland; however, it is also present in the skin, expressed by melanocytes, keratinocytes, Langerhans cells, endothelial cells, mast cells and fibroblasts [10]. The cutaneous melanocortin system is well characterized [49] with melanocortin receptor (MC-R) expression in nearly all cell types, including fibroblasts, adipocytes, endothelial cells and mast cells [50]. MC-1R is the most prevalent amongst the five melanocortin receptors, with high affinity for α-MSH and ACTH.

POMC-derived peptides influence several processes including melanogenesis and skin immunity, and are also suggested to have a role in the hair cycle, sebum and eccrine gland function and epidermal proliferation [50]. The known functions of melancortins in cutaneous biology continue to expand with potential clinical applications. Human sebocytes increase lipid droplet formation in response to MCs, suggesting acne vulgaris may be affected. Evidence suggests MCs are involved in keratinocyte proliferation and differentiation, with potential repercussions in regenerative processes [49]. In addition, although the mechanism is not completely understood, it is believed that MSH induces melanocyte proliferation and melanogenesis through engagement of the MC1-R, serving as a substrate or promoter of the enzyme tyrosinase [19].

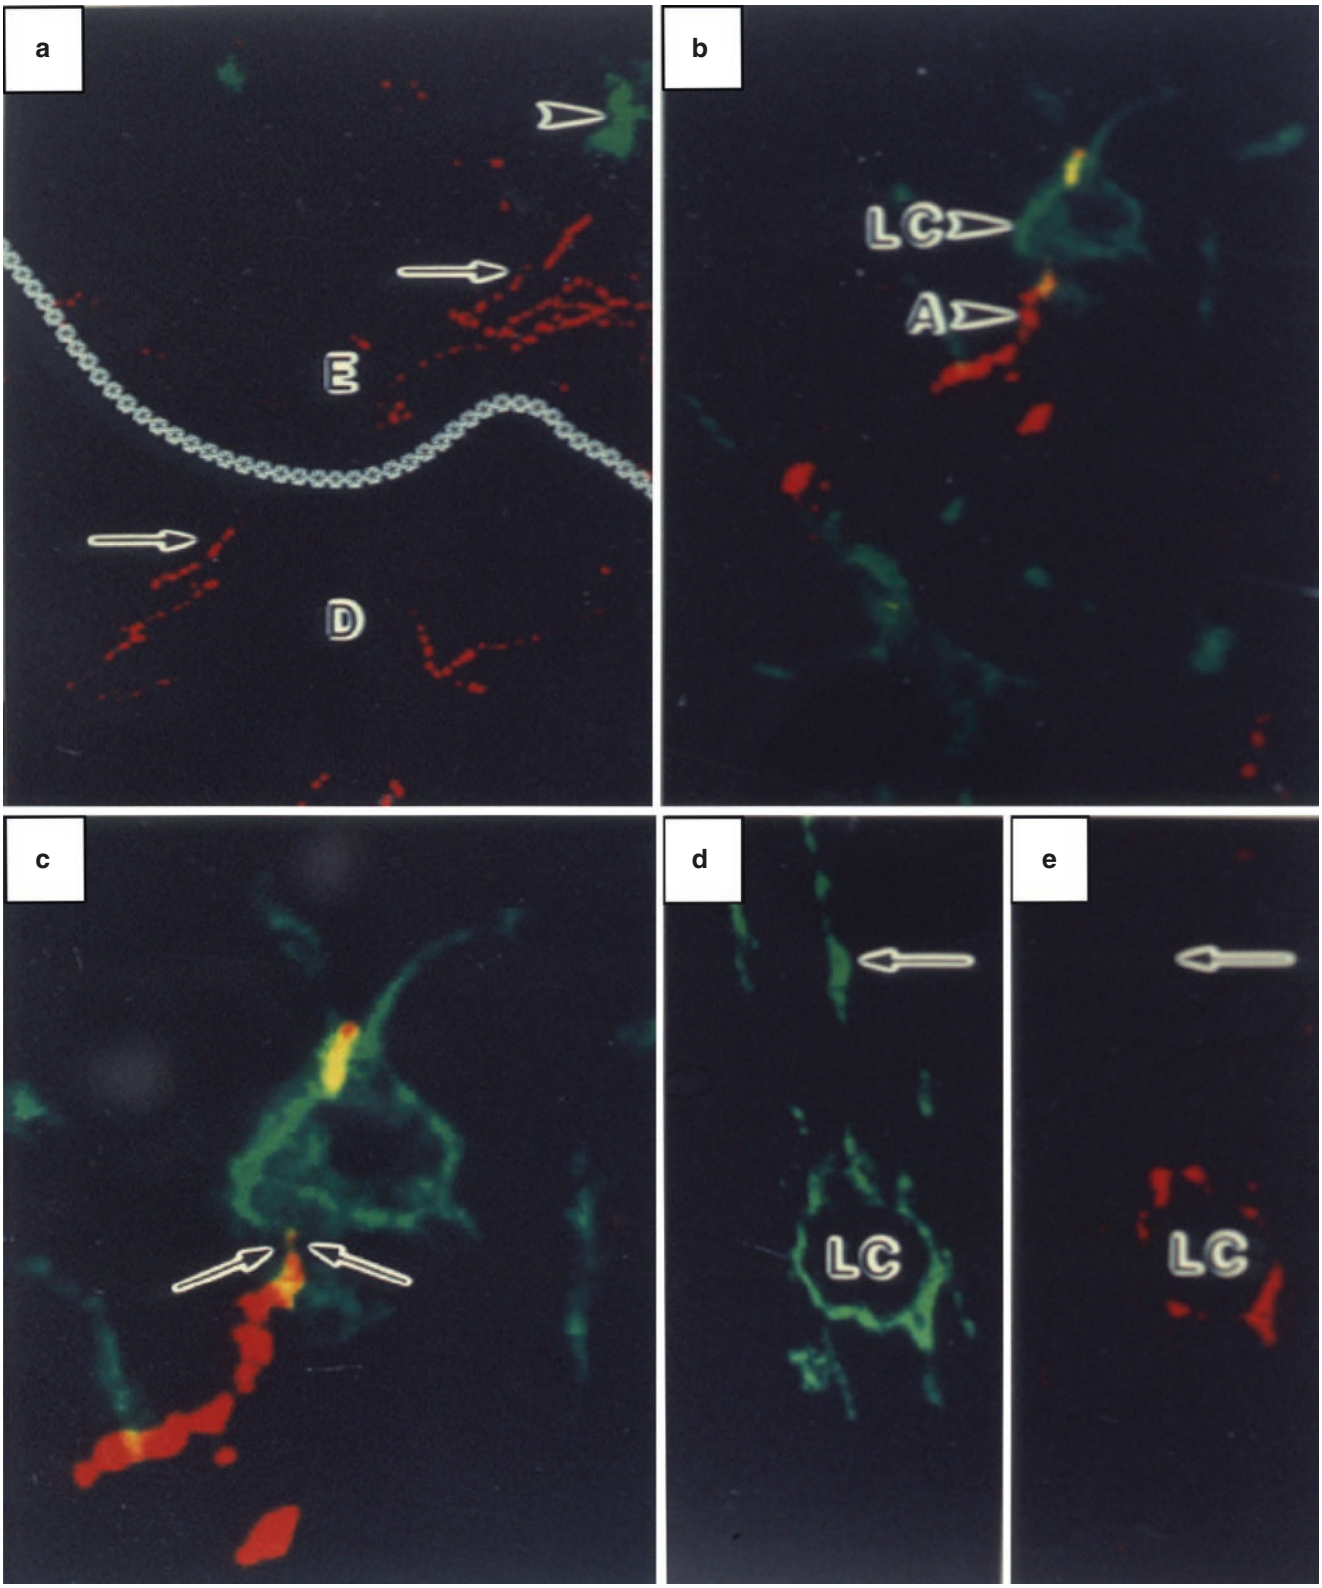

Fig. 12.1 Laser confocal scanning microscopy illustrating the anatomic association between Langerhans cells (LCs) and CGRP-containing nerve axons (*A*; *arrows*) in the dermis (*D*) and epidermis (*E*) (dermal-epidermal junction demarcated by *asterisks*). LCs, shown in *green*, were stained with an antibody against CD1a. Nerves, shown in *red*, were stained with an antibody against CGRP. (**a**) CGRP-positive axons in the epidermis and dermis (*arrows*) and CD1a-positive LCs (*arrowheads*). (**b**, **c**) Apparent contact of CGRP-positive axon and a LC. (**d**, **e**) Single channel analysese of LC CD1a reactivity (*D*) and CGRP staining (*E*). (Reprinted with permission from Hosoi et al. [40])

POMC mRNA and related peptides such as α-MSH and ACTH are upregulated by UVR. Mid-range UVR [UVB radiation (280–320 nm)] upregulates ACTH, α-MSH and MC-1R in epidermal melanocytes and increases MC-1R expression in cultured normal and malignant melanocytes and keratinocytes, the latter associated with increased melanogenesis in cell culture and *in vivo* [9, 49]. The melanogenic and dendritogenic effects of α-MSH and ACTH on the skin and follicular melanocytes may correlate with tanning and hair color, respectively [49].

POMC-derived peptides play a role in immunity and inflammation, especially α-MSH. α-MSH is anti-inflammatory and may be involved in host defense. More specifically, it has been shown to inhibit neutrophil migration and block the production of inflammatory cytokines, including IFN-γ, TNF-α, IL-1 and IL-6, by macrophages [51]. In studies of human microvascular endothelial cells, α-MSH has been found to suppress lymphocyte adhesion and inhibit lipopolysaccharide-mediated upregulation of ICAM-1, CAM and E-selectin receptors [51]. α-MSH also inhibits contact hypersensitivity and induces hapten-specific tolerance through IL-10 upregulation in a murine model [52]. Recent experiments demonstrated that α-MSH encourages dendritic cells to induce a T regulatory cell immune response, which in turn suppressed the proliferation of and cytokine secretion from Th17 cells obtained from individuals with psoriasis [53].

α-MSH has also been found in a murine model to augment antitumoral immunity by enhancing $CD8^+$ T cell cytolytic activity via interactions at the MC-1R [54]. These studies demonstrated that α-MSH-stimulated $CD8^+$ T cells were associated with significant *in vitro* as well as *in vivo* anti-tumor effects [54]. In addition, the anti-TNF and antimicrobial effects of α-MSH suggest it may reduce replication of the human immunodeficiency virus (HIV), because TNF promotes HIV replication [55]. Furthermore, its anti-inflammatory properties in animal models of hepatic inflammation and arthritic processes suggest that it may be an important anti-inflammatory agent in the treatment of inflammatory diseases in humans [56–58].

Catecholamines

Sympathetic fibers of the autonomic nervous system travel with sensory nerve fibers and as single fibers to innervate blood vessels, hair follicles and sweat glands [5]. Keratinocytes also synthesize catecholamines [9, 59]. Catecholamines inhibit antigen presentation in Langerhans cells through the β2 adrenergic receptor [60]. The sympathetic neurotransmitter norepinephrine and the co-transmitter adenosine triphosphate (ATP) have been shown to act synergistically to induce IL-6 production by human dermal microvascular endothelial cells [61]. As IL-6 is important in the differentiation of Th17 cells, this finding suggests a possible link between stress-associated activation of the sympathetic nervous system and Th17-cell-mediated immune responses [61]. This might help to explain the role of stress in exacerbating psoriasis and other skin disorders in which Th17 mechanisms play a role [61, 62].

Interestingly, evidence exists that norepinephrine plays a role *in vivo* in enhancing CHS through involvement in the trafficking of skin dendritic cells to draining lymph nodes, possibly through effects on α-adrenergic receptors [63]. Thus, the effects of catecholamines on skin immunity may be complex, with the outcome dependent upon factors such as the timing of exposure and the presence of other regulatory factors.

Adenosine 5′-Triphosphate (ATP)

The nucleotide ATP is a ubiquitous carrier of energy involved in countless cellular processes. Several lines of evidence suggest extracellular ATP participates in inflammatory and regenerative responses in the skin and affects melanocyte and Langerhans cell function [64]. ATP plays a role in the nociceptive signaling pathways following cutaneous cell injury [65] and may contribute to the pathophysiology of inflammatory skin conditions such as rosacea by augmenting the production of inflammatory mediators by endothelial cells [66]. The human microvascular endothelial cell line HMEC-1 expresses a variety of ligand-gated purinergic P2X receptors and G protein-coupled purinergic P2Y receptors which, when activated with ATP or the long-lived ATP analog ATPγS, was associated with increased production of the inflammatory cytokine IL-6 and the chemokines IL-8, MCP-1 and GRO-α [31, 66] Furthermore, *in vitro* studies revealed that tetracycline inhibited ATPγS- and TNFα-induced release of GRO-α and IL-8 by HMEC-1 cells and human dermal microvascular endothelial cells, a finding that may account, in part, for the beneficial effects of these agents in treating various inflammatory disorders [67].

Purinergic agonists also appear to enhance Langerhans cell antigen presenting function when exposure occurs along with activation by an additional signal (lipopolysaccharide) [68]. In this regard an ATP analog and $P2X_7R$ agonist 2′(3′)-*O*-(4-benzoylbenzoyl) ATP (BzATP) was shown to induce Th17-type immune responses in lesional and non-lesional skin from patients with psoriasis [69]. The authors interpreted this as due to action at the $P2X_7$ receptor, which is coupled to G_S-dependent intracellular changes in cAMP and its downstream effectors; however, BzATP also has high potency at $P2X_1R$ [70] as well as activity at other P2 receptors [15]. Investigators observed that this response was carried out via antigen-presenting-cell-dependent mechanisms

and was mediated by the pro-inflammatory cytokines IL-6, TNF-α and IL-1β and IL-23 [69]. Among other pro-inflammatory activities, these cytokines promote Th17 cell differentiation, supporting the apparent role of Th17 cells in the pathogenesis of psoriasis [69]. Furthermore, IL-6 secretion from endothelial cells is upregulated synergistically in response to ATP and norepinephrine signaling [61], and may contribute to the pathogenesis of psoriasis by inhibiting regulatory T cell functions [69]. These data may better explain the relationship between sympathetic nervous system activity and psoriasis flares. The function of ATP in the neuropeptide milieu of epidermal and dermal cell types and sensory nerves in the skin remains the subject of ongoing investigations.

Neuropeptide Y (NPY)

NPY is a 36-amino-acid peptide identified predominantly in periarteriolar nerve fibers in the dermal plexuses and, epidermal basal cells as well as sweat glands, sebaceous glands and hair follicles. It also appears to be produced by Langerhans cells [71]. NPY causes vasoconstriction and may also play a role in eccrine sweat production. It also reportedly has antimicrobial properties [72].

Catestatin

Catestatin is a 21-amino-acid neuropeptide derived from chromogranin A, which is a neuroendocrine pro-hormone and a member of the granin family of peptides [31]. This family of proteins is found within secretory vesicles of nerve, endocrine and immune cells that release antimicrobial peptides derived from chromogranin A [73]. Catestatin is upregulated in response to injury [74]. It displays antimicrobial properties against cutaneous pathogens including gram-positive and negative bacteria, yeast, and fungi [74, 75], and also acts as a chemoattractant for monocytes [76]. Furthermore, catestatin was observed to stimulate keratinocytes to migrate and produce IL-8, suggesting a role in immunomodulation [77]. Additionally, catestatin has been shown to induce human mast cell migration, degranulation, and pro-inflammatory cytokine and chemokine production [75]. This may contribute to the known role that mast cells play in cutaneous neurogenic inflammation.

Neurogenic Inflammation

Cutaneous neurogenic inflammation implies the role of nerves in cutaneous inflammation. The neuropeptides secreted by sensory nerves evoke an inflammatory response referred to as neurogenic inflammation. The axon-reflex model implies that tissue injury triggers a signal to the dorsal root ganglion toward the central nervous system (orthodromic response) with return of the signal from branch points in the reverse direction (antidromic signaling) to exert effects at the local level. The orthodromic response transmits pain whereas the antidromic response leads to the release of neuropeptides in the innervated tissue [12].

Various inflammatory cells are known to express neuropeptide receptors. Neutrophils express receptors for SP including NK_1, NK_2 and NK_3 [78]. SP reportedly upregulates neutrophil expression of COX-2 and PGE_2 [78]. Furthermore, mast cells express receptors for various neuropeptides including VIP, NYP, SP, CGRP, POMC, galanin, neuromedin U, PACAP, neurotensin and CRH [78]. Although located throughout the body, mast cells localize near blood vessels, nerve fibers and lymphatic vessels [31]. More specifically, mast cells and nerves engage in a bidirectional interaction in which degranulation provokes membrane depolarization of sympathetic neurons [78]. Pre-treatment of mast cells with selective antagonists of substance P and CGRP in a murine model was observed to decrease neuropeptide-associated degranulation, supporting the role of this interaction in neurogenic inflammation [78].

The most prominent neuropeptides in UVR-induced neuroinflammation are SP and CGRP. SP and CGRP mediate vasodilatation and SP and NKA are responsible for plasma extravasation [22]. SP is well known to provoke erythema and edema by mast cell-dependent and independent pathways [10]. The flare is the result of the antidromic arm of the axon reflex leading to the local release of neuropeptides such as SP and CGRP [20]. Both H1 receptor antagonism and local anesthetic injection have been shown to reduce the spread of the flare response to SP in human skin, suggesting a prominent role of histamine in neurogenic inflammation [79].

Cutaneous/Dermatologic Diseases

The relationship between neuropeptides and dermatologic diseases has been explored for decades. In inflammatory processes, the neuro-immuno-endocrine-cutaneous nexus participates in the trigger and maintenance of inflammation in healthy and pathologic skin. Understanding the role of neurotransmitters and their receptors may lead to the identification of novel therapeutic targets for the treatment of several common cutaneous diseases.

There are several lines of evidence suggesting a neurogenic component in dermatologic disease. Neuropeptides may induce or alleviate urticarial symptoms, hypersensitivity reactions and rosacea, and may play a role in the pathophysiology of pruritus, psoriasis, atopic dermatitis, alopecia areata, vitiligo and nodular prurigo [2, 12]. Several of these conditions are discussed below.

Urticaria

Urticaria presents as transient swellings or wheals caused by plasma leakage. The primary effector cell in the pathogenesis of urticaria is the mast cell [5]. Neuropeptides such as SP, VIP and somatostatin active mast cells to secrete histamine and other mediators that induce urticaria and mediate the late-phase response [5, 80]. SP and CGRP exert effects in cases of chronic urticaria and ACTH is present in the cutaneous mast cells of patients with urticaria pigmentosa [81, 82]. The expression of the POMC gene in mast cells suggests that α-MSH may be contributing to the cutaneous hyperpigmentation seen in patients with urticaria pigmentosa [83]. These studies suggest an interrelationship between the cutaneous nervous system and mast cells in the pathophysiology of urticaria.

Pruritus

Pruritus is one of the most common symptoms encountered in dermatology and significantly impacts quality of life. Itch may be peripheral (dermal or neuropathic) or central (neuropathic, neurogenic or psychogenic) in origin. Neuropathic itch originates at any point along the afferent pathway and is the result of damage to the nervous system whereas neurogenic itch is induced centrally. In the skin, itch is induced by the stimulation of specialized C-fibers by various pruritogens. This is followed by the release of neuropeptides from the cleavage of type-2 proteinase-activated receptors (PAR-2) by tryptase to release histamine, CGRP and SP [84].

It is important to understand the underlying mechanisms to provide effective management and treatment. Multiple cutaneous mediators such as histamine, prostanoids, cytokines and kinins induce pruritus [80]. Pruritus-inducing mechanisms of these mediators include nerve fiber sensitization and receptor stimulation, direct pruritogenic effects and mast cell activation [7]. Histamine is well known for its pruritic effects, especially in urticaria. However, in conditions such as atopic dermatitis the inability of antihistamines to eliminate itch suggest that other mediators are involved as well. Intradermal injection of SP, VIP and somatostatin evokes pruritus; however, CGRP does not have pruritogenic effects in humans [80]. SP is released from C-fiber nerve terminals by the action of mast cell tryptase on PAR-2 in the terminals to directly cause itching and by inducing mast cells to release histamine. Lesional skin in chronic pruritus demonstrates a predominance of dermal SP-containing nerve fibers relative to sympathetic nerve fibers [85]. Additional studies have shown that the pruritic lesional skin of patients with psoriasis contained an increased number of both SP-positive nerves and NK_2 receptor-positive cells. These data suggest that antagonizing the SP receptors NK_1 and NK_2 may be useful in treating patients with pruritic skin disorders [86].

Experimental evidence suggests that the itch circuitry responsible for chronic pruritus may be under tonic inhibitory control by specific types of sensory neurons that are sensitive to mechanical stimulation [87]. These effects are thought to be mediated by members of the TRPV1 family of ion channels [87]. In a murine model, toxin-mediated ablation of GRP- and neuromedin B receptors was associated with abolition of scratching behavior after intradermal application of various pruritogens [88, 89].

There are continuing new developments surfacing in the understanding of the pathogenesis of pruritus including the identification of IL-31 as a role-player in inflammation and pruritus [90]. IL-31 is a known product of mast cells as well as Th2 cells [88]. Interestingly, blood levels of IL-31, CGRP, and SP were recently found to be significantly higher in psoriasis patients than in a control group while the level of CRH was reduced [82]. After 20 treatments with narrow-band UVB radiation, the IL-31 level was significantly reduced, suggesting a possible role in some manifestations of psoriasis [91]. IL-31 levels are also reportedly increased in the serum of patients with chronic urticaria and atopic dermatitis [88]. IL-31 receptors have been found on DRG neurons, suggesting that IL-31 may directly activate these sensory nerve fibers, and perhaps offering an explanation for its role in inducing the sensation of itch [88].

Atopic Dermatitis

Atopic dermatitis (AD) is characterized by cutaneous hyperreactivity to nonspecific stimuli leading to a cycle of pruritus, scratching and further worsening of skin lesions [92]. AD is characterized by increased amounts of Th2-derived cytokines [93], as well as an increased density of nerve fibers and neuropeptide levels in the various stages of skin lesions seen in this condition [94]. The diameter of these fibers are larger than those in nonatopic control subjects possibly due to keratinocyte-derived, nerve growth factor (NGF) [95]. The free nerve endings in the skin of atopics also lack a surrounding sheath of Schwann cells suggesting an active state of excitation [94].

SP is a potent pruritogenic neuropeptide in AD that, along with CGRP, is down regulated by phototherapy [96, 97]. An increase in nerve fibers containing SP and CGRP is often observed although Fantini et al. demonstrated a decrease in SP and an increase in VIP levels in chronic lesions of AD [98, 99]. In lesional skin of AD and nummular dermatitis patients, SP and CGRP, but not VIP, fibers in the dermis are elevated compared to nonlesional controls, and are likely maintained by an increased number of mast cells [100]. Intradermal SP increases nitric oxide and enhances

SP-induced pruritus while acute stress triggers SP-induced cutaneous mast cell degranulation [7]. Elevated VIP was found to be present in eczema [101].

Plasma levels of NGF and VIP are reportedly higher in patients with AD than in psoriatic patients and healthy controls [102]. SP plasma concentrations were higher in a specific sub-group of AD patients with "extrinsic AD," a definition that referred to patients who presented with IgE-mediated sensitization to common food and/or aeroallergens based on skin prick tests and/or elevated total IgE serum levels [102]. Investigators using a skin model based on the coculture of human dermal fibroblasts, keratinocytes and porcine DRG neurons found that neural-derived CGRP enhanced both keratinocyte proliferation and epidermal thickness, phenotypic changes consistent with the atopic phenotype. This isolate skin cell model reportedly allowed investigators to study the interaction of nerve and skin cells under defined conditions in which the effects of porcine neurons, which are most similar to their human counterparts, could be assessed. Interestingly, a thicker epidermis was seen when keratinocytes came from atopic skin [103]. These results were interpreted as demonstrating that epidermal nerve endings enhance the morphologic changes associated with the atopic phenotype [103]. Pharmacologic inhibition of CGRP signaling, but not SP signaling, reversed the atopic phenotypic changes. The strong effects of neuronal integration appeared to be mediated by upregulation of CGRP receptor mRNA components in both healthy and atopic models. These data may suggest a relationship between the skin barrier dysfunction characteristic of AD and abnormal CGRP signaling [103].

Allergen-induced late-phase reactions in patients with AD sensitive to a known allergen have been associated with infiltrates of inflammatory cells expressing CGRP and VEGF, suggesting a role of these compounds in mediating the erythema and inflammation that may be associated with allergic inflammation [104]. In situ hybridization revealed that neutrophils and T cells were the predominant CGRP-producing cells in late-phase edema [104]. Studies comparing these results with patients that have allergic diatheses, but not AD, do not appear to have been performed.

Evidence suggests that there may be a relationship between atopic dermatitis and its associated psychological symptoms, including anxiety and depression, which may be accounted for by cutaneous neuropeptide activity. One study demonstrated that SP and NGF are useful serum markers of disease activity in patients with AD, which was evaluated clinically using three different scoring systems [105]. Indeed, in another study NGF-reactive cells were detected more abundantly in epidermal and dermal AD-involved skin [106]. NPY-positive cells were also detected in greater abundance in the epidermis of patients with AD compared to healthy controls. Investigators reported that pruritus in patients with AD was positively correlated with state and trait levels of anxiety, and hypothesized that anxiety may induce pruritus through NPY- and NGF-dependent mechanisms in the skin that are believed to involve mast cells, fibroblasts, lymphocytes and eosinophils [106].

Recently, inherited mutations in filaggrin have been appreciated for the role they may play in AD pathogenesis. Filaggrin (filament-aggregating protein) and its precursor profilaggrin are among the main components of the F-type keratohyaline granules that comprise the stratum granulosum, and as such, filaggrin plays an integral role in maintaining skin hydration [107]. The relationship of filaggrin to AD appears to involve the role it plays in maintaining epidermal barrier function, the integrity of which is known to be lost in many patients with AD. There are more than 45 known mutations in the filaggrin-encoding gene, FLG, at least four of which are believed to contribute to AD pathogenesis [107, 108]. The most common loss-of-function mutation in FLG is found in almost one-third of European Caucasian patients [109]. However, the four recurrent FLG mutations associated with AD only have an estimated combined allele frequency of approximately 7–10 % [108], and at least 50 % of AD patients have no FLG defects [107]. Furthermore, patients with FLG mutations may develop other conditions, such as ichthyosis vulgaris, without developing AD [107]. Recent evidence suggests that the relationship of preexisting FLG mutations and AD development may be related to the expression of immune modulators such as thymic stromal lymphopoietin (TSLP), which is known to be involved in initiating allergic inflammatory responses [110]. Interestingly, keratinocytes that differentiate in the presence of Th2 cytokines show a lower filaggrin protein expression, independent of underlying FLG mutations [109]. The established role of neuropeptides in regulating the aberrant cutaneous immune responses seen in AD suggests that the pathogenesis of this disorder is multi-faceted and involves a complex interaction between nerve-derived signaling molecules, Th2-type immune responses and abnormal skin barrier function.

Psoriasis

Psoriasis is a multifactorial disease characterized by symmetric plaque lesions. The possibility of a neurogenic component is supported by the temporal onset or exacerbation of lesions with emotional stress, the appearance of lesions at sites of injury or trauma (Koebner phenomenon - believed to be initiated by the release of proinflammatory neuropeptides in traumatized skin) and by observations that lesions resolve in areas of denervation or following central nervous system lesions such as ischemic stroke [80, 111].

NPs and sensory nerve density are increased in lesional skin [80]; however, levels of SP and VIP vary in psoriasis. Elevated levels of both SP and VIP [112], normal SP and elevated VIP [101] and increased SP and normal VIP levels [113] have all been demonstrated in psoriatic lesions. There are conflicting reports of CGRP expression in lesional and nonlesional skin compared to normal controls. Moreover, VIP expression is reported to be increased, yet a statistical difference is not consistently observed between lesional and normal skin [111]. Serum CGRP and VIP are both reportedly elevated in psoriatic individuals. Treatment with anthralin or psoralen plus long-wave UVR [UVA radiation (320–400 nm)] (PUVA) led to a decrease in serum VIP while CGRP remained elevated [114]. Below we discuss evidence that VIP may be involved in biasing immune responses toward the Th17 pole, which suggests the potential relevance of these findings to enhancing the current understanding of psoriasis pathogenesis. Compared to psoriatic lesions, a lower level of SP is seen in lichen planus and lichen simplex chronicus while higher levels are observed in spongiotic dermatoses [113]. Serum beta-endorphin is elevated in psoriatic patients and is likely produced by inflammatory cells within psoriatic plaques [115]. PACAP-38 is also increased in lesional psoriatic skin and recent evidence suggests NGF is involved in the pathogenesis of psoriasis [28, 80]. Keratinocyte hyperproliferation is a histologic feature in psoriasis and NGF is suggested to induce keratinocyte proliferation and prevent apoptosis [111]. SP reportedly upregulates keratinocyte-derived IL-32 and mast-cell-derived tryptase in psoriatic lesional skin [116]. Additional evidence for neuropeptide-mediated mast cell involvement in psoriasis pathogenesis comes from investigations revealing that SP stimulates mast cells to increase CRH receptor (CRHR-1) expression, which in turn enhances NK_1 gene transcription, mediating SP signaling [117]. Overstimulation with CRH, as in chronic stress, reportedly leads to downregulation of CRHR-1 on the surface of mast cells, which may account for previous observations of decreased CRHR-1 gene expression in psoriatic lesional skin [117]. Together, these data may account for the relationship of stress-induced activation of the hypothalamic-pituitary-adrenal axis to psoriasis flares.

Novel murine models of psoriasis have enabled further studies of the role of neurocutaneous immunity in the pathogenesis of this disorder. The KC-Tie2 murine model is engineered to overexpress the angiopoietin receptor Tie2 in keratinocytes [32]. Tie2 receptor activation is associated with reactive oxygen species generation, which may mediate keratinocyte proliferation via VEGF production and angiogenesis [118]. KC-Tie2 mice spontaneously develop features characteristic of human psoriasis including increased numbers of dermal $CD4^+$ T cells, epidermal CD8+ T cell infiltrates and pro-inflammatory cytokines such as IFN-γ, TNF-α, IL-1α, IL-6, IL-12, IL-22, IL-23 and IL-17 [118]. In this model, systemic administration of the T-cell calcineurin inhibitor cyclosporin A was associated with significant improvement in the psoriasiform phenotype and a reduction in lesional T cells and their associated pro-inflammatory cytokines, an observation consistent with the role that T lymphocytes are believed to play in psoriasis pathogenesis [118]. In these experiments, antigen presenting cells remained high in lesional skin, which may have accounted for incomplete resolution of the disease phenotype [118]. In fact, clodronate-liposome-mediated depletion of antigen presenting cells in KC-Tie2 mouse skin was associated with resolution of the acanthotic skin phenotype, decreased dermal angiogenesis and normalization of the levels of multiple pro-inflammatory cytokines.

Additional investigations using the KC-Tie2 model revealed that denervation of cutaneous sensory nerves led to significant drops in lesional dendritic and $CD4^+$ T cells, reminiscent of denervation in human patients with diseases of the nervous system. However, administration of an SP agonist prevented decreases in $CD11c^+$ and $CD4^+$ cells, but had no effect on acanthosis [119]. Interestingly, administration of CGRP reversed the improvement in acanthosis and prevented the denervation-mediated decrease in numbers of $CD4^+$ cells [119]. Perhaps the relationship of sensory nerve activation to disease activity, i.e. secondary to external stimulation such as pressure, may partially contribute to the aforementioned Koebner phenomenon [119].

The imiquimod mouse model of psoriasis uses a toll-like receptor (TLR) 7 agonist to induce a psoriatic phenotype [120]. Investigators using this model to study the pathogenetic mechanisms of psoriasis found that IL-23-mediated activation of IL-17 and IL-22 cells was requisite in triggering the psoriasiform phenotypic changes characteristic of this model [120]. Additional investigations found that IL-22, a cytokine produced by Th1, Th17 and Th22 cell populations as well as by innate immune cells, is required for the imiquimod-induced psoriasiform inflammatory changes characteristic of this murine model, supporting the known role of these novel T cell populations in triggering psoriasis [121]. Recent evidence suggests that nociceptive sensory neurons expressing specific ion channels including TRPV1 are essential for driving this inflammatory through stimulating dermal dendritic cell to produce IL-23 which, in turn, induces dermal gamma-delta T cells to produces IL-23-dependent inflammatory cytokines [122]. Accordingly nociceptive sensory neuron loss was associated with a reduction in both local swelling and inflammatory infiltrates [122]. Furthermore, imiquimod treatment was associated with increased levels of IL-17A, IL-17F and IL-22, consistent with previous reports demonstrating the role of these cytokines in psoriasiform inflammation [122]. Finally, recent experiments have demonstrated that cutaneous denervation results in the loss of imiquimod's ability to

induce the psoriatic phenotype, highlighting the essential role of cutaneous nerves and the neuropeptides they secrete in triggering this skin disorder [123].

Vitiligo

Vitiligo is a depigmenting disorder often presenting in a symmetric or segmental distribution. The segmental or unilateral form of the disease is characterized by a neural-like distribution, suggesting that nerve-derived mediators may contribute to pigment loss [124]. Early studies reported a lack of depigmentation in vitiligo patients below regions of sympathectomy or nerve injury, further supporting the connection between cutaneous innervation and vitiligo pathogenesis [125].

There are changes in neuropeptide distribution in vitiligo-affected skin. Experimental examination of vitiliginous skin found reduced expression of α-MSH and the pro-convertases PC1 and PC2, which are responsible for cleaving POMC to α-MSH [126]. This may simply represent the decreased number of melanocytes characteristic of this condition [126]. However, reduced α-MSH expression may also contribute to the pathogenesis of vitiligo [126]. *In vivo* studies of plasma α-MSH levels in patients with vitiligo found that the median plasma level of this neuropeptide was significantly lower than in control persons, although no difference was observed between patients with active and stable vitiligo lesions [127]. The clinical efficacy of α-MSH analogues, with or without adjuvant narrow-band UVB phototherapy, in treating vitiligo provides further evidence that this neuropeptide is involved in the disease process [128, 129]. Apart from abnormal α-MSH levels, an increase in NPY, CGRP and SP has been demonstrated, whereas no changes in VIP were observed, supporting the concept that neuropeptides are involved in the pathogenesis of vitiligo [85, 130–134].

Alopecia Areata

Alopecia areata (AA) is characterized by non-scarring patches of hair loss. The pathogenesis is complex and unclear, with immunologic, genetic, environmental and psychological mechanisms implicated. Stressful life events may trigger or exacerbate the disease [135]. Enhanced expression of corticotrophin related hormone (CRH), ACTH and α-MSH in sites of AA suggest that the local stress response contributes to normal hair cycling [136]. SP contributes to down-regulation of stress-associated NGF receptors (TrkA) in murine hair follicles, promoting the apoptotic and catagenic effects of NGF [137]. SP has also been shown to induce mast cell degranulation and CD8+ T lymphocyte activation by Langerhans cells [138].

AA has been proposed to be a condition involving Langerhans cell antigen presentation and neuropeptides that trigger an inflammatory response in the vicinity of hair follicles with mechanisms that include mast cell degranulation [139]. An *in vivo* study of lesional and non-lesional skin in patients with alopecia areata reported that $CD8^+$ cells predominate in lesional skin; these authors hypothesized that Langerhans cells stimulated the $CD8^+$ T lymphocytes [139]. CGRP is reportedly decreased in alopecia areata lesions [140]. Recent studies of human scalp specimens found that CGRP down-regulates IFN-γ-induced MHC class I antigen expression but does not affect MHC class II expression, suggesting that CGRP may play a role in influencing immune privilege of human hair follicles [141]. Other investigations have elucidated immunomodulatory roles of proopiomalenocortin-derived peptides and TGF-β1 in anagen hair follicle epithelial cells [142, 143]. The full nature of the role that NPs play in regulating hair follicle immune privilege and contributing to the pathogenesis of alopecia areata remains unknown.

Allergic Contact Dermatitis (ACD)

In a murine model, topical application of SP, CGRP and somatostatin reportedly enhances allergic and irritant contact dermatitis [144]. SP acts as an adjuvant to raise the immunogenicity of cutaneously applied haptens to promote the induction of CHS, and when it is inhibited, decreases the CHS and DTH responses in humans [80]. Furthermore, the inhibition of SP-degrading peptidases leads to an exaggerated ACD response suggesting SP may be capable of boosting both the sensitization and elicitation phase of ACD [18, 144]. The effects of SP signaling in ACD appear to be mediated by transient receptor potential A1 (TRPA1) ion channels found on cutaneous sensory neurons [145]. Genetic ablation and/or pharmacologic inhibition of these channels in a murine model was associated with a decrease in findings characteristic of the ACD phenotype including skin edema, nerve growth, leukocyte infiltration, keratinocyte hyperplasia and anti-histamine-resistant pruritus [145].

In contrast to the effects of SP in eliciting the ACD phenotype, intradermal administration of CGRP suppresses the induction of contact hypersensitivity at the injected site [146]. Furthermore, treatment of epidermal antigen presenting cells with CGRP *in vitro* inhibits their ability to present antigen for immunization of naïve mice [146] or elicitation of DTH in previously sensitized mice by subcutaneous injection [40]. More recently, CGRP was shown *in vitro* to inhibit Th1-type CHS while promoting Th2-type CHS [43]. The difference between these results and those seen with topical application may represent concentration-dependent effects, the effects of secondary mediators induced in unknown

third-party cell targets or other factors peculiar to the route of administration. α-MSH inhibits both the induction and elicitation of CHS responses in mice [52]. These data support the conclusion that NPs have a modulatory role in the pathogenesis of ACD [147].

Rosacea

Rosacea encompasses a broad category of disorders characterized by cutaneous inflammation and abnormal vasoregulation in response to a variety of external stimuli. The direct interaction between cutaneous nerves and the inflammatory cells involved in rosacea pathogenesis is supported anecdotally by the role of spicy food, temperature extremes, pH changes, exercise and alcohol in triggering disease flares. Some of these effects have recently been shown to be mediated by the neurovascular transient receptor potential vanilloid receptor 1 (TRPV1) [148]. The TRPV1 family consists of 28 membrane channels that are expressed on neuronal and nonneuronal channels, including keratinocytes and endothelial cells [149]. These channels are thought to display greater sensitivity at baseline in patients with rosacea [149].

Recent studies have shown an intimate relationship between cutaneous sensory nerves, blood vessels and mast cells [150]. Mast cell density is upregulated in all subtypes of rosacea [150], and various NPs are believed to contribute to the pathogenesis of this disorder. CGRP release mediates potent vasodilatory effects on facial arterioles, producing clinical symptoms of flushing [149]. SP is believed to contribute to rosacea through various mechanisms [149, 151, 152]. SP produces local edema via its activity at the NK_1 receptor on postcapillary venules [149]. SP also induces mast cells to produce TNF-α, IL-3, and a variety of other chemokines that regulate antigen presentation, account for Th1 cell infiltrates in lesional skin and recruit neutrophils to the perifollicular region, contributing to pustule formation [152]. Neuropeptides may also alter antigen presentation to $CD8^+$ T lymphocytes [148]. Sustained, chronic inflammation in patients with rosacea is believed to be related mainly to the activity of Th1 cells, macrophages and mast cells [148].

Recent molecular studies revealed that PACAP and VIP are significantly enhanced in lesional skin of patients with rosacea. PACAP may mediate vasodilatation, and both PACAP and VIP are known to induce mast cell degranulation [153]. The role of catecholamines in inducing cutaneous flushing and telangiectasia indicates that the condition may respond to pharmacologic therapies that antagonize adrenergic receptors [154]. Further elucidating the role of these and other neuropeptides in rosacea pathogenesis is crucial, particularly because current treatment of this condition focuses on alleviating symptoms rather than targeting underlying disease mechanisms [149].

Acne Vulgaris

Acne vulgaris is among the most common chronic inflammatory disorders of the skin. Its multifactorial pathogenesis involves abnormal follicular development, aberrant hormonal regulation of sebaceous gland activity and a dysregulated inflammatory response to local pathogens.

Facial lesional skin from patients with acne is reportedly characterized by an increased number of SP-containing nerves and mast cells [155]. Sebaceous glands express receptors for a variety of neuropeptides, including VIP, CGRP and NPY [156]. Sebocytes also reportedly respond strongly to CRH and α-MSH [157]. The neuropeptide α-MSH enhances lipidogenesis and dose-dependently inhibits the secretion of IL-8, a signaling molecule believed to be involved in the pathogenesis of acne vulgaris [158]. Immunohistochemical studies have revealed that MC-1R expression is markedly increased in the sebocytes and keratinocytes of acne-involved and non-involved skin in patients with acne vulgaris, compared to normal individuals, suggesting a prominent role for α-MSH in acne pathogenesis [159]. CRHR-1 expression is also reportedly higher in lesional skin of acne patients [157]. CRH induces lipid synthesis and enhances the expression of local enzymes involved in testosterone production [158].

Neuropeptide receptor binding may therefore influence the clinical course of acne by affecting local proliferation, differentiation, and androgen metabolism within sebaceous glands [157]. This may partially account for anecdotal evidence suggesting a relationship of acne flares to physical or psychological stress [157].

Ultraviolet Radiation

UVR produces changes in the skin such as erythema and has immunosuppressive and carcinogenic effects as well [5]. UVR acts on keratinocytes, mast cells, Langerhans cells, dermal fibroblasts and endothelial cells to induce the release of various cytokines, neurohormones and growth factors [22]. Afferent sensory nerves are a source of inflammatory mediators, notably neuropeptides following UVR exposure. Ultraviolet B radiation (290–320 nm) induces CGRP, NKA and SP release from cutaneous sensory nerves and NGF release from epidermal keratinocytes [9]. Langerhans cells are also a source of NGF that, along with NGF from keratinocytes, leads to an increase in nerve fibers in sun-exposed skin. CGRP and α-MSH appear to be immunosuppressive in the skin, at least partially through IL-10 production, and SP is involved in the healing of photodamaged skin [19]. CGRP also inhibits the upregulation of IL-12 p40, IL-1β and CD86 [160].

UVR-induced immune suppression of CHS and DTH is believed to be partially mediated by IL-10, TNF-α and the histidine metabolite cis-urocanic acid. Urocanic acid exists

in the epidermis primarily as the trans isomer. UVB (and UVC) radiation induces a trans-cis isomerization and considerable evidence supports a role for cis-urocanic acid in UVR-induced immune suppression [161].

Experimental observations indicate that mast cell products such as histamine are important in downstream systemic immunosuppression [31], effects that may be carried out via neural mechanisms. Evidence suggests sensory C-fibers and mast cells form a functional unit with bidirectional effects [162]. Cis-urocanic acid can activate mast cells by its effects on release of neuropeptides by afferent sensory nerves [163]. Furthermore cis-urocanic acid induction of the release of neuropeptides such as CGRP may participate in the regulation of UVB-induced inflammation and Langerhans cell function [164].

UVR leads to the release of both pro and anti-inflammatory mediators and it is the balance of these factors that ultimately determine the host response and clinical outcome. Pro-inflammatory neuropeptides include SP, NKA and CGRP, whereas immunosuppressive or anti-inflammatory neuropeptides include CGRP and α-MSH [22, 165]. CGRP can be pro or anti-inflammatory depending on the experimental system. As mentioned previously, CGRP immunosuppression has been observed in low dose and high dose models of UVB-induced immunosuppression. CGRP release in response to low dose UVR exposure locally impairs contact hypersensivity responses [46], a phenomenon that may be related to the ability of CGRP to trigger mast cells to release stored TNF-α, which in turn down-regulates Langerhans cell density and function [47]. In the high-dose or systemic model of UVR-induced immunosuppression (sensitization at a non-irradiated site is impaired) CHS responses were inhibited when mice were pretreated with CGRP antagonists [48].

Wound Healing

Studies suggest that the nervous system is important in wound healing and tissue repair. Patients with sensory defects due to injury or a disease process such as diabetic neuropathy, spinal cord injury or lepromatous leprosy have non-healing ulcers [22]. Neuropeptides participate in wound repair by initially evoking vascular responses and then influencing the proliferation and differentiation of target cells in the healing process [80]. CGRP promotes human keratinocyte and endothelial cell proliferation [166] and together with SP, has proliferative effects on culture fibroblasts [80]. The role of SP is further supported by the finding of elevated neutral endopeptidase expression in wounds and in the skin and ulcers of diabetics, indicating that it may contribute to deficient neuroinflammatory signaling and impaired wound healing [167, 168]. In recent experiments, sensory-neuron derived SP was found to promote wound healing in a tissue-engineered murine model [169]. These effects were reproduced by adding SP to a deinnervated model, and were completely blocked by antagonism of the SP NK-1 receptor on keratinocytes, suggesting that SP plays an important role in, but is not essential for, proper wound healing [169].

Hair Cycling

The cyclical activity of the hair follicle appears to be regulated by a "biological clock" that also affects local neuropeptide expression. The pattern of sensory innervation is also hair cycle-dependent with an increase in nerve fibers seen during growth (anagen), followed by a decrease during regression (catagen) and persistently low levels during the resting stage (telogen) [153].

The corticotrophin-releasing hormone (CRH)/POMC system may regulate the hair follicle pigmentary unit [170]. The expression and processing of POMC and its melanocortin derivatives (α-MSH, ACTH, β-endorphin) vary in the hair follicle as a function of their anatomic location and melanogenic activity [170]. The POMC system appears to be most expressed during early stages of melanocyte differentiation and becomes down-regulated in mature melanocytes suggesting additional systems are involved in maintaining melanogenesis [171].

Stress leads to premature termination or arrest of hair in telogen in a NGF- and mast-cell-dependent manner, suggesting that interference with neuropeptide signaling may be an effective measure in the management of stress-induced hair loss [153]. In a murine model of depilation-induced hair cycling, a rapid surge in skin NGF content occurred within one day of depilation, followed by elevated SP-containing nerve fiber count 2 days later [172]. This evidence supports the role of these neuropeptides in contributing to the anagen phase of hair cycling [172]. Additionally, recent evidence points to a potential role for exogenous α-MSH administration in mitigating chemotherapy-induced alopecia [173].

Photoaging

Chronic, excessive exposure to sunlight results in skin changes termed photoaging. Mast cell mediators participate in the dermal changes associated with photoaging [174] and the correlation between the degree of epidermal innervation and chronic photodamage suggests a possible role of neural influences on photodamaged skin [175]. Toyoda et al. demonstrated an increase in dermal nerve fibers, notably CGRP-positive fibers and increased tissue levels of SP, CGRP and NGF in sun-exposed skin compared to sun-protected skin [176]. Furthermore, mast cells were intimately associated with fibroblasts and contained larger amounts of SP when compared to controls [176]. These findings support a role for

cutaneous neurogenic factors and mast cells in chronic ultraviolet injury and potential target for future therapeutic options [176].

Melanoma

The role of α-MSH in experimental models of melanoma is controversial [177]. In the human metastatic melanoma cell lines HBL and A375SM, α-MSH inhibits invasion through a layer of human fibronectin. Furthermore, immunohistochemical analysis has demonstrated that there is enhanced expression of CRH, ACTH and α-MSH in human melanoma, squamous cell carcinoma and basal cell carcinoma tumors. This suggests a possible role of the stress response in the pathogenesis of skin malignancies [178]. These findings suggest melanocortins, notably α-MSH may offer new insight into the understanding of the biology of skin cancers, notably melanoma, and potential therapeutic interventions.

Melanocortin receptors are widely distributed in the human body and of the five receptor types, the MC-1 receptor (MCR1) is expressed in cutaneous cells (keratinocytes, fibroblasts, melanocytes) and melanoma cells. Previous data demonstrate MCR1 variants predispose to cutaneous melanoma independent of skin type and hair color, and the Asp84Glu variant confers the highest risk [179]. MCR1 gene variants are shown to be independent risk factors for nonmelanoma skin cancer [180]. However, recent analyses show the association of MC1R variants and constitutive pigmentation phenotypes is less than previously reported and has a low rather than high penetrance susceptibility locus for melanoma [181].

A recent observational study of 184 lesions found that NPY expression is significantly enhanced in cutaneous melanoma, particularly the nodular variety [182]. Furthermore, NPY expression was associated with invasiveness independent of other proliferative markers [182]. The relationship of this neuropeptide to the pathogenesis of melanoma is not clearly understood.

Conclusion

The skin is part of an active neuro-immuno-endocrine network with influential connections to both the local and central levels of the immune system [50]. There are complex interactions between nerve fibers, neuropeptides, target cells and proteases that are now beginning to be understood. Research in this highly sophisticated system has significantly increased our understanding of neuropeptides and their activities in the skin. The relevance of understanding this intimate relationship is clear as the pathogenesis of several dermatologic conditions involve the neuro-immune-endocrine network described herein. A further understanding of these mechanisms may promote novel approaches to the treatment of skin disorders, with potential therapeutic targets that may include neuropeptides, receptors and proteases, suggesting a promising future for the implications of this growing focus of investigation [20].

Questions

1. Neuropeptides known to be in the skin include:
   A. Norepinephrine
   B. Acetylcholine
   C. Adenosine Triphosphate
   D. Calcitonin gene-rated peptide
   E. Tryptase

2. Clinical and experimental evidence exists that nerves in the skin play a role in:
   A. Regulating the expression of psoriasis.
   B. Regulating vasomotor tone.
   C. Biasing Langerhans cell antigen presentation toward IL-17A responses.
   D. Regulating release of chemotactic polypeptides by endothelial cells.
   E. All of the above

3. Adenosine triphosphate is:
   A. A sensory neuropeptide
   B. A sympathetic nerve co-transmitter
   C. A carrier of energy
   D. a & b
   E. b & c

4. Substance P does each of the following except:
   A. Stimulates macrophages to generate prostaglandin E2
   B. Induces release of histamine from mast cells
   C. Increases release of proinflammatory cytokines from keratinocytes
   D. Inhibits expression of the adhesion molecules P-selectin, intracellular adhesion molecule-1 and vascular cell adhesion molecule-1.
   E. Induces nitric oxide production by endothelium

5. The following are all true of proopiomelanocortin peptides except:
   A. Proopiomelanocortin is only synthesized in the pituitary gland
   B. Proopiomelanocortin-derived peptides regulate melanogenesis
   C. Proopiomelanocortin-derived peptides regulate immunity and inflammation

D. Administration of alpha-melanocyte-stimulating hormone inhibits the induction of contact hypersensitivity in mice.
E. Alpha-melanocyte-stimulating hormone biases dendritic cells towards inducing a T regulatory cell immune response.

Answers

1. D
2. E
3. E
4. D
5. A

Cell Death and Skin Disease

13

Erin Harberts, Kerry Heitmiller, and Anthony A. Gaspari

Abstract

Cell death is a necessary part of the life of an organism. In order to grow and maintain health at an organismal level, tissues and cells must be able to withstand injury, die, or recover. The skin is perhaps the most dramatic example of this paradigm. Skin cells are constantly exposed to the external environment and the associated stressors. One of the critical mechanisms by which epithelial tissue is able to adapt to external injury is by undergoing programmed cell death. The process by which a cell dies has become recognized as a critical factor in determining the type of immune response that it stimulates locally and systemically. Some modes of cell death are considered pro-inflammatory, *e.g.*, pyroptosis and necrosis, and are mostly associated with microbial infections and pathogenic conditions that lead to significant tissue damage. Other modes of cell death are considered to be immunologically silent, such as apoptosis and autophagy, and are usually associated with homeostatic cell death and maintenance of healthy, mutation-free tissue. All of the aforementioned cell death pathways have been, and continue to be, extensively studied and have specific characteristics, molecular markers, and signaling molecules associated with them. This chapter focuses on the mechanisms which epithelial cells use to die, the consequences of these different types of death, and some of the skin diseases associated with dysfunctional programmed cell death.

Table 13.1 Summary of canonical cell death pathways

Type of death	Characteristics	Molecular markers	Critical signaling molecules
Apoptosis	Can be induced by extracellular (TNF-α, FasL, TLRs…) or intracellular (ROS, cytochrome-c) stimuli Initiated by formation of the apoptosome Considered 'anti-inflammatory'	Ladder; Blebbing; TUNEL positive; extracellular Annexin-V; Cleavage of: caspase-3, Rip1, iCAD, PARP; Cytoplasmic cytochrome-c; Membrane integrity maintained	TNFR, Fas, TRAIL, TLR4, TLR2, Bax, Bak ↓ FADD, TRADD, MyD88, APAF, other DD mlcls ↓ Caspase-8, −9, −6, −7, −3
Necrosis/ Necroptosis	Classical inflammatory cell death Originally thought to be 'unordered', now specific signaling pathways have been identified	Release of PAMPS/DAMPS; Increased TNF-α; Cell swelling; Upregulation of Rip3; Phosphorylation of MLKL	Any apoptotic initiator in presence of caspase inhibitor, DNA damage ↓ Rip1, Rip3 ↓ MLKL
Autophagy	Homeostatic process Can lead to cell death by destruction of cellular components Involves formation of autophagosome which fuses with lysosome Is regulated by status of other cell death pathways	Covalent bonding of Atg5 with Atg12; Formation of LC3-II	Beclin, PI3K ↓ LC3-1, Atg family proteins ↓ Lysosomal fusion
Pyroptosis	Initiated by activation of the caspase-1 inflammasome Dependent on intracellular PRR, many of which require a 'first hit' to be upregulated Leads to inflammatory cell death	Release of PAMPs/DAMPs; Increased IL-1β and IL-18; Cell swelling; Cleavage of caspase-1; TUNEL positive	NLRP1, NLRC4, Aim2, other intracellular PRR ↓ ASC, CARD domain containing adaptors ↓ Caspase-1

death. The process by which a cell dies has become recognized as a critical factor in determining the type of immune response that it stimulates locally and systemically [1–4]. Some modes of cell death are considered pro-inflammatory, *e.g.*, pyroptosis and necrosis, and are mostly associated with microbial infections and pathogenic conditions that lead to significant tissue damage [5]. Other modes of cell death are considered to be immunologically silent, such as apoptosis and autophagy, and are usually associated with homeostatic cell death and maintenance of healthy, mutation-free tissue [6]. All of the aforementioned cell death pathways have been, and continue to be, extensively studied and have specific characteristics, molecular markers, and signaling molecules associated with them (Table 13.1) [7–15]. This chapter focuses on the mechanisms which epithelial cells use to die, the consequences of these different types of death, and some of the skin diseases associated with dysfunctional programmed cell death.

Apoptosis

Keratinocyte apoptosis is a classic example of how programmed cell death is utilized to maintain a healthy epidermal skin barrier. As a keratinocyte matures it moves from the basal side of the epidermis towards the apical interface with the environment. During this migration it halts proliferation, undergoes keratinization, and ultimately begins the process of apoptotic cell death so that it can be sloughed off once it reaches the apical surface. This apoptotic cell death can be acutely activated by environmental stress, such as UV-radiation, or can be slowly achieved for homeostatic maintenance of the epidermal tissue. The apoptotic death of these important barrier cells is inevitable and crucial to their function.

There are two classical pathways that, upon activation, lead to an immunologically silent apoptotic cell death, the extrinsic and the intrinsic pathways [16]. The extrinsic pathway is initiated by engagement of cell surface death receptors, most notably TNFR and Fas, that associate with the scaffolding proteins, TRADD and FADD, respectively, to create a death-inducing signaling complex (DISC) [17]. The intrinsic pathway is initiated by release of cytochrome-c from the mitochondria, followed by formation of the apoptosome [18]. Many varied conditions can cause the release of cytochrome-c from the mitochondria, including the build-up of reactive oxygen species (ROS), genomic instability, metabolic instability, and the recognition of any other condition in which it makes more teleologic sense for the cell to die rather than live. The apoptosome is initiated by the binding of cytochrome-c to APAF-1 which is then able to oligimerize to create a circular structure that activates the apoptosis execution proteins named caspases (Fig. 13.1).

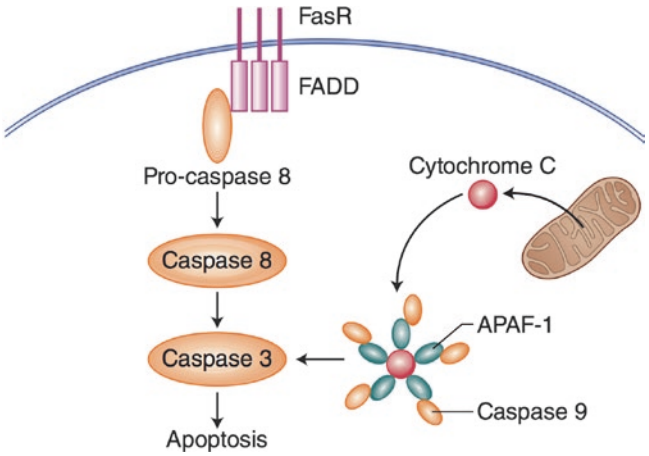

Fig. 13.1 Extrinsic and intrinsic apoptosis. For extrinsic apoptosis, engagement of Fas Receptor by Fas triggers a signal cascade that involves FADD, pro-caspase 8 activation, and programmed cell death by apoptosis. Intrinsic apoptosis can be triggered by intracellular ROS, resulting in the release of mitochondrial cytochrome c, which binds to APAF-1, resulting in executioner caspases that trigger apoptosis

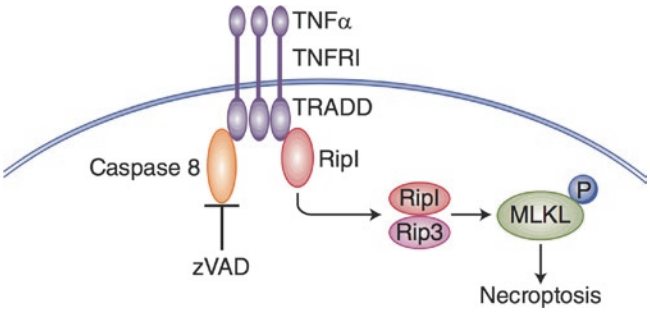

Fig. 13.2 Necroptosis. This form of cell death was originally identified using an extrinsic death pathway TNF-a receptor and its ligand TNF-a. When the activities of executioner caspases are blocked by a chemical such as z-VAD, an alternate, default death pathway becomes active (necroptosis). In this form of inflammatory cell death MLKL is phosphorylated, and migrates to the plasma membrane, resulting in membrane leakiness, and cell swelling and inflammatory death. Necroptotic cell death can occur in naturally occurring circumstances, such as reperfusion injury

Both pathways, either through a DISC or the apoptosome, result in cleavage of caspase-3 that, in turn, cleaves and activates caspase-activated DNase (CAD). Once activated, CAD translocates into the nucleus where it starts digesting genomic DNA, among other cellular components, which is released from the cell in apoptotic vesicles. This digestion process results in the "DNA laddering" that is a hallmark of apoptotic cells [19]. DNA laddering is the result of DNA cleavage by CAD between nucleosomes, which results in DNA fragments increasing in size consistently by about 180 base pairs, which is the amount of DNA wrapped around a histone. In addition to active cleavage of DNA, apoptotic cells undergo a loss of survival signals and homeostatic processes. Experiments using caspase inhibitors show that without the ability to activate the apoptotic pathway, cell death can be skewed to an inflammatory, caspase-independent cell death that is dependent on the formation of specific signaling complexes and is termed necroptosis [20].

Additionally, ER stress and activation of the associated unfolded protein response is another cause for the initiation of apoptosis. When secretory proteins are not able to fold correctly and emerge from the ER, the unfolded protein response is activated and can lead to activation of caspase-3 and subsequent apoptosis [21]. This is just one example of an instance where a cell cannot survive in its current state and so apoptotic death is initiated so that further damage to surrounding cells is not propagated, or survival of a terminally damaged cell is not prolonged [22]. Apoptosis is an elegant way that organismal homeostasis is able to be maintained at the cellular level.

Necrosis

The term necrosis is pathologically described as irreversible cell damage that leads to the extracellular release of intracellular material and destruction of surrounding tissue [23]. This definition originated mostly from gross observation of what was deemed to be 'necrotic' tissue. Such tissue can be separated into five main distinct categories that are based on morphological patterns: coagulative, liquefactive, caseous, fat, and fibrinoid necrosis [24–28]. As molecular biology techniques advanced, the definition of necrosis has evolved to include more biochemically defining characteristics. These include swelling of the cell followed by the release of specific damage-associated molecular patterns (DAMPs), and other pro-inflammatory molecules from dying cells [29]. Necrotic cell death was originally viewed as a 'back-up' or default way for a cell to die that simply involved the non-specific swelling and lysis of a cell. More recently several specific signaling pathways that result in necrosis have been identified, making necrosis an umbrella category for ordered cell death that results in a pro-inflammatory lytic cell death. Of the recently described necrotic signaling pathways, a process termed necroptosis has been the most thoroughly described.

Necroptosis is initiated by the Rip1-Rip3 protein complex and leads to inflammatory cell death [30]. The many consequences of and cellular mechanisms leading to the Rip1-Rip3 protein complex, and subsequently necroptosis, is still a widespread active area of investigation. However, to date, the necroptotic pathway has been most completely described downstream of extracellular death receptors, such as TNFR1 (Fig. 13.2). In this scenario, TNF-α engages TNFR1 inhibition of caspase-8 activation by zVAD has been shown to activate the necrosome which leads to a

necroptotic cell death. A limited number of markers of necroptosis have been identified, among them an increase in Rip3, and maintenance of intact Rip1, and phosphorylation of Mixed lineage kinase (MLKL) [31]. This is in contrast to Rip1 cleavage which is associated with caspase-8 activation and apoptosis [32, 33]. The recently reported ability of Rip1 to mediate production of TNF-α during necroptosis helps to describe the inflammatory nature of necroptotic cell death and may prove to also be a hallmark of necroptosis [34]. Many inflammatory and necrotic phenotypes are reported as a result of inhibiting the apoptosis pathway components. For example, mice in which caspase 8 is conditionally knocked-out in hepatic cells die of necrosis of the liver [35]. Also, FADD conditional knockout in intestinal epithelial cells leads to a spontaneous colitis phenotype that is rescued when Rip3 is also knocked out [36]. In a MyD88 deficient model it has also been found that necroptosis, rather than apoptosis, is activated in UV-radiated KC [37], suggesting an unexpected role for innate signaling pathways in dictating cell death outcomes. Previously described inflammatory phenotypes may now be better explained as a consequence of using necroptosis as a default death pathway when apoptosis is inhibited.

Pyroptosis

Pyroptosis is a pro-inflammatory cell death that is the result of the activation of an inflammasome. During pyroptotic cell death many pro-inflammatory zymogens are cleaved and activated by the pyroptosis executer protein, caspase-1 [38]. These zymogens include the extensively studied pro-inflammatory cytokines, IL-1β and IL-18, which lead to the wide spread inflammation associated with this type of programmed cell death [39]. Pyroptotic cell death is classically thought to require a priming step which initiates the production of the aforementioned zymogens and necessary machinery which can subsequently be activated to form an inflammasome [40]. However, more recently it has been reported that inflammasome activation can occur independently of an initial priming step, this is an active area of current investigation (Fig. 13.3) [41].

The inflammasome, is a cytosolic signaling complex that is dependent on the activation of intracellular pattern recognition receptors (PRR) and is anecdotally referred to as the 'wheel of death'. To initiate an inflammasome cytoplasmic PRRs identify an agonist and then begin to cluster into a wheel shaped aggregate [42, 43]. This signaling complex continues to recruit adaptor proteins, including apoptosis-associated speck-like protein containing a CARD domain (ASC), that scaffold to eventually include a CARD-domain containing protein [39]. The cluster of Caspase activation and recruitment domain (CARD)-domain containing proteins are

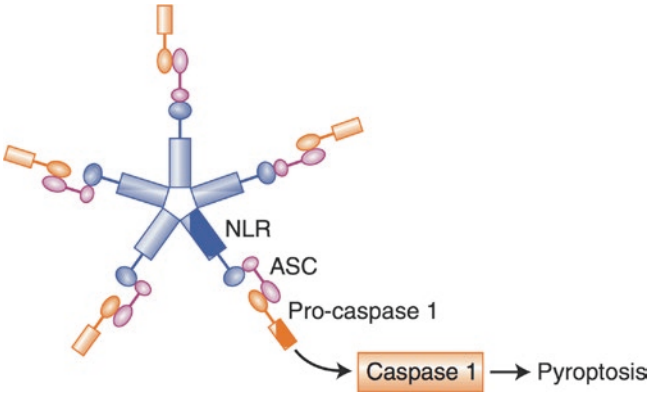

Fig. 13.3 Pyroptosis. This form of cell death is pro-inflammatory, because the inflammasome is activated by NLR, ASC and activation of caspase 1, resulting in the cleavage (activation) of IL-1beta and IL-18, two pro-inflammatory molecules. This form of cell death is activated by intracellular pattern recognition receptors (Nod receptors), which are typically mobilized by PAMPS forming a "wheel of death", but can also be mobilized by DAMPS (such as extracellular ATP)

then able to activate caspase-1, which directly activates the cell death and severe inflammation associated with pyroptosis. Inflammasome activation is also able to mobilize the adaptive arm of an immune response against the microbes it initially sensed [44]. Mobilization of both the innate and adaptive arms of the immune system combined with the death of the infected cell allows pyroptosis to be an effective way for our body to rid itself of pathogenic microbes.

Autophagy

Autophagy is a homeostatic cell process that can be, but is not always, associated with cell death [45]. This process is initiated when a cytoplasmic fraction is recognized as needing to be destroyed or recycled. The damaged/infected fraction of the cytosol is engulfed into a double membrane organelle termed the autophagasome which then fuses with a lysosome. The lysosomal enzymes then have access to the contents of the autophagosome which are promptly digested. If too much of the cytosolic fraction has been labeled for destruction by autophagasome, the cell can die by autophagy. This autophagic cell death is considered non-inflammatory and almost as 'silent' as apoptotic cell death (Fig. 13.4) [46].

Many different conditions can lead to the activation of autophagy all of which have certainly not yet been appreciated. The anti-inflammatory nature of autophagic cell death has been thought to serve several different purposes [47]. It is an inconsequential way of surveying the cytosol of a cell without initiating a robust immune response [48]. It has also been labeled as a way for cells to regulate and dampen inflammatory cell death that would otherwise run rampant

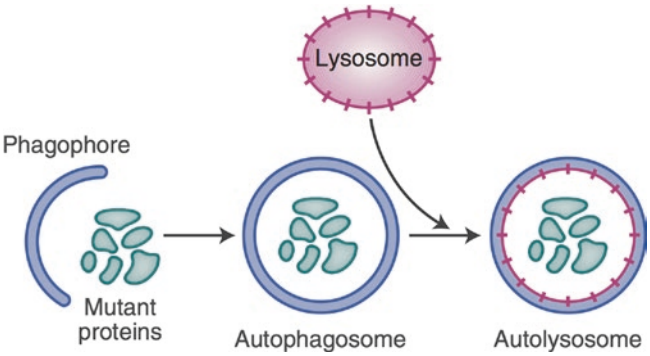

Fig. 13.4 Autophagy. This is a homeostatic process that may or may not result in cell death. Damaged intracellular organelles are engulfed by a membrane termed the autophagosome, which then fuses with a lysosome, resulting in the digestion of the damaged organelle. Limited autophagy does not result in cell death. Extensive organelle damage can lead to cell death: an autophagic, silent, non-inflammatory cell death

during a microbial infection. Activation of autophagy following disease-related oxidative stress can regulate the inflammatory response and widespread inflammation that would normally result from inflammasome activation by ROS [49].

Immune Signaling Resulting in Cell Death

Nod-Like Receptors (NLRs)

NLR signaling is most classically associated with activation of the inflammasome and subsequent pyroptotic cell death. However, in the years following their initial discovery it has been shown that signaling downstream of NLRs can lead to many more types of cell death than simply pyroptosis. For example, interferon-inducible protein AIM2 and NLRP3 inflammasomes have been reported to activate both pyroptotic and apoptotic cell death [50]. In fact, recent research has gone so far as to call NLRs the 'master regulators of inflammation' [51]. This title, while perhaps overstated, has some truth to it. NLRs have, to date, been associated with almost all reported types of programmed cell death. NLRs are also able to stimulate an autophagic response upon activation [52–55]. Furthermore, phagocytosis of autophagic cells has been found to activate the inflammasome and cause the production of many pro-inflammatory cytokines including TNF-α, IL-6, IL-8, and IL-1β [56].

However, activation of NLRs seems to be exclusive from necrosis; if a cell has activated inflammasomes, it will not die by necrosis. Lysosome rupture seems to initiate necrosis and control NLR signaling [57]. Importantly, the two main pathways leading to inflammatory cell death do not appear to overlap, which may allow for the organism to be able to recover from inflammation rather than compound it.

Non-classical Signaling Pathways and Mechanisms Controlling Cell Death

As members of the IL-1 family receptors, toll-like receptors (TLR) are classically known to induce inflammation and, similarly to NLRs, lead to the clearance of the pathogen that they sense. However, as more research is done on these extremely dynamic signaling pathways, it is becoming clear that they are capable of producing many more outcomes than initially thought. For example, extracellular TLRs primed during pyroptotic cell death causes different isoforms of damage associated molecular patterns (DAMPs) to be released, which skews the resulting immune response [58]. A pathway in which engagement of TLR2 and TLR4 signaling stabilizes the autophagy promoting protein Beclin-1 has also recently been described [59]. In this example of a non-classical cell death control mechanism, activation of a pro-inflammatory signaling pathway leads to immunologically silent autophagic cell death. This new association could represent an internal check for inflammation, which does not allow TLR-induced inflammatory responses to go out of control.

As previously mentioned, a novel MyD88-dependent TLR4 signaling pathway that directly activates apoptosis in response to UV has also recently been reported. In the absence of a functional TLR4/MyD88 signaling pathway, cell death after UV-irradiation is skewed to a more inflammatory ordered necrotic cell death termed necroptosis. Because TLR4/MyD88-deficient cells are dying in a more inflammatory and immunogenic way, $MyD88^{-/-}$ and $TLR4^{-/-}$ animals are resistant to systemic immune suppression caused by UV-irradiation, which plays a critical role in the development of UV-induced skin cancers. Activated apoptotic mechanisms previously thought to be a less damaging, less inflammatory, and therefore more desirable outcome during infection, may prove to facilitate the propagation of long-term consequences, such as carcinogenesis.

It is now clear that there is much more cross-talk between apoptosis, necrosis, and autophagic signaling pathways than previously appreciated. Signaling proteins once thought to be mutally exclusive are now being shown to play a role in multiple programmed cell death pathways [60]. If we can identify non-classical cell death pathways activated during tissue damaging circumstances, and determine the consequences of them, we may be able to skew toward alternative cell deaths that will allow for a more immunogenic environment, propagation of fewer potentially cancerous mutations, and an overall more favorable outcome.

Table 13.2 Diseases and therapies associated with different types of cell death

Disease/therapy	Pathophysiology	Related cell death	References
Psoriasis	Hyperproliferation of the epidermis T-lymphocyte mediated disorder Associated with comorbid chronic systemic inflammatory diseases (Crohn's Disease)	Decreased apoptosis	[61–70]
Systemic Lupus Erythematosus (SLE)	Antibodies against nuclear autoantigens Malar or discoid rashes, oral ulcers and photosensitivity	Increased apoptosis and decreased clearance of apoptotic bodies; secondary necrosis; increased apoptosis to UV light (photosensitivity)	[71–79]
Keloids	Overgrowth of granulation/scar tissue Increased fibroblast activity	Decreased apoptosis	[80–102]
SJS-TEN spectrum	Drug hypersensitivity reaction Blistering and widespread epidermal detachment	Increased KC apoptosis; evidence of necroptosis	[103–122]
Skin cancer	Tumor formation after chronic UVR exposure	Decreased apoptosis	[63, 123–145]
Crohn's Disease	Chronic inflammation of terminal ileum Abnormal immune response to commensal bacteria of the gut	Necroptosis, Necrosis	[36, 146–151]
Ischemic Reperfusion (IR) injury	Tissue ischemia followed by reperfusion that initiates an inflammatory response that may exacerbate local injury and lead to impaired remote organ function MPT-induced necrosis involving cyclophilin D and RIP kinase mediated necroptosis	Necrosis, Necroptosis	[152–169]
Graft vs. host disease (GVHD)	Most common complication of BMT Donor T cells recognize host tissue (APC) as foreign	Increased apoptosis	[107, 108, 170–188]
Photodynamic therapy (PDT)	Cell death induced by light after sensitizing the tissue with a photosensitizing agent ROS formation after photosensitizing agent exposed to light induces cell death	Apoptosis; necrosis/necroptosis	[189–195]
Ingenol Mebutate (Picato gel)	Rapid necrosis of cells in the lesion/tumor followed by neutrophil-mediated, antibody-dependent cellular cytotoxicity of the residual tumor cells	Necrosis	[196–205]
Cryosurgery	Direct cell injury followed by vascular stasis and tissue ischemia	Necrosis	[206–224]

Cell Death in Skin Diseases

Dysfunctional or altered cell death can result in a variety of different dermatological diseases with varying clinical presentations and characteristics. In many of these diseases, inflammatory responses of the immune system are altered in conjunction with impaired cell death leading to chronic inflammation or immune suppression. Not only is abnormal cell death involved in the pathogenesis of dermatological diseases, but cell death can also be induced using therapeutic techniques to treat a wide range of dermatological diseases (Table 13.2).

Conditions Associated with Decreased Apoptosis

There are several common skin disorders during which decreased apoptotic cell death causes a wide variety of pathogenic symptoms. These conditions include psoriasis, keloids, and skin cancer.

Psoriasis

Psoriasis is a chronic immune-mediated inflammatory skin disease usually manifesting as erythematous plaques with silvery scales, most often on the elbows, knees, hands, feet and lower back. While skin lesions are the most common manifestation, individuals can also develop psoriatic arthritis and nail dystrophy [61]. During psoriasis pathogenesis, epidermal KC associated with lesions become hyperproliferative and are resistant to apoptotic cell death. This resistance is due to both the overexpression of intracellular anti-apoptotic molecules and extracellular cytokines which influence cell fate [62, 63].

While psoriasis is classically viewed as a T-lymphocyte mediated inflammatory skin disease, macrophages have also been implicated as having a role in its pathogenesis [64]. Research using a mouse model of psoriasis has shown that elimination of macrophages attenuated psoriatic symptoms, suggesting that psoriasis development depended on macrophages and not necessarily T-lymphocytes. Macrophages are

the major source of TNF-α in the skin [65]. Previous studies have demonstrated that TNF and TNFR1 signaling is critical in the development of a psoriasis-like inflammatory skin disease in mice models [66]. Treatment with IL-11 or IL-4, which inhibit macrophage production of TNF-α [67, 68], has shown to improve symptoms in patients with psoriasis [69, 70]. Cells in psoriatic lesions may exhibit abnormal signaling and contribute to the inappropriate activation of the immune system. This deregulation of immune signaling alters the homeostatic apoptosis which is critical to maintaining a healthy epithelial layer.

Keloids

Keloids develop due to abnormal wound healing leading to overgrowth of granulation tissue that enlarges and often extends beyond the margins of the original wound. Keloids do not spontaneously regress and often recur after excision [80]. Keloid formation is believed to be attributed to increased proliferation and decreased apoptosis of fibroblasts [81–84]. Fibroblasts are important for producing and depositing ECM proteins during wound healing. Fibroblasts of normal skin tend to be quiescent with very low activity; however, keloid-derived fibroblasts have higher densities and proliferative activity [85]. Many studies have shown that keloid fibroblasts exhibit reduced apoptotic rates compared to normal fibroblasts [81–84]. These reduced rates in apoptosis have been attributed to alterations in gene expression in both the fibroblasts themselves and the surrounding KC [83, 84, 86–95].

Various immune cells such as T lymphocytes and macrophages have also been implicated in keloid formation since they are involved in coordinating fibroblast activity during wound healing [96–100]. Failure to clear the inflammatory cells at the wound site due to decreased apoptosis may lead to the imbalance of inflammatory cell populations observed in keloid tissue and the increased activity of fibroblasts contributing to keloid formation [101, 102]. Therefore, the decrease in apoptosis observed in keloid tissue seems to account for the persistence of cellular infiltrate and the accumulation and enlargement of granulation tissue at and beyond the wound site.

Skin Cancer

Skin cancer results when there is hyperproliferation and/or decreased apoptosis of mutated cells that form a tumor which progresses to a malignant state, usually after chronic ultraviolet radiation (UVR) exposure. Actinic keratoses (AK), squamous cell carcinoma (SCC), and basal cell carcinoma (BCC) have higher proliferation rates and decreased apoptotic rates compared to normal skin [63]. These differences were most likely associated with increased expression of anti-apoptotic molecules and decreased expression of death receptors that induce apoptosis [225–230]. Mutations in P53, a tumor suppressor gene, are also commonly associated with skin cancers [123–127] and is often induced by chronic UVR exposure, preventing cell cycle arrest or DNA damage-induced apoptosis [128–130]. Consequently, mutated cells are able to survive and clonally expand outside their original compartment eventually forming a tumor [131–133]. Clonal expansion not only requires a decrease in apoptosis of the mutant cells, but also apoptosis of the surrounding cells. Apoptosis of KC adjacent to the mutant cells allows the mutant clones to expand and develop into a tumor [133]. Therefore, it appears that both apoptosis and decreased apoptosis are critical at specific stages in skin carcinogenesis.

In addition to impaired apoptosis, UV-induced immune suppression plays an important role in skin carcinogenesis. Individuals on immunosuppressants have greater incidences of skin cancer on sun-exposed areas compared to immunocompetent individuals [134–136], further supporting the notion that UV-induced immune suppression is critical for the development of skin cancer. UV-induced DNA damage seems to trigger immunosuppression [137–141] by promoting the production of cytokines and apoptosis-inducing ligands like TNF and FasL [130, 142, 143], without which UV-induced immunosuppression does not occur and skin cancer incidence is decreased [144, 145]. Based on this evidence, skin cancer formation involves a state of immunosuppression and decreased inflammatory responses in combination with dysregulated apoptosis to allow the mutated cells to persist and progress into a tumor.

Conditions Associated with Increased Apoptosis

Just as there are several common skin disorders associated with decreased apoptotic cell death, there are many skin conditions with pathogenic symptoms due to increased apoptotic cell death. These conditions include SLE, SJS-TEN spectrum, and GVHD.

Cutaneous and Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is a chronic inflammatory autoimmune disease that affects multiple organs including the skin. Individuals with SLE can develop malar or discoid rashes, oral ulcers and photosensitivity [71]. SLE is characterized by the presence of autoantibodies against nuclear antigens. The pathogenesis of SLE is believed to be due to an increase in apoptosis and a decrease in the clearance of apoptotic cells [72–75]. Many studies have shown an increase in KC apoptosis in LE lesions compared to normal controls [76, 77], which may be mediated by increased Fas expression and decreased Bcl2 expression [77]. While the mechanism remains unclear, it appears that clearance of

apoptotic cells by phagocytes is impaired in lupus patients and mouse models. Accumulating apoptotic cells that would normally be cleared by phagocytes undergo secondary necrosis, releasing their intracellular contents and exposing their apoptosis-induced autoantigens to the immune system, which present as danger signals to APCs [78]. The antigens are taken up by DC leading to IFN-α production and activation of T and B cells [79]. Antibodies are produced against the autoantigens resulting in chronic inflammation and the development of SLE [79]. Therefore, while there is increased apoptosis which may be associated with immunosuppressive effects, the decreased clearance of the apoptotic cells results in secondary necrosis and the release of intracellular material, and exposure of the immune system to otherwise cryptic self-antigens. This activates the immune system leading to the chronic inflammatory state of SLE.

Severe Drug Hypersensitivity Syndromes

Stevens-Johnson Syndrome (SJS) and toxic epidermal necrolylsis (TEN) are life-threatening skin diseases caused by drugs or infections characterized by blistering lesions and widespread epidermal detachment [103]. SJS involves less than 10 % of the body surface area (BSA) and TEN involves greater than 30 % of the BSA [104]. The pathogenesis of SJS-TEN involves widespread KC apoptosis mediated by cytotoxic T lymphocytes (CTLs) [105]. CTLs may induce KC apoptosis via the perforin/granzyme pathway and/or the Fas/FasL pathway [106–108]. Increased levels of these apoptotic molecules have been found in epidermal KC, blister fluid and serum of TEN patients [106, 109–111]. While FasL on KC have been implicated in inducing KC apoptosis seen in SJS-TEN, soluble FasL (sFasL) from PBMC, not KC, has been suggested as the main mediator of KC apoptosis in SJS-TEN [112]. Whether FasL on KC or sFasL from PBMCs is responsible, evidence suggests that the Fas/FasL pathway is important in KC apoptosis and the pathogenesis of SJS-TEN. This is corroborated by the favorable outcomes observed in vitro and in vivo with administration of anti-Fas antibodies or IVIG, which contains naturally occurring anti-Fas antibodies [111, 113–120]. Along with Fas/FasL and perforin/granzyme pathways, granulysin has also been implicated in the pathogenesis of SJS-TEN [121]. Granulysin, a molecule demonstrated to be cytotoxic in vitro, showed the greatest staining in TEN skin biopsies compared to any other SJS-TEN-associated molecule and granulysin protein levels correlated with clinical severity [121]. This suggests that granulysin may contribute to epidermal destruction in SJS-TEN and may better explain the widespread KC apoptosis since granulysin can induce apoptosis without direct cell contact, unlike the Fas/FasL and perforin/granzyme pathways [121]. While most of the evidence points to apoptosis as the main mechanism of KC death and the development of SJS-TEN, recent studies have suggested that necroptosis may also be involved in the pathogenesis of SJS-TEN. It has recently been reported that severe adverse blistering reactions to topical therapies may be the result of secreted Annexin-V which initiates a necroptotic, rather than apoptotic, cell death [122]. Although the pathogenic mechanisms are still being elucidated, it appears that these drug sensitivity reactions involve an inflammatory response leading to inappropriate KC death and widespread epidermal detachment.

Graft Versus Host Disease

Graft vs. host disease (GVHD) is the main complication following a bone marrow transplant (BMT) [170]. GVHD is an immunological disorder affecting multiple organ systems mainly the skin, liver and gastrointestinal tract. The skin is the most frequently affected and usually the first organ involved. A pruritic, maculopapular rash develops that can spread all over the body typically sparing the scalp. GVHD is thought to progress in three stages. First, the host tissue is damaged as a result of the BMT conditioning regimen before the transplantation, usually with chemotherapy. The damaged host tissue produces proinflammatory cytokines which activate host APCs and upregulate MHC antigens on the APCs [171–182]. Second, donor T cells recognize the antigens on host APC leading to T cell activation, differentiation and migration. This recognition and activation can occur in MHC-mismatched and MHC-matched transplantations [183, 184]. Activated T cells then produce Th1 cytokines (IFN gamma, IL-2, TNF-α) [185, 186], which stimulate CTL. Third, CTL and inflammatory cytokines promote inflammation and tissue injury by inducing apoptosis. CTLs induce apoptosis mainly via the Fas/FasL or perforin/granzyme pathways [107, 108]. In the skin, Fas-mediated apoptosis by CTLs and TNF-α-mediated apoptosis seem to contribute the most to KC apoptosis and tissue damage [187]. Anti-Fas or anti-TNF-α antibodies were shown to diminish GVHD skin lesions [188] and using both anti-Fas and anti-TNF-α antibodies together completely blocked the skin lesions, suggesting that Fas and TNF-α signaling contribute to tissue injury in GVHD [188]. Based on current evidence, GVHD pathogenesis involves an inappropriate inflammatory response resulting in excessive apoptosis and tissue destruction that can affect a variety of organs, including the skin.

Conditions Associated with Necrosis/Necroptosis

Not only are there skin disorders associated with impaired apoptosis, there are many common dermatological conditions linked to necrosis or necroptosis. These conditions include ischemia reperfusion (IR) injury and Crohn's Disease.

IR injury involves tissue ischemia followed by reperfusion that initiates an inflammatory response that may exacerbate local injury and lead to impaired remote organ function [152]. While it is not well studied in the skin, IR injury has been well studied in the central nervous system and cardiovascular system and the pathogenesis of such injury involves fundamental processes that occur in the skin. IR injury can result after acute vascular occlusions followed by their respective reperfusion strategies, surgical procedures and shock or trauma [153]. Systemic effects of IR injury can include serious conditions like systemic inflammatory response syndrome (SIRS) and multiple organ dysfunction syndrome (MODS). Majority of the cell death in IR injury is believed to be attributed to necrosis [154, 155]. Various types of necrosis have been linked to the cell death seen in IR injury such as MPT-induced necrosis involving cyclophilin D [156], RIP kinase-mediated necroptosis [156] and PARP-mediated necrosis [157–161]. Necroptosis/necrosis leads to the release of intracellular molecules that can promote inflammation via interactions with TLRs and other receptors on immune cells [162, 163]. The postischemic organ also releases proinflammatory cytokines, which promotes the production of inflammatory mediators and inflammation at remote organs [163, 164]. Therefore, the damage that occurs promotes the widespread inflammatory response seen in IR injury. Necrostatin-1 (Nec-1), an inhibitor of RIPK1 and necroptosis, has been shown to be protective against IR injury in the heart, brain and kidney [165–169]; however, caspase inhibitors do not appear to offer any protective benefit against kidney IR injury [165]. This supports the notion that necroptosis/necrosis is principally involved in IR injury. It appears that the effects of tissue ischemia and subsequent reperfusion lead to activation of a variety of necrotic pathways resulting in cell death and an inflammatory response. Although not well studied, this phenomenon is likely to be highly relevant to dermatologic surgery, particularly survival of skin grafts and flaps used during reconstructive surgery after Mohs surgery for skin cancer.

Crohn's disease is an inflammatory bowel disease involving chronic inflammation primarily of the terminal ileum. Individuals with Crohn's disease often develop bloody diarrhea and crampy abdominal pain. The inflammation is thought to be triggered by an abnormal immune response to the commensal bacteria of the gut possibly as a result of a disruption of the intestinal epithelial barrier allowing the bacteria to translocate across the bowel wall and stimulate TLR signaling [36, 146–149]. Increased epithelial cell death is a hallmark of intestinal inflammation and believed to be a possible mechanism driving Crohn's disease [147]. Many studies have shown that the intestinal epithelial cells die by necrosis, specifically necroptosis [36, 149]. This necroptotic death of epithelial cells could be induced by TNF-α in vitro and was associated with increased expression of RIPK3, a key mediator of necroptosis [36, 149]. Studies of mice deficient in caspase 8 or FADD observed spontaneous development of epithelial cell necrosis, intestinal inflammation and loss of Paneth cells similar to that seen in Crohn's disease [36, 149]. Caspase 8 and FADD are known to be important mediators of apoptosis and regulators of necroptosis, normally keeping the necroptotic pathway silent. Treatment with Nec-1 was protective against the cell death and intestinal inflammation in murine models of Crohn's disease [36, 149]. Therefore, Crohn's disease appears to be driven by a disrupted intestinal barrier and inappropriately activated immune response leading to necroptosis of intestinal epithelial cells causing a chronic inflammatory condition.

Crohn's disease is associated with other chronic inflammatory diseases like psoriasis [150, 151]. The increased incidence of Crohn's disease among psoriatic patients may be related to the changes in cell death seen in these diseases. The decreased apoptosis seen in psoriasis may be linked to the increased necroptosis observed in Crohn's disease as apoptotic molecules have been implicated in negatively regulating necroptosis. Further studies are needed to investigate the role of necroptosis in psoriasis.

Therapies Associated with Cell Death

While impaired or abnormal cell death can lead to various dermatological diseases, cell death can also be manipulated for therapeutic purposes commonly used in the field of dermatology. These treatments include PDT, ingenol mebutate, and cryosurgery.

Photodynamic therapy (PDT) is a type of phototherapy in which cell death is induced by light after application of a photosensitizing agent. PDT is important in the treatment of many dermatological conditions such as psoriasis, eczema, non-melanoma skin cancer (NMSC) and melanoma [189]. When the photosensitizing agent is exposed to light, ROS formation results which induces cell death [190–192]. Many studies support the idea that PDT triggers necrotic cell death [192, 193]. However, PDT has also been shown to induce multiple modes of cell death including apoptosis, necrosis and autophagic cell death [192]. PDT using UVA and hypericin, a photosensitizing agent and major component of St. John's Wort, induced apoptosis in unpigmented cells (KC and non-pigmented melanoma cells) and induced necrosis in pigmented cells (MC and pigmented melanoma cells) [194]. It is likely that the presence of melanin and the site of hypericin localization after UVA exposure contributed to the induced mode of cell death. Hypericin disrupted the melanosome membrane in melanocytes and pigmented melanoma cells causing melanin to leak into the cytoplasm and act as an oxidant to induce cell necrosis. Hypericin localized to the mitochondria in unpigmented cells, leading to mitochondrial

damage, cytochrome c release and apoptosis. In pigmented cells, hypericin localized to the ER/Golgi which likely led to cell stress and necrosis. The presence or absence of RIPK3 has also been implicated as a determinant of the modality of cell death induced by PDT, suggesting that PDT may induce necroptosis depending on the cellular context [195]. Therefore, PDT induces and manipulates cell death processes to treat various skin diseases.

Ingenol mebutate is the active ingredient in the sap from the *Euphorbia peplus* plant [196–198] that has been used to treat a variety of skin lesions [199, 200] including warts, AKs [196, 199, 201, 202], and NMSC [203, 204]. Recent clinical trials have demonstrated that two or three applications of ingenol mebutate is effective in clearing AKs and BCCs. The efficacy of the treatment increased in a dose dependent manner [196, 201, 204] with only mild dose dependent dermatological side effects, confirming that short term use of ingenol mebutate is safe when treating a variety of skin lesions.

Ingenol mebutate has been shown to have a dual mode of action in treating skin lesions. First, rapid necrosis of cells in the targeted lesion is induced [198], which leads to the release of proinflammatory cytokines and activation of the immune system. Second, the activated immune system promotes an inflammatory response and neutrophil-mediated, antibody-dependent cellular cytotoxicity [198, 205], which destroy any residual cells from the lesion. This second mode of action is especially important in completely eradicating the abnormal cells as neutrophil deficient mice treated with ingenol mebutate exhibited tumor regrowth after 25 days compared to neutrophil replete mice who did not exhibit tumor regrowth [205]. Therefore, the inflammatory response and neutrophil-mediated, antibody-dependent cellular cytotoxicity are important to prevent tumor regrowth after the initial necrotic cell death, making ingenol mebutate an effective short term treatment for various skin lesions.

Cryosurgery is a therapeutic technique that involves tissue destruction by freezing, typically using liquid nitrogen [206]. It is widely used in dermatology to treat a variety of benign, premalignant, and malignant skin lesions [207–209]. Cryosurgery treats these lesions by ultimately inducing tissue necrosis [210]. Tissue injury is first induced by freezing, causing direct cell injury [210]. Cell freezing with low cooling rates leads to extracellular ice formation which increases the extracellular solute concentration causing osmotic dehydration of the cell and cell shrinkage [211, 212]. Cell shrinkage and the resulting increased intracellular solute concentration damage the plasma membrane and cellular constituents [213]. The extracellular ice crystals that form can also apply mechanical pressure on the weakened cell, contributing to the plasma membrane damage [212, 214]. Another consequence of freezing is intracellular ice formation, seen at higher cooling rates, which disrupts the cell membrane and cellular organelles leading to cell death [211, 215–220]. Thawing allows recrystallization to occur during which ice crystals can fuse and form larger crystals that are more likely to cause damage to the cellular membrane [211, 221–223]. In addition, as the ice melts, the extracellular fluid becomes briefly hypotonic, which drives water into the cell resulting in cell rupture due to the damaged plasma membrane [224]. Therefore, thawing further contributes to the cell death that was first induced by freezing.

In combination with direct cell injury, vascular stasis plays a major role in the tissue destruction after cryosurgery. Freezing completely terminates circulation in the vessels within the treated region of the tissue [223, 231, 232]. After thawing, there is vasodilation and an increase in blood flow followed by increased vascular leakage due to endothelial cell damage [232], edema, platelet aggregation and blood flow cessation, particularly in the microvasculature [233]. The occlusion of blood flow leads to tissue ischemia and subsequent tissue necrosis [224, 234]. Vascular stasis is believed to be the major mechanism of tissue necrosis induced by cryosurgery.

Some studies suggest that further damage occurs after vascular stasis and tissue necrosis due to an immune response. After the tissue undergoes a necrotic cell death, intracellular contents are exposed which trigger an immune response [235, 236] against the targeted tissue [237]. This suggests that an immune response after cryosurgery contributes to the death of cells that were not immediately killed by freezing and thawing. Edema of and around the treated tissue is observed after cryosurgery, providing further evidence of the activation of the immune system and inflammatory response after tissue necrosis [212, 224]. However, this mechanism is still being elucidated and requires further study. Overall, cryosurgery is an effective therapeutic technique for targeted tissue destruction that induces cell death and an inflammatory response to eliminate unwanted tissue.

Conclusion

As evidenced by the dermatological diseases discussed, cell death can play a significant role in the pathogenic symptoms of a variety of disorders and can significantly influence inflammation. Therefore, it appears that necrosis promotes inflammatory responses while apoptosis has anti-inflammatory effects. However, SJS-TEN spectrum, SLE and GVHD exhibited an increase in apoptosis and an increased inflammatory response, which seems contradictory to the findings that apoptosis is anti-inflammatory/immunosuppressive. These contradictions may be explained by additional factors related to the pathogenesis of these diseases. SJS-TEN spectrum, as recent studies have suggested, may involve necroptosis, which would better explain the increased inflammatory response. SLE

not only involves increased apoptosis but also decreased clearance of apoptotic cells which leads to secondary necrosis and drives the inflammatory response/state seen in individuals with SLE. GVHD, like SJS-TEN spectrum and SLE, exhibits an increase in apoptosis and inflammatory response; yet, further studies are needed to explain this discrepancy by looking for necrotic/necroptotic markers in patients with GVHD. Overall, changes in cell death significantly influence inflammation in a variety of dermatological diseases. In particular, this inflammatory response seems to be related to a decrease in apoptosis and/or an increase in necrosis. Understanding this concept has helped and will continue to help develop more advanced techniques to treat these inflammatory dermatological diseases.

Questions

1. How can a keratinocyte undergoing apoptotic cell death be differentiated from one that is dying by necrosis/necroptosis?
   A. DNA "laddering"
   B. Cellular "blebbing" on electron microscopy
   C. Lack of phosphorylation of MLKL
   D. Cleavage of RIP1
   E. All of the above
   F. None of the above

Correct Answer: (E) All of the above cellular and biochemical events described above are hallmarks of apoptosis, and distinguish this form of cell death from necroptosis

2. What type of cell death may be advantageous to promote in a patient presenting with symptoms of hyper-immune cell activation and several areas of inflammatory skin lesions?
   A. Necroptosis
   B. Pyroroptosis
   C. Apoptosis
   D. Autophagy

Correct Answer: (C) Apoptosis is a non-inflammatory type of cell death, and can actually suppress antigen presenting cell function, and thus dampen immune cell activation. This is not true for the other types of cell death or autophagy

3. Crohn's disease is associated most strongly with which mode of cell death?
   A. Apoptosis
   B. Pyroptosis
   C. Autophagy
   D. Necroptosis

Correct Answer: (D) Crohn's disease has been associated with necroptotic cell death, which is thought to contribute to the pathogenesis of the gut-associated inflammation

4. What conditions/symptoms would be present in a patient in which the skin is undergoing extensive necroptosis?
   A. Fever
   B. Inflammation
   C. Elevated TNF-alpha
   D. Sloughing of dead skin
   E. None of the above
   F. All of the above

Correct Answer: (F) All of the above symptoms are associated with necroptosis

Adipose Tissue and Cutaneous Inflammation

14

Anna Balato and Matteo Megna

Abstract

Adipose tissue (AT) is a highly dynamic and interactive organ with both immune and endocrine roles. It plays a major role in inflammation through the production of a huge class of bioactive mediators termed adipokines. Since adipocytes, macrophages and other cell types resident in AT are a non neglectable source of these mediators, together they might perpetuate a vicious cycle of macrophage recruitment and production of pro-inflammatory cytokines, playing a major role in the development and sustainment of inflammatory conditions. Therefore, given AT proprieties and widespread localization in human body which is also responsible for the strict and extensive contact between skin and subcutaneous fat, AT is able to significantly influence the immune responses, the immune skin system and consequently the pathogenesis of several cutaneous inflammatory disorders.

Keywords

Skin tissue • Adipose tissue • Cutaneous inflammation • Psoriasis • Inflammatory cytokines • Tissue structure • Adipogenesis • Leptin • Immune system • Adiponectin • Hidradenitis suppurativa • Skin diseases • Atopic dermatitis

Abbreviations

AD	Atopic dermatitis
ANA	Anti nuclear antibody
aP2	Adipocyte fatty acid binding protein
apoE	Apolipoprotein E
ASP	Acylation stimulating protein
AT	Adipose tissue
BAT	Brown adipose tissue
BMI	Body mass index
CCL	Chemokine (C-C motif) ligand
CMKLR1	Chemokine-like receptor-1
CORS-26	Collagenous repeat containing sequence of 26 kDa protein
CRP	C-reactive protein
CSF	Colony stimulating factor
DCs	Dendritic cells
dcSSc	Diffuse cutaneous SSc
FFAs	Free fatty acids
FGF	Fibroblast growth factors
GH	Growth hormone
hBD2	Human βdefensin-2
HGF	Hepatocyte growth factor
HS	Hidradenitis suppurativa
ICAM-1	Intercellular adhesion molecule-1
IGF-1	Insulin like growth factor-1
IFN	Interferon
IL	Interleukin
IL-1RA	Interleukin-1 receptor antagonist
IP-10	Interferon-gamma inducible protein 10
LPS	Lipopolysaccharide
MCP-1	Monocyte chemotactic protein-1
MIF	Macrophage migration inhibitory factor
MIP-1α	Macrophage inhibitory protein-1 alpha
MMP	Matrix metalloproteinase
NGF	Nerve growth factor

WAT	White adipose tissue

Introduction

Adipose tissue (AT) has long been neglected and misunderstood, merely considered as an inert energy storage organ providing thermal and mechanical insulation. This stereotype has been completely abolished in the last two decades with the discovery of its ability to act as an endocrine organ and to produce several cytokines as well as many different mediators, being also a resource of stem cells. AT is now seen as a highly dynamic organ, being involved in a wide range of physiological and metabolic processes. The growing knowledge of genetics, growth factors and cytokines as well as the role of AT in their production and regulation, almost daily turns our attention to the intrinsic connection of increased AT mass with different diseases, such as metabolic and cardiovascular ones (atherosclerosis, diabetes, dyslipidemia, obesity, etc.) [1]. Modern society is characterized by an epidemic of obesity highlighting the importance of increased fat mass in the development of different pathologic conditions: adipocytes are a critical component of metabolic control and endocrine organs, possibly having both good and bad effects [2]. In particular, several studies show that obesity is characterized by a state of chronic low-grade inflammation in which AT plays a key role [3–6]. Indeed, increasing evidences show a potential pro-inflammatory role of AT which may also exert its effects in the skin system influencing the pathophysiology of several cutaneous diseases. The aim of this chapter is to review the main features of AT focusing on the relationship with skin inflammation and cutaneous diseases.

Adipose Tissue Structure

In humans, AT is traditionally classified as white adipose tissue (WAT) and brown adipose tissue (BAT), two histologically and functionally distinct types of AT. WAT is the predominant form of AT found in adults whereas BAT is principally found in neonates, having largely disappeared within the first years after birth [7, 8]. However, since WAT is involved in many different functions being able to act as an endocrine/immune organ whereas BAT is mainly implied in the production of heat [7, 8], for this chapter we will focus on WAT as regarding AT. AT represents a loose connective tissue structured in lobules of adipocytes, held in place by fibrous septa and surrounded by a rich capillary and innervation network. It is a heterogeneous tissue with mature adipocytes representing the most common type of cells (around 40 %) [9]. Mature white adipocytes are spherical and can vary enormously in size with a diameter ranging from 20 μm to >200 μm due to their unlimited capacity for growth. Lipids within these adipocytes are organized in a large unilocular droplet, mainly containing triglycerides (TGs) (up to 95 %). The lipid droplet in mature adipocytes occupies the majority of the cell volume, stretching the nucleus and the cytoplasm to a small edge around the droplet [7]. Although the adipose depot can increase from 20 % of total body weight in lean individuals to >50 % in morbidly obese individuals, the number of adipocytes appears to remain fairly constant in lean and obese individuals, once adulthood is reached [10]. In contrast, the adipocyte turnover is highly dynamic, with approximately 10 % of the cells renewed annually [10]. Apart from adipocytes, AT is also characterized by the presence of preadipocytes (immature adipocytes) and the stromal-vascular fraction [9]. This cell population is known to consist of various cell types, including endothelial cells and fibroblasts as well as a large proportion of immune/hematopoietic cells including macrophages and lymphocytes which have been largely involved in the inflammatory process linked to the onset of obesity [11–13]. Particularly, it has been reported that macrophages represent about 10 % of the total AT cell population [14] with their number being directly correlated with adiposity and adipocyte size without showing significant differences between subcutaneous and visceral AT [15–17]. Notably, both the adipocytes and the non-adipocyte cells of AT are able to secrete adipokines, bioactive proteins which participate in a wide variety of physiological or physiopathological processes, including immunity and inflammation [14, 18, 19]. Each cell population present in AT has its own secretion profile and specific regulation, accounting for the different proprieties and processes in which AT could be involved: it is also AT multifarious composition which renders itself an important and central mediator of metabolism and inflammation [20].

Adipose Tissue: Development and Adipogenesis

The development of AT occurs to a large extent postnatally and continues throughout life. The acquisition of fat cells appears to be an irreversible process, as apoptosis has not been shown to be significant under physiological conditions [21]. Like all tissues, organogenesis of AT takes place in early life during gestation (between 14 and 16 weeks of fetal life with a cranial to caudal and proximal to distal gradient) [22]. Adipocytes differentiate from a pluripotent mesenchymal stem cell whose commitment into the adipocyte lineage is triggered by mechanisms yet to be identified [23]. This process creates an unipotent adipoblast which subsequently gives rise to an early preadipocyte of first order which expresses early genes such as α2 chain of collagen 6, insulin-like growth factor (IGF)-1, and lipoprotein lipase [24, 25]. After mitosis and clonal expansion, the preadipocyte of second order arises and undergoes growth arrest. Only these preadipocytes can differentiate into mature adipocytes by reentering into the cell cycle and the subsequent clonal expansion. The ability of growth-arrested preadipocytes for further differentiation depends on the expression of early and intermediate markers of differentiation [26]. Among them, the peroxisome proliferator-activated receptor (PPAR) γ appears as the central regulator of adipogenesis playing a dominant role in fat tissue development [27]. As a consequence of all these transcriptional main events, immature adipocytes begin to accumulate lipid droplets and to express late markers of differentiation (glucose transporter-4, perilipin, and lipogenic and lipolytic enzymes) whereas mature adipocytes are characterized by the expression and secretion of highly specific and very late markers of differentiation such as leptin [28], adiponectin [29], resistin [30], visfatin [31], omentin [32], adipsin [33], and collagenous repeat containing sequence of 26 kDa protein (CORS-26) [34]. These molecules not only regulate metabolism [35] but also represent pro- and anti-inflammatory mediators of the AT [18, 36]. After birth, adipocytes can undergo hyperplasia and hypertrophy. In growth stages (childhood and adolescence), adiposity is increased mainly through hyperplasia [37], whereas in adult life adipocytes mostly increase in size [10]. Indeed, the number of adipocytes is usually constant in adults in which the capacity of preadipocytes to become fully functional mature adipocytes declines [10, 38]. Moreover, it has been demonstrated that the key regulator of adipogenesis PPARγ2 is more highly expressed in younger patients than in older patients [39]. However a late hyperplastic development of AT still remains possible. Indeed, a significant proportion of stromal-vascular cells from the subcutaneous AT of elderly subjects is able to differentiate into adipose cells [40] indicating that these adipose precursor cells should be responsible for the formation of new fat cells known to continue to take place in severely obese adult patients [41].

Adipose Tissue: General Details

AT has a generalized distribution throughout the body, surrounding and infiltrating the subcutaneous region, visceral organs, and a variety of muscle groups [42]. Particularly, subcutaneous AT is located underneath the skin and is responsible for the distinct body compositions of human males and females, accounting for temperature regulation and thermal isolation whereas visceral AT fills in space gaps between organs and maintains them in the adequate position [43]. In humans, abdominal fat mass is predominant in males whereas the subcutaneous fat mass is more important in females. The features of fat distribution are fundamental: it has been recognized that the cardiovascular risk of obesity and increased body weight are more related to body fat distribution rather than total body fat. Individuals with upper abdominal, central or android obesity are at a greater risk than those with gluteofemoral, peripheral or gynoid obesity [44, 45]. Indeed, subcutaneous fat accumulation represents the normal physiological buffer for excess energy intake with limited energy expenditure. It acts as a metabolic sink where excess free fatty acids (FFAs) and glycerol are stored as TGs in adipocytes [46]. When the storage capacity of subcutaneous AT is exceeded or its ability to generate new adipocytes is impaired, fat begins to accumulate in areas outside the subcutaneous tissue. About 80 % of all body fat is in the subcutaneous area [47, 48] with the femerogluteal regions, back and anterior abdominal wall being the most represented, whereas visceral fat is mainly present intra-abdominally tending to increase with age in both genders [48]. The endocrine function and features of adipocytes differ between subcutaneous AT and visceral AT. For example, large adipocytes, which are insulin-resistant, are present in a greater number in visceral AT, whereas small adipocytes, which are insulin-sensitive and have high avidity for FFAs and TGs uptake, are more common in subcutaneous AT [49, 50]. Adipokines, factors which can influence the immune system, are differently produced by these two types of AT with adiponectin [46, 51], C-reactive protein (CRP), tumor necrosis factor-α (TNF-α), interleukin (IL)-6 [16, 52, 53] and monocyte chemotactic protein (MCP)-1 [2, 54] being more expressed in visceral AT whereas leptin is more expressed in subcutaneous AT [48]. These findings may be explained by the fact that inflammatory cells (especially macrophages) tend to be more prevalent in visceral compared with subcutaneous fat [55, 56]. Moreover, because of its anatomical position, visceral fat seems to be more involved in immune and inflammatory processes. Indeed, visceral AT venous blood is drained directly to the liver

through the portal vein allowing direct hepatic access to FFAs and adipokines secreted by visceral adipocytes which can activate hepatic immune mechanisms with production of inflammatory mediators such as CRP, IL-6, etc. [50, 57] Thus it is apparent that differential regional deposition of AT can impact on disease outcome, perhaps mediated by their altered adipokines repertoire.

Adipose Tissue as an Endocrine Organ

The identification and characterization of leptin in 1994 firstly and firmly established AT as an endocrine organ as well as initiated a more intense research in this field [58]. Leptin is a hormone with structural homology to cytokines that regulates growth, metabolism, and behavior being secreted primarily from adipocytes in direct proportion to AT mass and nutritional status [59, 60]. It shows many paracrine effects including stimulation of anorexigenic peptides in the hypothalamus, improvement of insulin sensitivity, alteration of several sex and growth hormones, as well as regulation of immune functions and angiogenesis [61]. Accounting for its numerous endocrine activities, AT is able to release other hormones such as IGF-1 which is expressed by stromal-vascular cells and is strictly interrelated with the growth hormone (GH) creating a system termed the GH-IGF axis with known effects on metabolism and growth [62, 63] being also a major site for metabolism of sex steroids [64] and for numerous receptors that allow AT to respond to afferent signals from traditional hormone systems as well as the central nervous system [65]. Thus, besides the biological repertoire necessary for storing and releasing energy, AT contains the metabolic machinery to permit communication with distant organs. Through this interactive network, AT is integrally involved in coordinating a variety of biological processes including energy metabolism, neuroendocrine and immune function. Indeed, other secretory products of AT, the so-called adipocytokines or adipokines (interchangeable terms used to identify cytokines/bioactive peptides produced by AT) (Table 14.1), are able to clearly regulate energy homeostasis, appetite/satiety, and insulin sensitivity as well as influence neuroendocrine, endothelial, immunological, hematological, angiogenetic, and vascular functions in a systemic (endocrine) and/or local (paracrine and autocrine) manner [59, 65, 66]. The diversity of the adipokines, both in terms of protein structure and of putative function, is considerable [35, 67]. Therefore, we will use the term "adipokines" because it seems rather more satisfactory than "adipocytokines" since it does not imply that the proteins belong to a particular functional group. Indeed, adipokines includes different factors such as cytokines, chemokines, growth factors, acute phase proteins, factors directly affecting metabolism, etc. (Table 14.1). Moreover, the important endocrine function of AT is further emphasized by the adverse metabolic consequences of both AT excess and deficiency. Both AT excess or obesity, particularly in the visceral compartment, and AT deficiency or lipodystrophy are associated with features of metabolic syndrome and pro-inflammatory states [68, 69]. Although adipocytes express and secrete several factors such as leptin and adiponectin, many secreted and bioactive proteins are derived from the non-adipocyte fraction (stromal-vascular cells) of AT [59] together functioning as an integrated unit, making AT a true, complex and highly active metabolic and endocrine organ [70, 71].

Adipose Tissue and Immune System

In the last decade, AT has been recognized to be an active source of several pro-inflammatory cytokines, chemokines, growth factors and complement proteins [74, 75]. Indeed, it is well known that apart from adipocytes, AT contains numerous mature immune cells including macrophages and lymphocytes [11–14] which are important source of inflammatory cytokines and factors as also adipocytes can be. Monocyte infiltration and differentiation in AT has been shown to correlate with adipocyte hypertrophy, as well as body mass [16] and the expansion of AT in obesity is associated with an increased infiltration with macrophages of the M1 or "classically activated" phenotype from the circulation [76]. These macrophages are usually recruited to sites of tissue damage and have been reported to be in a pro-inflammatory state with increased expression of TNF-α [77]. The cellular mechanisms responsible for this enhanced macrophage recruitment remain largely unknown, but it has been suggested that dysregulated adipokines production and increased adipocyte size might contribute to this phenomenon in a crosstalk between adipocytes and macrophages [78]. More recently, different surveys have shown that AT harbors mast lineage cells that are able to home to organs such as intestine and skin where they fulfill their role. The role of AT as a reservoir of mast cell precursors is interesting according to its strategic location (disseminated all over the body, in the vicinity of visceral organs or skin) and rich vascularization (allowing efficient precursor emigration). In normal physiological states, AT contains only a few mature mast cells whereas their number is increased in obesity [79–81]. Since mast cells produce a large panel of multifunctional molecules including cytokines, growth factors, or enzymes [82, 83] they may contribute to the secretory potential of AT. Expansion of AT, which occurs in obesity, is characterized by chronic low-grade inflammation (persistent and elevated levels of inflammatory factors, including IL-1β, IL-6, and TNF-α) [84]. The consequences of this inflammatory state are also especially dire at epithelial tissues where intraepithelial γδ T lymphocytes normally help maintain barrier function and protect from pathogens [85–88]. However, γδ T cells are sensitive to inflammation and their function

Table 14.1 Adipokines [8, 14, 18, 20, 65, 66, 72, 73]

Acute phase proteins, cytokines and chemokines	**Adhesion molecules and ECM components**	**Factors directly affecting metabolism**
α1-acid-glycoprotein	α2-macroglobulin	Adipocyte fatty acid binding protein (aP2)
Chemerin	Collagen I, III, IV, VI	Adiponectin
Chemokine (C-C motif) ligand 5 (CCL-5)	Fibronectin	Adipsin
CRP	Gelsolin	Apelin
Haptoglobin	Intercellular adhesion molecule-1 (ICAM-1)	Apolipoprotein E (apoE)
Interferon (IFN)-β and IFN-γ	Lysyl oxidase	Cholesteryl ester transfer protein
IL-1, 4, 6, 8, 10, 15, 17D, 18	Matrix metalloproteinase (MMP)-1,2,7,9,10,11,14,15	Leptin
IL-1Ra, sIL-1R, IL-1RII, sTNFR	Vascular cell adhesion molecule-1 (VCAM-1)	Lipoprotein lipase
IFN-γ inducible protein 10 (IP-10)		Omentin
Macrophage inhibitory protein-1 alpha (MIP-1α)		Resistin
Macrophage migration inhibitory factor (MIF)		Retinol binding protein 4
MCP-1		Vaspin
Plasminogen activator inhibitor (PAI)-1		Visfatin
Serum amyloid A3		
TNF-α		
Growth and angiogenic factors	**Other factors**	
Angiopoietin 1 and 2, angiopoietin-like proteins	Acylation stimulating protein (ASP)	
Fibroblast growth factors (FGF)	Angiotensinogen	
IGF-1	CORS-26	
Hepatocyte growth factor (HGF)	Complement-like factors	
Nerve growth factor (NGF)	Hepcidin	
Stromal derived factor-1 (SDF-1)	Nitric oxide	
Transforming growth factor (TGF)-α and β	Prostaglandin E2 (PGE2) and prostacyclin (PGI2)	
Tissue factor	Tissue inhibitor of metalloproteinases	
Vascular endothelial growth factor (VEGF)		

becomes impaired by obesity-associated inflammation. AT expansion results in the recruitment of cytotoxic CD8+ T cells and macrophages with increased release of TNF-α, IL-6, and IL-1β as well as depletion of regulatory T cells (Tregs). These events contribute to an increase in systemic inflammation that results in the dysregulation of γδ T cell function and subsequently a decline in barrier homeostasis which may lead to impaired wound healing, increased infections, and susceptibility to inflammatory disease [89]. Moreover, the strict relationship between AT and immune system has always been highlighted by the anatomical close contact between lymph nodes and AT (e.g. lymph nodes are generally surrounded by pericapsular AT). Histological examination of the outer capsule of lymph nodes reveals a fairly thin, loose layer of collagenous material, with numerous very fine lymph vessels that branch from the main vessel and enter the node over almost its entire surface [90]. Such tiny vessels are permeable to large molecules and certain small cells [91] and their arrangement increase the area of vessels passing through the AT immediately surrounding the node, where they may take up lipolytic products released by adjacent adipocytes into the extracellular space. Other sites where lymphoid tissues are in similar intimate contact with adipocytes include the omentum [91, 92] and bone marrow: [93] AT around lymph nodes is a specialized tissue whose function is strictly correlated with lymph node cell populations (e.g. lymph node lymphocytes and tissue dendritic cells (DCs) that acquire their fatty acids from the contiguous adipocytes potentially being influenced by them [94]. Therefore, lymphocytes are often found in close proximity to the adipocytes surrounding the lymph node; consequently, there may be paracrine relationships between the lymphocytes and adipocytes, allowing the exchange of information between the two [17]. However, despite the significative and non negligible presence of immune cells in AT as well as the close contact between lymph nodes and AT, researches into the functional association between AT and the immune system only began in the early 1990s, when adipsin secreted from adipocytes was shown to be identical to complement factor D produced in the immune system [95, 96]. Since

then, many more protein secretions and/or cytokine receptors have been described [97]. In most cases, cytokines such as TNF-α were isolated first from the immune system and later found to be secreted by and/or taken up by adipocytes, but others, notably leptin [98], were identified first in AT and later shown to modulate immune function.

Adipokines and Other Mediators: Role in Inflammation

AT is highly dynamic and interactive, playing a central signaling role in the regulation of energy homeostasis, appetite, inflammation, and insulin sensitivity. However in contrast to numerous and excellent publications describing its role in metabolic syndrome and atherosclerosis [99, 100], reviews on the inflammatory role of AT outside the field of metabolism are rare [18, 78, 101]. AT plays a major role in inflammation through the production of a huge class of mediators, the adipokines. Since both adipocytes, macrophages and other cell types present in AT are a non neglectable source of bioactive mediators, they might together perpetuate a vicious cycle of macrophage recruitment and production of pro-inflammatory cytokines, playing a major role in the development and sustainment of inflammatory conditions, especially including skin diseases also due to the anatomical and strict relationship between skin system and AT.

Adiponectin

Adiponectin, also known as Acrp30, AdipoQ, apM1, and GBP28, is a 30-kDa polypeptide highly and specifically expressed in differentiated adipocytes which circulates at high levels in the bloodstream [102]. It is mainly expressed in adipocytes, being higher in subcutaneous than visceral AT [103]. Adiponectin shows anti-inflammatory effects on endothelial cells through the inhibition of TNF-α induced adhesion-molecule expression [104], interferes with the function of macrophages [104, 105], induces the production of important anti-inflammatory cytokines, such as IL-10 and IL-1 receptor antagonist (IL-1RA), by human monocytes, macrophages and DCs, hampers IL-6 production, inhibits the actions of TNF-α and suppresses the production of interferon (IFN)-γ by lipopolysaccharide (LPS) stimulated human macrophages [105, 106]. Moreover, the presence of adiponectin in T-cell proliferation assays results in a decreased ability to evoke an allogeneic T-cell response, and adiponectin also markedly reduces the phagocytic capacity of macrophages as well as TNF-α production by macrophages [106]. Adiponectin is also able to decrease endothelial vascular cell-adhesion molecule (VCAM)-1, intercellular adhesion molecule (ICAM)-1 and selectin expression [20] and, by decreasing reactive oxygen species (ROS), is an antioxidant [107]. Adiponectin, acting on natural killer (NK) cells, a key component of innate immune system, suppresses the IL-2-enhanced cytotoxic activity of NK cells without affecting their basal cytotoxicity [108] and is also able to inhibit Toll-receptor activation and its consequences [109]. In addition, it increases nitric oxide production in endothelial cells and stimulates angiogenesis. A strong and consistent inverse association between adiponectin and both insulin resistance and inflammatory states has been established [102, 110]. Taken together, these studies suggest that adiponectin is a unique adipocyte-derived hormone with anti-diabetic, anti-inflammatory, and anti-atherogenic effects. Indeed, adiponectin expression is decreased by pro-inflammatory cytokines such as TNF-α and IL-6 [111, 112] and, in obesity, due to the elevated level of these pro-inflammatory cytokines, serum adiponectin is reduced and negatively correlated with Body Mass Index (BMI) [113, 114].

Leptin

Leptin, a 16-kDa nonglycosylated peptide containing 167 amino acids, is mainly produced by adipocytes presenting as an important mediator of immune-mediated diseases and inflammatory processes [115]. Its synthesis is greater in subcutaneous AT rather than visceral AT [116]. Leptin is considered to be a pro-inflammatory cytokine and it has structural similarity to other pro-inflammatory cytokines such as IL-6, IL-12 and granulocyte-CSF [117]. It promotes proliferation and differentiation of hematopoietic cells, alters cytokine production by immune cells, stimulates endothelial cell growth and angiogenesis, and accelerates wound healing [28, 118]. In monocytes and macrophages, leptin increases the production of pro-inflammatory cytokines such as TNF-α, IL-6 and IL-12 [119]. Leptin is able to stimulate the proliferation of human circulating monocytes in vitro and up-regulates the expression of activation markers such as CD25 (also known as IL-2Rα) and CD71 (the transferrin receptor) on these cells [120]. Furthermore, leptin also activates neutrophils, as assessed by increased expression of CD11b, stimulates neutrophil chemotaxis and the production of ROS by these cells, all of which are very important in innate immune responses and regulation of pathogen colonization of the skin and mucosa. This protein also regulates NK cells differentiation, proliferation, activation and cytotoxicity [121]. Further known direct actions of leptin on immune responses include the promotion of phagocyte function [122], the induction of the synthesis of eicosanoids [123] and nitric oxide [124], the protection of DCs from apoptosis and promotion of their LPS-induced maturation and of a cytokine production profile featuring low levels of IL-10 and high levels of IL-12, TNF-α and costimulatory molecules, which favours the proliferation of allogeneic CD4+ T cells [125]. Other major actions of leptin appear to occur on the level of adaptive immune responses, mainly in T cells regulation. Leptin induces cytokine producing capacity switch towards TNF-α and IL-2 [98, 126], particularly by increasing IFN-γ. Moreover, leptin causes generation, maturation, and survival of T cells, protecting them from apoptosis. It should however be noted that in models of severe inflamma-

tion, leptin appears to exert suppressive effects which are contrary to those described above leading to decrease of Th1 type cytokines, increase of Th2 cytokines and reduction in T cells proliferation. Thus leptin effects on the immune system appear to depend not only on the leptin concentrations, but also on the status of the immune system [127]. The complexity of the picture is increased by findings that leptin deficient mice show resistance to certain autoimmune diseases and the susceptibility is recovered by leptin administration [128, 129]. Indeed, leptin may lead to enhancement of autoimmune reactions, in part by reducing Tregs; in addition, its levels are reported to be increased in patients with autoimmune diseases [126]. Moreover, inflammatory cytokines, including TNF-α, and IL-1 are able to induce leptin production [130] with leptin deficiency itself being a known cause of impaired T cell-mediated immunity [131].

Resistin

Resistin, also known as ADSF and FIZZ3, is a 12.5 kDa protein secreted from adipocytes and macrophages that mostly circulates as a high-molecular-weight hexamer, appearing to have many features of an inflammatory cytokine [132]. Greater levels of resistin expression in AT are displayed by monocytes and macrophages versus adipocytes [133]. In humans, resistin appears to play a role in inflammation regulated by pro-inflammatory cytokines, including TNF-α and IL-6 which are also produced by AT. Indeed, resistin stimulates the production by various cell types of inflammatory cytokines such as IL-1, IL-6, IL-12 and TNF-α through a NF-kB-dependent pathway [134–136]. Particularly, even if resistin is minimally expressed in primary adipocytes, these may be target cells for resistin itself: it has been demonstrated that resistin could induce the expression of IL-6, IL-8, and TNF-α by AT [137]. In addition, resistin is also able to up-regulate endothelial cell production of ICAM-1, VCAM-1, endothelin-1 and MCP-1 [138, 139], thus producing a biochemical profile of dysfunctional endothelium. Moreover, resistin mRNA has been also found in human peripheral blood mononuclear cells (PBMCs) and it was reported that pro-inflammatory mediators such as IL-6, TNF-α, IL-1β, IL-12 or LPS can strongly increase the expression of resistin in PBMCs, and that resistin itself is able to stimulate its own production and the secretion of TNF-α, IL-1β, IL-6 and IL-8 in PBMCs as well as IL-12 in macrophages, creating a vicious cycle and suggesting a role in the process of inflammation [134–136].

Visfatin

Visfatin, also known as PBEF, has recently been identified as an adipocytokine that is secreted by adipocytes [140]. However, visfatin is not only produced by AT, but also by endotoxin-challenged neutrophils, in which it prevents apoptosis through a mechanism mediated by caspases 3 and 8 [141]. Circulating visfatin levels are closely correlated with AT accumulation. Visfatin mRNA levels increase in the course of adipocyte differentiation, and its synthesis is regulated by several factors, including glucocorticoids, TNF-α, IL-6 and GH [142]. This molecule binds to and activates the insulin receptor but does not compete with insulin, which indicates that the two proteins bind different sites on the insulin receptor. Visfatin was originally identified more than 10 years ago and since then, it has been linked to several inflammatory disease states [143, 144]. Furthermore, expression of visfatin has been shown to be up-regulated in activated neutrophils and to inhibit their apoptosis [141]. It has been shown that visfatin is able to induce chemotaxis and the production of IL1-β, TNF-α, IL-6 and co-stimulatory molecules by CD14+ monocytes, and to increase their ability to induce alloproliferative responses in lymphocytes [145]. By induction of co-stimulatory molecules such as CD80, CD40 and ICAM-1 visfatin promotes the activation of T cells [146]. Visfatin was also identified in inflammatory cells (lymphocytes) and its levels were reported to be increased in various inflammatory conditions [140]. However, future studies of the cell biology of this natural insulin mimetic and potential inflammation-regulating adipokine should help to define its role in insulin resistance and associated inflammatory disorders.

Chemerin

Chemerin is a 18 kDa chemokine, also known as TIG2 and RARRES2, that was found to be expressed primarily by mature adipocytes and found in ng/mL ranges in human plasma [147]. Various cell types involved in innate and adaptive immunity [plasmacytoid DCs (pDCs), myeloid DCs, macrophages and NK cells] express the orphan G protein-coupled receptor chemokine-like receptor-1 (CMKLR1), and chemerin is now known to function as a chemoattractant that promotes the recruitment of these cells to lymphoid organs and sites of tissue injury acting hence as a pro-inflammatory agent [148–151]. For example, it was found to promote the clustering of the Very Late Antigen (VLA)-4 and VLA-5 integrins at the cell surface, leading to adhesion of macrophages to VCAM-1 and fibronectin [152]. Serum chemerin levels correlate with levels of the pro-inflammatory cytokines TNF-α, IL-6 and CRP [153, 154]. Moreover, chemerin, whose synthesis is increased by TNF-α and Il-1β [155], seems to be able to decrease adiponectin and leptin expression [147]. While initial studies suggested that chemerin might modulate adipogenesis [156, 157] and that functional chemerin receptors were present on both immune cells and AT, little is known of its endocrine or paracrine roles.

Adispin, Apelin, Hepcidin and Vaspin

Adipsin, also known as complement factor D, is a serine protease mainly produced by adipocytes as well as monocytes and macrophages resident in fat [158, 159]. It presents high

levels of expression in AT and its circulating concentrations tends to correlate positively with the degree of adiposity, being elevated in obesity and reduced in individuals with total lipoatrophy, AIDS related cachexia and anorexia nervosa [160]. Adipsin mediates the rate-limiting step in the complement activation alternative pathway, underlying the role of AT in immune system biology [158, 159].

Apelin, a recently identified adipokine, which acts thorough the binding to a specific G-protein-coupled receptor named API, present on endothelial cells, vascular smooth myocytes, and cardiomyocytes [161, 162]. It is synthesized in adipocytes and strongly up-regulated by insulin; high plasma apelin levels were found in obese humans [163]. TNF-α may act as a key player in the up-regulation of apelin expression in adipocytes both in obese and lean humans [164]. It has been reported that apelin has a regulatory effect on neoangiogenesis, lymphangiogenesis and fibrogenesis [165, 166].

Hepcidin, first described as a small antimicrobial factor, is a peptide of 25 amino acids which regulates iron homeostasis inhibiting iron absorption by enterocytes, iron release from macrophages, and iron transport across the placenta [167, 168]. Even if it is mainly produced by the liver, AT is able to express hepcidin at both mRNA and protein levels and this expression is reported to be enhanced in obese patients [169]. Levels of hepcidin correlate with levels of CRP and IL-6 [168, 169] and they are reported to be associated with obesity but not liver disease [170]. Indeed, hepcidin expression in AT appears to be stimulated rather by inflammatory stimuli than by iron, particularly through IL-6/STAT3 pathway [171, 172].

Vaspin (visceral adipose-tissue derived serine protease inhibitor), also known as serpinA12, has similarities to adiponectin in that it improves insulin sensitivity. It is a serine protease inhibitor mainly but not exclusively produced by AT (e.g. it can be secreted by skin, stomach, hypothalamus, etc.) which is able to reduce levels of leptin, resistin, and TNF-α; [173, 174] it was also reported to be able to protect endothelial cells from pro-inflammatory cytokines induced inflammation and expression of adhesion molecules [175, 176] showing its multiple potential anti-inflammatory effects.

TNF-α

TNF-α is a cytokine present as either a 26 kDa transmembrane monomer or a 17 kDa soluble molecule. The TNF-α from AT is thought to be primarily produced by macrophages though isolated adipocytes are also known to produce this cytokine [59, 177]. Adipocytes also express both types of TNF-α receptors as membrane bound and soluble forms [178]. TNF-α is a powerful local regulator within AT, acting in both an autocrine and a paracrine manner to influence a range of processes, including apoptosis [97]. Moreover, TNF-α changes the expression of several adipocyte secreted factors, being also the key regulator of several pro-inflammatory compounds; particularly, it enhances the production of IL-6, MCP-1, resistin and visfatin whereas it is able to decrease adiponectin and leptin concentrations [179–181]. TNF-α stimulates adhesion of monocytes to the surface of endothelial cells by enhancing the expression of adhesion molecules (ICAM-1, VCAM-1) being a key cytokine of inflammatory processes [182]. AT expression of TNF-α is increased in obese humans and is positively correlated with adiposity and insulin resistance [178, 183] so that it appears as one of the key links between metabolic disorders and TNF-α mediated skin diseases [e.g. psoriasis and the development of the so-called psoriatic march [184] as well as hidradenitis suppurativa (HS) [185, 186]; indeed, both skin disorders are linked with obesity and metabolic syndrome].

IL-6

Approximately 20–30 % of IL-6 in the circulation is produced by AT [187]. However, IL-6 can be secreted by numerous cell types present in AT with macrophages contributing up to 50 % of AT-derived IL-6 [16] with around 10 % of circulating IL-6 being attributed to synthesis by adipocytes [61]. Within AT, IL-6 and IL-6R are expressed by adipocytes and AT matrix [59]. Like leptin, production of IL-6 by AT increases with increasing adiposity, and circulating IL-6 concentrations are highly correlated with percentage of body fat [188]. Expression and secretion of IL-6 are 2–3 times greater in visceral relative to subcutaneous AT [48, 59]. IL-6 synthesis and secretion by adipocytes is thought to be constitutive but is also stimulated by numerous factors including β-adrenergic agonists [187] and IL-1β [189]. Initial studies also indicated that endothelin-1 may induce adipocyte secretion of IL-6 [190]. Several studies have associated IL-6 polymorphisms with obesity [191] but clear mechanisms have yet to be identified. Circulating IL-6 is the single most important factor controlling the hepatic acute-phase response, the rapid, coordinated physiologic reaction to tissue damage or infection designed to recruit host defense mechanisms, eliminate damaged cells, contain pathogens, and begin tissue repair [57]. Indeed, IL-6 is known to increase the secretion of CRP, a clinically used marker of inflammation, as well as the synthesis of other acute phase response proteins including fibrinogen, serum amyloid-A and α-1 antichymotrypsin [192]. Moreover, IL-6 is also able to inhibit adipogenesis and decrease secretion of anti-inflammatory factors such as adiponectin.

Other Cytokines

Numerous other cytokines are present in AT. For example, IL-15 is secreted from AT, has several functional similarities to IL-2, and it is thought that these two interleukins negatively regulate one another. IL-10 secretion from human AT

has also been described [20]. The expression of IL-17D has been showed in adipocytes; [193] it seems that this cytokine is able to stimulate the production of IL-6 and IL-8 from endothelial cells [193]. IL-8 is secreted from both AT explants and cultured adipocytes [194] though others have suggested that IL-8 expression and production is primarily from non-adipocyte cells found in AT [195]. Production and concentrations of IL-8 appear to be AT depot dependent and stimulated by TNF-α [194, 196], differentially regulated in lean and obese men [197] as well as women [198] and influenced by plasma non-esterified fatty acids in overweight men and women [199]. IL-8 production in AT may provide another link between AT and obesity associated diseases. In addition, several reports indicate that circulating levels of IL-18 are elevated in obesity and that they fall following weight loss [200, 201], raising the possibility that AT may be an important direct source of this cytokine in plasma. Indeed, adipocytes and the stromal-vascular fraction of AT are also able to produce IL-18, raising the possibility of cross talk between adipocytes and other cellular components within the tissue [202]. IL-18 acts as a pleiotrophic pro-inflammatory cytokine inducing the expression of chemokines, cytokines, angiogenesis-related, and adhesion molecules such as IL-8, TNF-α, vascular endothelial growth factor (VEGF), and ICAM-1 [203–205]. Even if TNF-α stimulation is able to significantly increase IL-18 production in adipocytes [202] they seem unlikely, however, to contribute significantly to the circulating levels of this cytokine and to the increased levels associated with obesity; therefore, in contrast to other inflammation related factors such as IL-6, TNF-α, MCP-1, and adiponectin, IL-18 cannot be considered a major adipokine.

MCP-1

MCP-1, also referred to as chemokine (C–C motif) ligand (CCL)2, is a chemokine that recruits monocytes to sites of inflammation and has been shown to induce insulin resistance and macrophage infiltration in AT [206]. MCP-1 is expressed and secreted by both adipocytes and stromal-vascular cells [207]. Increased circulating MCP-1 is associated with increased circulating monocytes [208] and MCP-1 expression appears to be highly regulated by TNF-α [209] and, to a lesser extent, by IL-6 and GH [210]. MCP-1 exhibits depot-dependant differences in expression [55] and appears to respond to surgically induced weight loss with a decrease in gene expression [211]. Obesity is associated with increased AT infiltration by macrophages [16, 207] and activated macrophages are able to secrete inflammatory factors, including TNF-α and IL-6. MCP-1 is increased by leptin, obesity, and insulin-resistance-inducing hormones [212].

CRP

The possibility that AT directly contributes to the circulating pool of CRP is suggested by a study which showed that the gene encoding CRP is expressed in AT [213]. However, it is not clear whether CRP expression in adipocytes is significant. Indeed, it seems that AT is not so able to produce significant amounts of CRP [18]. However, IL-6 is highly secreted by AT in obesity and this is the major cytokine regulating the hepatic production of CRP [57, 214]. Thus, AT may be a major player in the raised circulating levels of CRP in obesity, but through the indirect route of adipocyte-derived IL-6. The circulating level of CRP rises with BMI [215, 216], and elevated levels of this inflammatory marker have been associated with both obesity and diabetes, falling with weight loss [217].

As showed above, AT is able to produce plenty of factors so that it could deeply influence the inflammatory response and immune system. Even if it is important to note that these mediators are not all exclusively derived from AT, the factors mainly produced by adipocytes (e.g. adiponectin, leptin and to a less extent visfatin and resistin), can circulate at high concentrations making AT an active and complex actor in inflammation and immunity (Table 14.2).

Adipose Tissue in Dermatologic Inflammatory Diseases

As the outermost protective barrier of our body, the skin consists of three layers: epidermis, dermis and a subcutaneous layer which is mainly composed of AT. Given that AT is able to secrete various bioactive proteins, it is not surprising that it may have dynamic functions in skin physiology and pathophysiology. For example, by producing various interleukins, subcutaneous AT may regulate B- and T-lymphocytes in concert with the epidermal keratinocytes, deeply influencing cutaneous inflammation and the development of several skin diseases [1]. Without any doubts, psoriasis represents the dermatologic inflammatory disorder which has been most intensively investigated regarding relationships with increased fat mass and adipokines. However, the literature is also constantly enriched with studies which try to elucidate the role of AT and adipokines in different skin diseases, such as atopic dermatitis (AD), HS, etc., highlighting the growing interest in this topic.

Psoriasis

Psoriasis is a chronic skin inflammatory disease which is now considered a systemic immune mediated disorder. It is well established that obesity is a risk factor for psoriasis [218, 219]. Obesity is one of the most common psoriasis comorbidities. Indeed, obesity prevalence is significantly higher than in general population [218, 220] and it appears to be associated with increased morbidity of psoriasis [221, 222]. Psoriasis is positively correlated with higher BMI, which is

Table 14.2 The role of the main distinctive adipokines in inflammation and immunity [8, 117, 127]

Adipocytokines	Inflammatory effect	Effects on Innate immunity	Effects on adaptive immunity
Adiponectin	Anti-inflammatory	↓Endothelial adhesion molecules ↓ NF-kB ↓ TNF-α ↓ IL-6 ↓ IFNγ ↑ IL-10 ↑ IL-1RA ↓ Phagocytosis	↓ B-cell lymphopoiesis ↓ T-cell responses, activation and proliferation ↓ T-cell activation and proliferation
Leptin	Pro-inflammatory	↑ TNF-α ↑ IL-6 ↑ IL-12 ↑ Neutrophil activation ↑ ROS ↑ Chemotaxis ↑ NK-cell function	↑Lymphopoiesis ↑ Thymocyte survival ↑ T-cell proliferation ↑ T-cell activation ↑ TH1 response (IL-2 and IFNγ) ↓ TH2 response (IL-4)
Resistin	Pro-inflammatory	↑ TNF-α ↑ IL-1β ↑ IL-6 ↑ IL-12 ↑ NF-kB ↑ Endothelial adhesion molecules	–
Visfatin	Pro-inflammatory	↑ IL-6 ↑ IL-8 ↓ Apoptosis of neutrophils	–

also associated with more severe psoriasis and negatively impacts long-term treatment options [223–225]. Moreover, there is increasing evidence that progressive weight loss can produce significant improvements in the severity of psoriasis [226–228] and another direct evidence that obesity may be causal in psoriasis is the fact that bariatric surgery can produce rapid remission from psoriasis [227, 229, 230]. Obesity, with its low-grade systemic inflammation state, and in particular AT, with its immune and endocrine roles, are able to influence the pathogenesis and the development of psoriasis in numerous different ways. For example, the consequences of obesity induced chronic inflammatory state are also especially dire at epithelial tissues with the resulting dysregulation of γδ T cells which may contribute to susceptibility to psoriasis in obese subjects. Indeed, a reduction of a subset of γδ T cells (Vγ9Vδ2) in peripheral blood and their subsequent increase in the epidermis has been documented in psoriasis patients [231]. These cells were able to produce inflammatory cytokines and mediate crosstalk with keratinocytes, suggesting a role for these T cells in the development and the exacerbation of the dermatosis [231]. However, a crucial role in the connection between obesity and psoriasis is indubitably played by the adipokines secreted by AT. Various cells in AT are able to produce TNF-α, as well as other cytokines involved in psoriasis, such as IL-1, IL-6, IL-17 and IFN-γ [20, 66, 97, 232]. The abnormal adipokine levels reported in psoriasis suggest that the systemic inflammation associated with the disease may be linked with AT inflammation, similar to that seen in obesity. Central obesity is associated with greater amounts of inflammatory visceral fat, which is more hypertrophied, contains more macrophage infiltration, has an increased presence of activated T cell populations and expresses a more pro-inflammatory cytokine profile, marked by increased TNF-α, IL-6 and IL-17, and decreased adiponectin [16, 77, 233]. Interestingly, a similar inflammatory state of activated T cells and increased pro-inflammatory cytokines has been described in psoriasis, and is thought to be responsible for the induction of psoriatic plaque formation [234]. All the above mentioned factors, as well as other adipokines such as leptin, are recruited and stimulated in obesity and may have an autocrine and paracrine effect on nearby skin [232, 235]. In particular, leptin levels (both serum and tissue leptin) are enhanced in psoriasis also due to possible functional polymorphism of its gene [236–238] and their concentrations have been also shown to correlate with psoriasis severity [237]. In addition, tissue leptin receptor expression is reported to be significantly higher in patients with severe psoriasis than in patients with mild–moderate psoriasis and controls [237]. Leptin decreases T cells autoregulation, is potentially involved in inflammatory processes stimulating cytokine release and its raised levels may mediate proliferative and antiapoptotic activities in a number of cell types including T cells as well as the increased production of pro-inflammatory cytokines such as IL-6 and TNF-α, some of the major cytokines acting in psoriasis pathogenesis [126, 239, 240]. Moreover, leptin synergistically with IL-1β enhances

the production of the antimicrobial peptide human βdefensin-2 (hBD2), whose levels are elevated in psoriasis [241, 242]. In particular, hBD2 seems to be involved in the development of skin inflammation by binding to the CC chemokine receptor 6, consequently inducing chemotaxis of memory T cells or immature DCs and the production of IL-6, CCL20, and CCL5 in keratinocytes [243, 244]. The released hBD-2 may in turn act on keratinocytes, inducing their proliferation and production of pro-inflammatory cytokines/chemokines in an autocrine/paracrine manner, sustaining the dysregulations observed in psoriasis [243]. Thanks to all these proprieties, leptin is able to deeply regulate immune response, being involved in psoriasis pathogenesis, especially its effects on T cells differentiation to Th1 phenotype, induction of pro-inflammatory cytokines by keratinocytes and promotion of keratinocyte proliferation as well as angiogenesis [126, 245–248]. However, there are other several adipokines which are both dysregulated in obesity and psoriasis. For example, resistin leads to up-regulation of inflammatory processes, including TNF-α secretion, is increased in serum of patients with psoriasis, correlating with obesity and increased severity of psoriasis [249, 250]. These evidences support the view that resistin may be involved in the pathogenesis of psoriasis, especially in overweight individuals, possibly by augmenting cytokine expression by the inflammatory infiltrate. On the other hand, levels of adiponectin are lower in psoriatic skin compared with controls (also independently of cardiometabolic risk factors) and in obese psoriatic patients versus normal weight psoriasis subjects [251, 252]. In addition, it has been shown that patients with psoriasis, plasma adiponectin negatively correlated with psoriasis severity and that successful anti-inflammatory treatments may elevate adiponectin levels [253, 254]. All these observations constitute some indirect evidence that the immunological and metabolic alterations associated with obesity may be linked with the pathophysiology of psoriasis. Further data which highlight the complexity of the biologic relationship between AT and psoriasis came from Albanesi et al. who reported elevated serum chemerin levels in psoriatic patients and expression of chemerin in early psoriatic lesions as well as pre-psoriatic skin adjacent to active lesions, in parallel to infiltration by pDCs and neutrophils [255]. However, in chronic plaques low chemerin levels and low pDCs infiltration were found whereas immunoreactive chemerin was present in fibroblasts, mast cells and endothelial cells in early lesions [255, 256]. Taken together all these evidences suggested a role for chemerin in the early phases of psoriasis development. Conversely, the relationship between increased fat mass, psoriasis and adipokines alteration is not always so clear and linear as is highlighted by few papers which show controversial results compared with the above mentioned [250, 257]. In this context the case of an adipokine, such as vaspin, is paradigmatic since it is reported to be elevated in serum of obese subjects [258] whereas serum vaspin is not enhanced in psoriasis patients, being also entirely independent of BMI. Moreover, its expression is decreased in lesional psoriatic skin [259, 260]. However, the literature is full of evidences regarding the strict link between obesity and psoriasis; nevertheless, a causal relationship between them has not been fully established yet. Obesity may occur as a consequence of psoriasis or the obese state may well exacerbate the severity of the disease.

Atopic Dermatitis

AD is a chronic, recurrent, pruritic inflammatory disorder of the skin that has reached epidemic proportions throughout the world, especially in children and adolescents who also showed significantly increased rates of obesity versus previous decades [261–265]. Several studies reported that obesity, particularly when it begins early in life, is associated with increased risk and severity of AD in children whereas other investigations provided evidence of an association between obesity and increased AD also in adult individuals, proposing AD as yet another harmful consequence of obesity [266–270]. To date, the mechanism behind the association of obesity and AD remains unclear. However, few studies indicated that the immunomodulatory effects of obesity might be most profound during the first 2 years of life suggesting a possible effect on the immature immune system. Indeed, obesity is associated with a variety of immune sequelae, including accumulation of macrophages and cytotoxic T cells in AT, production of TNF-α and IL-6, and increased secretion of leptin. This has numerous pro-inflammatory effects on the immune system, including proliferation and activation of circulating monocytes and CD41 and CD81 T cells, polarization of T cells toward a Th1 response, activation of NK cells, promotion of neutrophil chemotaxis and upregulation of numerous cytokines [16, 98, 121, 129, 271–273]. Indeed, the prevalence of AD is reported to be somewhat increased in children with high leptin levels [274]. In addition, obesity is associated with low levels of adiponectin, whose reduced expression has also been detected in AD subjects [274]. Moreover, recently Machura et al. reported that children with AD showed elevated apelin concentrations, apelin/BMI ratio and resistin levels versus healthy children despite similar body weight whereas Suga et al. observed that visfatin levels were increased in both serum and skin lesions of AD patients suggesting that these adipokines may be implicated in AD immunopathogenesis [275, 276]. However, studies on visfatin in AD children are controversial since another survey reported lower serum concentration versus healthy controls [275]. Finally, it is also reported that non obese children with AD show an increased prevalence of fatty liver, a known risk factor for lifestyle-related diseases such as obesity, versus non obese healthy controls [277]. The reasons for this association is not well elucidated but it is speculated that AD subjects may present an enhanced permeability of the small intestine which

leads to fatty acid dysregulation which is involved in the pathogenesis of both AD and fatty liver [278, 279].

Hidradenitis Suppurativa

HS is a chronic inflammatory skin disorder characterized by recurrent, painful nodules, abscesses, and draining sinuses, with resultant scarring. Obesity has been associated with HS in up to 75% of cases and, compared to controls, HS was significantly associated with higher BMI [280–282]. In addition there seems to be a relationship between obesity and the severity of HS so that obesity is considered as a HS severity risk factor [283, 284]. Moreover, weight loss of more than 15% is reported to be associated with a significant reduction of disease severity [285]. In general, it seems that obesity is able to confer a 1.2-times greater risk for developing HS [282]. Consequently, obesity is considered to participate in the pathophysiology of this skin disorder [280, 281]. A disturbance of the cutaneous innate immune system has been implicated in the key pathogenic steps of HS such as follicular occlusion and chronic inflammation [281]. Moreover, HS has been associated with abnormal expression of antimicrobial proteins, deficiency of IL-20 and IL-22, and elevated TNF-α, IL-1β, and IL-8 levels leading to sustained inflammation and chronic pro-inflammatory state [186, 286–289]. Since AT is a significant source of different pro-inflammatory molecules, which levels are up-regulated when AT is excessively present such as in obesity, it is not unreasonable to hypothesize that AT and its secretory products may participate in the pathomechanisms of HS and the related cutaneous immune system dysregulations. Indeed, obesity is causally linked to a systemic low-grade inflammatory state with increased levels of pro-inflammatory cytokines in the blood (e.g. IL-1, IL-6, IL-8, TNF-α, CRP) [97, 290, 291] and many of these factors are enhanced and involved also in HS pathogenesis. Furthermore, PBMCs in the obese are in a constant pro-inflammatory mode and demonstrated a significant increase in NF-kB binding and an increase in the transcription of pro-inflammatory genes regulated by NF-kB in these cells [292]. Therefore, even if obesity may not be the primary causative factor in HS, the above mentioned data suggest how it may contribute to HS pathogenesis. However, since a pro-inflammatory state has been also thought to be the driving force for an increase in obesity and metabolic syndrome, to date it is not known if the HS triggers these pathologies or if obesity and metabolic disorders predispose the individual to the development of the inflammatory skin disorder.

Other Skin Diseases

Several links between adipokine dysregulation and skin inflammatory diseases, pathologies which are characterized during their natural course by cutaneous inflammatory phases and/or a more widespread alteration of the immune system are reported in literature. For example, laboratory assessments of patients with systemic lupus erythematosus (SLE) indicated elevated leptin levels which might contribute to systemic inflammation even if to date the clinical and pathogenic significance of this elevation remains unknown [293–296]. However, Yu et al. showed that leptin was able to promote Th17 responses in normal human CD4+ T cells, both in vitro and in vivo, by inducing RORγt transcription. Since Th17 cells play an important role in the development and maintenance of inflammation and autoimmunity, the authors hypothesized the involvement of leptin in autoimmunity and in the connection between metabolism/nutrition and susceptibility to autoimmunity [297]. Several other adipokines are reported to be altered in SLE. Indeed, SLE was independently associated with higher resistin levels and the presence of an association between resistin and inflammation, low complement levels, bone mineral density, and renal function is suggested [298, 299]. In addition, lupus erythematous skin lesions significantly express chemerin (in the endothelium of dermal blood vessels and venules of secondary lymphoid organs) and harbor CMKLR-expressing pDCs, suggesting that chemerin is involved in the recruitment of these cells and other leukocyte populations in this disease [148, 300]. Moreover, visfatin concentrations are reported to be significantly higher in patients with SLE which might reflect inflammation in this systemic disease [293]. However, few other surveys showed controversial data investigating adipokines profile in SLE patients (e.g. lower or unchanged levels of leptin and no significant differences for resistin) [301, 302].

In regard to other disorders, serum leptin concentrations were reported to be significantly increased in systemic sclerosis (SSc) patients versus healthy subjects with similar BMI, however without being significantly correlated or associated with disease duration, clinical activity score, skin score, CRP and antinuclear antibody (ANA) test results [303]. The possible involvement of adipokines in SSc development (where inflammation occurs prior to fibrotic response) is highlighted also by Masui et al. who reported that adiponectin serum levels where significantly lower in patients with diffuse cutaneous SSc (dcSSc) versus those with limited cutaneous SSc and that these levels inversely correlated with the activity of progressive skin sclerosis in dcSSc patients, suggesting that adiponectin serum concentrations may serve as a useful marker to evaluate the activity of progressive skin sclerosis in dcSSc [304]. Consequently, the authors hypothesized that decreased serum levels of an anti-inflammatory factor such as adiponectin may be associated with increased IL-6 levels through modulating the TNF-α action, which promotes the inflammatory process in early dcSSc leading to resultant fibrosis. Indeed, other authors investigating adiponectin, IL-6, IL-2, CRP, ANA and antibodies to extractable nuclear antigens levels in 39 SSc patients speculated that adiponectin could play a protective role in skin related changes during SSc by

observing that lower adiponectin serum levels were associated with an advanced stage of skin fibrosis and also because adiponectin is reported to exert anti-fibrotic proprieties [305, 306]. All these findings are reinforced by the study of Arakawa et al. who showed that adiponectin mRNA levels were reduced in skin tissues from patients with dcSSc [307]. Finally, another example could be represented by sarcoidosis. Indeed, very recently Harpsøe et al. conducted a study on 75,008 women who were followed during a median time of 11 years in order to investigate a possible aetiological link between obesity and certain autoimmune diseases [308]. In the sub-group of obese women a high risk was observed for sarcoidosis. Nevertheless its aetiology remains unknown; the disease involves immunological changes similar to those seen in obesity, including TNF-α production [309, 310] and its development may depend on a combination of genetic factors, the triggering antigen itself and immune system status in which the immunologic alterations caused by obesity could play a role [311].

Conclusion

AT has both immune and endocrine roles producing numerous molecules including cytokines, chemokines, growth factors, hormones etc. Therefore, given its proprieties and widespread localization in the human body which is also responsible for the strict and extensive contact between skin and subcutaneous AT, it is indisputable that AT is able to significantly influence the immune responses, the immune skin system and consequently the pathogenesis of several cutaneous inflammatory disorders. We have just shown above the main examples of this interesting relationship trying also to highlight its numerous different molecular and biological basis. Without any doubts, further investigations are needed to deeply investigate AT functions and its ability to regulate skin immune system and cutaneous inflammation.

Questions

1. What cell type does NOT constitute normal adipose tissue?
   A. Adipocytes and pre-adipocytes
   B. Vascular cells
   C. Stromal cells
   D. Lymphoid/hematopoietic cells
   E. Neutrophils

Correct answer: (E) Neutrophils do not normally constitute adipose tissue. This cell type can migrate into adipose tissue during inflammatory responses.

2. How can the adipose tissue act as an endocrine organ?
   A. Secretion of hormone s such as leptin and IGF-1
   B. Producing GH
   C. Producing insulin
   D. Modulating TSH

Correct answer (A) Secretion of hormones such as Leptin and IGF-1. Adipose tissue does not produce GH, Insulin or modulate TSH.

3. What is the principal adipokine and its relative functions?
   A. Insulin, which controls appetite.
   B. Leptin, which regulates growth, metabolism, and behavior
   C. Growth hormone, which repairs tissue damage
   D. Testosterone, which controls sex drive.

Correct answer: (B) Leptin controls growth, metatolism and behavior. None of the other hormones are derived from adipose tissue, and are thus not considered to be adipokines.

4. What is the role of adipose tissue in a chronic inflammatory skin disease such as psoriasis?
   A. Metabolize drugs used to treat psoriasis
   B. Enhances the absorption of lipophilic drugs such as acitretin
   C. Plays a role in suppressing immune responses
   D. Cells in adipose tissue produce inflammatory cytokines involved in pathogenesis of psoriasis

Correct answer: (D) Inflammatory cells that reside in adipose tissue can produce a number of cytokines involved in psoriasis, such as IL-1, IL-6, IL-17 and IFN-γ.

Cytokines and Chemokines

15

Matthew J. Turner

Abstract

Cytokines are small proteins used for intercellular communication in the immune system and beyond. They are subclassified based on membership in tumor necrosis factor, interleukin, interferon, transforming growth factor beta and chemokine superfamilies. Readily observed and easily accessible for manipulation and isolation, the skin is an excellent model system for studying the biology of cytokines. Important insights into mechanisms of cutaneous inflammation and immunity in health and disease have been and continue to be translated into the practice of dermatology and other areas of medicine. Cytokine-targeted therapies are now commonplace in the practice of dermatology, with many cytokine or cytokine receptor-target therapies in clinical trials for dermatologic diseases. As the list of available therapeutics grows, it is incumbent upon physicians to understand when and how to use these medications for safe and effective outcomes. To achieve this goal, a sound understanding of mechanisms of cutaneous inflammation and immunology mediated by cytokines is important.

Keywords

Cytokines • Chemokines • JAK-STAT signaling • Macrophages • Dendritic cells • Keratinocytes • Interleukins • Interferon family • T cell trafficking

Introduction

Cytokines are structurally and functionally heterogeneous soluble proteins that, following active or passive release from cells, bind and signal through ligand-specific receptors on target cells. While it may be evident that signals transduced by cytokines are dependent on the cytokine and its receptor (s), other key determinants dictating functional consequences of cytokine receptor engagement include the cell type expressing the receptor and the niche where it resides. In this way, the human body uses a relatively small number of soluble molecules to orchestrate an almost incomprehensible number of developmental and effector functions. The influence of cytokines on T helper (Th) cell development is an excellent example of this concept and will be referred to throughout this chapter (Fig. 15.1). For example Th9 cell development requires a dendritic cell to present antigen and provide proper co-stimulation to a naïve T cell in the lymph node in the presence of the cytokines, interleukin 4 (IL-4) and transforming growth factor beta (TGF-β). In contrast, omitting TGF-β leads to Th2 cell development (Fig. 15.1). The ensuing sections attempt to focus on those aspects of cytokine production and function involved in normal and pathologic aspects of inflammation and immunity in the skin. After a brief overview of JAK/STAT signaling, this chapter will describe the biology of individual cytokines in the context of the superfamilies to which they belong; these superfamilies are defined as tumor necrosis factor (TNF), interleukin, interferon, transforming growth factor beta (TGFβ) and chemokine. To illustrate how cytokines contribute to cutaneous inflammation in

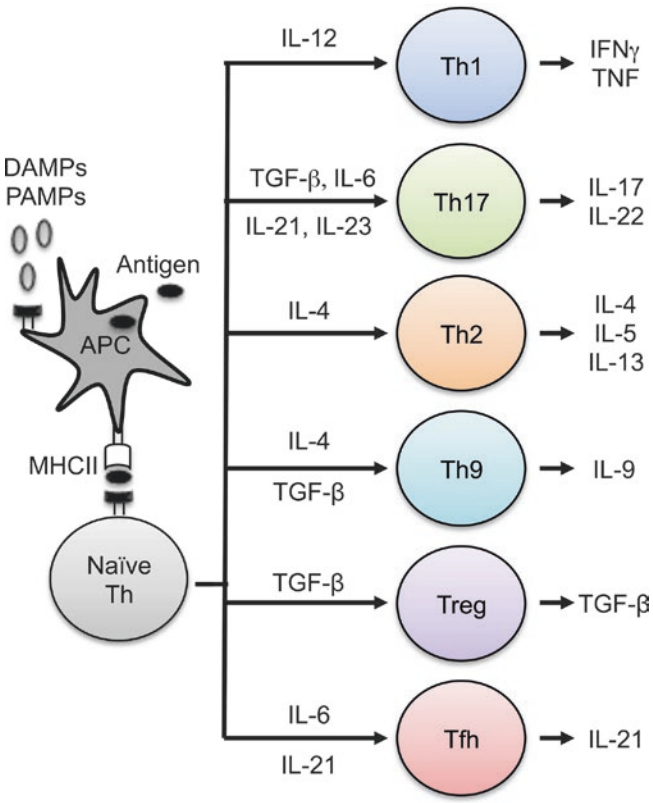

Fig. 15.1 Effect of cytokines on T helper (*Th*) cell development. Schematic depicts a mature dendritic cell (*APC*) in the lymph node presenting antigen (*black oval*) in the context of an MHC class II molecule to a naïve Th cell. Damage- or pathogen-associated molecular patterns (*DAMPs and PAMPs*) promote maturation and cytokine production by the APC. Development of Th subsets (*Th1, Th2, Th9, Th17*), $CD4^{+}FoxP3^{+}$ regulatory T cells (*Treg*) and follicular helper cells (*Tfh*) is dictated by interaction with the APC and specific cytokines or combinations of cytokines including interleukins (*IL*) and transforming growth factor beta (*TGF-β*). These Th subsets in turn produce specific cytokines including interleukins, TGF-β and interferon gamma (*IFNγ*) (Adapted from figure courtesy of Mark H. Kaplan, Ph.D.)

dermatologic disease and summarize much of the information presented in this chapter, Table 15.1 synthesizes many of the important characteristics of cytokines implicated in psoriasis or atopic dermatitis (AD) pathogenesis.

JAK-STAT Signaling

Cells use cytokines to communicate with themselves and other cells via cytokine-specific receptors. Receptor engagement activates intracellular signaling pathways that dictate target cell responses. Regulation of target gene expression is an important effect of cytokine stimulation. Many cytokines, namely interleukins and interferons, use receptors that activate Janus kinases (JAK1, JAK2, JAK3 and Tyk2) to initiate signal transduction; Janus kinases in turn phosphorylate signal transducer and activator of transcription (STAT) proteins which include STAT1, STAT2, STAT3, STAT4, STAT5 and STAT6. Phosphorylated STAT proteins then homo- or heterodimerize and translocate to the nucleus where they regulate cytokine-dependent target gene expression (Fig. 15.2). Janus kinase inhibitors are currently in clinical trials for psoriasis and atopic dermatitis. Thus, understanding the concepts of how JAK and STAT proteins function will likely become more important to the practice of dermatology. The specific JAK and STAT proteins used by individual cytokines will be discussed in the coming sections.

TNF Family

The tumor necrosis factor superfamily (TNFSF) originally consisted of TNF and lymphotoxin; at least 16 more members have been identified [1]. In addition to immunomodulation, some TNFSF members also regulate processes like organogenesis, epithelial cell development and bone remodeling [2]. Some of the other family members are linked to pathogenesis of rare diseases like X-linked hypohidrotic ectodermal dysplasia, Stevens-Johnson Syndrome/Toxic epidermal necrosis and hyper IgM syndrome, but the most important by far to the current understanding of cutaneous immunology, pathogenesis and therapy for dermatologic diseases is TNF [3–5].

The TNFSF is composed of cell surface-bound and/or soluble proteins, most of which are synthesized as heterotrimeric transmembrane proteins [6, 7]. The trimeric TNF homology domain of many TNFSF members can be liberated from the cell surface (i.e. solubilized) by specific proteases [6]. Surface bound and/or soluble forms of the trimeric TNF homology domains act as ligands for their cognate receptor(s) [7]. In humans, the TNF receptor superfamily (TNFRSF) includes at least 29 members [8]. Most are synthesized as transmembrane proteins; some undergo proteolysis to generate soluble receptors, while others are synthesized *de novo* as soluble receptors. The extracellular domain or soluble forms of these receptors bind TNFSF members, while the intracellular portions of the transmembrane forms mediate signal transduction. The TNFRSF are divided into activating and death receptors. Activating receptors trigger nuclear factor kappa B (NF-kB) and mitogen-activated protein kinase (MAPK) signaling, promoting cellular survival, proliferation and differentiation. Death receptors initiate apoptosis or necroptosis [8].

Table 15.1 Role of selected cytokines in psoriasis or atopic dermatitis pathogenesis

Disease	Cytokine	Sources	Stimuli	Target	Effect	Tx
Psoriasis	TNF	DC, M, K Th17, Th22	TNF, IL-1, GM-CSF, DAMP, PAMP	K, DC, T	Chem; N recruit; K prolif; AMP; IL-1,-6,-20R,-23,-36, DC mig/mat, Th17/Th22 dev	Y

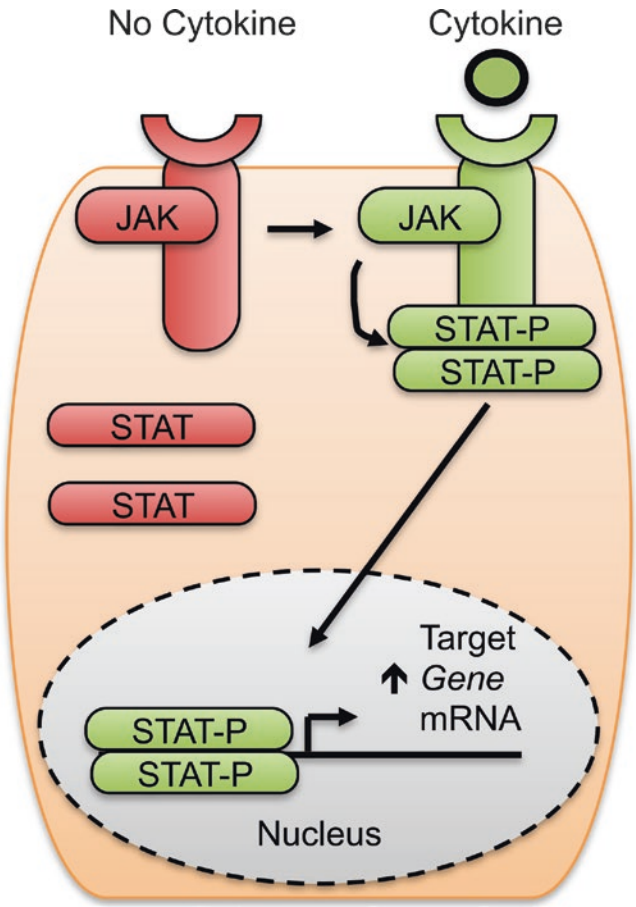

Fig. 15.2 Overview of Janus kinase (*JAK*) and signal transducer and activator (*STAT*) signaling pathway utilized by many cytokines. In the absence of cytokine, the cytokine receptor, JAKs and STATs are inactive (*red shading*). Cytokine (*green circle*) activates the pathway (*green shading*). Activated JAKs phosphorylate STAT proteins (designated STAT-P). STAT-P then dimerizes and translocates to the nucleus to regulate target gene expression

Tumor Necrosis Factor

Multiple cell types including macrophages, dendritic cells and keratinocytes produce TNF [9–11]. Production is regulated at transcriptional and post-transcriptional levels and is induced by cytokines (e.g. GM-CSF, IL-1 & TNF) and danger signals, the latter of which are subclassified as pathogen- and damage-associated molecular patterns (PAMPs and DAMPs) such as lipopolysaccharide and the host protein HMGB1, respectively [12–15].

After synthesis, TNF is expressed on the cell surface as a homotrimer, which can activate TNF receptors directly or undergo site-specific cleavage by the proteases ADAM10 and 17 releasing a homotrimeric soluble form [13, 16, 17]. While the membrane-bound form is important for secondary lymphoid tissue development, defense against intracellular pathogens and limiting chronic inflammation and autoimmunity, the soluble form promotes acute and chronic inflammation [18, 19]. These differential effects are in part explained by the fact that the membrane-bound form of TNF can activate both TNF receptors (TNFR1 and TNFR2), while the soluble form can only engage TNFR2 [13, 20]. While TNFR1 is widely expressed on many cells types, TNFR2 expression is more restricted to leukocytes, endothelial cells, keratinocytes and several other cell types [21]. TNFR2 is an activating receptor, while TNFR1 is both a death and activating receptor.

Given the pleiotropic functions and numerous contexts in which TNF acts, it is beyond the scope of this chapter to discuss all that this molecule does in the skin. Instead its role in psoriasis will be presented as an example of how TNF regulates cutaneous inflammation (see also Chap. 21). Increased quantities of TNF mRNA and protein are detected in psoriatic lesions [22]. Potential sources of TNF in psoriatic lesions include myeloid cells (e.g. TNF/iNOS-producing dendritic cells), T helper cell subsets (Th17 and Th22) and keratinocytes [23, 24]. In response to TNF, keratinocytes can proliferate and produce chemokines, cytokines and antimicrobial peptides; chemokines produced by TNF-stimulated keratinocytes recruit myeloid dendritic cells, Th17 cells and neutrophils, promoting inflammation [23]. Conversely, TNF acts on immature dendritic cells in the skin to promote their maturation and migration out of the skin and into draining lymph nodes where they present antigen to naïve T cells [23]. In the lymph node, TNF can promote differentiation of Th17 and Th22 cells from naïve T cells [25]. The Th17 and Th22 subsets can then return to the skin where they produce effector cytokines including IL-17A, IL-17F and/or IL-22, that can stimulate keratinocytes, leading to epidermal hyperplasia, production of antimicrobial peptides, chemokines and other cytokines, further promoting inflammation and disease [23]. The pleiotropic functions of TNF in psoriasis pathogenesis demonstrate how this cytokine is a central mediator of disease, which helps explain why TNF inhibitors are so efficacious for treatment of psoriasis and other dermatologic conditions [26, 27].

Interleukins

The term *Interleukin* (meaning between leukocytes) was originally proposed in 1979 in an effort to distinguish between two biochemically distinct lymphocyte activating proteins, interleukin 1 (IL-1) and interleukin 2 (IL-2) [28]. Since then, the list of interleukins has grown, now ending at IL-38 [29]. Some interleukin designations are further subdivided (i.e. IL-1α and IL-1β or IL-36α, β, γ) as a result of identifying cytokines (encoded by different genes) that signal via the same receptor. Based on similarities in structure, function and/or receptor usage, interleukins can be subdivided into families. In this section, the defining characteristics

of a given interleukin family will be presented followed by a more detailed discussion of the family members most relevant to understanding cutaneous immunity, inflammation and disease. The families discussed are, IL-1, common gamma chain (γ_c), beta chain, IL-6, IL-10, IL-12, and IL-17.

Interleukin 1 Family

The IL-1 family consists of structurally similar but functionally diverse cytokines with a number of critical pro- and anti-inflammatory actions that govern cutaneous inflammation, immunity and disease. In humans, there are at least 11 members of the IL-1 family, most of which are receptor agonists (IL-1α, IL-1β, IL-18, IL-33, IL-36α, IL-36β, IL-36γ and IL-37), with the remainder being receptor antagonists (IL-1Ra, IL-36Ra and IL-38) [29]. With the exception of IL-37, which can bind to IL-18α alone, IL-1 family members that act as receptor agonists bind heterodimeric receptors [29]. The receptor complexes for IL-1α, IL-1β, IL-33 and IL-36α, IL-36β and IL-36γ are composed of a ligand-selective subunit bound to IL-1 receptor accessory protein (IL-1RAcP), while the IL-18 receptor is composed of two unique subunits, IL-18Rα and IL-18Rβ. The IL-1 receptor family members consist of an extracellular immunoglobulin-like domain and an intracellular portion that includes a TIR domain, the latter of which is also present in toll-like receptors (TLR). The TIR domain recruits the adaptor protein MyD88 to initiate downstream signaling events leading to MAPK and NF-kB activation and subsequently, target gene expression [30]. Unique aspects of IL-1 family member synthesis, processing and release will be discussed in the coming sections.

Interleukin 1

The designation IL-1 refers to two structurally distinct proteins, IL-1α and IL-1β that are encoded by different genes but share common receptors (i.e. IL-1R1/IL-1RAcP or IL-1R2/IL-1RAcP receptor complexes) [30]. There is also an endogenous IL-1 receptor antagonist, IL-1Ra, a recombinant form of which has been used therapeutically to treat IL-1-mediated inflammatory diseases [31]. Similar to TNF, IL-1α and IL-1β are considered innate cytokines, playing a key role in promoting local and in some cases, systemic inflammation and immunity. In addition to contributing to homeostatic aspects of cutaneous immunity and inflammation, IL-1 is implicated in the pathogenesis of Still's disease, pyoderma gangrenosum (PG), Behçet's disease, hidradenitis suppurativa (HS) and a number of autoinflammatory diseases. Importantly, IL-1 blockade can be an effective therapy for these diseases [32–34]. Host defense against bacterial pathogens is also mediated by IL-1, as are various aspects of keratinocyte proliferation, differentiation and function (see also Chap. 16) [35–37].

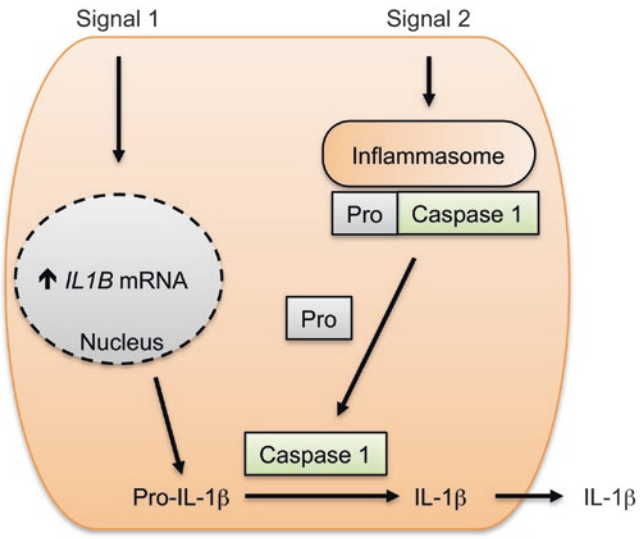

Fig. 15.3 Two-signal model for production of IL-1β in host cells. Signal 1 (e.g. cytokine) induces expression of *IL1B* mRNA, which is then translated in an inactive protein (Pro-IL-1β). Signal 2 (e.g. ATP) stimulates the same cell activating the inflammasome, which then generates Caspase 1 from its inactive precursor, Pro-Caspase 1. Caspase 1 then cleaves Pro-IL-1β, generating IL-1β that is then secreted from the cell

Keratinocytes and other epithelial cell types constitutively produce IL-1α [38]. Unlike IL-1β and most other cytokines, IL-1α is synthesized as a precursor containing a nuclear localization sequence allowing IL-1α to traffic into the nucleus, bind chromatin and regulate transcription [29]. Cellular damage or necrosis promotes release of IL-1α into the local milieu thereby promoting local (neutrophil-mediated) inflammation; as such IL-1α is classified as an alarmin. In contrast, IL-1α remains tightly bound to chromatin during apoptosis, thus restricting inflammation [29].

The disparate effects of IL-1β, compared to IL-1α, are largely a function of differences in cellular processing and cellular sources rather than differences in signaling pathways used by these cytokines [29, 38]. Sources of IL-1β include monocytes, macrophages and dendritic cells and keratinocytes [30]. Like IL-1α, IL-1β is synthesized as a precursor. Unlike IL-1α, production and release of the active form of IL-1β is a highly regulated process mediated by an intracellular complex known as the inflammasome (Fig. 15.3). Production of IL-1β begins with transcription of the *IL1B* gene and synthesis of Pro-IL-1β. Multiple stimuli (referred to as signal 1) promote *IL1B* transcription (e.g. TNF, TLR ligands and IL-1) [29]. Unlike IL-1α, the IL-1β precursor (Pro-IL-1β) does not activate IL-1 receptors. Instead, Pro-IL-1β must first undergo proteolysis to generate mature IL-1β [39]. Proteolysis of Pro-IL-1β is performed by caspase-1, which itself must first undergo proteolytic cleavage by the inflammasome. Stimuli that trigger inflammasome activation (referred to here as signal 2) include DAMPs like ATP, pore forming bacterial toxins and others [36]. Upon

activation, the inflammasome cleaves procaspase-1 to caspase-1; caspase-1 in turn cleaves Pro-IL-1β generating IL-1β, which is then secreted (Fig. 15.3).

Gain of function mutations in genes encoding proteins in inflammasome underlie a number of autoinflammatory diseases with cutaneous manifestations including: pyogenic arthritis, pyoderma gangrenosum and acne (PAPA) syndrome as well as the periodic fever syndromes, familial Mediterranean fever (FMF) and cold induced autoinflammatory syndromes-1 (CIAS-1), like Muckle-Wells syndrome, familial cold urticaria and neonatal-onset multisystem inflammatory disease [40]. In patients with CIAS-1 spectrum disease, periodic fevers result from increased circulating levels of IL-1β acting as a pyrogen, while urticarial eruptions may be due to skin-resident mast cell-derived IL-1β stimulating increased permeability of cutaneous blood vessels [41, 42]. The critical role of IL-1β in autoinflammatory diseases is highlighted by their responsiveness to IL-1-blocking therapeutics [40].

Several key aspects of host defense against cutaneous infections with *Staphylococcus aureus* are dependent on IL-1 [36]. In this setting, cell wall components from *S. aureus* (e.g. lipotechoic acid and bacterial peptidoglycan) activate TLR2 on keratinocytes and macrophages stimulating IL-1 production [43]. Keratinocytes in turn produce IL-1α, and lesser amounts of IL-1β, while macrophages primarily produce IL-1β [36]. Activation of IL-1 receptors for IL-1α or IL-1β, then stimulates keratinocyte production of antimicrobial peptides, neutrophil-attracting chemokines and other cytokines, like IL-6. Antimicrobial peptides can directly combat the infection, while chemokines and IL-6 can recruit neutrophils into the skin; notably, IL-1 can also prolong neutrophil survival, further promoting neutrophil-mediated clearance of the infection [36, 44].

Interleukin 33

Interleukin 33 (IL-33) is a dual function protein that acts as a cytokine and a nuclear factor that may regulate NF-kB-dependent genes [45, 46]. Cellular damage or necrosis releases IL-33 promoting local inflammation; thus IL-33 is an alarmin like IL-1α [47]. Conversely, proteolytic cleavage inactivates IL-33 during apoptosis preventing IL-33-mediated inflammation [48]. The IL-33 receptor is expressed on Th2 cells, innate lymphoid type 2 cells (ILC2), macrophages, mast cells, eosinophils and other cells. Effects of receptor engagement are cell type specific explaining the pleiotropic functions of IL-33 [49]. For example, IL-33 promotes Th2 cell development and cytokine production, mast cell maturation and activation and polarization of macrophage development towards an M2 phenotype [50, 51]. Paradoxically, IL-33 can promote Th1-polarized inflammation via NK and $CD8^+$ T cell stimulation [50]. Expression of IL-33 is increased in lesional skin keratinocytes in atopic dermatitis (AD), psoriasis and lichen planus [52, 53]. In AD, IL-33 concentrations are reportedly increased in the peripheral blood of patients with moderate to severe disease and are reduced following effective topical therapy with steroids or calcineurin inhibitors [52, 54]. These results suggest keratinocyte damage or death in AD lesional skin (possibly secondary to scratching the skin) release IL-33 into the circulation, the consequences of which are not defined in this context.

Interleukin 36

The IL-36 family includes receptor agonists IL-36α, IL-36β and IL-36γ, hereafter referred to as IL-36. The family also includes IL-36Ra, a receptor antagonist [55]. The IL-36 receptor is composed of IL-36R and IL-1RAcP and utilizes signal transduction pathways like that described above for other IL-1 family members. Loss of function mutations in the *IL36RN* gene (encodes IL-36Ra) cause some familial and sporadic cases of generalized pustular psoriasis and Acrodermatitis Continua of Hallopeau [56, 57]. Loss of IL-36Ra function is thought to lead to unopposed activation of IL-36 signaling.

The IL-36 receptor is expressed on keratinocytes, monocytes and some dendritic cells [55, 58, 59]. Keratinocytes can produce IL-36α, IL-36β, IL-36γ and IL-36Ra [55]. Transcripts encoding IL-36 family, in low abundance under non-inflammatory conditions, are increased under inflammatory conditions as seen in psoriatic lesions or keratinocytes stimulated with TNF, IL-17, or IL-1 [55]. In human keratinocytes, IL-36 stimulates production of chemokines known to attract T cells, neutrophils and macrophages [58]. In contrast, stimulation of monocytes and myeloid dendritic cells with IL-36 triggers IL-1β and IL-6 production and increased proportions of cells expressing the co-stimulatory molecule CD86 and MHC class II [58]. These observations suggest IL-36 family members are important mediators of inflammation in the skin. Consistent with results from genetic studies suggesting a role for IL-36 in psoriasis pathogenesis, IL-36 is reported to promote psoriasiform inflammation in mice [55–59]. Integrating our current understanding of psoriasis pathogenesis and IL-36 biology, the literature suggests the following role for IL-36 in disease: (1) innate cytokines like IL-1β and TNF as well as IL-17A can stimulate IL-36 production by keratinocytes; (2) IL-36 stimulates keratinocytes to produce multiple chemokines promoting migration of neutrophils, macrophages and T cells in and into the skin; (3) IL-36 stimulates some dendritic cell subsets promoting antigen presentation to T cells and production of innate cytokines like IL-1β and IL-6; (4) IL-1β, TNF, and IL-17A promote various aspects of inflammation in psoriatic lesions and further production of IL-36 by keratinocytes leading to a vicious cycle and persistent disease. Thus, IL-36 or its receptor may become viable therapeutic targets for psoriasis and

potentially other dermatologic conditions. Future investigation is still needed to clarify the role of IL-36 in other aspects of normal or pathologic inflammation and immunity in the skin.

Common Gamma Chain Receptor Family

The common gamma chain (γ_c) receptor family includes IL-2, IL-4, IL-7, IL-9, IL-15 and IL-21 [60]. The γ_c receptor subunit that defines the family is a transmembrane protein that transduces signals in part through JAK3 [61]. Receptor signaling is initiated by heterodimerization or heterotrimerization with ligand-specific receptor subunits [62]. These receptors signal via JAK-STAT, PI3K-Akt and RAS/MAPK pathways promoting cell survival, proliferation and regulation of target gene expression [63]. The JAK-STAT family members activated by these cytokines is ligand-specific. Recently, a secreted form of γ_c generated by alternative splicing has been identified in mouse and human T cells and appears to act as a decoy receptor for some γ_c family cytokines [64].

Cytokines in the γ_c family regulate lymphoid cell development, survival and/or function (see also Chap. 8) [65]. Additional targets include mast cells, myeloid cells and other hematopoietic cells. Genetic deficiency of functional γ_c chains or JAK3, leads to severe combined immunodeficiency (SCID), highlighting the importance of this receptor family in host immunity and inflammation [66]. Cutaneous manifestations of these forms of SCID include eczematous dermatitis and infections with *S. aureus*, HPV or *Candida spp*. and graft versus host disease (GVHD) [67]. The diverse cutaneous and systemic manifestations seen in these forms of SCID reflect broad defects in IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21 function.

In the coming sections, the roles of IL-2, IL-4 and IL-9 in cutaneous immunity and inflammation will be presented. The functions of IL-7, -15 and -21 in the skin are less well defined and will be discussed only briefly. Owing to overlap in cytokine receptor usage with some γ_c family members, IL-13 and TSLP will also be discussed in this section.

Interleukin 2

Interleukin 2 (IL-2) is the founding member of this family. Activated T cells produce IL-2, as do B cells and some dendritic cells [68–70]. There are two receptor complexes for IL-2, a heterodimer of the β and γ_c chains and a heterotrimer of the high affinity subunit IL-2Rα (i.e. CD25) bound to the β and γ_c chains [71]. While IL-2Rα increases binding affinity for IL-2, the β and γ_c chains regulate signal transduction. Shared usage of β and γ_c chains explains similarities in biologic effects of IL-2 and IL-15, while use of distinct high affinity receptor subunits (i.e. IL-2Rα vs. IL-15Rα) helps explain differences between these cytokines [72].

One or both forms of the IL-2 receptor are expressed on T cells, B cells, NK cells, monocytes and macrophages [71, 73, 74]. In addition to PI3K-Akt and RAS/MAPK signaling, receptor engagement activates JAK1 and JAK3 triggering phosphorylation of STAT1, STAT3 and STAT5. T cell survival and proliferation are important effects of IL-2 during antigen-specific immune responses, as in allergic contact dermatitis [75]. Based on the ability of IL-2 to promote T cell survival and proliferation, recombinant human IL-2 became one of the first FDA-approved immunotherapies for metastatic melanoma [76, 77]. In contrast, an IL-2-diphtheria toxin fusion protein is used to trigger death in cells expressing IL-2Rα; this agent is used to treat some forms of cutaneous T cell lymphoma (CTCL) [78]. Interleukin 2 also regulates peripheral tolerance through effects on regulatory T cells, promotion of Fas-mediated activation-induced cell death of Th cells, and by restraining $CD8^+$ T cell responses [79, 80]. Some of the aforementioned immunostimulatory and immunosuppressive effects of IL-2 are lacking in IL-2Rα deficient patients, leading to features of autoimmunity and immunodeficiency as well as cutaneous manifestations including psoriasiform dermatitis and alopecia universalis [81].

Interleukin 4 and 13

Interleukin 4 (IL-4) is a canonical Th2 cytokine produced by Th2 cells, mast cells, basophils and eosinophils [82]. There are two functionally distinct heterodimeric IL-4 receptor complexes. The first (Type I receptor) is specific for IL-4 and is composed of IL-4Rα and γ_c; the second (Type II receptor) binds IL-4 or IL-13 and is composed of IL-4Rα and the IL-13Rα1 [83]. The Type I receptor is expressed on T and B cells, myeloid cells and fibroblasts and acts through JAK1 and JAK3 leading to phosphorylation of STAT3 and STAT6. The Type II receptor is also expressed by myeloid cells and fibroblasts and is selectively expressed on smooth muscle and epithelial cells, including keratinocytes and acts through JAK1, JAK2, JAK3 and TYK2 and activation of STAT3, STAT5 and STAT6 [82–84].

Effects of IL-4 are pleiotropic and cell-type dependent. Depending on the presence or absence of TGF-β, IL-4 can polarize naïve $CD4^+$ Th cell differentiation towards Th2 or Th9 lineages; IL-4 can also promote T cell survival (Fig. 15.1) [85, 86]. In B cells, IL-4 promotes survival, B cell receptor and MHC class II expression, and IgE class switching [87–89]. Mast cell survival and proliferation are also promoted by IL-4 [90]. In keratinocytes, IL-4 impairs differentiation, which correlates with impaired epidermal barrier function in vivo [91–93]. Dendritic cell maturation and eosinophil chemotaxis are also stimulated by IL-4 [94, 95].

Interleukin 13 is another Th2 cytokine and is produced by Th2 cells, ILC2, mast cells, eosinophils, basophils and NKT cells [96, 97]. The Type II receptor (shared with IL-4), mediates many of the overlapping biologic effects of IL-4 and IL-13 including IgE class switching, dendritic cell maturation, mast cell activation and eosinophil recruitment [83]. A second receptor, IL-13Rα2, is IL-13-specific and is generally regarded as a decoy receptor; though some IL-13Rα2-specific functions have been demonstrated in mouse models of allergic lung inflammation [83, 98].

The aforementioned functions of IL-4 and IL-13 explain why they are key mediators of allergic inflammation in multiple tissues and are implicated in the pathogenesis of various aspects of atopy, including AD [99]. Both cytokines are detectable in acute and chronic AD lesions and mediate key aspects of AD pathogenesis, epidermal barrier dysfunction and Th2-polarized inflammation. A neutralizing antibody against IL-4Rα that prevents IL-4 and IL-13 signaling is in clinical trials for AD [100].

Interleukin 9

Interleukin 9 is produced by several Th subsets, most notably Th9 cells, and mast cells; of note Th9 cell development is dependent on IL-4 and TGF-β (Fig. 15.1) [86, 101]. Type I interferons, IL-1, IL-6, IL-10, IL-12, IL-21, IL-25 and LPS promote IL-9 production in relevant cells types [86, 102, 103]. The IL-9 receptor is a heterodimer of IL-9R and γ_c that signals via JAK1 and JAK3 and then, STAT1, STAT3 and STAT5 [86, 104]. This receptor can be expressed on mast cells, Th2 cells, Th17 cells, ILC2, B cells, smooth muscle cells and some epithelial cells [86, 105]. Stimulation with IL-9 promotes mast cell proliferation and production of proteases and a variety of cytokines including IL-1β, IL-5, IL-6, IL-13, TGF-β [106, 107]. This cytokine also promotes Th17 development, ILC2 survival and production of IgE and IgG by B cells [86, 105].

Recently, IL-9 was implicated in the pathogenesis of psoriasis and mouse models of melanoma [108–110]. With respect to psoriasis, Th9 cells were more abundant in psoriatic lesions, suggesting a role in disease [108, 111]. In mouse models of melanoma, IL-9 can exert anti-tumor effects; although the proposed mechanisms underlying these observations varied with one report demonstrating mast cell-dependent anti-tumor effects of IL-9 and another suggesting that IL-9 indirectly promotes effector $CD8^+$ T cell recruitment into tumors [109, 110].

Thymic Stromal Lymphopoietin

Thymic stromal lymphopoietin (TSLP) is included in this section because its receptor is composed of IL-7Rα and a γ_c-like receptor-subunit, TSLPR. In contrast to IL-7, which regulates development, proliferation and/or survival of lymphoid cells, TSLP promotes allergic inflammation in skin and other epithelial surfaces [112–114]. Upon stimulation with TSLP, its receptor activates JAK1 and JAK2 and subsequently, STAT1, STAT3, STAT4, STAT5, and STAT6, which then regulate TSLP target genes [74].

Keratinocytes and dendritic cells can produce TSLP [115]. Production of TSLP by keratinocytes is increased in lesional skin of AD and Netherton syndrome, both of which are characterized by epidermal barrier dysfunction and Th2-polarized inflammation [115, 116] (see also Chap. 22). Interestingly, experimentally induced epidermal barrier disruption and/or injury trigger TSLP production by keratinocytes in normal human skin [117]. In Netherton syndrome and AD, excessive serine protease activity can also stimulate the protease activated receptor 2 and consequently, TSLP production by keratinocytes. Activation of TLR2 signaling in keratinocytes by membrane fragments of *S. aureus*, a common skin pathogen that also colonizes the skin of patients with AD, can stimulate TSLP production [118]. Inflammatory cytokines can also promote TSLP production by keratinocytes and dendritic cells [114]. Thus, there are multiple potential stimuli to explain the increased production of TSLP by keratinocytes in lesional skin of patients with AD and Netherton syndrome, the downstream consequences of which will be described below.

Dendritic cells, Th2 cells, regulatory T cells, ILC2, mast cells, eosinophils, B cells and NKT cells express the TSLP receptor [114, 119]. Stimulation of dendritic cells with TSLP polarizes naïve T cell differentiation towards Th2 cells and promotes production of the chemokines CCL17 and CCL22, which can act as chemoattractants for Th2 cells. Moreover, stimulation of Th2, ILC2 and mast cells promotes Th2 cytokine production. Several mouse models of AD-like inflammation demonstrate that keratinocyte-derived TSLP production is sufficient to drive allergic inflammation, even in the absence of T cells [120]. Recently, TSLP was shown to directly stimulate sensory neurons in the skin leading to pruritus (itch) in mice injected with recombinant TSLP [121]. These findings indicate TSLP can directly promote allergic inflammation (via actions on leukocytes) and itch (via actions on neurons); both properties of TSLP are likely to be germane to AD pathogenesis. A phase I clinical trial with a humanized TSLP neutralizing antibody has been completed with healthy patients and patients with AD; however the results of these studies are not available at *ClinicalTrials.gov*.

Beta Chain Family: Interleukin 5

This family includes IL-3, IL-5 and granulocyte monocyte colony stimulating factor (GM-CSF) and is defined by use of the common β chain receptor (different from IL-2 receptor β chain) [122]. The common β chain receptor is widely

expressed in hematopoietic cells, while expression of ligand-specific subunits is more restricted [123]. Functional receptors are heterodimers of the ligand-specific subunit and the common β chain [122]. Sources of IL-5 include Th2 cells, ILC2, mast cells, NK cells, $CD8^+$ T cells, eosinophils and endothelial cells [96, 123]. The IL-5 receptor is composed of IL-5Rα and common β chain subunits; receptor engagement activates JAK1, JAK2, STAT1, STAT3 and STAT5 as well as RAS-MAPK and PI3K signaling [123]. As in other tissues, IL-5 promotes infiltration, survival and effector functions of eosinophils in the skin [123]. Like other Th2 cytokines, IL-5 is implicated in AD pathogenesis. However, treatment of moderate to severe disease with two weekly doses of an IL-5 neutralizing antibody failed to achieve the desired clinical endpoint suggesting IL-5 neutralization may not be sufficient to treat AD [124]. Interestingly, peripheral eosinophilia rapidly improved in patients treated with this antibody. While tissue eosinophilia was not assessed and the treatment course was short, these findings suggest eosinophils may not be required for persistence of AD lesions [124].

Interleukin 6 Family

This family is defined by shared receptor subunit usage amongst all or some of its members. Interleukins in this family include IL-6, IL-11, IL-30 and IL-31. Members that are not interleukins include oncostatin M, leukemia inhibitory factor and others [125, 126]. Most family members use a common receptor subunit named glycoprotein 130 (gp130), while other members (e.g. IL-31) are included in this family due to structural similarities with IL-6 or shared usage of receptor subunits with other family members and/or usage of gp130-receptor subunits [125, 126]. This discussion will focus on IL-6 and IL-31, both of which are implicated in important aspects of cutaneous immunity and inflammation in health and/or disease [125, 126].

Interleukin 6

A variety of cells produce IL-6 including lymphocytes, monocytes, macrophages, fibroblasts, keratinocytes, endothelial cells and others [125]. Stimuli for IL-6 production include PAMPs (e.g. LPS), cytokines (e.g. IL-1, TNF, IL-17) and others. The functional repertoire of IL-6 is extensive with effects on the acute phase response, thermal regulation, angiogenesis, pathologic bone resorption, lipid metabolism and many other physiologic and pathophysiologic processes. However, this section will focus on functions of IL-6 relevant to dermatologic diseases [125].

The IL-6 receptor is composed of gp130 and IL-6R. While gp130 is widely expressed, IL-6R is primarily restricted to lymphocytes, monocytes and neutrophils [125]. Receptor engagement activates JAK3, STAT3, MAPK and PI3K/Akt pathways [127]. A soluble form of the IL-6R subunit (similar to IL-15Rα) can also initiate signaling but the details of this are beyond the scope of this discussion [128]. Effects of IL-6 receptor activation are cell type specific. In B cells, IL-6 stimulates immunoglobulin production and plasma cell differentiation; the role of IL-6 in plasma cell differentiation may be an indirect effect mediated by IL-21 produced by IL-6 stimulated T cells [129]. Other effects of IL-6 on the T cell compartment are promotion of Th17 and follicular helper T cell (Tfh) cell development and suppression of regulatory T cell (Treg) development and function (Fig. 15.1) [130, 131]. As described below, IL-6 also promotes neutrophil accumulation in the skin [125].

While IL-6 can contribute to many normal (e.g. promotion of sterile inflammation after wounding) and pathologic processes in the skin, this section will focus on the roles of IL-6 in cutaneous bacterial infections and psoriasis. As noted earlier, IL-1 is a central mediator of host defense following cutaneous infections with *S. aureus*. One of the downstream mediators of this host defense mechanism is IL-6, which is produced by keratinocytes and myeloid cells in response to IL-1 [36]. Like IL-1, IL-6 stimulates production of chemokines that attract neutrophils; moreover, IL-6 stimulates endothelial cells to induce expression of adhesion molecules needed for neutrophil migration into the skin from the blood. The Th17 cell subset is thought to be an important source of IL-17A and IL-17F during cutaneous infections and in psoriatic lesions. Differentiation of Th17 cells from naïve T cells is promoted by IL-6, suggesting another, albeit indirect, mechanism whereby IL-6 can contribute to host defense against cutaneous bacterial infections and psoriasis pathogenesis (Fig. 15.1) [36]. For completeness sake, it should be noted that IL-17 producing cell types other than Th17 cells are also implicated in pathogenesis of cutaneous infections and psoriasis pathogenesis and that these populations do not appear to be IL-6 dependent [36, 132].

Interleukin 31

Like other Th2 cytokines, IL-31 is an important mediator of allergic inflammation and has been implicated in AD pathogenesis (see also Chap. 22) [126]. The Th2 cell subset produces IL-31 in response to IL-4 or IL-33, and mast cells can produce IL-31 upon stimulation with the antimicrobial peptides LL-37 and β-defensins [133, 134]. The IL-31 receptor is expressed on neurons, keratinocytes and some dendritic cell subsets, monocytes and macrophages [126, 135–137]. In contrast to most IL-6 family members, the IL-31 receptor does not utilize gp130; instead it is composed of a gp130-like subunit, IL-31Rα, and the oncostatin M receptor [138]. Receptor engagement activates JAK1, JAK2, STAT1, STAT3, STAT5, PI3K/Akt and MAPK signaling [138]. Like TSLP, IL-31 can directly stimulate neurons and provoke scratching of the skin in mice, suggesting IL-31 can directly induce

pruritus (see also Chap. 12) [126, 139]. In vitro studies also suggest IL-31 impairs keratinocyte proliferation and differentiation, which may impair epidermal barrier function [135]. Finally, stimulation of $CD1c^+$ dendritic cells with IL-31 promotes production of inflammatory cytokines and chemokines [137].

Pruritus is a characteristic feature of AD; IL-31 and TSLP are proposed to be important triggers for pruritus in this disease (i.e. they are pruritogens). In support of this, IL-31 expression is increased in lesional and nonlesional skin of patients with AD and in lesions of prurigo nodularis [126]. Serum levels of IL-31 are also elevated in AD and correlate with disease severity [140]. Based on the functions mentioned above, it is also possible that IL-31 contributes to pathogenesis via impairment of epidermal barrier function and promotion of cytokine and chemokine production. According to *ClinicalTrials.gov*, patients are currently being recruited for a phase I clinical trial of an IL-31 blocking antibody in healthy subjects and patients with AD.

Interleukin 10 Family

The IL-10 family includes IL-10, the IL-20 subfamily, which includes IL-19, IL-20, IL-22, IL-24, IL-26 and the type III interferon subfamily consisting of IL-28A, IL-28B and IL-29 [141]. This cytokine family is defined by common usage of type 2 cytokine receptors and structural similarities, the details of which will not be discussed in this chapter [141]. Despite structural similarities between these cytokines and similarities in receptor usage, the functions of many IL-10 family members are quite varied. This section will discuss IL-10 and IL-22 individually and then the IL-20 receptor cytokines, IL-19, IL-20 and IL-24. Though the details of type III interferons biology will not be reviewed here, these cytokines have recently been implicated in psoriasis pathogenesis and host defense against cutaneous viral infections; the reader is referred to the cited references for further information on these cytokines [141–147].

Interleukin 10

Interleukin 10 is one of the prototypic anti-inflammatory cytokines [141]. Multiple cells can produce IL-10 including lymphocytes (T, B & NK cells), macrophages, dendritic cells, mast cells, eosinophils, neutrophils and keratinocytes [141, 148]. The inductive stimuli regulating IL-10 production vary by cell type. In Th2 cells, IL-4 and IL-27 can stimulate IL-10 production; IL-6 and IL-27 can also stimulate IL-10 production by Th1 cells and Th17 cells [149, 150]. In addition to Th cells, several regulatory T cell subsets can produce IL-10; for instance, $CD4^+FoxP3^+$ regulatory T (Treg) cells produce IL-10 in response to IL-2 and IL-4 [151, 152]. Regulatory B cells also produce IL-10 [153]. In macrophages and dendritic cells, TLR (e.g. TLR2, TLR3, TLR4 and TLR9) engagement can also stimulate IL-10 production [154, 155].

The IL-10 receptor is primarily expressed on lymphoid and myeloid cell lineage cells and is composed of IL-10R1 and IL-10R2 [141, 156]. Receptor engagement by an IL-10 homodimer activates JAK1, TYK2, STAT1, STAT3 and STAT5 [157]. Two anti-inflammatory mechanisms by which IL-10 acts include the inhibition of various aspects of antigen presentation by macrophages and dendritic cells and attenuation of cytokine production by T cells [157]. Interestingly, multiple viruses, including Epstein Barr virus and cytomegalovirus produce IL-10 homologs, which are thought to attenuate antiviral immune responses [158]. With respect to dermatologic disease, the anti-inflammatory effects of IL-10 are likely to play a role in regulating many aspects of cutaneous inflammation and immunity. The list of dermatologic diseases in which IL-10 is implicated as a mediator of pathogenesis or a potential therapy is long including multiple infectious, inflammatory, autoimmune and neoplastic conditions [159]. Notably, clinical trials with recombinant IL-10 for psoriasis or wound healing did not show significant benefit [160].

Interleukin 22

Cellular sources of IL-22 include T cells (e.g. Th17, Th22, γδT cells), NK cells, and a subset of ILC3 [161–165]. Development of IL-22 producing cells and/or production of IL-22 are regulated by cytokines in a cell-type dependent manner. Development of Th17 cells, which produce IL-17 and IL-22, is driven by IL-6, IL-21 and TGF-β; whereas, development of Th22 cells, which produce IL-22 but not IL-17, is stimulated by IL-6 and TNF (Fig. 15.1) [25, 166–169]. Stimulation with IL-23 can induce IL-22 production by some T cell subsets and ILC3 [170–172]. While TGF-β promotes Th17 development, it inhibits IL-22 production by Th17 and Th22 cells [25, 173].

The IL-22 receptor, composed of IL-10R2 and IL-22R, is expressed on keratinocytes and other epithelial cells [141, 156, 174]. Receptor activation signals through JAK1, TYK2, STAT1, STAT3 and STAT5 and MAPK and Akt pathways [141]. In keratinocytes, IL-22 impairs differentiation and promotes proliferation (and thus epidermal hyperplasia) and increases expression of β-defensin 2, β-defensin 3, S100A8 and S100A9, all of which are molecular, cellular, or histologic features of psoriatic lesions [173, 175–177].

Psoriasis, AD and other diseases are mediated, in part, by IL-22 (see also Chap. 21) [23, 178]. In psoriasis and AD, increased levels of IL-22 and IL-22 producing cell subsets

are described in lesional skin, and lesion resolution is associated with reduced IL-22 expression [23, 162, 178–186]. In both diseases, IL-22 is thought to act on keratinocytes leading to acanthosis and increased expression of S100A8, S100A9 and other proteins. While IL-22 can promote production of β-defensin 2 and β-defensin 3, expression is higher in psoriatic lesions than in AD; this may be due to Th2 cytokines attenuating expression of these β-defensins in AD [177, 187–189]. According to *ClinicalTrials.gov* AD patients are being enrolled for a clinical trial using an antibody to IL-22.

Interleukins 19, 20 & 24 (IL-20 Receptor Cytokines)

Interleukins 19, 20 and 24, hereafter referred to as IL-20 receptor cytokines, are discussed together due to overlapping receptor usage and biologic effects. Keratinocytes and other epithelial cells, monocytes, some T cells and melanocytes can produce one or more IL-20 receptor cytokines; myeloid dendritic cells expressing IL-20 are also present in psoriatic lesions [190–196]. In keratinocytes, IL-1β, IL-17A, IL-22, UVB light and wounding promote IL-20 receptor cytokine production [191, 197–199]. In monocytes, LPS, GM-CSF and TNF stimulate production [141, 196, 200, 201]. Both receptors for these cytokines are expressed by keratinocytes [176, 191]. Receptor engagement activates STAT3 driving keratinocyte proliferation and epidermal hyperplasia [176, 191]. Other effects of one or more of these cytokines on keratinocytes include increased expression of S100A7, as well as *TNFA* and *MRP14* transcripts [176, 202].

Similar to IL-22, IL-20 receptor cytokines are implicated in psoriasis pathogenesis with expression of all three cytokines being increased in lesional skin [191, 196]. These cytokines are thought to contribute to epidermal hyperplasia in psoriatic lesions [176]. Consistent with this idea, local or systemic therapy for psoriasis reduces both epidermal hyperplasia and expression of these cytokines [203, 204]. It is uncertain whether targeting IL-20 receptor cytokines is a viable therapeutic option for psoriasis. According to *ClinicalTrials*.gov, one clinical trial with an anti-IL-20 blocking antibody was discontinued due to apparent lack of response; however, it is possible that IL-19 or IL-24 activities are sufficiently redundant to compensate despite IL-20 blockade. Paradoxically, IL-20 receptor cytokines were recently shown to exacerbate cutaneous infections with *S. aureus* in mice [205]. This is attributed to IL-20 receptor-mediated attenuation of IL-1β production, thereby decreasing the frequency of IL-17A producing T cells, which are important for host defense against infections with *S. aureus* [36, 205, 206]. This suggests the IL-20 receptor may be a viable therapeutic target for management of cutaneous infections with *S. aureus*.

Interleukin 12 Family

This family includes IL-12, IL-23, IL-27 and IL-35, all of which are heterodimers generated from the following subunits: p19, p28 (i.e. Ebi3) p35 (i.e. IL-12p35) and p40 (i.e. IL-12p40) [207]. Interleukins 12 and 23 are important pro-inflammatory cytokines in psoriasis and other diseases, and neutralizing antibodies against these cytokines are used to treat several of these diseases including psoriasis [208–211]. Understanding the roles of IL-12 and IL-23 in psoriasis and host defense against mycobacterial infections helps the clinician use these biologics effectively and safely. The other members of this family, IL-27 and IL-35, are primarily anti-inflammatory cytokines, but their roles in cutaneous immunology are less well defined and will not be discussed further in this chapter [207].

Interleukin 12

Interleukin 12 (IL-12p70) is composed of p40 and p35 and expressed by dendritic cells, monocytes, macrophages, B cells and neutrophils [212]. Stimulation of macrophages and dendritic cells with a variety of PAMPs causes IL-12 production [213, 214]. Cytokines (i.e. IFNγ, IL-4 and IL-13) and physical contact with T cells can also promote IL-12 production [215–217]. The IL-12 receptor, composed of IL-12Rβ1 and IL-12Rβ2, is expressed on T and NK cells [207]. Receptor engagement activates JAK2, Tyk2 and STAT4, triggering IFNγ production by T and NK cells [207, 218]. Stimulation of dendritic cells and monocytes with IFNγ can in turn stimulate additional IL-12 production resulting in a positive feedback loop [216]. Interleukin 12 also orchestrates differentiation of naïve T helper cells into Th1 cells, which are key producers of IFNγ (Fig. 15.1) [219, 220]. The ability of microbial products to trigger IL-12 production by dendritic cells and IL-12 to in turn dictate naïve T cell differentiation to Th1 cells is an example how cytokines link innate and adaptive immune responses.

Multiple dermatologic conditions are mediated by IL-12, some of which have been successfully treated with a p40 neutralizing antibody, which blocks both IL-12 and IL-23 [221–227]. As noted above, multiple clinical trials have established the efficacy of this antibody for psoriasis; there are case reports of therapeutic benefit in AD, HS and Behçet's disease as well [228–230]. Host defense against mycobacterial infections is also critically dependent on IL-12-driven production of IFNγ, as discussed later in this chapter.

Interleukin 23

Interleukin 23 is a heterodimer of p19 and p40, the latter of which is shared with IL-12 [231]. Dendritic cells and macrophages produce IL-23 following activation of various pattern recognition receptors (e.g. TLR4), cytokine stimulation (e.g. TNF and IL-12) and contact-dependent interactions with T

cells [212, 231, 232]. The IL-23 receptor is expressed on Th17 cells, some γδ T cells and ILC3 and is composed of IL-23R, and IL-12Rβ1; receptor engagement signals through JAK2, Tyk2, STAT3 and STAT4 [166, 231, 233–235]. Activation of STAT3 in naïve T cells with specific cytokines (e.g. IL-6) drives Th17 differentiation and IL-23 receptor expression; moreover, IL-23 stimulation further promotes IL-23R expression in these cells [166, 236]. In contrast, the IL-23 receptor is stably expressed on a subset of γδ T cells and is expressed on a subset of ILC3 [235, 237]. In Th17 cells and IL-23R$^+$ γδ T cells, IL-23 can promote expansion of these subsets and IL-17 production [166, 235, 236]. Moreover, IL-23 stimulates IL-22 production by IL-23R$^+$ ILC3 [237].

Interleukin 23 is implicated in the pathogenesis of psoriasis and many other dermatologic diseases [223, 224, 226, 227, 238–242]. Expression of both IL-23 subunits is increased in psoriatic lesions [238]. Moreover, several IL-23 responsive subsets of IL-17 producing cells are more abundant in psoriatic lesions; IL-17 and IL-22 expression are also increased in lesional skin [235, 237]. As noted, neutralization of p40 and thus IL-12 and IL-23 is an effective therapy for psoriasis. While, both cytokines likely contribute to disease, IL-23 is probably more important as demonstrated by the therapeutic efficacy of an IL-23 neutralizing antibody for psoriasis [243, 244]. In psoriasis, IL-23 is thought to drive IL-17 production; the therapeutic efficacy of IL-17 and IL-17 receptor blocking antibodies in clinical trials (discussed below) for psoriasis further supports the conclusion that IL-23 plays a more dominant role in psoriasis pathogenesis than does IL-12 (see also Chap. 43).

Interleukin 17 Family

The 6 members of this family are designated IL-17A, IL-17B, IL-17C, IL-17D, IL-17E and IL-17F; IL-17E is also known as IL-25 [245]. Emerging data suggest IL-25 can promote allergic inflammation in the skin; the reader is referred to the cited references for further information [120, 245–252]. The roles of IL-17B thru D in cutaneous immunology are not well established and will not be discussed further in this chapter. Family members IL-17A and IL-17F are important regulators of cutaneous immunity, inflammation and disease and will be discussed jointly due to shared receptor usage and biologic functions.

Interleukins 17A & 17F

Interleukin 17A, also known as IL-17, activates the same receptor as IL-17F, explaining the similar biologic functions of these cytokines. These cytokines can exist as homodimers or heterodimers of IL-17A and F [245]. Cells that produce IL-17A and/or F include several T cells subsets (i.e. Th17, Tc17 and γδTcells), NKT cells and a subset of ILC3 [165, 253–258] Investigations of IL-17 biology identified Th17 cells, a novel developmentally and functionally distinct population of T helper cells differentiated from naïve T cells stimulated with IL-1β, IL-6, IL-21, IL-23 and/or TGF-β; Th17 cell can produce IL-17A and F (Fig. 15.1) [253, 259]. Activation of the TCR and/or stimulation with IL-1 or IL23 can stimulate IL-17 production by Th17 cells, NKT cells and γδTcells [257, 260–262].

The receptor for IL-17A and F, referred to here as the IL-17 receptor, is a heterodimer of IL-17RA and IL-17RC [263]. T cells, B cells, macrophages, endothelial cells, fibroblasts and epithelial cells, including keratinocytes, express the IL-17 receptor [245]. Receptor engagement in keratinocytes recruits the adaptor protein Act1 and TRAF6 stimulating TAK1-mediated activation of NF-kB and C/EBP and MAPK-mediated activation of AP-1, culminating in transcriptional changes in IL-17 target genes [264–266]. Target genes induced by IL-17 receptor activation include those encoding pro-inflammatory cytokines (TNF, IL-1, IL-6, G-CSF, GM-CSF), chemokines (CXCL1, 3, 5, 6 and 8; CCL2, 7 and 20), antimicrobial peptides/proteins and matrix metalloproteinases [62, 245, 267–269]. Many chemokines produced by IL-17-stimulated keratinocytes recruit neutrophils into the skin, while keratinocyte-derived CCL20 can recruit dendritic cells and CCR6$^+$ T cell subsets, including Th17 cells [268].

While IL-17A and F are implicated in the pathogenesis of other dermatologic conditions, this section will focus on the role of these cytokines in psoriasis and cutaneous infections [23, 36, 224, 270–273]. In psoriasis, IL-17 is thought to stimulate keratinocyte-derived chemokine and growth factor production (i.e. G-CSF & GM-CSF) leading to recruitment of neutrophils, T cells (e.g. Th17 cells) and dendritic cells into lesional skin [23]. Cellular sources of IL-17 in psoriasis include Th17 cells, γδT cells, NKT cells and ILC3 [23, 274]. Data from clinical trials suggest neutralizing antibodies to IL-17A and the IL-17 receptor (anti-IL-17RA) will be effective therapies for psoriasis (see also Chap. 43) [210, 275–277].

With respect to cutaneous infections, IL-17A and/or F play important roles in host defense against *S. aureus* and *Candida spp*. [36, 273]. As noted, neutrophil influx into the skin, a critical aspect of host defense against *S. aureus* infections, is regulated by chemokines and growth factors produced by IL-17 stimulated keratinocytes [36]. Host defense against cutaneous *Candida spp*. infections is also regulated by IL-17A and IL-17F as defective IL-17 signaling can cause chronic mucocutaneous candidiasis (CMC) [273]. In CMC, mutations in IL-17RA and IL-17F have been identified in some patients, while others have mutations that impair development of IL-17 producing T cells or mutations that lead to development of IL-17 neutralizing antibodies [273].

Interferon Family

Interferons were originally described over 50 years ago as soluble cell/tissue-derived factors that *interfered* with the ability of viruses to infect other cells or tissues [278]. Since that time, over a dozen interferons have been identified in humans. This section will focus on the two canonical classes of interferons, types I and II, which are distinguished by receptor usage and partially divergent downstream signaling pathways. There are over a dozen type I interferons in humans; all use the same receptor. In contrast, there is only one type II interferon, IFNγ, which uses a unique receptor. Interferons are important for various aspects of host defense against pathogens and are involved in pathogenesis of multiple inflammatory diseases. As such, the following sections will provide more detail on the biology of type I and type II interferons and the dermatologic diseases associated with each type.

Type I Interferons

Within this family are multiple interferon alpha (IFN-α) proteins and IFN-β, as well as IFN-k and -ω [279]. Virtually all nucleated cells can produce at least one type I interferon, affording a means of defense against viral infections and other pathogens; however, some cell types, namely plasmacytoid dendritic cells, produce larger quantities of type I interferons [280, 281]. Type I interferon production is triggered by various PAMPs, which are not limited to viral products; for example, activation of TLR4 by LPS can trigger type I interferon production by macrophages. The toll-like receptors, TLR3, TLR4, TLR7 (target of imiquimod), TLR8 and TLR9 are important inducers of type I interferon production [282].

The type I interferon receptor (IFNAR) is widely expressed on nucleated cells and is composed of IFNAR1 and IFNAR2 subunits and signals via JAK1, Tyk2, STAT1, STAT2 and interferon response factor (IRF) 9 [283]. Following IFNAR activation, a STAT1/STAT2 heterodimer forms and binds to the protein IRF9; this protein complex then translocates to the nucleus to regulate hundreds of interferon target genes. Upregulated interferon target genes include those encoding antiviral proteins with multiple mechanisms of action as well as MHC class I molecules, chemokines and other proteins. Activation of IFNAR has anti-proliferative and in some cases (e.g. keratinocytes), pro-differentiation effects [284]. Thus interferons limit propagation of virus by directly interfering with viral replication, limiting host cell proliferation and promoting presentation of viral antigens in the context of MHC class I to T cells [284]. Other effects of type I interferons include T cell, NK cell, macrophage and myeloid dendritic cell activation and promotion of T cells survival [23, 281].

The local and systemic actions of type I interferons have also been exploited therapeutically for dermatologic disease. For example, recombinant type I interferons are used to treat some cases of malignant melanoma and CTCL [285, 286]. Moreover, imiquimod, a TLR7 agonist, stimulates type I interferon production and is used topically to treat verruca vulgaris and molluscum contagiosum [287, 288]. Type I interferons are also implicated in the pathogenesis of psoriasis, lichen planus, cutaneous and systemic lupus, dermatomyositis, systemic sclerosis and sarcoidosis [23, 289–291]. In psoriasis, type I interferons derived from plasmacytoid dendritic cells and/or other cell types may initiate lesion formation through activation of myeloid dendritic cells that in turn produce IL-12 and IL-23 [23]. In support of this idea, psoriasis can develop or flare in patients treated systemically with type I interferons or topically with imiquimod [292, 293].

Type II Interferon (IFNγ)

Interferon gamma is a key mediator of many aspects of cutaneous and systemic immunity. In contrast to type I interferons, IFNγ production is limited to NK cells, T cell subsets (Th1 and $CD8^+$ T cells) and ILC1 [294, 295]. Myeloid cell-derived cytokines including IL-12, IL-15 and/or IL-18 as well as IL-2 can stimulate production of IFNγ by T and NK cells [296, 297]. The IFNγ receptor, IFNGR, is a heterodimer of IFNGR1 and IFNGR1. In contrast to its ligand (IFNγ), IFNGR is widely expressed on a variety of cell types including keratinocytes, macrophages and dendritic cells [295]. Activation of IFNGR activates JAK1 and JAK2, and then, STAT1, which in turn regulates IFNγ target genes [295].

In contrast to type I interferons, IFNγ promotes MHC class II expression, is less critical for host defense against viruses and is more important for host defense against pathogens that target macrophages like *Mycobacterial spp*. [284, 295]. One of the critical functions of IFNγ in host defense is macrophage activation, a process in which activation of IFNGR leads to production of cytokines, nitric oxide and reactive oxygen species, which all contribute to clearance of intracellular pathogens that infect macrophages (i.e. *Mycobacterial spp*., as well as some fungi, parasites and other bacterial species) [298]. The critical role of IFNγ (and IL-12 which triggers IFNγ production) and macrophage activation in host defense against *Mycobacterial spp*. is highlighted by the fact that that human immunodeficiency disorders limited to type II interferon and/or IL-12 signaling (e.g. mutations in IFNGAR1, IFNGAR2, STAT1) greatly increase susceptibility to developing mycobacterial infections [298]. Other diseases in which IFNγ is implicated in pathogenesis include vitilgo, alopecia areata, allergic contact dermatitis, psoriasis and AD [23, 299–302].

A final note on IFNγ and its relevance to dermatology-interferon gamma release assays (IGRAs) are used to identify patients at risk for latent or active infections with *Mycobacterium tuberculosis* [303]. These tests involve incubating whole blood or PBMC with purified antigens from *M tuberculosis*; some T cells in the blood samples of patients with prior exposure to, or latent/active infection with *M tuberculosis*, can recognize these antigens and respond by producing IFNγ which is quantified [303]. Sufficiently high levels of IFNγ production in this assay alert the clinician to the possibility of latent or active infection. In addition to helping identify and treat patients at risk for infection, the results of this test help guide decisions regarding use of immunosuppressive medications for dermatologic and other disease indications.

Transforming Growth Factor β (TGF-β) Family

This family includes three isoforms of TGF-β (encoded by different genes) [304]. The isoform of TGF-β whose role in cutaneous immunology and disease is best understood is TGF-β1; hereafter though, all isoforms will be referred to collectively as TGF-β. In contrast to many cytokines described in this chapter, TGF-β and one or more of its receptors are expressed by most nucleated cells; sources of TGF-β in the skin include fibroblasts, macrophages and keratinocytes [305–308].

Like IL-1β and IL-18, TGF-β is synthesized in an inactive form and requires proteolytic cleavage to generate an active cytokine [309]. Unlike IL-1β and IL-18, maturation of TGF-β requires intracellular and extracellular processing (Fig. 15.4). Initially, the *TGFB* mRNA is translated into Pre-pro-TGF-β, which then undergoes proteolysis, removing the signal peptide and generating two proteins, a monomer of latency associated peptide (LAP) and a monomer of TGF-β; two LAP molecules form a homodimer, as do two TGF-β molecules, which then bind to each other (Fig. 15.4). Homodimers of LAP and TGF-β then bind another protein called latent TGF-β binding protein (LTBP) [309]. This complex is then secreted and can bind to the surface of cells bearing receptors for LAP or via binding of LTPB to extracellular matrix (ECM) components like collagen [310]. In this complex, TGF-β is inactive; depending on its location (i.e. ECM versus cell surface), proteolytic cleavage by a variety of different proteases or LAP receptor-mediated conformational changes liberate TGF-β, which can then bind and activate its receptors (Fig. 15.4) [310].

There are three receptors for TGF-β designated I, II and III [304, 311]. The type III receptor binds to TGF-β but does not activate downstream signaling cascades [311]. Binding of TGF-β to the type II receptor recruits the type I receptor, triggering phosphorylation of the proteins SMAD2 and 3, which then recruit SMAD4 (Fig. 15.4).

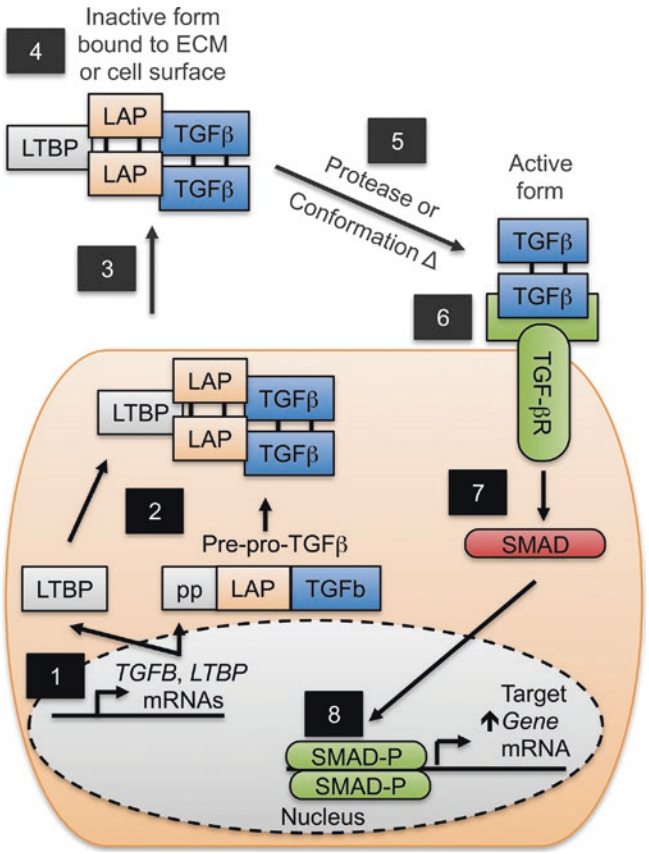

Fig. 15.4 Sequence of TGF-β production and receptor activation (*TGF-βR*): (*1*) *TGFB* and latent TGF-β binding protein *LTBP* mRNA is translated into Pre-pro-TGF-β and LTBP. (*2*) Pre-pro-TGF-β is cleaved into latency associated protein (*LAP*) and TGF-β followed by formation of a multi-protein complex of LAP, TGF-β and LTBP. (*3*) The complex is secreted. (*4*) It then binds extracellular matrix (*ECM*) components or LAP receptors on cells. (*5*) Proteolysis or conformational changes in the complex liberate TGF-β. (*6*) TGF-β then binds TGF-βR. (*7*) The TGF-βR then converts inactive SMAD proteins (*SMAD*) into an active phosphorylated form (*SMAD-P*). (*8*) Complexes of SMAD-P then translocate to the nucleus to regulate TGF-β target genes

This complex in turn binds to and regulates the expression of TGF-β target genes [312].

While TGF-β has many functions, the focus here will be on wound healing and cutaneous immunity. In the skin and other organs, TGF-β regulates extracellular matrix (ECM) production by stimulating synthesis of collagen, fibronectin and integrins by fibroblasts; ECM degradation is also suppressed by TGF-β via reduced metalloproteinases production and increased synthesis of protease inhibitors [313]. These effects of TGF-β are thought to be important for ECM formation and preservation during the wound healing processes including scar formation. Excessive TGF-β activity is thought to contribute to hypertrophic and keloid scar formation and sclerotic or fibrotic disorders like systemic sclerosis (scleroderma) and nephrogenic systemic fibrosis [313–315]. Immunoregulatory effects of TGF-β include promotion of Treg, Th9 and Th17

cell development and inhibition of Th1 and Th2 cell differentiation (Fig. 15.1) [309]. In addition, TGF-β (along with IL-10 and IL-35) is an important effector molecule that regulatory T cells use to suppress effector T cells [316].

Chemokines

Chemokines are an entity unto themselves in structure, function and signaling mechanisms. They are critical regulators of leukocyte recruitment directing cell migration between secondary lymphoid tissues, the blood and peripheral tissues [317, 318]. The two largest subgroups of chemokines are designated CXC and CC, so named for the configuration of four conserved cysteine residues in these molecules. Chemokines activate G protein coupled receptors designated as CCR for CC chemokines and CXCR for CXC chemokines. Receptor engagement activates multiple signaling pathways that culminate in cytoskeletal reorganization, integrin activation and chemotaxis along a chemokine gradient [319]. Given similar mechanisms by which chemokines and their receptors act, this section will not discuss all chemokine and chemokine receptors used to recruit different leukocyte subsets to and from the skin, blood and lymph nodes; instead the role of chemokines in dendritic and T cell trafficking from and to the skin, respectively, will be presented as examples of how chemokines regulate leukocyte movement. In addition, Table 15.2 lists chemokines and chemokine receptors that promote chemotaxis of specific leukocyte subsets.

Dendritic Cell Trafficking from the Skin to Lymph Nodes

Sensitization to antigens encountered in the skin is dependent on acquisition of antigen by immature dendritic cells (see also Chap. 9) [317, 318]. Immature dendritic cells in the skin (and other sites) are adept at antigen uptake. Keratinocyte-derived CCL20 binding to CCR6 on Langerhans cells helps maintain this population of dendritic cells in the epidermis [318, 320, 321]. Antigen uptake and inflammation promote Langerhans cell maturation and migration to the skin from draining lymph nodes [318]. Inflammatory stimuli like TNF promote Langerhans cell migration out of the epidermis and into the dermis via downregulation of CCR6 and upregulation of CXCR4, the latter of which is engaged by the chemokine CXCL12 [318]. In the dermis, Langerhans cells and other dendritic cell subsets upregulate CCR7 that directs migration towards CCL19 and CCL21 produced in the lymph node [318, 322, 323]. In lymph nodes, mature dendritic cells present antigen to naïve T cells, promoting differentiation into effector memory T cells that mediate various aspects of host defense (Fig. 15.1) [317].

Table 15.2 Representative chemokines and receptors used by leukocyte subsets

Target cell	Chemokine receptor	Chemokine
T cell	CCR4	CCL17 (K, DC, E, M); CCL22 (K)
	CCR6	CCL20 (K, E, M)
	CCR8	CCL1 (E, Ma)
	CCR10	CCL27 (K)
	CXCR3	CXCL9, 10, 11 (K, F, E, M)
	CXCR4	CXCL12
B cell	CXCR4	CXCL12
Monocyte	CCR1	CCL3
	CCR2	CCL2
	CCR5	CCL5, 8, 13
	CCR6	CCL20 (K, E, M)
	CXCR1	CXCL6, 8
	CXCR2	CXCL1
	CXCR3	CXCL9, 10, 11 (K, F, E, M)
	CXCR4	CXCL12
	CX3CR1	CX3CL1
Eosinophil	CCR3	CCL24, 26
Neutrophil	CCR1	CCL3
	CXCR1	CXCL6, 8
	CXCR2	CXCL1, 2, 3, 5, 6, 8

K keratinocyte, *DC* dendritic cell, *M* monocyte, *E* endothelial cell

T Cell Trafficking from the Blood to Skin

The entry of leukocytes into the skin from the blood begins in postcapillary venules with rolling on selectins expressed on the luminal side of the endothelium (see also Chap. 8) [324]. Rolling is followed by firm adhesion of leukocytes to the endothelium via integrins, a process promoted by stimulation of rolling leukocytes with chemokines [324].

Chemokines regulate T cell trafficking into the skin [317, 318]. Chemokine receptors important for directing T cells from the blood and into the skin include CCR4, CCR6, CCR8, CCR10 and CXCR3 [318]. An important marker of skin-homing (and skin resident) T cells is cutaneous lymphocyte antigen (CLA) which contributes to T cell rolling in postcapillary venules in the skin [325, 326]. The majority of CLA^+ T cells express CCR4, one of the ligands for which CCL17 is produced by keratinocytes, dendritic cells and endothelial cells [318, 325]. Activation of CCR4 by CCL17 promotes T cell entry into the skin from postcapillary venules [318]. Ligands for CCR6, CCR10 and CXCR3 include CCL20, CCL27, and CXCL10, produced by keratinocytes. Multiple cell types other than keratinocytes also produce chemokines mediating recruitment of leukocytes into the skin.

Chemokines and chemokine receptors are implicated in the pathogenesis of numerous dermatologic diseases; in fact,

it would be challenging to conceive of an inflammatory, infectious or autoimmune disease in which chemokines are not involved. Notable examples include CTCL, GVHD, vitiligo and alopecia areata [300, 327, 328]. According to *ClinicalTrials*.gov, clinical trials are ongoing for a CCR4 blocking antibody in CTCL and a CCR5 antibody for GVHD. Thus, knowledge about chemokine and chemokine receptor biology is on the verge of impacting how dermatologists and other clinicians manage disease in their patients.

Concluding Remarks

Much has changed in dermatology and cutaneous immunology since the term *cytokine* was coined 40 years ago. Even since the last edition of this text, a number of novel cytokine or chemokine-targeted therapies have entered clinical trials and/or routine clinical practice for dermatologic diseases. These are certainly exciting times, but the employment of novel immunomodulators will require an evermore sophisticated and nuanced approach to know how and when to safely and effectively use these therapies. In order to achieve these goals a sound understanding of cytokine and chemokine biology will be important.

Acknowledgments I thank my wonderful wife Denise C. Turner and my outstanding mentor Dr. Jeffrey B. Travers for their hard work in organizing references and editing this chapter, respectively. I thank my excellent co-mentor Dr. Mark H. Kaplan for providing the digital image from which Fig. 15.1 was adapted. I thank the Dermatology Foundation, Indiana University, the Veterans Administration, my colleagues and most importantly, my family for their support of this and other academic efforts.

Questions

1. "Drug X" inhibits IL-12, TNF and IFNγ. Which of the following is correct regarding potential uses and risks of using this drug?
   A. Drug X is likely to trigger a flare of psoriasis
   B. Drug X is unlikely to be effective for sarcoidsosis
   C. Drug X may trigger reactivation of tuberculosis
   D. Drug X is likely to trigger a flare of hidradenitis suppurativa
   E. Drug X is unlikely to have any efficacy in treating psoriasis

2. The cytokines IL-4, IL-5, TSLP and IL-31 are implicated in atopic dermatitis pathogenesis. Which of the following is correct regarding these cytokines?
   A. TSLP activates keratinocytes
   B. Neuron-derived IL-31 causes pruritus
   C. IL-4 promotes keratinocyte differentiation
   D. IL-5 promotes eosinophil infiltration into skin
   E. TSLP is made by neurons

3. Type I interferons (IFN), IL-12 and IL-23 are implicated in psoriasis pathogenesis. Which of the following is correct?
   A. IL-12 promotes IFNγ production by macrophages
   B. IFNγ promotes IL-12 production by T cells
   C. Plasmacytoid dendritic cells produce large quantities of Type I IFN
   D. The p19 subunit is shared between IL-12 and IL-23
   E. Blockade of Type I IFN signaling can trigger psoriasis flares

4. Cytokines in the IL-1 family regulate many inflammatory pathways and dermatologic diseases. Which of the following is correct?
   A. Production of IL-1β is decreased in autoinflammatory diseases
   B. The TIR domain is shared between IL-1 family and toll-like receptors
   C. Inhibition of IL-36 activity may trigger a flare of psoriasis
   D. IL-1α and IL-1β signal via different receptors
   E. Caspase 1 cleaves and inactivates IL-1β

5. What is the best answer regarding the role of cytokines in host defense against microbial pathogens?
   A. Mutations in *TNF* cause chronic mucocutaneous candidiasis
   B. Blockade of IL-17A and F can prevent chronic mucocutaneous candidiasis
   C. Defective IL-4 and 13 signaling increase the risk of mycobacterial infections
   D. IL-1α and β regulate host defense against cutaneous *S. aureus* infections
   E. Inhibition of IL-17A and IL-17 F can prevent cutaneous *S. aureus* infections

Answers

1. C
2. D
3. C
4. B
5. D

Bacterial Infections

16

Lloyd S. Miller

Abstract

Bacterial skin infections are a major cause of morbidity and mortality and consequently exert a significant medical and economic burden on healthcare resources. In an era of declining antimicrobial drug development and rising antibiotic resistance among clinical bacterial isolates, there are serious concerns that current antibiotic therapy will not provide a durable solution to this public health threat. If future immune-based therapies are to provide an alternative or complementary therapy to antibiotics, a greater understanding of the key innate and adaptive cutaneous immune responses provide host defense bacterial skin infections is essential. This chapter focuses on the host defense mechanisms against two of the most common bacterial skin pathogens, *Staphylococcus aureus* (*S. aureus*) and group A *Streptococcus*.

Keywords

Staphylococcus aureus • *Streptococcus pyogenes* • Group A *Streptococcus* • Antimicrobial peptides • Pattern recognition receptors • Toll-like receptors • Inflammasome • Innate immunity • Adaptive immunity

Staphylococcus aureus

S. aureus is a Gram-positive extracellular bacterium that is the most common cause of skin and soft tissue infections in humans such as impetigo, folliculitis/furunculosis, cellulitis and infected wounds and ulcers [1–3]. *S. aureus* skin infections result in 11–14 million outpatient visits and nearly 500,000 hospital admissions annually in the U.S. [4, 5]. In addition, *S. aureus* infections can become more invasive and lead to life-threatening infections such as lymphangitis, septic arthritis, osteomyelitis, pneumonia, abscesses of various organs, meningitis, bacteremia, endocarditis and sepsis [6, 7]. *S. aureus* colonization of the skin and mucosa is found in ~30 % of the general population and is a major risk factor for infection [8–10]. Patients with atopic dermatitis, diabetes mellitus, renal disease (hemodialysis), HIV infection, a history of intravenous drug abuse and preexisting tissue injury or inflammation (e.g. ulcer, surgical wound) are predisposed to *S. aureus* infections [3]. In addition, community-acquired methicillin-resistant *S. aureus* (CA-MRSA) strains are becoming increasing resistant to multiple antibiotics and are causing severe skin infections in healthy people outside of hospital settings and without known risk factors for infection [6, 11, 12]. In particular, USA300 isolates are the most common CA-MRSA strains that cause the majority of skin infections presenting to emergency rooms in the U.S. [13, 14].

Clinical Manifestations

S. aureus cutaneous infections result in a variably pyogenic immune response characterized by purulent lesions with surrounding erythema, warmth and induration [1–3].

Fig. 16.1 *S. aureus* cellulitis on the lower leg. The involved skin characteristically shows signs of inflammation, including erythema, warmth, edema, and pain (Photograph is courtesy of the Victor D. Newcomer collection at UCLA and Logical Images, Inc.)

Fig. 16.2 *S. aureus* folliculitis/furuncles (boils). Typically, infected hair follicles present as follicularly-based erythematous, warm, edematous, and pus-filled papules and nodules (Photograph is courtesy of the Victor D. Newcomer collection at UCLA and Logical Images, Inc.)

Microscopically, these lesions are comprised of collections of neutrophils, a hallmark of *S. aureus* infections [15, 16]. Superficial *S. aureus* infections result in impetigo, an infection confined to the upper layers of the epidermis [1–3]. However, *S. aureus* skin infections can become more invasive and involve dermal planes and subcutaneous tissues as seen in cellulitis (Fig. 16.1) or deep ulcerative lesions as seen in ecthyma [1–3]. *S. aureus* also infects individual hair follicles leading to folliculitis, furunculosis and carbuncle formation when multiple follicles become involved (Fig. 16.2) [1–3]. Lastly, *S. aureus* can cause superinfection of inflammatory skin diseases such as atopic dermatitis and intertrigo [17].

Innate Immune Responses Against *S. aureus*

Innate immune responses are directed against conserved components of microorganisms called pathogen associated molecular patterns (PAMPs) [18, 19]. The host cellular receptors that recognize different PAMPs are called pattern recognition receptors (PRRs) [18, 19]. PAMPs are predominantly expressed by microorganisms and not by host cells, thus enabling the host's immune system to recognize the pathogen rather than self [18, 19]. In this section, soluble factors of the innate immune system such as antimicrobial peptides and complement will be discussed, followed by a review of the known PRRs, inflammasomes and the role of innate immune system cells such as neutrophils and monocytes/macrophages in host defense against *S. aureus*.

Soluble Mediators of Innate Immunity Against *S. aureus*

Antimicrobial Peptides

Antimicrobial peptides are polypeptides that have antimicrobial activity at physiologic conditions and are believed to function by disrupting bacterial membranes [20–23]. There are several human antimicrobial peptides involved in skin host defense, including defensins (α and β), cathelicidin, RNase 7, dermcidin and REG3A (Table 16.1) [20–24].

Alpha-defensins (also called human neutrophil peptides, HNPs) are produced by neutrophils, whereas β-defensins are produced predominantly by epithelial cells (including keratinocytes) and are also produced by macrophages and dendritic cells [25]. Cathelicidin is produced constitutively by neutrophils and can be induced in epithelial cells, including keratinocytes [20, 26, 27].

There are six known human α-defensins (HNP1-6), which constitute ~50 % of the peptides found within neutrophil granules [28]. Notably, HNPs 2 and 5 (and not HNPs 1, 3, 4, and 6) have antimicrobial activity against *S. aureus in vitro* [29]. The antimicrobial activity of α-defensins is likely important in host defense since *S. aureus* produces proteins such as staphylokinase, which directly binds to α-defensins to inhibit their activity [30]. In addition, MprF and products of the *dlt*ABCD operon reduce the negative charge of the bacterial membrane via lysinylating phosphatidylglycerol [31] and alanylating teichoic acids [32] in the bacterial cell envelope, respectively, to reduce the activity of α-defensins.

Table 16.1 Soluble mediators and pattern recognition receptors that contribute to host defense against *S. aureus* skin infections and colonization

	Cellular expression in skin	*S. aureus* evasion mechanisms	Mechanisms of action
Antimicrobial peptides			
α-defensins (human neutrophil peptides [HNPs])	Neutrophils	Staphylokinase, MprF, *dlt*ABCD operon	Antimicrobial activity, chemotaxis of T cells and immature dendritic cells
hBD2	Keratinocytes macrophages DCs	IsdA, *dlt*ABCD operon	Antimicrobial activity, chemotaxis of immature dendritic cells and memory CD4+ T cells via CCR6
hBD3	Keratinocytes	*dlt*ABCD operon	
LL-37	Keratinocytes macrophages neutrophils	IsdA, aureolysin, MprF, *dlt*ABCD operon	Antimicrobial activity, chemotaxis of neutrophils, monocytes and T cells via FPRL1
Dermcidin	Eccrine glands	Extracellular proteases, *dlt*ABCD operon	Antimicrobial activity
RNase 7	Keratinocytes	*dlt*ABCD operon	Antimicrobial activity
REG3A	Keratinocytes		Antimicrobial activity
Complement			
C3a, C5a	Serum	SCIN	Chemotaxis of neutrophils
C3b	Serum	SCIN, Efb, C4BP, staphylokinase	Opsonophagocytosis
Mannose-binding lectin (MBL)	Serum	SCIN, Efb, C4BP, staphylokinase	Activation of the lectin complement pathway, opsonophagocytosis,
Toll-like receptors (TLRs)			
TLR2	Multiple	SSL3	Recognize *S. aureus* lipopeptides, LTA, PGN
TLR9	Multiple		Recognize *S. aureus* DNA in endosomes
NOD2	Multiple		Recognize cytosolic muramyl-dipeptide (a breakdown product of *S. aureus* PGN)
Inflammasomes			
NLRP3/ASC	Multiple		Activated by *S. aureus* toxins, ATP & K+ efflux to induce pro-IL-1β processing
AIM2/ASC	Multiple		Activated by cytosolic *S. aureus* DNA to induce pro-IL-1β processing
Formyl peptide receptors			
FPR1, FPR2, FPR3	Macrophages Neutrophils	CHIPS	Recognize formylated peptides to promote chemotaxis, phagocytosis and oxidative burst
Tumor necrosis factor-α receptor 1 (TNFR1)			
TNFR1	Multiple		BINDS *S. aureus* protein A to promote inflammation
Peptidoglycan recognition proteins (PGLYRP1)			
PGLYRP1	Neutrophils		BINDS *S. aureus* PGN to induce antimicrobial activity
PGLYRP2	Keratinocytes		BINDS *S. aureus* PGN
PGLYRP3,4	Keratinocytes Hair follicles Sebaceous glands Sweat glands		BINDS *S. aureus* PGN

There are four well-characterized human β-defensins (HBD1-4), which are expressed by various epithelial cells, including keratinocytes, as well as by activated monocytes/macrophages and dendritic cells. HBDs 1, 2, and 4 have been shown to have only a weak bacteriostatic effect against *S. aureus in vitro* [33, 34]. In contrast, HBD3 has strong *in vitro* bactericidal activity against *S. aureus* [35]. hCAP-18 is the only known member of the human cathelicidin family and is the precursor to the active cleaved C-terminal peptide LL-37 [36–38]. Like HBD3, LL-37 has been shown to have potent antimicrobial activity against *S. aureus* [36–38].

Keratinocyte production of HBD2, HBD3, and LL-37 can be induced by live or heat-killed *S. aureus* and by *S. aureus* components, including lipopeptides and lipoteichoic acid (LTA) via activation of TLR2 [39–42]. Thus, human keratinocytes can upregulate the production of HBD2 and HBD3 in response to *S. aureus* or its components, thereby increasing the innate immune response in the skin. Interestingly, activation of the epidermal growth factor receptor (EGF-R) by wounding of human skin *in* vitro resulted in increased production of HBD3 and antimicrobial activity against *S. aureus* [43, 44]. Thus, wounded skin may resist infection by *S. aureus* via production of HBD3 [43, 44]. In addition, vitamin D has been shown to increase LL-37 production by keratinocytes, neutrophils and monocytes/macrophages [45–47], suggesting vitamin D may also promote host defense against *S. aureus* [48, 49]. Of note, the important role of HBDs and LL-37 in host defense against *S. aureus* in skin is illustrated by the expression of the surface protein, iron surface determinant A (IsdA), by *S. aureus*, which renders the bacteria resistant to hBD2 and LL-37 by decreasing the bacterial membrane hydrophobicity [50]. *S. aureus* also produces aureolysin, a protease that cleaves LL-37 to inactivate its activity [51]. Moreover, MprF is not only effective against α-defensins (see above) but can also neutralize the activity of LL-37 [52].

Newer antimicrobial peptides have been identified in skin that have activity against *S. aureus*, including RNase 7, which is produced by keratinocytes and can prevent skin colonization with *S. aureus* [53], dermcidin, which is produced by eccrine glands and secreted in human sweat [54, 55], and REG3A [24], which is produced by keratinocytes and the mouse homolog, REG3γ, has activity against *S. aureus* pneumonia [56]. Of note, *S. aureus* secretes extracellular proteases that degrade and neutralize the activity of dermcidin [57]. It should be highlighted that the *S. aureus*-derived products of the *dlt*ABCD operon appear to have a global effect on inhibiting antimicrobial peptide activity by decreasing the negative charge on the bacterial surface, since a mutant *S. aureus* strain deficient in D-alanylated teichoic acids (*dltA* mutant) was more susceptible to killing by HBD2, HBD3, LL-37, RNase 7 and dermcidin [58].

Antimicrobial peptides may also be involved in the pathogenesis of certain inflammatory skin diseases. HBD2 and HBD3 are expressed at increased levels in the hyperproliferative and inflammatory skin disease, psoriasis, which has been associated with a Th1 and Th17 cytokine profile [33, 35, 59, 60]. In contrast, levels of HBD2, HBD3, and LL-37 are expressed at significantly lower levels in atopic dermatitis, another inflammatory skin disease that is associated with a Th2 cytokine profile [59, 60]. These findings provide an explanation of why *S. aureus* colonization and superinfection is more frequently seen in atopic dermatitis and rarely in psoriasis.

Lastly, antimicrobial peptides not only have microbicidal activity, but also promote the recruitment of immune system cells to the site of infection. For example, HNPs promote chemotaxis of T cells and immature dendritic cells, HBDs promote chemotaxis of immature dendritic cells and memory CD4 T cells, and LL-37 promotes chemotaxis of neutrophils, monocytes, and T cells [61–63]. The chemotactic activity of HBDs and LL-37 is mediated by the chemokine receptor CCR6 and the formyl peptide receptor-like 1 (FPRL1), respectively [61–63].

Complement

The complement system includes a family of serum proteins, proteolytic fragments and cell surface receptors [64, 65]. There are three main functions of complement activation: (1) direct killing of bacteria via formation of the membrane attack complex (MAC), which perforates cell membranes; (2) promotion of phagocytosis by opsonizing the bacterial surface with complement components such as C3b; and (3) recruitment of immune system cells to the site of infection by generating the complement chemoattractant peptides C3a and C5a [64, 65]. There are three pathways of complement activation: the classical, alternative and lectin pathways [64, 65]. Each pathway requires generation of an enzyme complex called the C3 convertase [64, 65]. In the classical pathway, generation of the C3 convertase involves the interaction of complement components with natural IgM antibody or antigen specific IgG antibody that is bound to antigens of the pathogen [64, 65]. In the alternative pathway, there are low levels of direct activation of the C3 convertase by components of the pathogen [64, 65]. In the lectin pathway, the C3 convertase is activated via recognition of carbohydrate groups on the surface of the bacteria via mannose-binding lectin (MBL) or via H-, L-, or M-ficolin and MBL-associated serine proteases (MASP1, 2 and 3) [66].

There have been several reports demonstrating the key role of complement in host defense against *S. aureus* (Table 16.1). First, in a mouse model of *S. aureus*-induced arthritis and bacteremia, depletion of complement components resulted in higher mortality and significantly decreased neutrophil recruitment and impairment of phagocytosis [67]. In another study, complement mediated opsonization by C3b as

well as activation of complement receptor 1 (CD35) (the primary receptor for C3b) were more critical in controlling *S. aureus* bacteremia than C5a or generation of the MAC [68].

MBL is also important in host defense against *S. aureus* infections [69–71]. For example, individuals with an MBL gene mutation, who have impaired MBL-dependent opsonization, suffer from recurrent *S. aureus* infections [72]. MBL as well as IgG directed against glycoepitopes on teichoic acid facilitates complement-mediated opsonophagocytosis of *S. aureus* [73, 74]. In addition, MBL-deficient mice had only a slightly decreased survival whereas C3-deficient mice and mice deficient in both MBL and C3 had markedly decreased survival compared with wildtype mice after an intravenous challenge of *S. aureus* [69, 70]. Thus, C3 and complement activation may play a more important role than MBL in host defense against *S. aureus* [69, 70]. Finally, MBL can bind to *S. aureus in vitro*, resulting in increased phagocytosis [71]. Taken together, MBL is involved in activation of the lectin complement pathway and in opsonization of *S. aureus*.

S. aureus has several mechanisms to counteract complement activity. *S. aureus* produces a protein called staphylococcus complement inhibitor (SCIN), which blocks activation of the complement cascade by inhibiting the C3 convertase [75]. In addition, *S. aureus* secretes extracellular fibrinogen-binding protein (Efb) and extracellular complement-binding (Ecb) proteins, which bind C3 and blocks C3 opsonization [76–78]. *S. aureus* also produces C4b-binding protein (C4BP) that cleaves CD4b into inactive forms iC4b and C4d, which decreases C3b-mediated opsonization [79]. Lastly, staphylokinase (SAK) inhibits opsonization of *S. aureus* and subsequent phagocytosis by converting plasminogen into plasmin on the bacterial surface, which leads to removal of the anti-staphylococcal opsonins IgG and C3b [80].

Pattern Recognition Receptors that Recognize Components of *S. aureus*

Toll-Like Receptors

Toll-like receptors (TLRs) are important PRRs involved in host defense against a variety of pathogenic microorganisms, including *S. aureus* [18, 19]. Activation of TLRs initiates several signaling cascades including NF-kB activation, ultimately leading to production of cytokines, chemokines, antimicrobial peptides and up-regulation of costimulatory and adhesion molecules involved in innate and adaptive immune responses [18, 19].

Of the known human TLRs (1-10), TLR2 has been the most implicated in host defense against *S. aureus* (Fig. 16.3, Table 16.1). TLR2 is expressed on the cell surface of numerous cell types in the skin, including keratinocytes, Langerhans cells, monocytes/macrophages, dendritic cells, mast cells, endothelial cells, fibroblasts and adipocytes [81–89]. TLR2 can be activated by live or heat-killed *S. aureus* as well as the *S. aureus* components, lipopeptides, lipoteichoic acid (LTA) and peptidoglycan (PGN) [90].

With regard to *S. aureus* skin infections, TLR2-deficient mice develop larger skin lesions than wildtype mice after *S. aureus* skin inoculation [91–93]. Human keratinocytes also express TLR2 and can be activated by live or heat-killed *S. aureus* and *S. aureus* components, resulting in increased production of cytokines such as IL-1β, IL-8, TNFα and production of HBD2 and HBD3 [82, 85, 86, 94]. Polymorphisms in TLR2 have been linked to increased severity of atopic dermatitis [95–98], which is frequently associated with superinfection by *S. aureus* [99, 100]. In addition, TLR2 was found to enhance barrier repair in human skin and the reduced expression of TLR2 in atopic dermatitis may contribute to the impaired skin barrier in this disease [101]. Most recently, a study in mice found that activation of TLR2 promoted the shift from acute Th2-mediated dermatitis to chronic cutaneous inflammation in a mechanism that involved IL-4 suppression of IL-10 [102]. This study provides additional rationale for the therapeutic targeting of IL-4, which is currently under investigation against atopic dermatitis in human trials [103].

Since *S. aureus* lipopeptides, LTA and PGN have distinct biochemical structures, it was unclear how one receptor could recognize such a broad spectrum of molecules [104]. However, TLR2 interacts with other TLRs and additional co-receptors, which enables TLR2 to recognize these different ligands. TLR2 heterodimerizes with TLR1 or TLR6 to recognize tri-acyl and di-acyl lipopeptides, respectively [105, 106]. Therefore, the ability of the host to recognize certain lipopeptides depends on the formation of TLR2 heterodimers. CD14, a membrane protein that lacks an intracellular signaling domain, was initially characterized as a TLR4 co-receptor for LPS of Gram-negative bacteria [104]. However, CD14 also acts as a TLR2 co-receptor to recognize *S. aureus* LTA and PGN [107, 108]. CD14 is likely involved in cutaneous immunity against *S. aureus* since studies have demonstrated that increased CD14 expression in keratinocytes inhibited growth of *S. aureus* [49, 109]. In addition, CD36 represents another TLR2 co-receptor involved in the recognition of *S. aureus* LTA (which is di-acylated) and in the activation of signaling via the TLR2/6 heterodimer [92, 110]. The importance of TLR2 is exemplified by the existence of superantigen-like protein 3 (SSL3), a *S. aureus*-derived factor that binds and inhibits the function of TLR2 [111, 112].

TLR9 is an intracellular TLR that is found spanning the membranes of endosomes that has been shown to recognize hypomethylated CpG (cytosine-phosphate-guanosine) motifs of bacterial DNA and is involved in promoting type I interferon responses [113–115]. Although the role of TLR9 against *S. aureus* skin infections is not entirely clear,

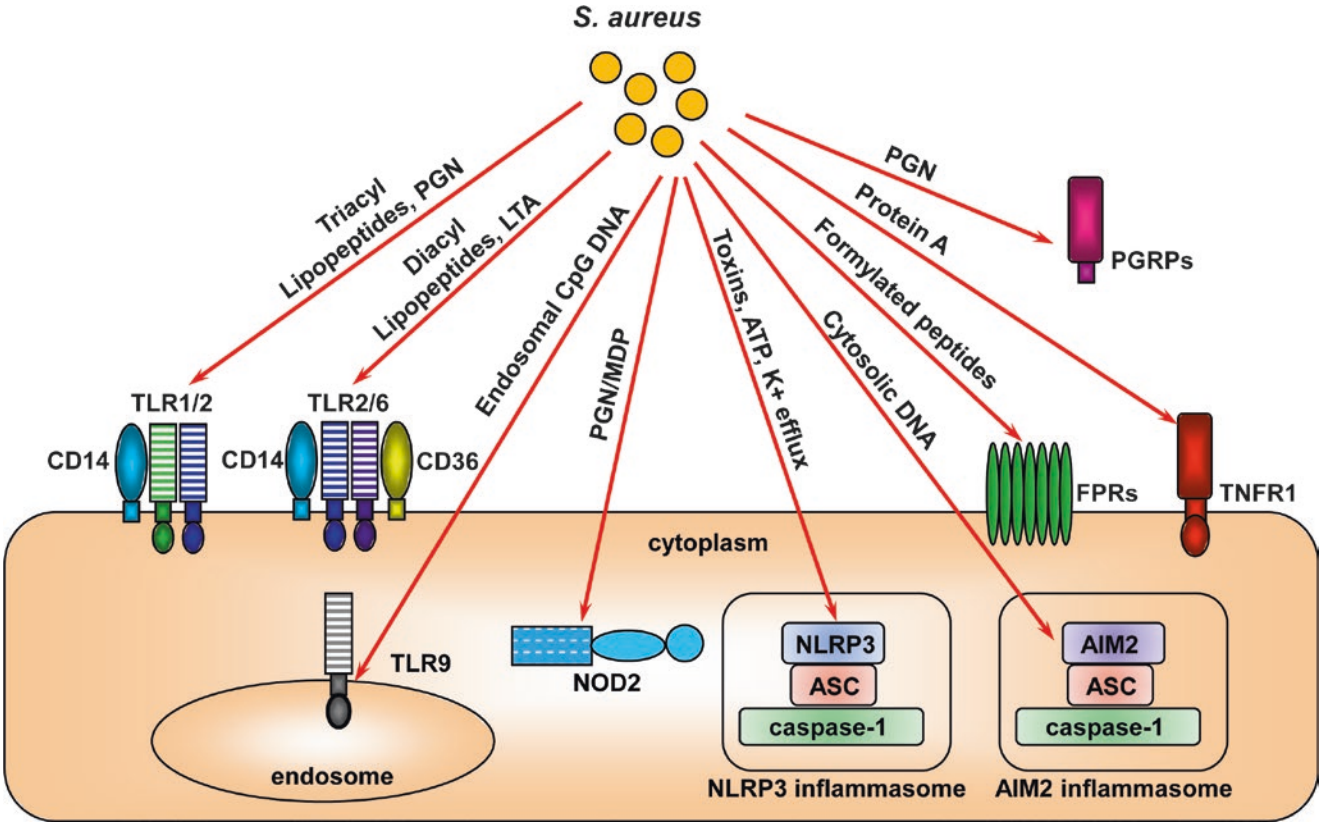

Fig. 16.3 Pattern recognition receptors (PRRs) of host cells involved in recognizing components of *S. aureus* and initiating immune responses. The *S. aureus* components recognized by these PRRs and the cellular localization of these PRRs are shown

TLR9-deficient mice have been found to have enhanced clearance against a *S. aureus* pneumonia infection, suggesting that TLR9 responses may not be associated with protection against *S. aureus* infections [116].

Nucleotide-Binding Oligomerization Domain Proteins (NOD1 and NOD2)

In contrast to TLR2, nucleotide-binding oligomerization domain proteins (NOD1 and NOD2) are found in the cytosol and detect breakdown products of PGN [117]. NOD1 recognizes breakdown products of Gram-negative PGN [117]. In contrast, NOD2 recognizes muramyl dipeptide (MDP), which is a breakdown product of both Gram-positive and Gram-negative PGN [117], and has been shown to recognize MDP-derived from *S. aureus* PGN (Fig. 16.3, Table 16.1) [118]. After ligand detection, NODs activate a signaling pathway that results in NF-kB activation and transcription of host genes involved in innate and acquired immune responses [117].

Since NOD2 is a cytoplasmic receptor, this calls into question whether an intracellular PRR could be involved in recognition of a *S. aureus* infection, since *S. aureus* has classically been considered an extracellular pathogen. However, several studies have found that *S. aureus* can invade the cytoplasm of various cells, including keratinocytes, epithelial cells, fibroblasts, endothelial cells, osteoblasts and neutrophils [119]. Once *S. aureus* enters the cytoplasm, host and/or bacterial enzymes may break down *S. aureus* PGN into MDP that can be recognized by NOD2 [119]. A few studies have found that NOD2 is involved in host defense against *S. aureus* skin infections in mice [91, 120]. Moreover, NOD2 expressed by keratinocytes can induce inflammatory cytokines such as IL-1β, IL-6 and IL-17C [121, 122], which promote antimicrobial mechanisms (e.g., neutrophil recruitment and activation and expression of antimicrobial peptides) against *S. aureus* [91, 120, 122]. Finally, NOD2 may also play a role against human *S. aureus* infections because polymorphisms in NOD2 (like TLR2) were identified in patients with atopic dermatitis [123, 124].

Inflammasomes

IL-1β plays a critical role in the recruitment of neutrophils to the site of *S. aureus* infection in the skin [91, 93, 125, 126]. Although, PRRs such as TLRs and NODs can induce transcription and translation of pro-IL-1β (as well as

pro-IL-18) [127], a second signal is required to induce cleavage of pro-IL-1β (and pro-IL-18) into its active and secreted form. This process is typically mediated by inflammasomes, which are cytoplasmic protein complexes that regulate caspase-1-mediated proteolytic processing of pro-IL-1β into active IL-1β (Fig. 16.3, Table 16.1) [128–130]. There are several known inflammasome complexes, which are reviewed elsewhere [128–130]. However, the NLRP3 (NOD-, LRR- and pyrin domain-containing 3) inflammasome has been the primary inflammasome complex implicated in IL-1β processing in the context of *S. aureus* infections (Fig. 16.3). In *S. aureus*-infected macrophages *in vitro*, the NLRP3-inflammasome processes IL-1β in a mechanism that involves activation of this inflammasome by *S. aureus* toxins (α-, β-, and γ-toxins and Panton-Valentine leukocidin [PVL]), ATP/$P2X_7R$ activation and phagosomal rupture [131–136]. This may be relevant to *S. aureus* skin infections *in vivo*, since mice deficient in ASC (apoptosis-associated speck-like protein containing a CARD), which is a critical component of the NLRP3 inflammasome, has the same impaired immune response against *S. aureus* skin infections as IL-1β-deficient mice [126]. In addition, the AIM2 (absent in melanoma 2) inflammasome, which like NLRP3 requires interaction with ASC [137–139], was recently shown to be important for host defense against a *S. aureus* brain abscess infection [140]. AIM2 recognizes cytosolic bacterial DNA [137–139] and the AIM2/ASC inflammasome may recognize *S. aureus* DNA in the cytosol to promote host defense. Interestingly, in certain cell types, such as neutrophils, processing of IL-1β can be mediated in an inflammasome-independent manner via the activity of other proteases, such as elastase, proteinase 3, cathepsins and matrix metalloproteinases (MMPs) [141–145]. In addition, neutrophils have been shown to be an important source of IL-1β during *S. aureus* skin infections in mice and it is likely that both inflammasome and non-inflammasome mechanisms contribute to IL-1β processing and release in neutrophils [91].

Formyl Peptide Receptors (FPRs)

Bacteria but not mammalian cells produce peptides and proteins containing formylated methionine [146]. These formylated non-self peptides and proteins can be recognized by formyl peptide receptors (FPRs) on host cells (including macrophages and neutrophils) (Fig. 16.3, Table 16.1) [146]. There are three known human FPRs, FPR1, FPR2 and FPR3 [146]. In particular, human FPR1 and the mouse ortholog mFPR1 as well as human FPR2 have been implicated in promoting neutrophil chemotaxis, phagocytosis and oxidative burst against *S. aureus* infections [147–149]. The importance of FPRs in host defense against *S. aureus* is demonstrated by the activity of the chemotaxis inhibitory protein of staphylococci (CHIPS), which blocks the chemotactic activity of FPR1, FPR2 and FPR-like 1 inhibitory proteins (FLIPr and FLIPr-like) [150, 151].

Tumor Necrosis Factor-α Receptor 1 (TNFR1)

TNF-α receptor 1 (TNFR1) is a receptor for TNF-α that is expressed on many different cell types. *S. aureus* protein A, which is known to bind the Fc portion of antibody, was found to activate TNFR1 to trigger production of proinflammatory cytokines and chemokines and contributed to virulence in a mouse model of *S. aureus* pneumonia (Fig. 16.3, Table 16.1) [152, 153]. A similar mechanism of protein A and TNFR1 interaction has been shown to occur in human keratinocytes, which induces production of proinflammatory cytokines and chemokines [154]. However the relevance of TNFR1 in contributing to the pathogenesis of *S. aureus* skin infections *in vivo* is unclear since TNFR1-deficient mice had similar lesion sizes and bacteria clearance as wildtype mice during an *in vivo S. aureus* skin infection [93].

Peptidoglycan Recognition Proteins (PGRPs)

In humans, there are four PGRP genes (PGLYRP1, 2, 3, 4, formally named PGRP-S, -L, -Iα, and -Iβ based on their short [S], long [L] and intermediate [I] transcript lengths) [155]. All of these gene products are secreted proteins (Fig. 16.3, Table 16.1) [155]. PGLYRP1 is expressed within tertiary granules of neutrophils and it has been shown to bind *S. aureus* PGN to promote antimicrobial activity [156, 157]. PGLYRP2 is expressed in keratinocytes and has an active amidase that cleaves *S. aureus* PGN [158]. PGLYRP3 and PGLYRP4 are also expressed in the kertainocytes as well hair follicles, sebaceous glands and sweat glands [159]. It is unclear whether these PGRPs play an important host defense role against *S. aureus* skin infections. However, PGLYRP2-deficient mice had no immune impairment against a systemic challenge with *S. aureus* [160].

Cellular Innate Immune Responses Against *S. aureus*

Neutrophils

Neutrophils are first responders of the innate immune system and are recruited to sites of *S. aureus* infection [15, 16]. Neutrophilic responses are thought to be crucial for immunity against both primary and recurrent *S. aureus* infections since patients with congenital or acquired defects in neutrophil number, recruitment or function (e.g., congenital conditions such as chronic granulomatous disease and acquired conditions such as neutropenic chemotherapy

patients or patients with impaired neutrophil function in diabetes or renal insufficiency) are highly susceptible to *S. aureus* infections in many tissues and organs, including the skin [127]. Keratinocytes and other resident skin cells produce neutrophil-attracting chemokines such as neutrophil chemotactic factor IL-8 (CXCL8), growth-related oncogene-α, -β, -γ (GRO-α, -β, -γ), neutrophil-activating peptide-2 (NAP-2; CXCL7) and epithelial cell-derived neutrophil-activating peptide-78 (ENA-78, CXCL5) [161]. All of these chemokines contain glutamic acid-leucine-arginine (ELR) residues preceding the first cysteine and activate the receptors CXCR1 and CXCR2 on neutrophils to promote chemotaxis and are thus called ELR+ chemokines [161]. The antimicrobial peptide LL-37 and the complement components C3a and C5a are also strong neutrophil chemoattractants [161, 162]. In addition, neutrophils themselves release leukotrienes, which are proinflammatory molecules that are chemoattractant for most leukocytes [161].

One of the main neutrophil functions is to engulf microbes into a phagosome, which fuses with a lysosome to form a phagolysosome (Fig. 16.4) [15, 16]. In the phagosome, reactive oxygen species (ROS) are produced such as superoxide (O_2–), hydrogen peroxide (H_2O_2), and hyperchlorous acid (HOCl) by the enzymes NADPH oxidase, superoxide dismutase and myeloperoxidase (MPO), respectively. These ROS are toxic to certain bacterial pathogens, but *S. aureus* is somewhat resistant to ROS-mediated killing alone [15, 163]. However, ROS also promote killing of bacteria such as *S. aureus* by producing a charge across the phagocytic vacuole membrane, resulting in K^+ influx and release of proteases and antimicrobial peptides from neutrophil granules into the vacuole [16]. Some of the components of neutrophil granules that are important in bacterial killing include proteinases (e.g. cathepsin G, elastase, and proteinase 3), α-defensins, lysozyme, acid hydrolases, lactoferrin (which sequesters iron and copper), transcobalamin II (which binds cyanocobalamin [vitamin

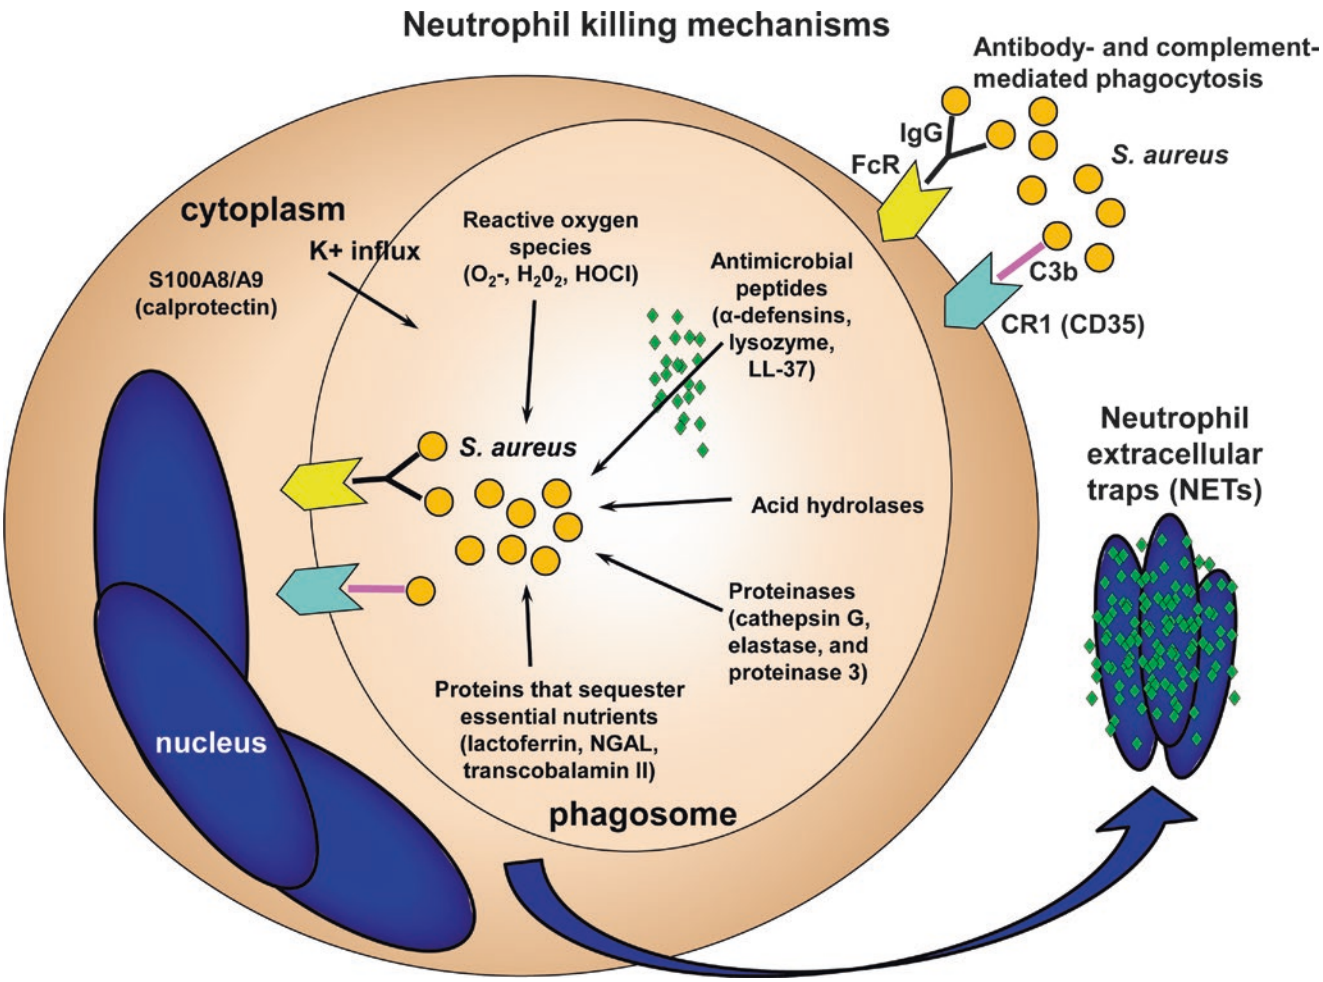

Fig. 16.4 Neutrophil antimicrobial mechanisms against *S. aureus*

B12]), and neutrophil gelatinase-associated lipocalin (NGAL) [164]. NGAL is an antimicrobial protein that binds to bacterial siderophores and blocks their ability to extract iron needed for bacterial growth [164]. If neutrophils escape the phagosome and enter the cytoplasm, approximately 40–50 % of the protein found in the cytoplasm is comprised of calprotection, a complex of S100A8 and S100A9 proteins, which chelates $Mn2^{+}$ and $Zn2^{+}$ and sequesters these essential nutrients to prevent bacterial growth [164]. Finally, neutrophils can release antimicrobial peptides, proteases and chromatin through NETs (neutrophil extracellular traps), which trap and promote antimicrobial activity against *S. aureus* [165, 166].

Recently, a host defense circuit has been uncovered that triggers neutrophil recruitment to a site of *S. aureus* skin infection in mice (Fig. 16.5). This process begins with recognition of the *S. aureus* skin infection by PRRs such as TLR2, NOD2 and FPRs, which leads to production and secretion of IL-1β in a mechanism involving activation of the NLRP3/ASC inflammasome [91, 93, 126]. IL-1β then acts on IL-1R-expressing resident skin cells and subsequent signaling via MyD88 leads to production of neutrophil-attracting chemokines (KC, MIP2) and granulopoiesis factors (G-CSF and GM-CSF) to mediate neutrophil recruitment [91, 93, 126]. Interestingly, a major cellular source of IL-1β at the site of *S. aureus* infection in the skin were neutrophils, which amplified and sustained the neutrophilic response for optimal abscess formation and bacterial clearance [91]. It should also be mentioned that IL-1α also contributed to IL-1R/MyD88-mediated host defense against a superficial *S. aureus* skin infection in mice [125], which is consistent with the identification of an IL-1α autocrine signaling loop in keratinocytes to continuously produce neutrophil-attracting chemokines [167, 168]. A similar mechanism involving IL-1α/β in host defense may exist in humans since pediatric

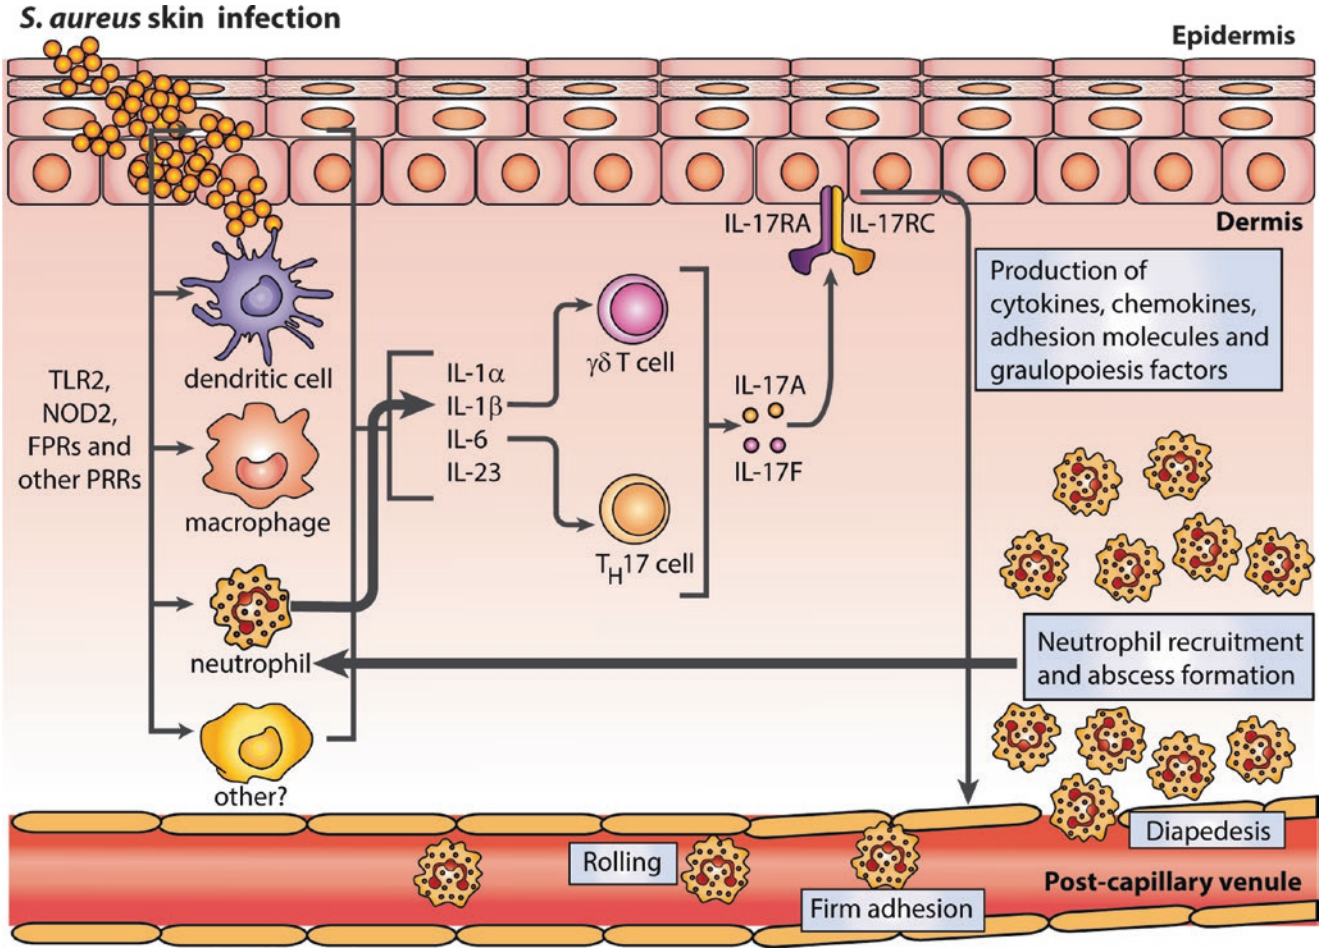

Fig. 16.5 Proposed host defense circuit for neutrophil recruitment to a site of *S. aureus* infection in the skin. Recognition of *S. aureus* components by PRRs (TLR2, NOD2, FPR1) and activation of cells in the skin to produce IL-1α, IL-1β, IL-6 and IL-23, which are required to activate γδ T cells and/or Th17 cells to produce IL-17A and IL-17 F. IL-17A/F subsequently activates IL-17 receptors, expressed primarily on keratinocytes, to produce cytokines, chemokines, adhesion molecules and granulopoiesis factor to promote neutrophil recruitment from the circulation to the site of infection. Finally, neutrophils, themselves, are important sources of IL-1β, which can amplify and sustain the neutrophil recruitment response for optimal abscess formation

patients with a deficiency in MyD88 or IRAK4 (signaling molecules downstream of IL-1Rs and TLRs) are highly susceptible to pyogenic bacterial infections, including *S. pneumoniae*, *S. aureus* and *P. aeruginosa* [169–171]. In these patients, the *S. aureus* infections were limited to the skin in most cases (84 %) [169–171], which is different than patients with impaired neutrophilic responses because they have a systemic susceptibility to *S. aureus* infections [127]. Furthermore, the MyD88/IRAK4-deficient patients developed pus at sites of infection in the absence of neutrophilia, suggesting an impaired ability to sustain the neutrophilic response [170], which is consistent with the findings in mice [91, 93, 126].

The critical role of neutrophils in host defense against *S. aureus* is further illustrated by the existence of mechanisms that *S. aureus* possesses to inhibit neutrophil recruitment and function [172]. For example, *S. aureus* inhibits neutrophil extravasation by producing staphylococcal superantigen-like 5 (SSL5) that blocks P-selectin-mediated neutrophil rolling, and extracellular adherence protein (Eap) that binds to ICAM-1 to inhibit adherence to endothelium [76]. *S. aureus* also inhibits neutrophil chemotaxis via production of Staphopain A, which blocks activity of CXCR2 chemokines [173], and CHIPS that inhibits neutrophil chemotaxis by blocking CD5aR, FPR1, FPR2, FPRL1 and FLIPr and FLIPr-like receptors [150, 151]. *S. aureus* also produces factors that inhibit neutrophil function. For example, the yellow carotenoid pigment of *S. aureus*, staphyloxanthin, which is responsible for its golden color, is an antioxidant that blocks ROS-mediated killing of *S. aureus* [174]. In addition, *S. aureus* produces catalase and alkyl hydroperoxide reductase, which converts hydrogen peroxide to water, and two superoxide dismutase enzymes, which degrade superoxide, to impair ROS-mediated killing [172]. *S. aureus* also produces nuclease and adenosine synthase that degrade NETs, thereby evading their antimicrobial function [175, 176].

Monocytes/Macrophages

Similar to neutrophils, monocytes/macrophages are recruited to the site of a *S. aureus* infection and are important in phagocytosing *S. aureus*. Monocytes/macrophages (as well as neutrophils) express Fc and complement receptors that facilitate phagocytosis by recognizing immunoglobulin or complement components opsonized on the bacterial surface [172, 177]. The importance of phagocytosis is exemplified by the existence of several mechanisms that *S. aureus* utilizes to evade this process [177]. For example, *S. aureus* has protein A on its surface that binds the Fc portion of IgG, resulting in the binding of IgG in an incorrect orientation for detection by Fc receptors [177]. In addition, fibrinogen binding proteins and clumping factor A (ClfA) bind fibrinogen and impair macrophage phagocytosis [177]. *S. aureus* also secretes toxins that are pore-forming proteins that damage membranes of host cells such as macrophages leading to lysis and the prevention of phagocytosis [172]. There are two main families of these pore-forming toxins: (1) single-component α-hemolysin or α-toxin and (2) biocomponent leukotoxins, including γ-hemolysin or γ-toxin, Panton-Valentine leukocidin (PVL), leukocidin A/B (LukAB), LukED, LukGH, and leukocidin M/F-PV-like [172]. The toxins facilitate lysis of host cells by interacting with specific targets, some of which have been identified. Alpha-toxin targets ADAM10 [178], PVL targets C5a receptors [179], LukAB targets CD11b [180] and LukED targets CCR5, CXCR1 and CXCR2 [181, 182]. Finally, *S. aureus* possesses phenol soluble modulins, including four PSMα peptides (PSMα1-PSM α4), PSMβ1, PSMβ2, and PSMδ (δ-toxin), which have the ability to lyse human erythrocytes and leukocytes, including neutrophils [183]. In addition, CA-MRSA strains are known to produce high levels of PSMα peptides that contribute to the enhanced virulence of USA300 isolates [184].

Adaptive Immune Responses Against *S. aureus*

The innate immune system provides the first line of defense against microbial pathogens, while the cell-mediated and humoral immune responses of adaptive immunity are later recruited. The adaptive immune system can be divided into T cell- and B cell-mediated immune responses and the role of these adaptive immune responses against *S. aureus* will be discussed in this section.

T Cell Immune Response

A number of different observations have provided evidence that T cells play an important role in host defense against *S. aureus* skin infections. First, patients with HIV infection are at an increased risk for colonization and skin infection with *S. aureus* [185–188]. In addition, the low serum $CD4^+$ T cell counts of HIV patients is a risk factor for *S. aureus* infection [185].

Second, patients with the inflammatory skin disease atopic dermatitis, which is associated with a Th2 cytokine profile (i.e. IL-4, IL-13, and IL-10), have increased colonization and superinfection with *S. aureus* [189, 190]. Although the reason for the increased *S. aureus* superinfection in atopic dermatitis is likely multifactorial (including a defective epidermal barrier and impaired innate immune responses such as decreased expression of antimicrobial peptides), Th2 cytokines have also been implicated. For example, IL-4 has been shown to increase the expression of fibronectin and fibrinogen receptors on host cells, which promotes more efficient binding of *S. aureus* to the stratum corneum [191]. In addition, *S. aureus* via the *S.*

aureus-derived factors fibronectin-binding protein (fnbp) and clumping factor (Clf, also known as fibrinogen-binding protein) more efficiently bind to skin from atopic dermatitis patients [192]. Also in atopic dermatitis, *S. aureus* produces superantigens such as staphylococcal enterotoxins A and B (SEA and SEB) and toxic shock syndrome toxin-1 (TSST-1) that exacerbate the inflammatory response by nonspecifically activating T cells [190, 193–196]. *S. aureus* superantigens also can skew the cutaneous immune response towards the Th2 cytokine profile, thereby increasing *S. aureus* superinfection in atopic dermatitis [197]. Recently, *S. aureus* δ-toxin has been shown to induce allergic skin inflammation via mast cell activation in mice, providing yet another mechanism by which *S. aureus* contributes to the pathogenesis of atopic dermatitis [198]. Taken together, T cells likely play an important role in colonization and superinfection of atopic dermatitis lesions by increasing levels of Th2 cytokines, activation of T cells by superantigens and other toxin-mediated effects on promoting skin inflammation.

Third, recent evidence suggests that Th17 cells and IL-17 responses in humans may also be protective against *S. aureus* skin infections. The differentiation of naïve T cells into Th17 cells has been shown to be mediated by IL-6, IL-21, IL-23, TGFβ and/or IL-1β, which cause expression of the transcription factor RORγt in mature Th17 cells, which produce IL-17A, IL-17F, IL-21 and IL-22 [199, 200]. The strongest evidence for a protective role of Th17 cells against *S. aureus* skin infections comes from the study of the rare orphan disease hyper-IgE syndrome (HIES) (also called Job's syndrome after the biblical character Job whose faithfulness was tested by an affliction with sores and boils over his entire body [201]). HIES patients suffer from an eczema-like skin eruption and chronic and recurrent skin infections with *S. aureus* and *C. albicans* [201]. HIES patients were found to have loss-of-function mutations in the signaling molecule STAT3 [202, 203], which rendered them deficient in Th17 cells [204–206]. Additionally, patients with IL-17RA or IL-17F deficiency were found to also be susceptible to *C. albicans* and to a lesser extent *S. aureus* SSTIs [207]. These findings suggest that STAT3 and IL-17/Th17 responses, in particular, play a key role in host defense against *S. aureus* infections in skin. However, although *S. aureus*-specific Th17 cells are found in blood from healthy humans [208], it remains unknown whether Th17 cells in patients without rare genetic conditions promote protection against *S. aureus* skin infections [209, 210].

Similarly, although initial investigations in mice suggested that Th1 responses, including IFNγ responses, promoted neutrophil recruitment against a *S. aureus* skin surgical wound infection [211, 212] and intravenous *S. aureus* infections [213–215], more recent studies have revealed that IL-17 responses in mice, like in humans, are critical for cutaneous host defense against *S. aureus* skin infections. In a mouse model of *S. aureus* skin infection, IL-17A/F produced by γδ T cells (rather than Th17 cells) was essential in producing neutrophil-attracting chemokines and granulopoiesis factors to promote neutrophil recruitment and bacterial clearance (Fig. 16.5) [216]. Interestingly, IL-17A/F in the infected skin was not induced in IL-1R- or MyD88-deficient mice, indicating that the γδ T cell IL-17A/F required IL-1R/MyD88 activation [216]. Another study found that IL-17A/F-deficient mice suffer from spontaneous *S. aureus* skin infections [217]. In addition, several Th17 cell-inducing vaccines (the candidal adhesion protein rAls3p-N, *S. aureus* clumping factor A [ClfA], *S. aureus* iron regulated surface determinant B [IsdB] and a UV-irradiated *S. aureus* vaccine) protected mice against an intravenous and/or cutaneous *S. aureus* challenge [213, 218, 219], suggesting that Th17 cell-inducing vaccines could potentially be effective against *S. aureus* cutaneous infections in humans. Interestingly, IL-20 cytokines (IL-19, IL-20 and IL-24) have been shown to enhance a *S. aureus* skin infection in mice by inhibiting IL-1β and IL-17 responses and treatment with an antibody against the shared receptor IL-20RB resulted in improved outcomes [220]. Finally, two recent studies have found that Th17 cells and IL-17-producing γδ T cells were protective against a recurrent *S. aureus* skin infection model and a *S. aureus* surgical wound model in mice, respectively [221, 222]. The mechanism for how anti-*S. aureus* Th17 are generated is an active area of investigation but a recent study found that Langerhans cells in mouse epidermis produced elevated amounts of IL-6, IL-1β, and IL-23, which promoted Th17 differentiation in response to cutaneous challenge with *S. aureus* and *C. albicans* [223]. Similarly, IL-6, IL-1β, and IL-23 also contributed to Th17 cell differentiation of *S. aureus*-specific Th17 cells isolated from human blood [208].

B Cell Immune Response

The B cell-mediated immune response against *S. aureus* involves the production of antibodies directed against specific antigenic components of *S. aureus*. These antibodies play an important role in opsonizing *S. aureus* and facilitating antibody-mediated phagocytosis by neutrophils and macrophages [209, 210]. After an acute *S. aureus* infection (including skin infection), antibody levels have been shown to rise, including specific antibodies against toxins (e.g., α-toxin, PVL), virulence factors (e.g., superantigens), cell-wall proteins (e.g., ClfA) and non-protein antigens (capsular polysaccharides, LTA and PGN) [224]. One study demonstrated that the antibody repertoires differed in patients with superficial versus deep-seated *S. aureus* skin infections [225]. Studies using various animal models of *S. aureus* infection have provided further

evidence that antibodies against different *S. aureus* components can provide some level of protection against *S. aureus* infection [209, 210].

The importance of B cell responses and antibodies in host defense against *S. aureus* infections is further provided by the existence of protein A, an important virulence factor that *S. aureus* uses to counteract antibody-mediated responses [226]. Protein A of *S. aureus* binds antibody in the incorrect orientation, thus enabling *S. aureus* to evade antibody detection and subsequent antibody-mediated phagocytosis [226].

There have been attempts to develop vaccines and passive immunization strategies to promote antibody-mediated responses against *S. aureus* in humans [209, 210]. These vaccines were designed to target molecules on bacterial surfaces to enhance opsonophagocytosis such as capsular polysaccharides, ClfA and IsdB [227–229]. However, to date, all of these vaccines have failed in clinical trials [227–229]. It is unknown whether an antibody-based vaccine alone will promote durable immunity against *S. aureus* skin infections. However, more recent vaccines were designed to target toxins and virulence factors rather than mechanisms such as opsonophagocytosis and this may be a more efficacious approach [209, 210]. Recently, a study in children with and without recurrent *S. aureus* skin infections found that high natural antibodies against α-toxin correlated with protection against recurrence [230], providing rationale for these newer antibody-based vaccination strategies that target *S. aureus* toxins.

Group A *Streptococcus*

Group A *Streptococcus* (*Streptococcus pyogenes*) is a Gram-positive extracellular bacterial pathogen that causes superficial and invasive skin infections such as impetigo, erysipelas, cellulitis, scarlet fever, and necrotizing fasciitis and is the most common cause of bacterial pharyngitis (especially in children) [231, 232]. Group A *Streptococcus* infections can cause other severe infections such as streptococcal toxic shock syndrome, septic arthritis, osteomyelitis, septicemia, pneumonia and meningitis [231]. In addition, after a group A *Streptococcus* infection, immunologic-mediated diseases such as guttate psoriasis, acute rheumatic fever, and glomerulonephritis may ensue [231]. The World Health Organization estimates that there are approximately 600 million cases of noninvasive pharyngitis and 110 million skin infections caused by group A *Streptococcus* globally per year [231]. In the U.S., there is an estimated 8950–11,500 cases of invasive group A *Streptococcus* infections annually (including erysip-

Table 16.2 Soluble mediators and pattern recognition receptors that contribute to host defense against group A *Streptococcus* skin infections

	Cellular expression in skin	Group A *Streptococcus* evasion mechanisms	Mechanisms of action
Antimicrobial peptides			
α-defensins (human neutrophil peptides [HNPs])	Neutrophils	SIC, generation of dermatan sulphate, *dlt*ABCD	Antimicrobial activity, chemotaxis of T cells and immature dendritic cells
hBD2	Keratinocytes, macrophages, DCs	SIC, *dlt*ABCD operon	Antimicrobial activity, chemotaxis of immature dendritic cells and memory CD4+ T cells via CCR6
hBD3	Keratinocytes	SIC, DRS, *dlt*ABCD operon	
LL-37	Keratinocytes, macrophages neutrophils	SIC, SpeB, *dlt*ABCD operon	Antimicrobial activity, chemotaxis of neutrophils, monocytes and T cells via FPRL1
Complement	Serum	M-protein	Complement cascade
C5a	Serum	C5a peptidase (ScpA)	Chemotaxis of neutrophils
C5b-C7	Serum	SIC	MAC (membrane attack complex)
Toll-like receptors (TLRs)			
TLR9	Multiple	Sda1	Recognize group A *Streptococcus* DNA
NOD2	Multiple		Recognize cytosolic muramyl-dipeptide (a breakdown product of group A *Streptococcus* PGN)
Inflammasomes			
NLRP3/ASC inflammasome	Multiple		Activated by group A *Streptococcus* streptolysin O to induce pro-IL-1β processing

elas, cellulitis, and necrotizing fasciitis), which result in 1050–1850 deaths [233]. Thus, group A *Streptococcus* continues to be a major cause of superficial and invasive skin infections both globally and in the U.S.

Clinical Manifestations

Group A *Streptococcus* causes superficial skin infections such as impetigo and invasive skin infections such as erysipelas, an infection of the superficial layers of the skin and cutaneous lymphatics (Fig. 16.6), or cellulitis, an infection involving the deep dermis and subcutaneous tissue [234]. Group A *Streptococcus* also causes necrotizing fasciitis, which is a severe skin and soft-tissue infection that results in total destruction of the deep fat and fascia and often precedes streptococcal sepsis, shock and multi-organ failure [234]. In addition, scarlet fever, which is usually associated with a streptococcal throat infection, is characterized by a morbilliform rash, strawberry tongue and desquamation of skin [231, 232]. This constellation of clinical findings in scarlet fever is caused by streptococcal pyrogenic exotoxins (Spe), especially SpeA, B and C, which act as superantigens [231, 232].

Innate Immune Responses Against Group A *Streptococcus*

The innate immune response against group A *Streptococcus* is similar to that against *S. aureus* and includes soluble factors such as antimicrobial peptides and complement components, PRRs such as TLRs and NOD2 and innate immune system cells such as neutrophils and monocytes/macrophages. However, there are some key differences in the immune response against group A *Streptococcus*, especially with regard to the recognition and activity of M protein expressed by group A *Streptococcus*.

Fig. 16.6 Group A *Streptococcus* erysipelas of the face. The involved skin shows a sharply demarcated, erythematous, and edematous plaque (Photograph is courtesy of the Victor D. Newcomer collection at UCLA and Logical Images, Inc.)

Antimicrobial Peptides

Both α- and β-defensins (HBD1-3) have direct antimicrobial activity against group A *Streptococcus* [235–238]. In addition, stimulation of keratinocytes with group A *Streptococcus* increases production of HBD2 [239]. Cathelicidin also has direct antimicrobial activity against group A *Streptococcus* infections in mouse models of skin infection and in cultures of human keratinocytes or mast cells [240–244]. Cathelicidin production is upregulated in wounded human or mouse skin, which protects the healing wound from infection by group A *Streptococcus* [245]. Thus, both defensins and cathelicidin have antimicrobial activity and play a key role in the innate immune response against group A *Streptococcus*.

The importance of antimicrobial peptides in the innate immune response against group A *Streptococcus* is further illustrated by the existence of several mechanisms that group A *Streptococcus* utilizes to inhibit their function. For example, group A *Streptococcus* produces streptococcal inhibitor of complement (SIC), which inhibits human α-defensins, HBDs 1-3, LL-37, and lysozyme [236, 238] as well as DRS (distantly related to SIC), which inhibits hBD3 [238]. SpeB can cleave and inactivate LL-37 [246]. GAS can also bind plasmin on the bacterial cell surface to facilitate degradation of LL-37 [247]. In addition, extracellular proteases released by group A *Streptococcus* can generate dermatan sulphate from host proteoglycans, which subsequently binds to and inactivates α-defensins [248]. Finally, similar to *S. aureus*, group A *Streptococcus* also secretes products from the *dlt*ABCD operon to reduce the negative charge of the bacterial envelope to resist the activity of LL-37 and other antimicrobial peptides [249].

Complement Activation

The importance of complement in the immune response against group A *Streptococcus* is illustrated by the existence of multiple factors produced by group A *Streptococcus* that inhibit complement activity [231]. The M protein of group A *Streptococcus* inhibits complement activity by several different mechanisms [250, 251]. M protein directly binds to and enhances the function of factor H (FH) and FH-like protein, host proteins that inhibit complement activation and prevent C3b-mediated phagocytosis [252–258]. In addition, a

fibronectin-binding protein (Fba) was shown to have similar FH/FH-like protein binding activity as M protein to inhibit complement and enhance virulence [259–261]. Group A *Streptococcus* M protein also binds to and enhances the function of C4b-binding protein (C4BP), a host protein that downregulates complement activation by accelerating the decay and prevent formation of C3- and C5-convertases [262–267]. Furthermore, M protein binds fibrinogen, which inhibits complement-mediated phagocytosis by reducing the amount of C3 convertase on the surface of group A *Streptococcus* [268]. In addition to M protein, group A *Streptococcus* also secretes C5a peptidase (ScpA), which cleaves C5a and inhibits neutrophil recruitment [269–273]. Finally, the group A *Streptococcus*-derived protein, SIC, not only inhibits antimicrobial peptides (see above), but also binds to C5b-C7 complexes and prevents formation of the MAC [274, 275].

Pattern Recognition Receptors that Recognize Components of Group A *Streptococcus*

The recognition of group A *Streptococcus* appears to be quite different from *S. aureus*, despite both of them being Gram-positive bacteria. Prior work has found that macrophages and dendritic cells produced TNFα and IL-6 in a mechanism independent of TLR2, TLR4 and TLR9 [276–278]. Rather, a major host recognition mechanism for group A *Streptococcus* involved the induction of type I interferon (e.g., IFN-α and IFN-β), which involved DNA from group A *Streptococcus* to activate signaling molecules IRF3, STING, TBK1 and partially MyD88 in macrophages and streptococcal RNA triggering of IRF5 and MyD88 in dendritic cells (DCs) [278]. Furthermore, the type I interferon response was protective against a lethal subcutaneous group A *Streptococcus* infection model in mice [278]. Other reports found a role of TLR9 in inducing hypoxia-inducible factor-1α (HIF-1α), nitric oxide and oxidative burst in host defense and clearance of group A *Streptococcus* in cutaneous and systemic infection models in mice [279]. Interestingly, certain strains of Group A *Streptococcus* possess a bacteriophage that encodes Sda1, which is a DNase that inhibits recognition of the bacterial DNA by TLR9, thus suppressing TLR9-mediated type I interferon-mediated host defense mechanisms [280]. Other PRRs might also be involved in recognition of Group A *Streptococcus*. For example, cell wall fragments from group A *Streptococcus* induced less joint inflammation in mice deficient in NOD2 than wildtype mice and the cell wall fragments were capable of activating NOD2 expressed by human macrophages, suggesting that NOD2 is a PRR for group A *Streptococcus* [281]. Finally, group A *Streptococcus* resulted in activation of the NLRP3/ASC inflammasome to trigger caspase-1 activation and IL-1β secretion in a mechanism that was dependent upon NF-kB and the virulence factor streptolysin O but independent of exogenous ATP, P2X7R and TLR signaling [282]. Taken together, the PRRs involved in recognition of group A *Streptococcus* are not entirely clear (and are different than those of *S. aureus*), but type I interferon responses, NOD2 and NLRP3/ASC inflammasome activation have been identified to be important for host defense. It should be mentioned that the M protein of group A *Streptococcus* has been shown to interact with TLR2 on human monocytes leading to production of IL-6, IL-1β and TNF-α [283]. However, the M protein also binds to CD46 (membrane cofactor protein) on the surface of human keratinocytes and this interaction facilitates the ability of group A *Streptococcus* to invade these cells [284–287]. Thus, the M protein of group A *Streptococcus* might induce inflammatory responses via TLR2 while also promoting invasion of host cells and disease pathogenesis [284–287].

Cellular Innate Immune Responses Against Group A *Streptococcus*

Neutrophils

Neutrophil infiltrates are the characteristic of acute Group A *Streptococcus* infections, which is consistent with its scientific name, *Streptococcus pyogenes* from the Latin for 'pus-generating' [288]. The importance of neutrophils in host defense against group A *Streptococcus* is further demonstrated by the existence of numerous mechanisms that group A *Streptococcus* utilizes to counteract neutrophil recruitment and function [231, 288, 289]. Regarding neutrophil recruitment, group A *Streptococcus* not only produces the C5a peptidase (see above), but also produces another peptidase called ScpC (also called SpyCEP) that degrades CXC chemokines (including IL-8 in humans and KC and MIP2 in mice) [290]. These chemokines are critical for neutrophil recruitment to sites of infection [290].

Group A *Streptococcus* has developed mechanisms to inhibit both complement- and antibody-mediated phagocytosis. As mentioned above, group A *Streptococcus* prevents complement-mediated phagocytosis via activity of M protein and Fba. In addition, group A *Streptococcus* secretes endoglycosidase (EndoS), and streptococcal pyrogenic exotoxin B (SpeB) [291–295]. These bacterial factors inhibit antibody-mediated phagocytosis by hydrolyzing N-linked oligosaccharides on opsonized IgG molecules and by cleaving opsonized IgG molecules into Fab and Fc fragments, respectively [291–295]. SpeB has been shown to degrade most immunoglobulin subtypes (IgG, IgA, IgM, IgD and IgE) [293]. Recently, another endoglycosidase, $EndoS_2$, has similar activity as EndoS to inhibit IgG-mediated phagocytosis [296]. In a mouse

skin infection model, group A *Streptococcus* mutant strains expressing protease-inactive SpeB caused significantly less necrosis and demonstrated less efficient systemic dissemination from the initial focus of skin inoculation [297]. There are also other IgG-degrading enzymes (Ide) produced by group A *Streptococcus*, including IdeS (also known as Mac-1), which cleaves the lower Fc region of surface bound IgG [298] and is also a bacterial homolog of the α-subunit of the β2-integrin Mac-1 that binds to CD16 (FcγRIIIB) on phagocytes to inhibit Fc-mediated phagocytosis [299]. Mac-2 is a similar IgG-degrading enzyme, has weaker endopeptidase activity than IdeS but can competitively block FcγRII and FcγRIII to inhibit antibody-mediated phagocytosis [300]. In addition, the hyaluronic acid capsule of group A *Streptococcus* can act as a physical barrier to nonspecifically resist phagocytosis [301]. Group A *Streptococcus* also resists antibody-mediated phagocytosis by forming large bacterial aggregates via binding fibronectin and recruiting collagen fibers [302]. Taken together, group A *Streptococcus* produces several different factors that can inhibit both complement- and antibody-mediated phagocytosis.

There are several mechanisms that group A *Streptococcus* utilizes to inhibit neutrophil function. First, group A *Streptococcus* can directly induce neutrophil lysis or apoptosis, effectively eliminating their antimicrobial activity [303, 304]. Second, in addition to SIC, which inhibits antimicrobial peptides (see above), group A *Streptococcus* produces several enzymes that inhibit ROS-mediated microbicidal toxicity such as glutathione peroxidase, superoxide dismutase, alkylhydroperoxidase and alkylhydroperoxidase reductase [305–307]. Furthermore, the bacteriophage-encoded Sda1, which is produced by certain strains of Group A *Streptococcus*, (see above) [308, 309], as well as the nuclease SpnA [310], degrade DNA in neutrophil NETs, thus inhibiting the antimicrobial and killing mechanisms of NETs.

Adaptive Immune Responses Against Group A *Streptococcus*

Both B and T cells play a role in adaptive immune responses against group A *Streptococcus* infections. In particular, antibodies and T cells that recognize antigenic components of M protein have been shown to produce protective immune responses that prevent colonization and infection by group A *Streptococcus* [311–319]. Similar to *S. aureus*, group A *Streptococcus* also produces several superantigens, including streptococcal pyrogenic exotoxins (SPEs) (serotypes A, C and G to M) and the streptococcal mitogenic exotoxin $SMEZ_n$ [320]. These superantigens nonspecifically activate T cells and contribute to the pathogenesis of group A *Streptococcus* infections [320].

The important role of adaptive immunity in host defense against group A *Streptococcus* has led to several different vaccination strategies to produce protective antibody responses [231, 321]. A safe human vaccine against group A *Streptococcus* has been challenging given the genetic diversity among clinical isolates as well as producing a vaccine that does not increase the risk for development of autoimmune sequellae such as acute rheumatic fever and acute poststreptococcal glomerulonephritis [231, 321, 322]. Since antibodies against M protein of group A *Streptococcus* have been shown to offer protection against colonization and infection, several vaccines have targeted different antigenic epitopes of the M protein, including 26- and 30-valent N terminal domain vaccines [314, 315] as well as vaccines targeting more conserved epitopes [316–319]. In addition, other vaccine approaches have been attempted, including vaccines directed against other streptococcal antigens, including the group A carbohydrate, C5a peptidase, fibronectin-binding protein A (FbaA), fibronectin-binding protein 54 (Fbp54), streptococcal protective antigen (Spa), SpeB, SpeC, serine protease (SpyCEP), serine esterase (SSe) and several other antigens [231, 321, 322]. These strategies have had varying successes in animal studies; whether the efficacy of these vaccines will translate to humans is not yet known. As newer technologies are becoming more available, such as high-throughput proteomics approaches [323–326], defining candidate vaccine targets with enhanced efficacy and broad strain coverage will greatly help in the development of a successful human vaccine against group A *Streptococcus* infections in the future.

Conclusion

Recent discoveries involving innate and adaptive immune responses against *S. aureus* and group A *Streptococcus* have greatly improved our understanding of these common skin infections. As antimicrobial resistance is creating a serious threat to public health, novel strategies to enhance protective host immune mechanisms against bacterial skin infections represent an alternative approach to combat these infections while minimizing antibiotic resistance. The mechanisms of cutaneous host defense and bacterial pathogenesis will be important factors to consider for the development of future immunotherapies and vaccine strategies against these common bacterial skin pathogens.

Questions

1. *Staphylococcus aureus* is a common cause of all of the following skin infections, EXCEPT:
   A. Cellulitis
   B. Impetigo

C. Ecthyma gangrenosum
D. Subcutaneous abscesses
E. Folliculitis

2. Group A Streptococcus is a common cause of all of the following skin infections, EXCEPT:
   A. Gas Gangrene
   B. Erysipelas
   C. Cellulitis
   D. Impetigo
   E. Necrotizing Fasciitis

3. Which human antimicrobial peptides have bacteriostatic or bactericidal activity against *Staphylococcus aureus*?
   A. Human beta-defensin 2
   B. Human beta-defensin 3
   C. RNase7
   D. Cathelicidin
   E. All of the above

4. Which pattern recognition receptors are correctly paired with the pathogen associated molecular pattern?
   A. TLR2 – lipoteichoic acid
   B. NOD2 – muramyl dipeptide
   C. AIM2 – hypomethylated double-stranded RNA
   D. A and B
   E. A, B and C

5. Which of the following is NOT associated with inflammasome activation?
   A. Are activated by *Staphylococcus aureus* pore-forming toxins
   B. Proteolytic processing of pro-TNF-alpha to active TNF-alpha
   C. Proteolytic processing of pro-caspase-1 to caspase-1
   D. Proteolytic processing of pro-IL-1beta to active IL-1beta
   E. Proteolytic processing of pro-IL-18 to active IL-18

Answers

1. C
2. A
3. E
4. D
5. B

Immunodermatology and Viral Skin Infection

17

Ramya Kollipara, Christopher Downing, Jacqueline Guidry, Michael Lee, Natalia Mendoza, Cesar Arias, Andrew Peranteau, and Stephen K. Tyring

Abstract

The skin is the largest organ in the human body, acts as our fist line of defense, and has a sophisticated array of cells and signaling molecules to help protect the body from infection. Yet even with this sophisticated defense, viruses cause a range of cutaneous diseases in humans, many of which are widespread in the population and cause significant morbidity and mortality, along with psychological and financial repercussions. Each virus has unique mechanisms by which it evades the immune system, replicates, and spreads. Some viruses infect the skin directly while others gain access systemically first. Infections can be acute or subclinical and then resolve, while others are persistent or can remain latent for years. This spectrum of presentations is mirrored by an equally wide array of evasion tactics that the viruses use to manipulate and escape both the adaptive and innate immune responses. In addition to highlighting viral responses, particular attention is also paid to the local immune response generated in the skin. Five viruses will be discussed in detail: herpes simplex virus, varicella zoster virus, human immunodeficiency virus, molluscum contagiosum virus, and human papilloma virus; along with the latest information on the development and advancement of both therapeutic and prophylactic vaccines.

Key Points

- As a complex immune organ, the skin plays a major part in protecting the body against viruses.
- Innate immunity involves an early response to foreign antigens but is not pathogen specific, whereas an adaptive response is specific for antigen recognition and develops memory but takes longer to activate.
- Viruses have developed methods to evade the skin immune response in order to establish infection or release their progeny.
- Vaccines can protect against viruses by helping to produce a rapid immune response, with high levels of protective antibodies for their target viral antigens.

A.A. Gaspari et al. (eds.), *Clinical and Basic Immunodermatology*, DOI 10.1007/978-3-319-29785-9_17

The skin is the largest organ in the human body and constitutes its first line of defense. It is not only a great physical barrier, but also has an amazing cellular army ready to defend the body from microorganisms such as viruses. This immune capacity was recognized 30 years ago and has since become an important topic of research. There is a wide spectrum of immune responses in the skin, and the mechanisms by which they are triggered are not fully understood. Almost every single microorganism (including bacteria, viruses, fungi, and parasites) is capable of inducing a specific skin response that translates into a particular clinical lesion. This interplay of responses is seen even within organisms of the same family (e.g., human papillomavirus [HPV] type I produces different lesions compared with HPV type 3). Moreover, the viruses are particularly difficult to control due to their ability to change and adapt to the medium. They have developed the capacity to escape the immune system and in some cases can coexist with the host without being noticed.

Viruses such as the human immunodeficiency virus (HIV), the human herpes simplex virus (HSV), the varicella-zoster virus (VZV), and HPV have high rates of morbidity and mortality, and they have an impact not only on the physical condition of the patient but also generate an enormous psychological trauma. The majority of the populations infected with these viruses are young, sexually active people, and as a result, spread within the population is favored and the socio- economic impact within the society is significant. Therefore, the development of vaccines against these viruses is one of the priorities of any health care system. The goal of a vaccine is to decrease the rapid and progressive spread of these diseases by producing a rapid immune response with high levels of protective antibodies for the target viral antigen. To achieve this response, the virus's behavior and the immune response it elicits must be properly understood.

The Immune System and the Skin

The skin is a vast immune organ (also known as skin-associated lymphoid tissue [SALT]), and all of its cells are part of an immunologic team (key players include keratinocytes, Langerhans cells [LCs], and skin tropic T cells, among others) [1, 2]. These cells carry out specific functions and are activated upon infection with certain viruses, and the interplay between them dictates the final immunologic outcome for the infecting virus.

The immune system is divided into two components: innate and adaptive (Table 17.1). Innate immunity is characterized by an early response to foreign antigens and is dependent on the particular environment present during the initial phase of that response. It is the first line of defense against infection and has a broad spectrum of activity (not pathogen specific), including the expression of stimulatory molecules by antigen- presenting cells and the secretion of cytokines and other inflammatory cell products with a limited repertoire of antigen recognition. This initial response does not develop a memory or long-lasting protective immunity. Nonetheless, it is a rapid response and its effectiveness is crucial for the next step (which is more specific and involves antibodies and cytotoxic effector cells) [3, 4]. The innate immunity detects pathogens and clears the majority of microbial assaults. It is activated by cell injury or cell death, generating inflammation and local vascular responses. The key cellular players recruited in this response are the parenchymal cells and local phagocytic dendritic cells (DCs) [1, 3, 4]. Among the local phagocytes, macrophages are one of the most important cells in this first response. They possess special receptors capable of recognizing the pathogen- associated molecular patterns (PAMPs), known as Toll-like receptors (TLRs). The TLRs activate a variety of signaling pathways involved in antiviral, antibacterial, antitumor, and antiinflammatory activities [1, 5].

Table 17.1 Comparison of innate versus adaptive immunity

Innate	Adaptive
Early response to foreign antigens	Occurs within days of infection
Rapid response is the first line of defense	Antigen specific
Broad spectrum (not antigen specific)	Develops immune memory
No memory or long-lasting protective immunity	Aids recovery from viral infection as well as preventing re-infection
Key players include T and parenchymal cells and phagocytic dendritic cells	Key players include T and B lymphocytes

Some of these TLRs involved in the recognition of viruses have been identified. An example is TLR9, which recognizes HSV DNA on DCs and induces antiviral mechanisms that include the secretion of type I interferons (IFNs) [1, 6]. The interactions between the TLRs and the virus are necessary to guide, in this case, the anti-herpes immunity toward an adaptive (specific) cellular response (T-helper-1 [Th1] type, see below) [7]. Other examples of TLR interactions and viruses include the production of IFN-β and different chemokines activated by TLR3 and the induction of phagocytosis and inflammation by TLR4 mediated by the secretion of IFN-β [6].

The adaptive response is specific for antigen recognition, occurs within days of the infection, and is the result of the interaction of T and B lymphocytes. The immune players are multiple and capable of developing a lasting immune memory. This response not only aids recovery from the primary viral contact but also protects against re-infection. T lymphocytes recognize a processed antigen (short peptides) bound

to the major histocompatibility complex (MHC) of the antigen-presenting cells (APCs). There are two major subsets of T cells: CD4 and CD8. CD4 cells recognize antigens bound to MHC class II (exogenous antigens taken from the extra- cellular milieu and processed in the endosome of the APC), while CD8 cells recognize the antigens bound to MHC class I (usually endogenous antigens) [3]. The activation of the CD4 cell results in the secretion of a variety of cytokines. Depending on the pattern of cytokine expression, the immune response is characterized as either a Th1 or Th2 response. Th1 cells secrete IFN-γ, which activates macrophages, natural killer cells, and cytotoxic CD8+ T lymphocytes (cell-mediated immunity). On the other hand, Th2 cells secrete mainly interleukin-4 (IL-4) and IL-10, helping the primed B lymphocytes to differentiate into plasma cells and secrete antibodies (humoral response) [3]. Also, an additional type of T cell has been shown to play an important role in the immune response against viruses. These cells, designated the regulatory T (T_{reg}) cells, carry the CD4+ and CD25+ antigens. T_{reg} cells recognize self antigens and prevent autoimmunity responses, regulate the responses to exogenous antigens, and are involved in the chronic and latent phases of viral infections [8, 9].

Viruses have developed a diversity of mechanisms to evade both the innate and adaptive immune response and thus establish an infection (or persist at least until a new progeny of viruses is released). Some of the cutaneous viruses share common evasion mechanisms and others have specialized systems to survive and become latent until they have a new opportunity to flare. Several of these mechanisms are discussed in detail in the sections that follow.

Human Herpes Virus

The human herpes simplex virus (HSV) types 1 and 2 are neurotropic viruses from the α-herpesvirus family. These viruses have a large molecular weight and harbor double-stranded DNA. The genome is in an icosahedral capsid, which is protected by a proteinaceous layer (tegument). The capsid is surrounded by a lipid bilayer with glycoproteins (envelope) [10]. Herpes simplex virus is distributed worldwide, affecting developed and developing societies. Animal vectors for human HSV have not been described, and humans appear to be the only reservoir [11]. Usually the first infection is asymptomatic, but this depends on the age and immune status of the host, the amount of the infective dose, and the presence of innate defenses that may abort the infection [12, 13]. About 80 % of the adult population in the developed world becomes seropositive to HSV-1 and more than 20 % are seropositive to HSV-2. People who experience a primary infection with one or more herpes viruses carry these viruses for the rest of their lives (usually in a latent state). The virus is retained in specific neural reservoirs and may become active with periodic episodes of viral replication and shedding [7].

Herpes simplex virus infection usually initiates in the mucosa. The virus replicates in epithelial cells and then enters the nervous system through the nerve termini. Control of the acute (and persistent) HSV infection involves the activity of natural killer (NK) cells, virus-specific CD4+ and CD8+ cells, IFNs, and virus-specific antibodies [14]. After entry into the mucosa and skin, HSV establishes a lifelong persistence in the neurons of the sensory ganglia. Herpes simplex virus persistence and latency have been demonstrated in human trigeminal, facial, and vestibular ganglia, and reactivations from these locations can cause herpes labialis, vestibular neuritis, and cranial nerve disorders among others [15]. The mechanisms of viral reactivation are not fully understood but are associated with different events such as ultraviolet (UV) light, stress, fever, infections, and immunosuppression [16]. Recent studies have demonstrated that certain neurons are more prone to productive infections versus other neurons that are more likely to exhibit viral latency indefinitely. This susceptibility appears to be governed by regulatory RNAs and other regulatory proteins yet to be identified [17]. Furthermore, it has been postulated that UV light triggers reactivation by inducing apoptotic signals and uncoordinated lytic gene expression [18]. The role of the immune system during the latent phase is crucial to maintain the virus under control [19].

Immune Response

Once the virus is in contact with host cellular receptors, the processes leading to viral infection are triggered. Glycoproteins in the lipid bilayer allow the viral envelope to fuse with the epithelial plasma membrane. Viral proteins are released into the cytoplasm and viral DNA enters the nucleus. This process triggers three phases of the innate response: (1) secretion of immune proteins, such as complement and natural antibodies; (2) an early-induced response, in which the main mediators are IFNs produced by the infected epithelial cells and resident DCs; and (3) the activation of inflammatory cells, such as neutrophils, macrophages, and NK cells [20]

At the site of mucosal contact the virus usually encounters several barriers, including mucus, normal bacterial flora, the glycocalyx, complement proteins, and natural immunoglobulin (IgM) antibodies [1, 20]. Although these substances act in concert to decrease the number of infected cells, HSV usually replicates successfully and triggers the early innate immune response. Humans may express different levels of natural antibodies to HSV, which is a reflection of their own past exposure experience [7, 20]

The early innate immune response has two goals: (1) limit viral replication and spread of the virus in uninfected cells, and (2) recruit other inflammatory cells [20]. The viral interaction with the epithelial cells may stimulate cell-surface TLR2 (e.g., in the genital mucosa) [1, 20]. With the activation of this receptor, the epithelial cells activate complement, chemokines, and IFN-α and -β soon (between 8 and 12 h) after the infection. Interferon-α and -β are produced by most cells types, but the DCs are responsible for the majority of their production. Interferon-α and -β are known to be two of the most important molecules to control HSV infection at this stage. Some studies suggest that resistance or susceptibility to HSV infection is directly correlated with the amount of IFN-α and -β produced [12].

Complement, chemokines, and IFN-α and -β activate the endothelial cells that express IL-8, tumor necrosis factor-α (TNF–α), IFN-γ, and granulocyte-macrophage colony-stimulating factor (GM-CSF), leading to neutrophil chemotaxis. Figure 17.1 illustrates the chemokine regulation of leukocyte movement [21]. The inflammatory reaction alerts the DCs and resident macrophages to the presence of the virus and induces a "state of awareness" or "antiviral status" in the uninfected cells [7]. Infected macrophages that are able to survive acute HSV infection become a significant source of inflammatory chemokines and cytokines including TNF-α, IL-1, IL-6, IL-8, IL-12, IL-18, RANTES (regulated on activation, normal T-cell expressed and secreted; a chemokine that is a chemoattractant for eosinophils, monocytes, and lymphocytes), as well

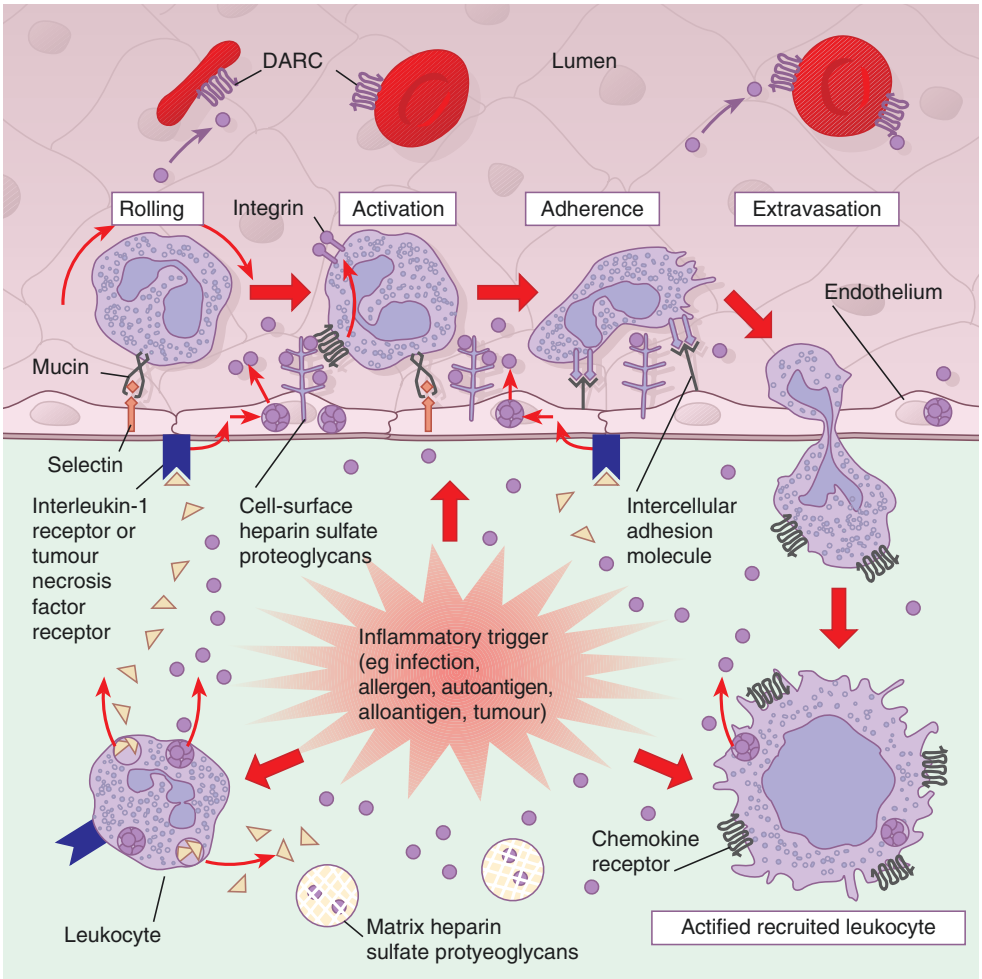

Fig. 17.1 Chemokine regulation of leukocyte movement. Chemokines are secreted at sites of inflammation and infection by resident tissue cells, resident and recruited leukocytes, and cytokine-activated endothelial cells. Chemokines are locally retained on matrix and cell-surface heparin sulfate proteoglycans, establishing a chemokine concentration gradient surrounding the inflammatory stimulus, as well as on the surface of the overlying endothelium. Leukocytes rolling on the endothelium in a selectin-mediated process are brought into contact with chemokines retained on cell-surface heparin sulfate proteoglycans. Chemokine signaling activates leukocyte integrins, leading to firm adherence and extravasation. The recruited leukocytes are activated by local proinflammatory cytokines and may become desensitized to further chemokine signaling because of high local concentrations of chemokines. The Duffy antigen receptor for chemokines (DARC), a nonsignaling erythrocyte chemokine receptor, functions as a sink, removing chemokines from the circulation and thus helping to maintain a tissue–bloodstream chemokine gradient. (From Luster [21]. Copyright © 1998 Massachusetts Medical Society. All rights reserved.)

as IFN-α and -β. Subsequently, the immature DCs capture viral antigens and transport them to the regional lymph node to alert and stimulate the adaptive immune response [7].

Once the DC exits the mucosa, the late-induced innate response begins at the infection site. Initially, an influx of neutrophils, monocytes, and NK cells is established. These cells traverse the activated capillary endothelial cells guided by the chemokines present at the infection site. The neutrophils secrete α-defensins that insert into the virion lipid envelope and trigger the degradation of phagocytosed virions [22]. They also secrete TNF-α, which acts synergistically with IFN-α and -β, as well as IFN-γ to produce lysis of the infected cells inhibiting viral replication [22]. Simultaneously, NK cells are activated by the binding of immunoglobulins to the viral antigen (through their Fc receptor [CD16] located on the cell surface) and are recruited by chemokines and cytokines (IFN-α and -β, IL-12, IL-15, IL-18) produced by the activated infected cells within 2–3 days after infection. The NKs participate in cytolysis of virus-infected cells by perforin/granzyme-mediated processes that result in phagocytosis and destruction of infected cells and viral particles [20]. The accumulation of viral antigens is followed by complement activation, facilitating the uptake of viral peptides by phagocytes [23]. These phagocytic cells produce antiviral cytokines and defensins such as nitric oxide (NO), which enhance the immune response and promote phagocytosis and destruction of virus particles and infected cells [20].

One of the key cells for the innate response against HSV is the macrophage. The molecular mechanisms of the immune response within macrophages have been extensively studied. Once HSV infects macrophages, these cells release a series of cell mediators such as TNF-α and IL-12 (which subsequently stimulates the production of IFN-α and -β). Interferon-α and -β induce the NK and T cells to secrete IFN-γ, which eventually controls the HSV replication and initiates the adaptive response [24, 25]. At this stage, the site of origin of IL-12 production is controversial. The majority of investigators suggest that DCs are the main producers of IL-12 [7, 26]. However, other authors indicate that the main source of this molecule is the recruited inflammatory cells [27].

The adaptive immune response begins when the DCs migrate to the regional lymph nodes. These cells mature and display viral peptides coupled with MHC molecules, secrete cytokines, and regulate the expression of other inflammatory molecules. The cytokines produce differentiation of the Th0 cells to either Th1 or Th2. For HSV, the Th1 response is indispensable for clearance of the infection (particularly for HSV-2) [28]. Other cells such as NK cells and macrophages also stimulate the switch from a Th0 to a Th1 response [28] (Table 17.2).

One of the most studied T cells during HSV infection is the CD8+ T cell. These cells are capable of expressing the lymphocyte-associated antigen (cutaneous leukocyte antigen [CLA]) [29, 30]. During recurrent and symptomatic infection, antigen-specific CD4+ T cells and NK cells infiltrate the dermis by day 2 of the lesion formation, whereas CD8+ dermal infiltration (which implies cytotoxic activity resulting in viral clearance) occurs a few days later [29, 30]. Therefore, CD8 cells appear to play an important role in containing HSV infection. Posaved et al. showed that the levels of CD8+ cytotoxic T lymphocytes (CTLs) correlate inversely with the severity of HSV-2 infection and temporally with the local clearance of the virus in lesions [31]. The data from the study of Koelle et al. suggest that the expression of the homing receptor (CLA) by the CD8+ T cells is programmed at the site of the original antigen encounter and promotes migration and immune responses in reactivation [29]. Additional studies indicate that this specific cell has the capacity of T-cell memory and self-renewal that is crucial to control the infection and symptomatic recurrences [31].

Table 17.2 Immune responses to herpes viruses

Complement-mediated activation of immune cells
Antibody mediated activation of immune cells
Secretion of interferons (IFNs) by the infected epithelial cells
Activation of neutrophils, macrophages, and natural killer (NK) cells
Activation of endothelial cells with secretion of tumor necrosis factor-α (TNF-α), interleukin-8 (IL-8), IFN, and granulocyte-macrophage colony-stimulating factor (GM-CSF)
Secretion of α-defensins by neutrophils
Activation of NK cells for cytolysis of virus-infected cells
Secretion of IL-12 and TNF-α by monocytes
Differentiation into Th1 and Th2 responses

Studies in vivo (mouse model) have demonstrated that CD8+ cells also play a crucial role in controlling the virus during the latent state [19, 32]. Latent herpes viral infection in humans in the trigeminal ganglia is accompanied by a chronic inflammatory process that involves elevated levels of cytokine transcripts such as IFN-γ, TNF-α (which affects viral replication), and chemokines, accompanied by persistent lymphocytic cell infiltration (CD8+ T cells, CD68+, and macrophages). It has been suggested that this phenomenon could be due to a low level of expression of viral genes during latency. The CD8+ T cells are capable of controlling the virus through cytokines, and this mechanism is likely to occur in response to the persistence of viruses that are prone to reactivate frequently, providing a survival advantage for both the host and the virus [19]. It is proposed that factors compromising CD8+ T cell function lead to virus escape from immune regulation and reactivation [33].

Immune Evasion Mechanisms

There appears to be a complex and well-balanced interaction between host cells and HSV. Success for the virus means a delicate balance between infection and latency. Therefore,

Table 17.3 Mechanisms of immune evasion in herpes viruses infection

Modulation of the activity of neutrophils, macrophages, or natural killer (NK) cells
Interference with monocyte function
Suppression of chemotaxis and phagocytosis
Modulation of the production of IL-1, TNF-α, IFN-α and -β
Reduced activity of NK cells
Inhibition of apoptosis

evasive strategies must be carefully designed to permit viral replication at certain stages that could potentially lead to transmission to other susceptible hosts in order to maintain the viral progeny. Humans and the herpes viruses have evolved together in a symbiotic relationship that has allowed the adaption of the virus to the host and the environment, maintaining a "truce" with the immune system without any serious threats to human life. Some of the identified mechanisms to evade the immune system include the ability of HSV to alter the activity of neutrophils, macrophages, or NK cells [31]. It is known that HSV interferes with monocyte function, suppresses chemotaxis and phagocytosis, and reduces the secretion of IL-1 and TNF-α [7, 20, 34]. It has also been reported that HSV reduced the activity of NK cells upon contact with infected cells, due in part to the interference with IFN-α and -β production [20, 34]. Furthermore, HSV produces many antiapoptotic factors, such as cathepsins and latency-associated transcripts (LATs), which allow for maximal viral replications. LATs have been recovered from latently infected neurons and have been shown to inhibit granzyme-B mediated apoptosis and capsase-8-dependent apoptosis [17]. It has been proposed that LATs increase the efficiency of latency and subsequent reactivation [33] (Table 17.3).

Vaccines

There are currently two different groups of vaccines targeting HSV: prophylactic and therapeutic. Prophylactic vaccines aim to protect seronegative patients against HSV infection. The goal of therapeutic vaccines is to reduce symptoms and infectivity (outbreaks and shedding) in patients who are already seropositive for HSV [35]. In the recent decades, the focus has been primarily on developing a prophylactic vaccine with varying results in trials. Two studies were carried out by GlaxoSmithKline, using a recombinant vaccine preparation containing HSV glycoproteins. The first enrolled patients who were seronegative for both HSV-1 and HSV-2. The second study allowed inclusion of HSV-1–seropositive patients [36]. The studies' primary end point was protection against genital HSV-2 clinical disease and the secondary end point was HSV-2 seroconversion. The first study did not show any difference in the primary end point between the group that received vaccine and the group that received a placebo. However, when a gender-stratified analysis was performed, the vaccine proved protective in females only (73%; 95% confidence interval [CI], 19–91%). The sex differences found in these studies might be explained by innate anatomic differences of the genital epithelial layers between men and women. The epithelial layer of male genitals consists mostly of stratum corneum, which is lacking in the genitals of women at the vaginal-cervical mucous membrane. Additionally, the secretions produced by the vagina and the genital mucous membranes contain antibodies and migratory leukocytes. Therefore, women appear to have enhanced immune responses mediated by helper T cells exhibiting a Th1 response, compared to men [37]. The Herpevac Trial for Woman was conducted to evaluate this sex difference in vaccine protection. Although the primary endpoint of HSV-1 and HSV-2 genital disease prevention was not achieved, the vaccine was found to be effective in decreasing infection caused by HSV-1 but not HSV-2 [38]. Further studies are needed to evaluate this unexpected outcome.

Recent HSV vaccine research has transitioned away from prophylactic vaccines to therapeutic vaccine candidates. There are currently three novel HSV vaccine candidates in phase I or II trials. The HerpV vaccine is composed of recombinant human heat shock protein-70, 32 different HSV-2 antigens and an adjuvant. This vaccine increased HSV-2 CD4+ and CD8+ T cell activity in HSV-2 seropositive patients in a phase I trial [39]. It is currently being evaluated for efficacy in prevention of shedding and lesions in a phase II trial [40]. The GEN-003 vaccine consists of the gD2 glycoprotein, ICP4 (a potent CD8+ T-cell immunogen) and Matrix M adjuvant. In animal models, this vaccine candidate decreased recurrence of lesions and viral shedding [41]. The GEN-003 vaccine has completed a phase I/II trial evaluating its efficacy as a therapeutic vaccine but the results of this trial have not been published [42]. Finally, the HSV529 vaccine is composed of a DNA replication defective HSV virus. This candidate vaccine has demonstrated efficacy in animal models and is in a phase I/II trial as a therapeutic and prophylactic vaccine [43]. Research on a prophylactic HSV vaccine needs to focus on inducing a stronger antibody response. In contrast, research on a therapeutic HSV vaccine needs to focus on prompting a more potent T-cell response [43].

Varicella-Zoster Virus

Varicella-zoster virus (VZV) is also an α-herpesvirus with a genome of ~125,000 base pairs (bp) with at least 70 unique open reading frames (ORFs) [44, 45]. It is characterized by a relatively short reproductive cycle, rapid cell-to-cell spread, and significant ability to establish latent infections (primarily in sensory ganglia) [45]. Humans are the only known natural

reservoir for VZV. This virus causes two different clinical syndromes: varicella (chickenpox) and herpes zoster (shingles). Varicella is usually a self-limited disease of childhood characterized by a very pruritic rash. The disease has a worldwide distribution, and transmission is more pronounced in temperate climates (where it is seen more frequently in children) than in tropical environments [11]. Approximately 20 % of those who had varicella later develop herpes zoster, which usually affects adults older than 50 years of age, although it can occur at any age [11, 46].

Immune Response

Initial clinical observations indicate that the primary site of inoculation is the respiratory tract. A rash usually develops after an incubation period of 10–12 days [11, 45, 46]. The entry of the VZV into a host cell requires fusion of the viral envelope with the host cell plasma membrane. This phenomenon is mediated by interactions of viral oligosaccharides with the heparan sulfate proteoglycans (via N-linkage) on the host cell surface. The fusion permits the entry of the viral proteins into the host cell cytosol and then to the nucleus where the nucleocapsid fuses with the outer nuclear membrane, releasing the viral DNA genome into the nucleus [47]. The spread of the virus is controlled by the innate and adaptive responses. The host cell membrane has specific glycoproteins such as gH, gL, gB, and gE that permit the fusion process between cells. These proteins are used by VZV to quickly spread to adjacent epidermal cells by inducing the fusion of the infected cells with noninfected ones [32]. Varicella-zoster virus has a special tropism for three major cell types: the peripheral blood mononuclear cells (PBMCs), skin cells, and sensory neurons [32]. This virus not only infects these cells, but also is capable of replicating inside them. This phenomenon of viral replication can be observed in intraepidermal vesicular lesions of the skin, which are loaded with free virus [11, 45, 47].

The virus infects the immature DCs of the respiratory mucosa, and these cells transport the virus to the T-cell–draining lymph nodes. From these nodes VZV is subsequently transported to the reticuloendothelial system and then is capable of gaining access to the bloodstream, causing a primary viremia. During this first viremic phase, VZV is able to reach the reticuloendothelial organs where it undergoes a phase of viral amplification. It was previously thought that VZV reached the skin during a second viremic episode that occurred in the late incubation period [47]. However, studies of viral infection in mouse models now suggest that infected T cells from the tonsil area are capable of transferring VZV to the skin immediately after entering the circulation during the primary viremia and that the prolonged interval between exposure and the skin rash reflects the time required for the virus to become recognized by potent innate immune barriers such as IFN-α [44, 47].

Varicella-zoster virus preferentially infects the active memory CD4 T cells that express skin homing markers such as CLA and the chemokine (C-C motif) receptor 4 (CCR4). These T cells are usually programmed for immune surveillance and then may facilitate the transfer of VZV into the skin [44]. It appears that VZV does not trigger any early inflammatory response that might block the appearance of virus-filled vesicles at the skin surface [44, 47]. The initial viremia is necessary to ensure that enough cutaneous lesions are formed to transmit the virus efficiently to other individuals as a viral survival mechanism. The T cells trafficking through the skin activate VZV replication at this site, and this process permits infection of more T cells that will return to the circulation [44].

The innate immune response is induced during the acute VZV infection. This response involves the release of IFN-α and IFN-γ and the secretion of cytokines such as IL-6 (by monocytes) via TLR2 [48]. This cell-mediated immune response contains VZV replication and prevents the host from a systemic disease (including severe compromise of organs such as lungs, kidneys, and spleen). The adaptive immune response begins with the presence of CD4+ T cells and the release of IL-2, IL-10, IL-12, and IFN-γ by Th1 and Th2 cells [49]. These cytokines cause the proliferation of VZV specific CD4+ and CD8+ T cells, which express MHC class I and II molecules and recognize the viral glycoproteins gE, gH, and gI, with the subsequent killing of the VZV-infected cells [50]. During the presence of rash, many mononuclear infiltrating cells are present. Most of these cells express CD4 and CD8, including CD45RO+ memory cells, skin homing CLA, and CCR4+ T cells. During this period, the skin shows expression of E-selectin (a cell adhesion molecule and CD antigen that mediates neutrophil, monocyte, and memory T-cell adhesion to cytokine-activated endothelial cells), intercellular adhesion molecule 1 (ICAM-1, a cell-surface ligand involved in leukocyte adhesion and inflammation), and vascular cell adhesion molecule-1 (VCAM-1, a cytokine- induced cell adhesion molecule present on activated endothelial cells, tissue macrophages, and DCs), allowing the migration of the inflammatory cells. The humoral immune response has a reduced role in controlling the virus. Immunoglobulin G (IgG), IgM and IgA appear to respond to some viral proteins. It seems that these antibodies neutralize cell-free virions and contribute in the lysis of infected cells [44] (Table 17.4).

During the resolution of varicella, VZV establishes latency in the trigeminal and dorsal root ganglia where it remains latent through the lifetime of its host. Approximately 20 % of infected people develop herpes zoster. Figure 17.2 illustrates the latent virus in a dorsal root ganglion and reactivated virus causing acute vesicular zoster rash [51]. In this period, the VZV multiplies and spreads centrifugally down the sensory

nerve, causing neuronal necrosis and intense neuritis. Recent studies have shown that VZV possesses multiple open reading frames (ORFs) that encode proteins present in the cytoplasm of neurons during latency and are localized in the cell nucleus during reactivation [52]. Some of these genes are involved in VZV assembly, replication (such as ORF2) and latency. ORF47 encodes a protein that is part of the VZV virion tegument and is essential for VZV growth in differentiated skin and T cells [53]. Studies of this peptide indicate that the blockage of the kinase function of this protein decreases the VZV virulence in the skin, suggesting interference with the production of complete VZV virions. This peptide has also been implicated as a latency- associated protein along with the products of the ORF4 and ORF63 [54–57]. Additionally, the mechanisms of latency appear to be controlled LATs. However, the exact mechanisms are not well understood [58].

Table 17.4 Immune responses to varicella-zoster virus (VZV)

Acute VZV infection
Release of IFN-α and IFN-γ
Secretion of cytokines such as IL-6 (by monocytes) via Toll-like receptor 2 (TLR2)
Release of IL-2, IL-10, IL-12, and IFN-γ by T-helper-1 (Th1) and Th2 cells
Proliferation of VZV specific $CD4^+$ and $CD8^+$ T cells
During skin rash
Expression of E-selectin, intercellular adhesion molecule 1(ICAM-1) and vascular cell adhesion molecule (VCAM-1)
Migration of inflammatory cells
Reduced role of humoral response in controlling the virus

Immune Evasion Mechanisms

Varicella-zoster virus utilizes several mechanisms to overcome the immune response. Major histocompatibility complex class II expression is restricted to APCs and is required to present the viral peptides to CD4 T cells. Usually, the host immune response to the virus produces the release of IFN-γ, which stimulates the expression of MHC II molecules. To evade the immune response and ensure replication, VZV produces a protein that interferes with Stat1 (a signal transducer and activator of transcription that mediates cellular responses to interferons). Stat1 interacts with P53 tumor

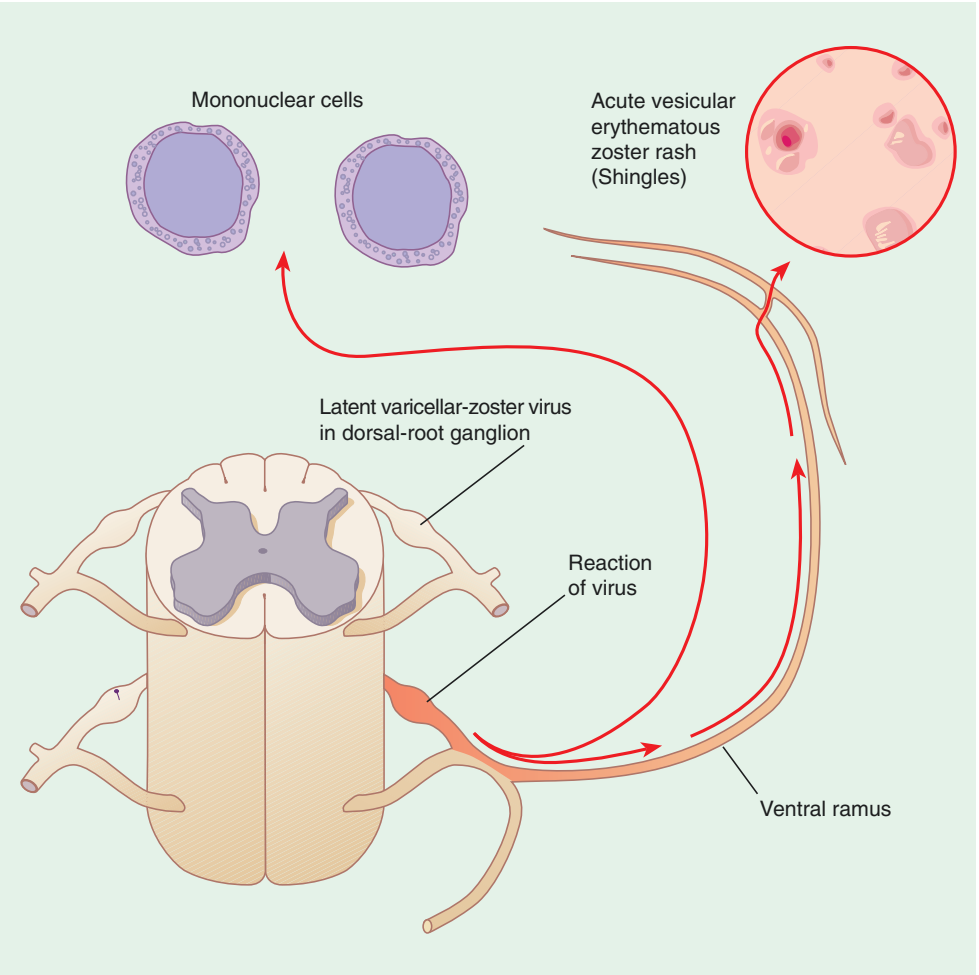

Fig. 17.2 Latent and reactivated varicella–zoster virus. Shown is a latent virus in a dorsal-root ganglion (white fusiform swelling) adjacent to the spinal cord and reactivated virus in a nearby dorsal-root ganglion (orange fusiform swelling) with transaxonal spread to the skin. The reactivated virus causes an acute, vesicular, erythematous zoster rash. (From Gilden et al [51]. Copyright © 2000 Massachusetts Medical Society. All rights reserved.)

suppressor protein and regulates expression of genes involved in growth control and apoptosis activation and thereby inhibits antiviral IFN-γ production in foci of infected skin cells [44]. Inhibition of IFN-γ results in decreased MHC II expression, which subsequently affects the efficiency of VZV specific immune responses. Varicella-zoster virus takes advantage of these circumstances, and as a consequence, the initial formation of VZV lesions in skin (varicella or during the VZV reactivation as zoster) is facilitated [44, 58, 59]. Additionally, VZV has mechanisms to delay clearance of virus-infected cells by interfering with the expression of MHC class I proteins that are necessary for CD4 and CD8 T-cell recognition [58]. This mechanism allows VZV to evade CD8 T-cell lysis during the viremic phase. The precise molecular event is related to the downregulation of MHC I by VZV via interference of its transport from the Golgi compartment to the plasma membrane [44] (Table 17.5)

Vaccines

Before the introduction in 1995 of Varivax, a live attenuated Oka strain of VZV, millions of children developed primary varicella (chickenpox). Varivax is indicated for vaccination against varicella in individuals 12 months of age and older and it is recommended as part of the childhood immunization schedule. Its effectiveness is greater than 95 % for varicella prevention. Herpes zoster is the result of the reactivation of latent VZV infection residing in sensory ganglia. In the United States, herpes zoster affects approximately 1,000,000 persons annually, with an incidence of 2.2 cases per 1000 persons of age or older [60, 61]. Results from several clinical trials have determined that a live, attenuated VZV vaccine using the Oka strain (Zostavax) is safe, elevates VZV- specific cell-mediated immunity, and significantly reduces the incidence of herpes zoster and postherpetic neuralgia in immunocompetent people over the age of 50. This vaccine is 14-fold more concentrated than VARIVAX and has been approved for use in the United States. It is expected to reduce the risk for herpes zoster by >50 % [61]. There have been concerns about the decline in Zostavax efficacy however. Although vaccine efficacy was maintained through year 5 after vaccination in the Short-Term Persistence Substudy, it steadily declined during that time period [62]. Figure 17.3 illustrates how the administration of zoster vaccine to older persons may prevent VZV-specific T cells from dropping below the threshold for zoster occurrence [63].

Human Papillomavirus

Human papillomaviruses (HPVs) are small DNA tumor viruses that have a circular double- stranded DNA genome of ~8 kb in length. They belong to a large group of recognized oncogenic viruses [64]. Human papillomavirus is a member of the Papillomaviridae family that includes over 120 different genotypes (defined by differences in their nucleotide sequence) [11, 65]. The HPV genome is composed of three regions: the long control region (LCR), the early region (E), and the late region (L). The early region consists of genes E1 to E8 (which encode nonstructural proteins for transcription,

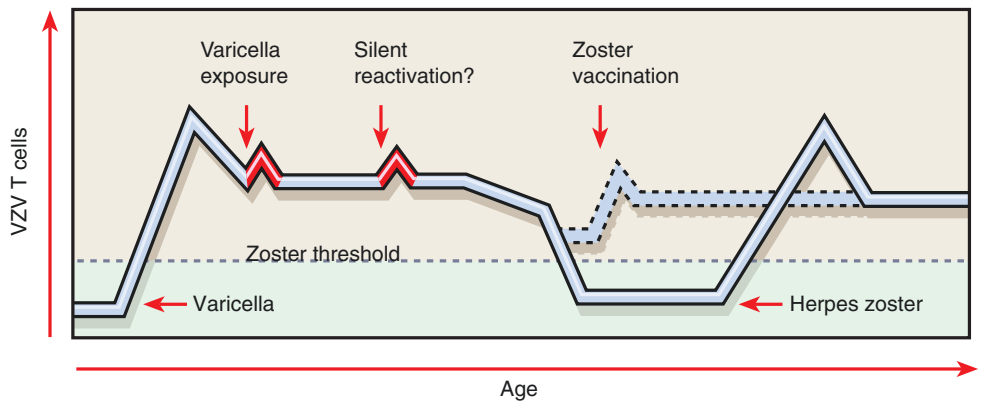

Fig. 17.3 Host factors in varicella-zoster virus (VZV) latency and reactivation. Varicella is the primary infection caused by VZV, and its resolution is associated with the induction of VZV-specific memory T cells (blue line). Memory immunity to VZV may be boosted periodically by exposure to varicella or silent reactivation from latency (red peaks). VZV-specific memory T cells decline with age. The decline below a threshold (dashed green line) correlates with an increased risk of zoster. The occurrence of zoster, in turn, is associated with an increase in VZV-specific T cells. The administration of zoster vaccine to older persons may prevent VZV-specific T cells from dropping below the threshold for zoster occurrence (dashed blue line). (From Arvin [63]. plasmid replication, and transformation), while the late region codes for the major (L1) and minor (L2) proteins that form the viral capsid. The current vaccines include the protein L1 as the major immunogenic antigen [66].

The HPVs are commonly categorized as having low or high oncogenic potential. Infections with the high-risk types such as HPV-16 and HPV-18 have been implicated in cervical-anogenital cancer and oral squamous cell carcinomas [11, 67, 68]. The infection of the genital tract by HPV is one of the most frequent sexually transmitted diseases [68, 69]. Approximately 75 % of sexually active individuals are infected by HPV during their lifetime. In the United States, it has been calculated that 6.2 million new cases of high-risk HPV infections occur each year, close to 20 million Americans are infected, and 1 % of sexually active adults have genital warts [65, 69]. It is estimated that >99 % of cervical, as well as >70 % of anal and vaginal cancers are related to HPV infection (cervical cancer is the second most frequent cause of death due to neoplasia among women worldwide). More specifically, about 30–40 % of penile, vulvar, and oropharynx cancers are related to the HPV-16 and HPV-18 [68, 70–72].

The majority of HPV clinical lesions are located in the genital area (70–90 %) in sexually active adolescents and young women. These lesions usually show clearance of the infection within 12–30 months [68]. Longer duration of infection is frequently related to the presence of cervical intraepithelial neoplasia (CIN) [73]. The prevalence and incidence of the HPV infection varies with age. The cause for this apparent variation is not clear. Many authors postulate that some (but not all) infected individuals develop an adaptive immune response against HPV that prevents future infections [74].

Immune Response

Human papillomavirus has a special tropism for the epithelial cells (they are epitheliotropic), infecting keratinocytes at a wide range of body sites where they cause aberrant cellular proliferation leading to benign warts or cervical cancer [3, 64, 75]. Initially, the virus infects primitive basal keratinocytes and starts DNA replication and transcription of the early genes at very low levels [76]. The peak of productive synthesis of virions is reached once the keratinocyte reaches higher strata of the epithelium. Thus, high levels of viral proteins and viral assembly occur only at the upper layers of the squamous epithelia (stratum spinosum and granulosum) [11]. At this point the cycle of replication and patterns of gene transcription are dependent on the stage of differentiation of the keratinocyte [76].

A significant amount of information regarding the immune response has been gathered from observations in animal models. Once the virus has reached the skin, it establishes itself at the basal cells of the epithelia where it starts replication. At this point the replication is minimal but becomes greater once the keratinocyte matures toward desquamation [77]. At the basal layer, there is practically no immune response against the virus (two to several months), but once it is detected by the immune system, replication increases and results in clinically detectable lesions [78, 79]. After a few months (which varies depending on the host), the infected keratinocytes express the late viral genes (encoding proteins L1 and L2) that trigger a full immune response [77–79].

The keratinocytes are able to secrete cytokines, growth factors, and chemokines upon viral stimuli. The host immune response dictates the emergence and characteristics of clinical lesions [76]. Some of the cytokines involved are transforming growth factor-β (TGF-β), TNF-α, and IFNs. TGF-β has been shown to inhibit the growth of nontumorigenic HPV-16 and HPV-18 immortalized cells, and it seems to control the expression of E6 and E7 (although some controversy exists on these facts) [76]. In normal cervical cells, TGF-β inhibits viral growth, but HPV can evade this control mechanism [76]. TNF-α, which is another product of the keratinocyte, may have an antiproliferative effect on the HPV-16–infected cells through cell cycle arrest (between the G0 and G1 phases of the cell cycle) [76, 80]. It has also been suggested that TNF-α acts as a repressor on the expression of E6 and E7 in the immortalized human keratinocytes [81]. The effects attributed to IFNs may be virus-type specific. These molecules also appear to inhibit the production of viral proteins [76].

The time between HPV infection and the development of a clinical lesion could vary from weeks to more than 9 months. This is an indication that HPV could modulate the immune system as evidenced by the following: (1) HPV infects mainly keratinocytes, which are cells programmed to die and desquamate in a specific and timely manner (apoptosis); and (2) the intracellular location of HPV in these cells allows the virus to hide and avoid immune surveillance. As a consequence, the apoptotic keratinocyte infected with HPV does not trigger a significant inflammatory reaction, eventually resulting in a persistent chronic infection [78, 82].

The adaptive immune response involves two phases: the recognition of antigen and the response to it. This adaptive immune response involves the LCs that capture the virus and its antigen for transport to local lymph nodes and presentation to naive T cells. The T cells return to the infected epithelial tissues via mechanisms that include secretion of chemokines and expression of adhesion molecules to clear the infection. In the recognition phase, the LCs are the major APCs. However, in some HPV infections, a depletion of these cells has been documented, which is associated with enhanced survival of HPV, prolonged courses of infection,

Table 17.6 Immune responses to human papilloma virus

Secretion by keratinocytes of cytokines, growth factors, and chemokines (TNF-α, transforming growth factor-β [TGF-β], and IFNs) upon viral stimuli
Langerhans cells capture of virus and its antigen
Transport to local lymph nodes and presentation to naive T cells

Th1 pattern of cytokines (IL-12, TNF-α, and IFN-γ)
Expression of the adhesion molecules for lymphocyte trafficking

and possibly malignancy [83–85]. At this stage, the infected keratinocytes produce IL-1α and TNF, which promote LC migration.

If the immune response is appropriate, the regression of warts usually follows. At this stage, a large infiltrate of T cells (CD4+ and CD8+) and macrophages is present, and the cytokines involved exhibit the Th1 pattern (IL-12, TNF-α, and IFN-γ plus the expression of the adhesion molecules for lymphocyte trafficking) (Table 17.6). A systemic T-cell response to E1 and E6 viral proteins is effective only at the peak of wart regression (although activity is present during the whole infective cycle) [78, 79].

In summary, HPV is capable of escaping the immune response for several months by modulating the inflammatory reaction from the keratinocytes after invasion. Nonetheless, in the majority of cases, the immune system finally catches up and is capable of detecting the virus, (probably when the replication turnover is highest) and thus is able to resolve the infection.

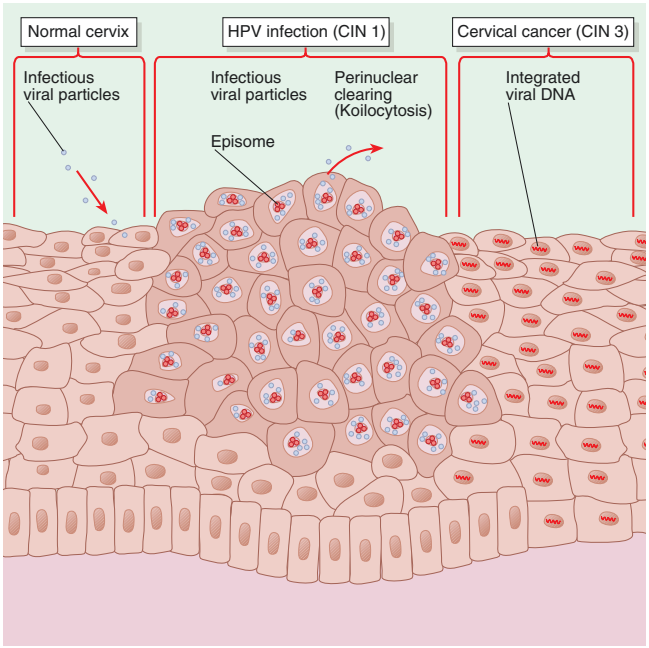

Fig. 17.4 Spectrum of changes in cervical squamous epithelium caused by human papillomavirus (HPV) infection. The left side of the figure shows normal cervical squamous epithelium. When HPV infection occurs (center), the virus exists in the cell nucleus as a circular episome. If the viral genome is intact, new infectious viral particles can be produced; their presence in the cell is indicated by perinuclear clearing, or koilocytosis. In cervical cancer (right), oncogenic portions of HPV DNA become integrated into the host's DNA, with disruption of the *E2* regulatory region and loss of other genes needed to form a complete virus. The cells are undifferentiated and do not show koilocytosis. CIN 1, cervical intraepithelial neoplasia grade 1. (From Goodman and Wilbur [93]. Copyright © 2003 Massachusetts Medical Society. Viral Oncogenesis

It is now accepted that HPV infection is necessary (but not sufficient) to cause cervical cancer, other anogenital neoplasms, and oral squamous cell carcinomas. Several viral types (such as 16 and 18) have been clearly identified as having high oncogenic potential. Low risk types include 6 and 11 [86]. Recently, significant evidence is emerging supporting the transition zone of the cervix as the location of persistent HPV infection. Specifically, it has been demonstrated that HPV exists in the latent state in the basal epithelial stem cells even after immune clearance of papillomas [87]. A recent animal model has shown that basal epithelial cells expressing the HPV 16 genes can undergo malignant transformation [88]. For high-risk HPV types, the proteins E6 and E7 appear to play a very important role in oncogenesis since they are able to inhibit two well-known oncogenic suppressor genes encoding the pRb (product of retinoblastoma tumor suppressor gene) and p53 proteins. E6 enhances the degradation of p53 via the ubiquitin-mediated proteolysis machinery (E3 ubiquitin ligase, UBE3A) and E7 interacts with the pRb [89]. Of note, Hyland et al. and McLaughlin-Drubin et al. recently demonstrated that E6 and E7 induce epigenetic reprogramming, specifically methylation/acetylation, modification of chromatin structure and subsequent activation of homeobox genes, in infected keratinocytes [90, 91].

Many studies have shown that the absence of mature APCs, CD50, and CD86 and the downregulation of TNF-α represent an inadequate immune response to HPV that leads to persistence of the viral infection in the CIN lesions. The LCs are also decreased in numbers and lack the expression of CD11a/18, CD50, CD54, CD58, and CD86. These changes alter the antigen-presenting capacity and can induce immune tolerance to the viral infection [92]. The immortalization of epithelial cells in CIN produced by HPV-16 is related to the lack of response to the inhibitory effect of TGF-β and the inhibition in keratinocytes of TNF-α by the HPV-16 E7 protein, resulting in uncontrolled growth of the infected cells and escaping of the virus from the immune system [76]. Figure 17.4 illustrates the changes in cervical squamous epithelium caused by HPV infection [93].

Immune Evasion Mechanisms

The reasons for the failure of the immune system to recognize HPV are not well understood. It appears that HPV is able to escape detection by the APCs. To survive and have enough time to replicate without detection, HPV has developed many strategies to evade the immune system. The special tropism for keratinocytes (as discussed earlier) is one of the first mechanisms of immune evasion [78].

Keratinocytes are powerful immune cells. They constitute almost 95 % of the cervical and skin epithelium and can express MCH II and co-stimulatory signals to T cells (such as ICAM-I) during inflammation [92]. If the immune response is activated, the HPV-infected keratinocytes release TNF-α, which negatively affects the replication of HPV [70, 92]. TNF-α upregulates the expression of ICAM-1 levels, which decrease the levels of IFN-γ. In CIN, the keratinocytes express less TNF-α, decreasing the stimulus to the LCs. This alteration also affects the expression of MHC II, and as a consequence the presentation of antigens is altered and the expression of the suppressive cytokine IL-10 is increased [68, 92]. These changes in the immunologic microenvironment (with inappropriate T-cell presentation) may contribute to the persistence and progression of the viral infection and development of a CIN lesion [84, 92, 94].

Another important mechanism of immune evasion by HPV involves the downregulation of the macrophage inflammatory protein-3α (MIP-3α), which allows the virus to persist in the epithelial cells without being recognized [95]. Macrophage inflammatory protein-3α is one of the most potent attractants of LC precursors and dermal dendritic cells, as well as T cells. It has been shown that infection of keratinocytes by HPV-16 expressing the E6 and E7 proteins decreases the production of MIP-3α [96].

Similarly, it has also been noted that in most cutaneous viral infections the number of epidermal LCs is significantly reduced (the decrease in numbers of LCs is more marked in lesions of CIN) [92, 96].

Recent studies support the findings that the E5 protein, found in HPV, downregulates the MHC class I molecules, which results in impaired cell lysis by the cytotoxic T lymphocytes. The E5 oncoproteins from multiple types of HPV share similar characteristics; they are small hydrophobic peptides located in the endomembranous compartments of the infected cell that contribute to the activation of growth factor receptors and downregulation of the MHC I [11, 97]. The exact mechanisms used by E5 to downregulate MHC I are not completely clear. Two proposed hypotheses include (1) the inhibition of acidification of the Golgi apparatus (where the MHC is assembled), and (2) a direct interaction between E5 and the heavy chain of the MHC [98, 99].

It has also been shown that the proteins E6 and E7 negatively affect the immune system by inhibiting the production of immune mediators [84]. Both proteins are inversely correlated with the expression of IL-18, which induces the secretion of IFN-γ and IL-8. E6 and E7 also reduce the production of chemokines and monocyte chemoattractant proteins in the genital mucosa of women [76] (Table 17.7).

Modulation of the immune response in the keratinocytes
Downregulation of the production of macrophage inflammatory protein-3α (MIP-3α)
Downregulation of MHC I molecules through the HPV protein E5
Reduction of chemokine and interleukin production by the HPV proteins E6 and E7

Vaccines

The prophylactic HPV vaccines are based on L1, a major capsid protein that is self-assembled into empty capsids, called virus–like particles (VLPs). VLPs are free of viral DNA and therefore are not infectious, but can provide a source of epitopes that can stimulate a neutralizing antibody response [3, 66, 100, 101]. Figure 17.5 illustrates a proposed mechanism of the immune response to HPV vaccines [102–105].

There are currently three approved vaccines for HPV. The first one is the bivalent HPV vaccine (Cevarix marketed by GlaxoSmithKline) that provides immunity against HPV strains 16 and 18. Gardasil, which is marketed by Merck, is a quadrivalent vaccine and confers immunity against strains 6, 11, 16 and 18. The recently approved Gardasil 9 protects against these four types as well as five addition types: HPV 31, 33, 45, 52 and 58. All three vaccines have demonstrated efficacy in phase III trials [106]. An 8.4 year follow-up study for Gardasil performed in the U.S., Canada, and Brazil reported 95.1 % vaccine efficacy for incident infection [107]. Comparative trials of the vaccines have demonstrated that Cevarix evokes a higher antibody titer than Gardasil. Specifically, one trial found that the HPV 16 antibody titer was 2.4–5.8 fold higher and the HPV 18 antibody titer was 7.7–9.4 fold higher with Cevarix than with Gardasil [108]. The HPV vaccination series is recommended in females aged 11–26 years and for males aged 11 or 12 years [106].

Human Immunodeficiency Virus

The human immunodeficiency virus (HIV) pandemic is one of the tragic legacies of the 20th century. HIV is currently one of the leading causes of mortality in sub-Saharan Africa, where more than 5.5 million inhabitants are infected with the virus [109]. In 2013, 35.3 million people were estimated to

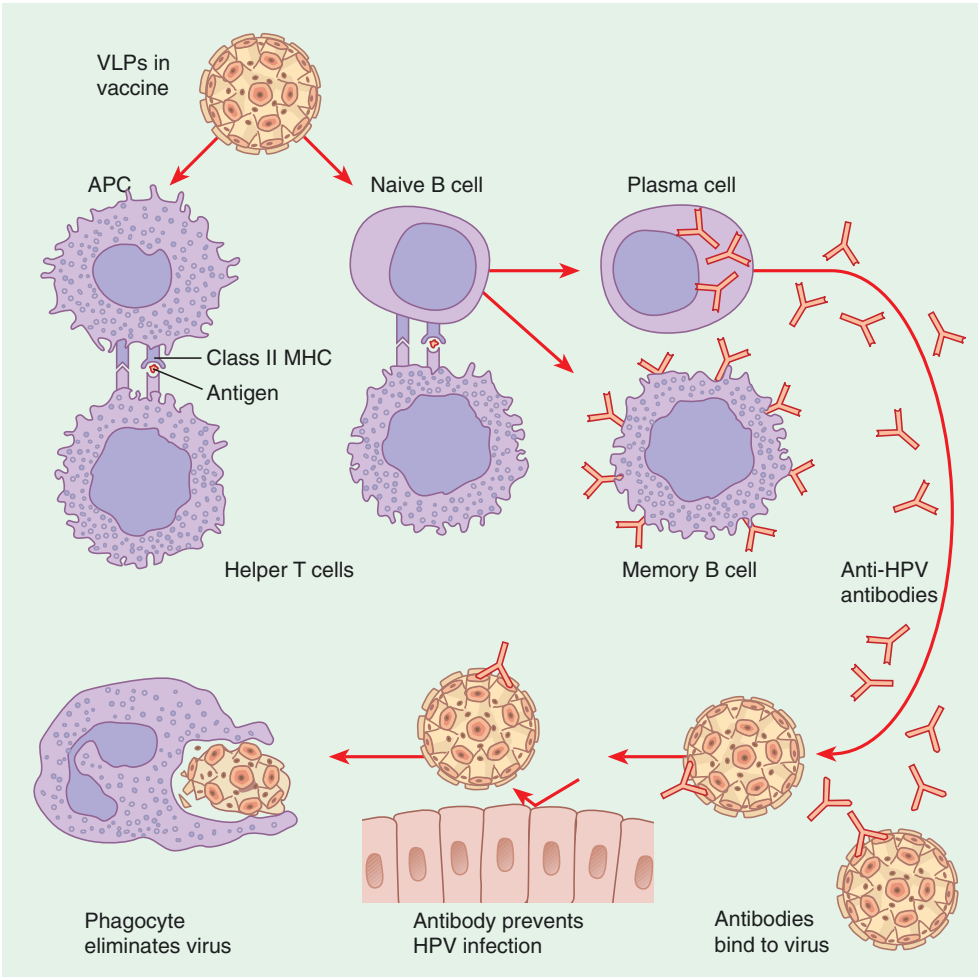

Fig. 17.5 A proposed mechanism for the immune response to HPV vaccines. It has been proposed that HPV L1 virus–like particle (VLP) stimulates an adaptive immune response in humans, resulting in the generation of type-specific neutralizing anti-HPV antibodies. The introduction of VLPs into the systemic circulation via vaccination (upper left) is followed by the ingestion, processing, and display of the VLPs complexed with major histocompatibility class II (MHC II) proteins by antigen-presenting cells (APCs). Naive T-helper cells interact with the aforementioned complex (upper left). The uptake, processing, and display of the VLPs on the B cells are shown (upper middle), which then can interact with T-helper cells that secrete cytokines necessary for B-cell differentiation. Activated B cells differentiate into either memory B cells or plasma cells (upper right). Plasma cells secrete anti-HPV antibodies with high affinity for the target antigen should the antigen enter the body again (upper right). Neutralizing anti-HPV antibodies bind to type-specific neutralizing epitopes on the surface of HPV virus antigens (lower right). The neutralizing anti-HPV antibodies can prevent HPV infection of the host epithelial cell (lower middle). The antibody-coated viruses are eventually eliminated from the body by phagocytes (bottom left) [102–105]. (From Merck & Co., Inc. Efficacy and Antibody Response to Human Papilloma Virus [HPV] Vaccines. Powerpoint Presentation. Copyright © 2006 Merck & Co., Inc. All rights reserved.)

be living with HIV or AIDS, and more than 35 million have lost their lives since the beginning of the epidemic [110].

Women are more susceptible to HIV infection than are men. It seems that the HIV male-to female transmission during sex is about twice that of female-to-male transmission [111, 112]. More than half of those living with HIV are women [110]. Among the several reasons for this variation is that women are exposed to higher concentrations of HIV present in semen (compared to vaginal fluid), and the mucosal area of exposure is greater in women than in men [113]. Furthermore, progression to AIDS is faster in females even though they have 40 % lower HIV loads and higher CD4+ T cell counts than males. Women also have increased generalized immune system activation and inflammation in response to HIV infection. These differences are thought to be due to the sex-based difference in innate immunity [114].

Immune Response

As a sexually transmitted disease, the usual portal of entry of the HIV is the anogenital mucosa. The vaginal and anal epithelium is usually moist, and secretions are continually passing through the intercellular spaces, making it more permeable

(as opposed to the tight and less easily penetrated squamous epithelium of the skin). The cells in the mucosal epithelium are connected by discontinuous patches of desmosomes (considered one of the weakest forms of intercellular junction) [11]. In the mucosal epithelium, the DCs play an important role during HIV infection. These cells are located at the sites of viral entrance, such as the rectal and vaginal mucosa, and at high viral replication sites, such as the lymph nodes [115]. The localization of DC cells makes them the key regulators of HIV transmission and subsequent viral spread [116, 117]. The DCs are APCs derived from bone marrow progenitors that home in on peripheral mucosal sites where they become immature DCs. After capturing an antigen and under the effects of the process of infection and inflammation, these cells turn into mature DCs and migrate to the lymph nodes, where the maturation process finalizes, making them capable of presenting the antigen to T cells [118].

To understand the events and mechanisms of HIV sexual transmission, the most useful animal model has been the rhesus macaque model infected with simian immunodeficiency virus (SIV), which is closely related to HIV. In macaques, the LCs are DCs located within the stratified vaginal squamous epithelia. The LC is the first infected cell after intravaginal exposure to SIV [119]. Extrapolating the animal data to HIV, upon contact with the mucosa, the HIV fuses to the immature DCs through two mechanisms: (1) CD4 cell surface receptors and the chemokine receptors (mostly CCR5), and (2) capture of the virus at the cell surface by DC-specific ICAM-3 grabbing nonintegrin (DC-SIGN) and other C-type lectins [120]. Once inside of the DCs, HIV can replicate and produce intact virions. Figure 17.6 illustrates interactions between HIV and the cell surface [121]. Subsequently, the virus exploits the natural trafficking properties of the DCs to transfer its virion progeny to its primary cellular target, the CD4 cell, located at the draining lymph nodes [115, 122]. This strategy explains the rapid and efficient movement of HIV mediated by the LCs from mucosal tissues (the normal sites of LC activation following antigen exposure) to the lymph nodes [120]. This phenomenon also explains the fact that small amounts of infecting viruses (or relatively few infected LCs) could lead to efficient infection of large numbers of CD4+ T cells [119].

Once HIV infected cells drain to the lymph nodes, they travel to the gastrointestinal tract during the earliest days of infection. The gastrointestinal tract, and specifically the intestinal mucosa, is one of the most important organs in HIV amplification. Beneath the intestinal epithelium, the lamina propria consists of an enormous collection of memory CD4+CCR5+ T cells. This collection of T cells exceeds the total number of T cells in all other body sites combined. Thus, infection of these T cells is largely responsible for early HIV amplification and chronic viral persistence. The peak viral replication in plasma during early replication corresponds to the massive infection of gut T cells. Lastly, this rapid viral replication in the gastrointestinal tract leads to the production of many escape mutants due to selection from reactionary adaptive immune responses [123].

During immune activation, mature LCs and other types of mature DCs have the ability to cluster with the T cells. The microenvironment in these cell clusters (DCs with T cells) has been described as an explosive site for HIV replication [124–126]. While a correlation of the DCs and decreased HIV replication at this stage has been observed, the exact mechanisms responsible for this phenomenon are not known [117, 127, 128]. The clustering of DCs and T cells could decrease T-cell activation and proliferation, thus blocking the spread of HIV after sexual exposure to virus. Blocking chemotaxis of T cells toward HIV-infected DC using chemokine or chemokine receptor antagonists could be one of the strategies, while another may involve blocking full activation of T cells by HIV-infected DCs by addition of antibodies that interfere with co- stimulatory molecule function [129]. Figure 17.7 illustrates possible mechanisms of the neutralization of HIV at mucosal surfaces by antibodies [130].

For HIV replication to occur, cellular activation is critical, and some studies suggest that T cells become activated and infected through cluster formation with infected LC and not by direct contact with free viruses produced by infected LCs or T cells [129]. The study of T cells during viral infection suggests that HIV infection of DCs induces expression of chemokines in these cells that differentially attract certain T-cell subsets. Results from these studies indicate that infection of CD4+ T cells is not a random event. It seems that expression of the HIV Tat or Nef proteins increases the CXCR4 expression within monocyte-derived DCs, allowing the virus to gain access to a wider range of potential target cells [116, 131, 132]. Other observed factors in chronic generalized immune activation include translocation of intestinal microbial products that stimulate the immune system, antigen nonspecific bystander activation of T and B cells by proinflammatory cytokines and depletion or dysfunction of CD4+ regulatory T cells that normally suppress chronic immune activation. Eventually, this generalized immune activation causes effector T cells to become functionally unresponsive to antigens, leading to a state of "immune exhaustion" [133].

A hypothesis to explain the skin manifestations of HIV infection is derived from the study of LCs and their role in viral pathogenesis. Nonetheless, not all the studies are consistent. Some studies have demonstrated a lack of depletion of T cells, LCs, and DCs in the skin of infected patients (although functionality was not assessed) but an increase in CD8 T cells in the perivascular dermis [134]. On the other hand, studies in macaques have shown that during the acute SIV infection, LC density is reduced in skin, but increased in

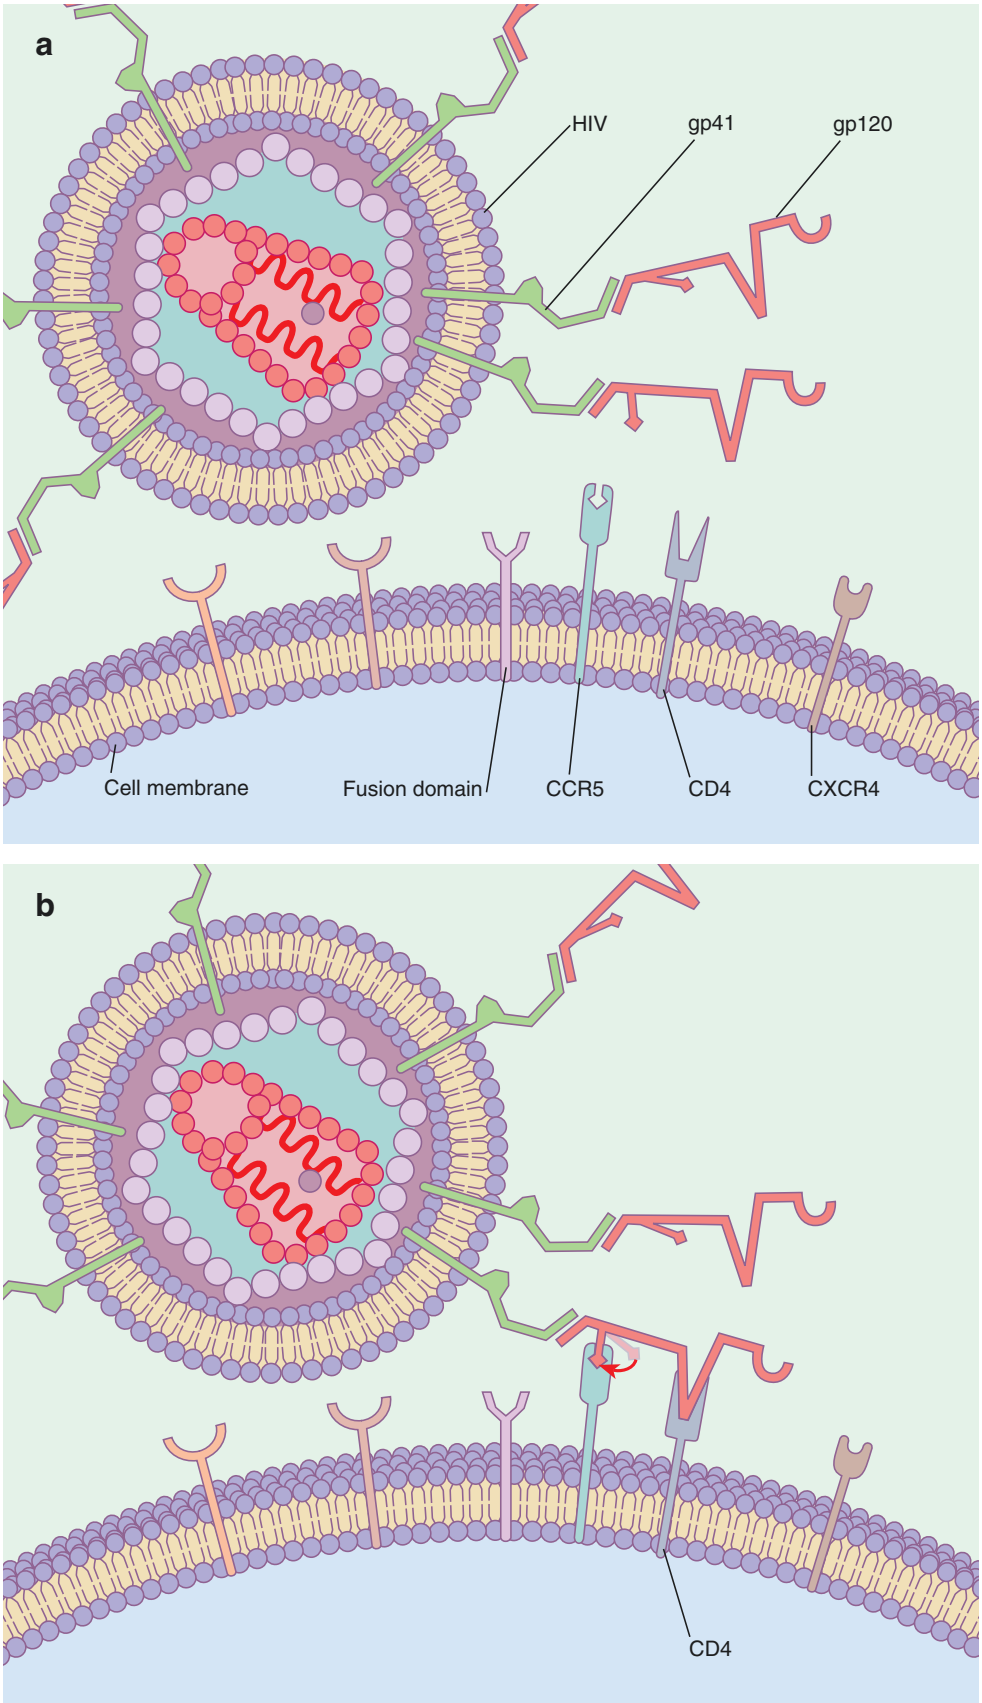

Fig. 17.6 Interactions between HIV and the cell surface. HIV interacts with a cell-surface receptor, primarily CD4, and through conformational changes becomes more closely associated with the cell through interactions with other cell-surface molecules, such as the chemokine receptors CXCR4 and CCR5 (**a**). Alternatively, some viruses, such as certain strains of HIV-2, could attach to CXCR4 directly [11]. The likely steps in HIV infection are as follows. The CD4–binding site on HIV-1 gp120 interacts with the CD4 molecule on the cell surface (**b**). Conformational changes in both the viral envelope and the CD4 receptor permit the binding of gp120 to another cell-surface receptor, such as CCR5 (**c**). This second attachment brings the viral envelope closer to the cell surface, allowing interaction between gp41 on the viral envelope and a fusion domain on the cell surface. HIV fuses with the cell (**d**). Subsequently, the viral nucleoid enters into the cell, most likely by means of other cellular events (**e**). Once this stage is achieved, the cycle of viral replication begins. (From Levy [121]. Copyright © 1996 Massachusetts Medical Society. All rights reserved.)

Fig. 17.6 (continued)

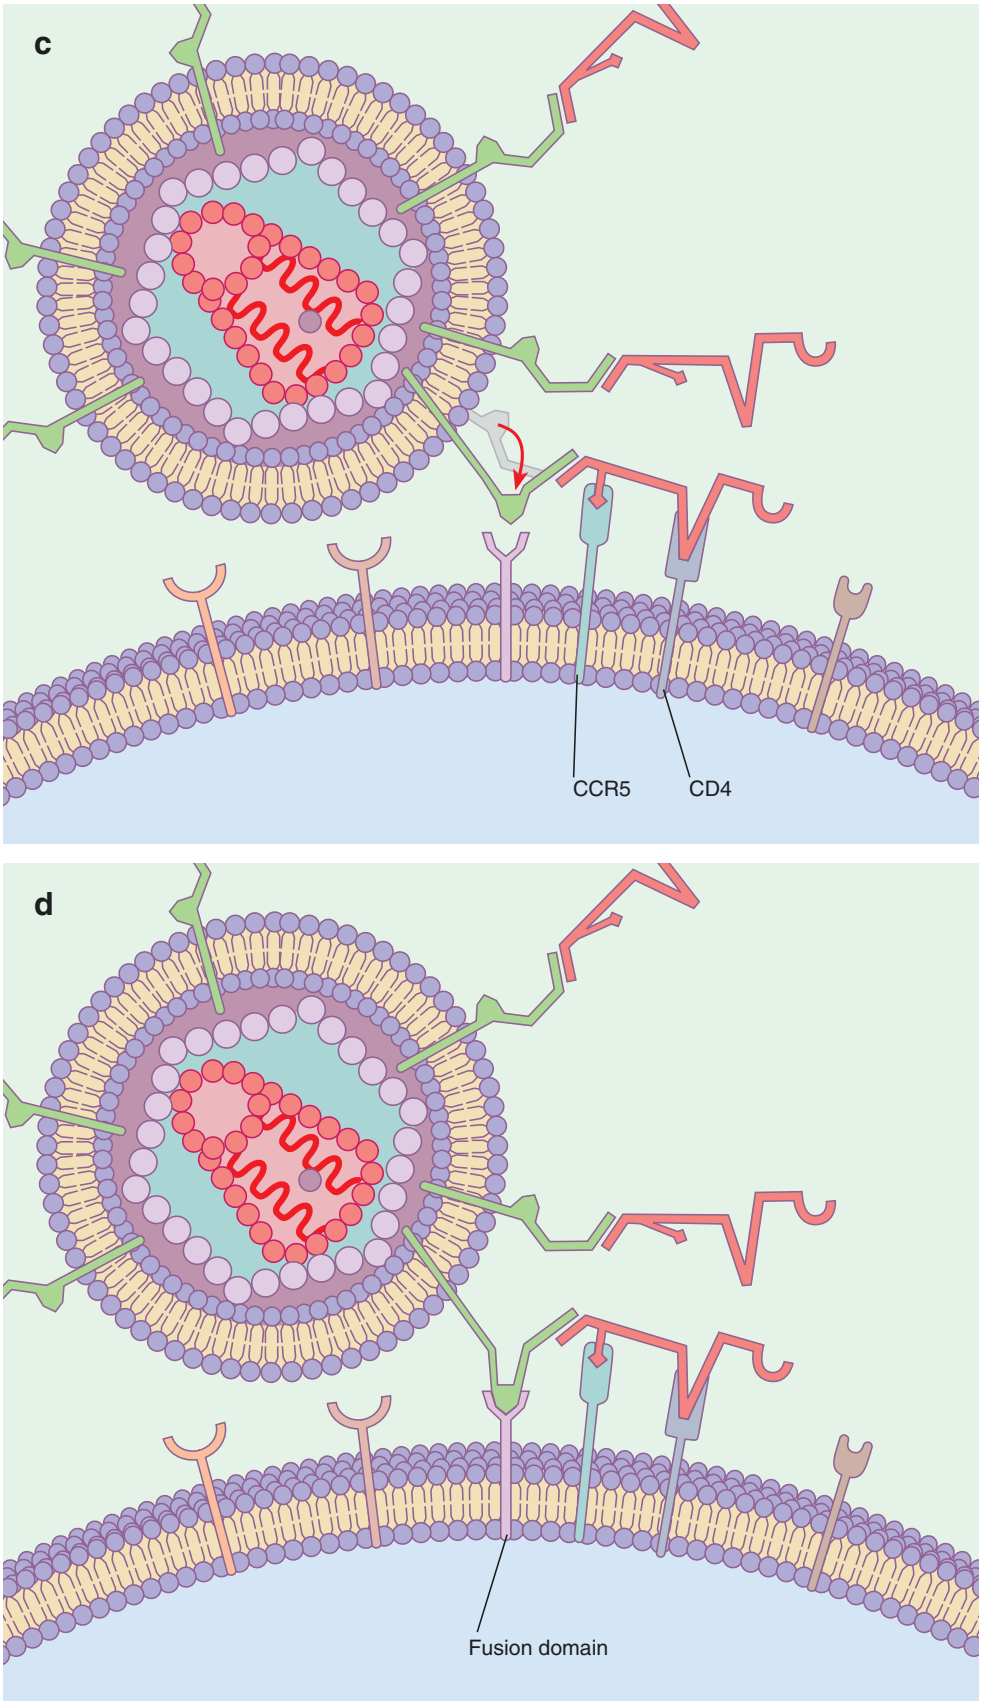

Fig. 17.6 (continued)

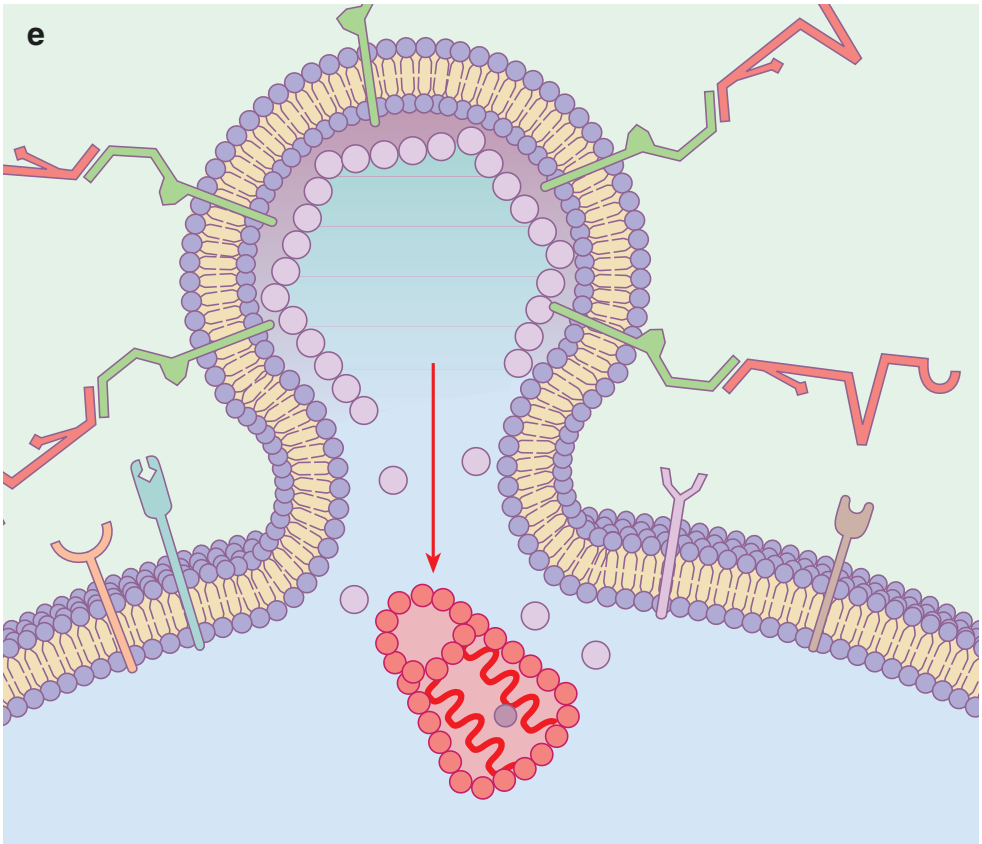

the lymph nodes (as activated DCs). In later stages of HIV infection (AIDS), the migration of DCs is suppressed, suggesting that changes in DC function at different stages of viral infection modulate replication, dissemination, and persistence of HIV. The depressed DC function during advanced HIV disease might increase the degree of immunosuppression [135].

Immune Evasion Mechanisms

A simple and useful way to understand viral pathogenesis has been proposed by Hilleman, who categorized viruses in two main groups: (1) those viruses that "hit and run" (e.g., cold viruses), and (2) those that "hit and stay" [136]. HIV belongs to the second group, since it infects the host and stays with it until death occurs. Nonetheless, to ensure the persistence of its progeny, it develops effective mechanisms of spread [136]. As specified before, the DCs are crucial for the generation and regulation of the adaptive immunity. HIV has developed clever strategies to exploit the DCs and carry out its replication cycle. Also, the interaction with the DCs allows HIV to disseminate and evade the antiviral immune response [116]. Since the DCs are the primary producers of IFN-α (which is a key antiviral molecule), alterations in these cells could be beneficial for viral survival and evasion [11]. Additionally, HIV is capable of downregulating the MHC class I molecules, and as a consequence has an effect on natural killer cells. HIV reduces the stimulation of NK cells by stabilizing surface expression of the nonclassic MHC class I molecule human leukocyte antigen E (HLA-E), which reduces the susceptibility to NK-cell-mediated cytotoxicity [137, 138]. Similarly, the CD8 T lymphocytes (CDL) directed against HIV recognize an important number of HIV epitopes. Mutation of these epitopes alters or abolishes CDL recognition, which results in escape of HIV from the immune system [139] (Table 17.8).

Vaccines

Despite 30 years of investigation, a vaccine for HIV still does not exist. In this time, 256 candidate vaccine trials (primarily phase I or II) trials involving more than 44,000 healthy patients have been conducted. Of these, there have been five novel HIV vaccine phase II and III trials in the past decade [140]. In 2003, the VAX 003 and 004 trials tested the immunogenicity of the recombinant protein gp120 (an HIV envelope immunogen). This vaccine stimulated antibody production but was not effective in inducing cellular immunity

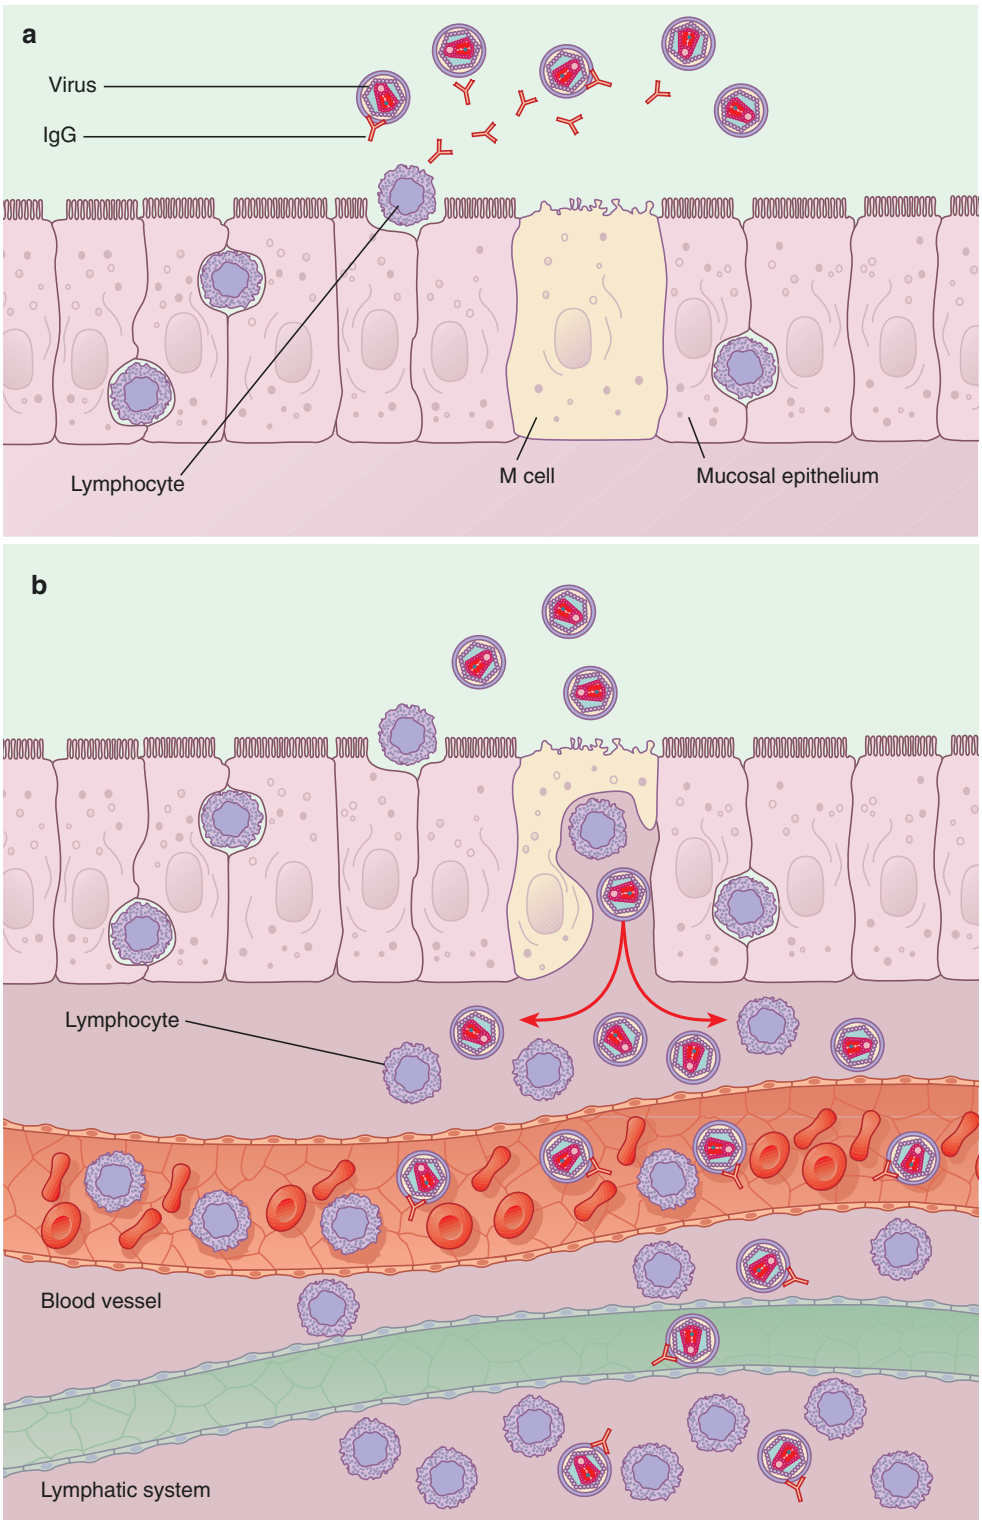

Fig. 17.7 Possible mechanisms of the neutralization of HIV at mucosal surfaces. (**a**) The transudation of passively infused immunoglobulin G (IgG) from vessels in the submucosa across the epithelium causes it to encounter virus at the mucosal surface. The virus is thus neutralized before it can encounter lymphocytes or M cells associated with the epithelium or underlying lamina propria. (**b**) IgG circulating in the blood or lymphatic system encounters virus that has been transported across mucosal surfaces by M cells. Antibodies neutralize the virus before it can spread from the site of infection. (From Nabel and Sullivan [130]. Copyright © 2000 Massachusetts Medical Society. All rights reserved.)

[141, 142]. The 2007 STEP trial tested a vaccine composed of the three HIV core proteins (Gag, Pol and Nef) delivered in an adenovirus vehicle. This candidate vaccine was found to be clinically ineffective and might have increased HIV-1 transmission. The 2013 HVTN 505 trial which tested an adenovirus vector that delivered the Gag, Pol, Nef and Env

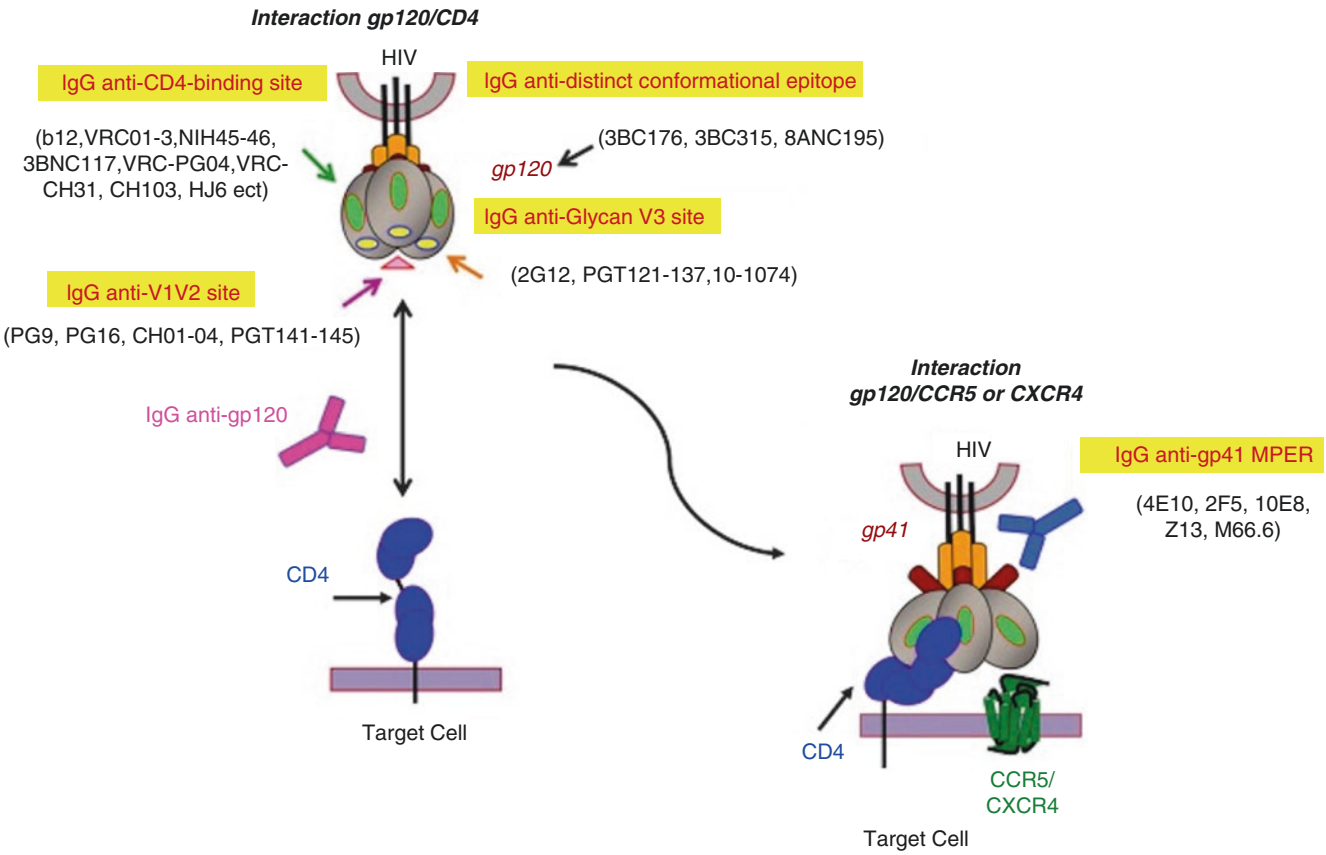

Fig. 17.8 Model representation of HIV-1 envelope glycoprotein structure and epitopes of broadly neutralizing antibodies. The surface receptor binding subunit gp120 and the fusion-mediating transmembrane subunit gp41 make up the functional HIV-1 envelope glycoproteins. The targets of broadly neutralizing antibodies (bNAbs) can be divided into several groups: (1) IgG anti-CD4-binding site, (2) IgG anti-V1V2 site, (3) IgG anti-*N*-linked glycan V3 site, and (4) IgG anti-gp41 membrane proximal external region (MPER). The IgG anti-distinct conformational epitope present on the envelope trimer, remains to be determined (Adapted from Dr. Béatrice Labrosse. Reprinted from Frontiers in Immunology, 5, Su & Moog, Which Antibody Functions are Important for an HIV Vaccine?, 289. 2014, with permission from Frontiers Media SA)

proteins after DNA priming was prematurely terminated due to inefficacy and an increase in HIV infection [143].

Finally in the 2009 RV144 trial, patients received two doses of gp120 protein from two different HIV variants and four doses of the HIV-avian pox virus [144]. The efficacy of protection of this regimen was 31 % of patients at 3 years but was deemed to be statistically insignificant [143, 144]. Further analysis showed that high anti-Env V1/V2 loop, non-neutralizing antibodies that triggered antibody dependent cellular cytotoxicity decreased the risk of HIV infection by 71 % [143]. Although the protection conferred by the RV144 trial vaccine was deemed statistically insignificant, this trial supported the idea that an ideal HIV vaccine might need to induce both humoral and cellular immune responses [145, 146]. In the last decade, generating a robust humoral response has centered on eliciting anti-HIV-1 antibodies with broadly neutralizing activity (bNAbs). These bNAbs target the V3 loop, the binding site for CD4 at the site of primary viral entry, viral glycans and the membrane proximal external region (MPER) on GP41 (Fig. 17.8) [146].

Molluscum Contagiosum

Molluscum contagiosum virus (MCV) is a double-stranded DNA poxvirus surrounded by a lipid envelope. It is the only poxvirus that commonly infects humans since the eradication of smallpox. The MCV causes benign proliferative lesions of the skin, which can last for several months in immunocompetent and immunocompromised individuals. Molluscum contagiosum virus has a worldwide distribution but is more prevalent in tropical areas [147]. It usually affects children, but it can also be transmitted sexually or through touch, such as in contact sports [148]. This virus is the largest of all animal viruses and it is easily visualized on light microscopy.

Immune Response

Molluscum contagiosum virus transmission is through direct skin contact with an infected individual. The MCV infections have a particular location on the epidermis, which

makes the virus "safe," almost beyond the reach of the immune system. Lesions in vivo are characterized by a lack of inflammatory cell infiltrates. The typical T or NK cells are usually not found at the base of molluscum lesions. Nonetheless, in the healing stage a mononuclear cell infiltrate is usually observed [11].

Regarding inflammatory mediators, studies have shown that chemokines such as growth regulated oncogene alpha (GRO-α) and IL-8 are inside the molluscum lesions and are released on clearing of the virus [150]. It is hypothesized that the immune response might be blocked by chemokine antagonists early in MCV infection, and in later stages of the infection the physical barrier (i.e., localization of the epidermis) or the formation of molluscum bodies may prevent detection by the immune system [147]. Some studies indicate that the production of antibodies does not occur in all patients with clinical MCV infection, or the antibody production is not stable during the clinical period [151].

Immune Evasion Mechanisms

Like many other viruses, MCV uses a variety of methods to escape the immune system. An MCV ORF (designated mcv148R) encodes a 104-aminoacid protein with significant homology to β-chemokines such as macrophage inflammatory protein (MIP)-1β. This homology has led investigators to believe that this virally produced chemokine may block the chemotactic activity of the host chemokines [147]. The MCV is also capable of blocking the signal necessary for successful migration of effector cells to the site of infection. Other MCV gene products such as MC53L and MC54L bind IL-18 with high affinity and prevent IFN-γ production, suggesting that these viral proteins antagonize the development of an inflammatory response to MCV infection in humans [149–151].

There is no vaccine currently available to prevent MCV infection.

Conclusion

The immune response to a viral infection is a complex phenomenon that is specific to each microorganism. Through a highly efficient process of evolution, the viruses have developed several immune evasion mechanisms that allow them to overcome the natural barriers of the skin, cause infection, and establish latency. The delicate balance between the host immune response and viral replication (and dissemination) will eventually dictate the clinical outcome. Factors influencing the host, such as age, immunocompetence, and development of immunity after exposure to the virus, all play a key role in altering this balance.

Questions

1. Herpes simplex virus produces latency associated transcripts (LATs) which have been found in high concentrations in latently infected neurons. LATs help to increase the efficiency of latency and subsequent reactivation by what mechanism?
   A. By interfering with production and secretion of IL-1 and TNF-α
   B. By destroying the homing receptor (CLA) on CD8+ T cells
   C. By inhibiting the production of proteins involved in the apoptosis pathway
   D. By altering the activity of neutrophils, macrophages, and NK cells

Answer/Explanation: answer C
The herpes simplex virus does alter the activity of neutrophils, macrophages, and NK cells. As such, it does interfere with the production and secretion of some pro-inflammatory cytokines, such as IL-1 and TNF. However, LATs are directly responsible for inhibiting granzyme-B and capsase-8 mediated apoptosis

2. Depletion of what cell line has been implicated with the enhanced survival, prolonged course of infection, and oncogenic transformation associated with some high risk HPV types?
   A. T helper cell
   B. Langerhans cell
   C. Macrophage
   D. NK cell

Answer/Explanation: answer B
Depletion of Langerhans cells has been documented in HPV infections along with a lack of expression of certain cell signaling molecules (CD54, CD86, TNF-α, etc.). Cumulatively, these features decrease the antigen-presenting capacity of Langerhans cells and can induce immune tolerance and ultimately oncogenic transformation

3. The early peak in viral replication that is integral for large scale HIV amplification and chronic viral persistence is directly attributable to infection of what cell line?
   A. CD4+CCR5+ T cells in the intestinal mucosa
   B. Dendritic cells (DC) located in draining lymph nodes
   C. CD4+ ICAM1+ T cells in keratinocytes
   D. Effector Th cells in mucosal surfaces

Answer/Explanation: answer A

HIV does initially infect DC and exploits their natural trafficking properties to transfer virus to CD4+ T cells in draining lymph nodes. However, the cell line directly responsible for the early peak in viral replication is infection of CD4+CCR5+ T cells in the lamina propria of intestinal mucosa. The collection of T cells here exceeds the total number of T cells in all other body sites combined and is responsible for the early and massive amplification of the virus

Parasitic Infections

18

Kassahun Desalegn Bilcha and Sidney Klaus

Abstract

Parasitic diseases involving the skin represent an important segment of the globe's emerging disorders that present a threat to the health of millions of people worldwide. Host immune responses to these diseases are complex and display a wide range of variability, involving both the innate and adaptive immune systems. Not all the host's efforts at eliminating the invading parasites are successful, and in some cases the host's immune response causes more damage than the parasite itself.

This chapter examines the immune mechanisms in three widely diverse parasitic diseases that involve the skin: cutaneous leishmaniasis, onchocerciasis, and schistosomiasis.

Keywords

Parasitic Infections • Skin infections • Host • Cutaneous leishmaniasis • Onchocerciasis • Schistosomiasis • Cell receptors • TH1 • TH2 • Hypersensitivity • HIV • skin disease

Key Points

- Cell-mediated immunoregulation plays the dominant role in resolving *Leishmania* infections.
- Most promastigotes deposited in the dermis are opsonized by serum complement and killed by complement-mediated lysis.
- The remaining promastigotes are phagocytosed via complement receptors on the macrophage membrane, which binds to gp63 and lipophosphoglycan.
- Macrophages release chemokines that attract more macrophages as well as natural killer (NK) cells and dendritic cells.
- *Wolbachia* bacteria living inside *Onchocerca volvulus* are the essential target of the host's inflammatory response in onchocerciasis.
- The initial reaction in schistosomiasis is predominated by Th1 response that later shifts to Th2 response.

Leishmaniasis

Leishmaniases are a groups of zoonotic, often debilitating, diseases of humans due to infection with intracellular protozoan parasites belonging to the genus *Leishmania*. The disease is an emerging uncontrolled and neglected infection affecting more than 12 million people worldwide, with an additional 350 million at risk of infection. The global yearly incidence of all forms is approaching two million cases [1]. Leishmaniasis is endemic in more than 98 countries belonging to the tropical regions of Africa, Asia, and South and Central America. It is also found in the southwestern part of the United States; in the Middle East; and in countries surrounding the Mediterranean Sea [2].

Fig. 18.2 Mucocutaneous leishmaniasis in an HIV-infected man

Fig. 18.3 Mucocutaneous leishmaniasis in an non-HIV-infected boy

The number of cases increases dramatically in areas of the world undergoing ecologic disruption, associated with rapid major shifts in population. More than 20 species of the genus *Leishmania* have been identified as causative agents of the disease.

The parasites exist in two morphologic forms during their life cycle: as elongated flagellated promastigotes in the gut of the sand fly vector, and as round to oval nonflagellated amastigotes in mammalian hosts.

The disease exists in three distinct clinical syndromes: The first one, cutaneous leishmaniasis (CL), is a localized lesion with single to multiple ulcers, satellite lesions, or nodular lymphangitis (Fig 18.1). Rarely, widespread involvements of the skin can occur in this form of the disease resulting in diffuse and disseminated cutaneous leishmaniases (DCL). The second, mucocutaneous leishmaniasis (MCL) occurs with marked involvement of the mucous membranes of the oral cavity, nasopharynx, and throat leading to partial or total destruction (Figs. 18.2 and 18.3). The third form, visceral leishmaniasis (VL), also called kala-azar, involves internal organs such as liver, spleen and bone marrow and is fatal if not treated. Skin involvement in the form of macular, papular or nodular widespread rash can occur in patients with VL, or, after they have been treated, and is called para-kala-azar or post-kala-azar dermal leishmaniasis (PKDL). The outcome of untreated cases depends on the species of *Leishmania* causing the infection as well as on the innate and adaptive immune responses of the host [3]. Although humoral immune responses can be demonstrated during the course of the infection, cell-mediated immunoregulation plays the dominant role in resolving the infection. Many of the details of the immune response have been derived from extensive studies of *Leishmania major* infections in two experimental mouse models: the resistant C57BL/6 strain and the susceptible BALB/c strain.

Early Events in the Immune Response

In humans, the disease is initiated by the bite of an infected female sand fly (of the genus *Phlebotomus* in the Old World and *Lutzomyia* in the New World). During the bite parasites are inoculated into the dermis; in most cases less than 100 parasites are transmitted by a single bite, although the number may reach as high as 1000 or more [4].

Because the sand fly is a "pool feeder" (it severs capillaries in its hunt for a blood meal) promastigotes are deposited in a small pool of blood within the dermis. The bite of the sand fly initiates a local inflammatory response, with the recruitment of neutrophils, natural killer (NK) cells, eosinophils, and mast

cells. The cellular response is rapid; neutrophils are the first cells to arrive at the site of the infection; in mice, they have been found collecting in the skin within 1 h of a parasite injection [5].

Most of the promastigotes deposited in the dermis are opsonized by serum complement and killed by complement-mediated lysis. The remaining promastigotes are phagocytosed via complement receptors expressed on the macrophage membrane, which binds to two abundant molecules on the surface of the parasites: gp63, a 63-kd neutral metalloproteinase; and LPG, a lipophosphoglycan [6].

Macrophages that have engulfed parasites release several chemokines, including CCL2, which attracts NK cells, dendritic cells (DCs), and additional macrophages to the site of the infection [7].

Components of sand fly saliva also have been shown to affect the immune response by exacerbating lesion development in resistant strains of mice [8, 9]. When maxadilan, a vasodilatory peptide isolated from sand fly saliva, was added to human peripheral blood mononuclear cells (PBMCs) the secretion of T-helper-1 (Th1) cytokines (interferon [IFN] and interleukin-12 [IL-12]) was decreased and the secretion of Th2 cytokines enhanced [10]. In addition salivary gland lysates (SGLs) also have been shown to augment the collection of inflammatory cells at the site of the bite and when added to experimental infections caused by *L. major* and *L. braziliensis* [11].

Once the promastigotes enter the macrophages, they transform into replicative amastigotes over a period of 2–5 days and are carried within modified lysosomal compartments known as parisitophorous vacuoles (PVs) [12]. A study of the ultrastructure of the vacuoles suggests a significant difference in packaging between Old World and New World leishmania. Amastigotes of *L. major* were found to be segregated into separate vacuoles during replication; in contrast, New World species of *Leishmania* were carried in large vacuoles occupied by many amastigotes [13].

Once inside the PVs the parasites produce antioxidant enzymes and are able to resist lysosomal hydrolases (the usual mechanism for clearing ingested pathogens). Within the cells the amastigotes replicate rapidly.

Macrophages that accumulate large numbers of replicating amastigotes rupture; the released parasites are taken up by neighboring competent cells. In especially inflamed skin lesions, most parasites are found in extracellular locations. One explanation is that high levels of inflammatory mediators interfere with receptors on the macrophages, blocking re-internalization of the parasites (Klaus S, unpublished data).

Antigen Transport and Presentation

At the same time that macrophages are ingesting parasites, Langerhans cells (LCs), which normally reside in the epidermis and are a potent type of antigen-presenting cell (APC), are stimulated. In a study of *L. major* infections in mice, LCs were found to be the dominant type of APC migrating from the skin to the regional lymph nodes via lymph channels [14, 15].

The ability of LCs (and other APCs) to identify the parasites has been attributed to Toll-like receptor 4 (TLR4), a member of a family of transmembrane receptors implicated in the recognition of a variety of microbial and foreign agents [16]. A study of TLR-deficient mice showed they had larger parasite burdens and were less efficient in the resolution of cutaneous lesions [17].

The extent to which macrophages also transport parasites and parasite antigen from the skin to the nodes is unresolved, although most studies indicate that LCs are the major carriers and shoulder most responsibility for antigen presentation to $CD4^+$ naive T cells within the lymph nodes [18].

The initial stages of the uptake of antigen by the LCs are rapid; experiments in mice have demonstrated that LCs can find and engulf parasites within 4 h of exposure (although the migration to the lymph nodes may take up to 3 weeks) [19]. The movement by the LCs to the nodes is influenced by chemokine expression. Studies have indicated that during the migration the level of expression of chemokine receptor CCR7 on the LCs is enhanced, while the level of CCR2 and CCR5 is downregulated [20].

It is during this stage of the adaptive immune response that naive $CD4^+$ T-helper cells (Th0) are programmed to develop into either Th1 or Th2 cells. Interleukin-12, a cytokine released by DCs, has a critical role at this stage in the immune response [21, 22]: IL-12, along with IL-1, serves as a promotor of the differentiation of Th1 cells in the lymph nodes from naive T0 cells. It also enhances chemokine gene expression in mice during the first 3 days of infection with *L. major* [23].

It is now clear that the successful clearing of amastigotes from infected macrophages in resistant mouse strains is mediated through the predominance of Th1 cells. The mechanism is through steps that link the production of IFN-γ, a major cytokine of Th1 cells, to the release of nitric oxide (NO), a compound within macrophages harboring amastigotes leading to their destruction. Nitric oxide ordinarily is present within an inactive form in the macrophages (iNO), which needs to be catalyzed by the enzyme NO synthase to become active. Interferon along with IL-12 and tumor necrosis factor (TNF), two other cytokines released by Th1 cells, make up the major upregulators of NO synthase, and the production of NO occurs only when the Th1 cells become predominant [24].

In contrast to the events within the resistant mice, in susceptible mouse strains (BALB/c) a type 2 response is initiated following infection with *L. major,* which tends to interfere with the protective activities. Th2 cells that become stimulated produce IL-4, IL-5, and IL-10, which have the capacity through mediators to inhibit the production of IFN-γ, downregulate the

expression of iNOS (and consequently NO), and thus inhibit macrophage function.

Although a great deal is known about the process of resistance in mice, much less is known about the human immune response to *Leishmania*. While mice can mount either a Th1 or Th2 response, Rogers and Titus [25] suggested that in humans the principal response is predominantly, if not exclusively, a type 1 response. Using an *in vitro* system they cocultured PBMCs from *Leishmania*-naive donors with *L. major* parasites and found that type 1 cytokines were stimulated, (IFN-γ and IL12), and that when PBMCs were cocultured with macrophages infected with parasites, augmented intracellular killing was observed [25].

Antibody Response

Anti-*Leishmania* antibodies, as measured by enzyme-linked immunosorbent assay (ELISA), can be found in low titers in individuals recovering from CL, but their role in recovery from the acute infection and in the prevention of re-infection is debated. Polyclonal activation of human B cells leads to the production of large amounts of parasite specific antibodies, and amastigotes released into the dermis from ruptured macrophages appear to be coated with antiparasite antibodies [26].

In mice, antibody levels do not correlate in general with resistance to disease, although their effect on the course of the infection may depend on genetic factors. For example, passive transfer of antibody fractions from immune mice to BALB/c mice did not affect their susceptibility to infection [27], yet ablation of B cells in resistant mice generated a non-healing response to *L. major* [28].

Delayed-Type Hypersensitivity and the Leishmanin Skin Test

Delayed-type hypersensitivity in leishmaniasis can be measured by the leishmanin skin test (LST), in which the extent of a skin reaction is measured 48–72 h after an intradermal injection of 0.2 mL of a killed suspension of cultured leishmania promastigotes in saline. A positive reaction indicates a type 1 $CD4^+$ cell-specific immune response. Because it is usually positive in individuals who have had CL, it has been used to measure the extent of infection among individuals living in endemic regions who have no history of overt disease. A study of 470 children living in endemic foci of *L. major* infection in Tunisia found that the proportion of asymptomatic infections among this group of children was approximately 10 % [29]. The LST also has been used as a predictor of susceptibility to subsequent disease, whether or not the individual had a history of a previous skin lesion.

Persistence of Parasites

In most cases of human cutaneous leishmaniasis it had been assumed that in skin lesions that had "healed" (either spontaneously or following treatment), the parasites had been eliminated by effector mechanisms involving IFN-γ and the generation of NO within the macrophages. It is now recognized that viable *Leishmania* organisms may persist in the skin long after the resolution of the clinical lesions [30]. Persistence has been documented in several ways: in biopsy samples from normal patients who have recovered from CL, in skin lesions of patients who recovered from CL but who later contracted HIV infection, and in skin lesions of patients who recovered from CL but later developed leishmania recidivans.

Schubach et al. [31] examined skin tissue obtained by biopsy at the sites of the scars from two patients from Brazil who had been infected with *Leishmania* 8 and 11 years earlier. The tissues from both patients grew out viable *Leishmania* parasites. A more recent study analyzed skin biopsies from scars of 32 patients with who had CL but who had been treated and clinically cured. *Leishmania* specific DNA was detected by polymerase chain reaction (PCR) in 30 of the patients, and parasites were isolated by culture in three [32].

The persistence of parasites in post-recovery CL is also evident in patients who later become infected with HIV. Studies of skin biopsies from such immunocompromised patients often show large numbers of amastigotes both within macrophages and free in the dermis. Parasites can also be seen within keratinocytes surrounding sweat ducts, and within the cells of the eccrine glands themselves [33]. Skin lesions in these patients often appear as isolated papules or plaques on exposed areas of the skin and are usually indistinguishable from similar lesions seen in non-immunosuppressed individuals. Skin lesions in HIV patients may also present as diffuse scaling plaques, which on biopsy show a high concentration of parasites [34].

Leishmaniasis recidivans (LR) is a rare clinical form of CL in which skin near the site of a previously healed acute CL lesion reappears as a dusky-red granulomatous plaque with active spreading borders. The clinical features resemble lupus vulgaris. Cultures of the skin lesion for *Leishmania* are usually negative, but with perseverance sparse parasites can be detected microscopically or by PCR. Leishmaniasis recidivans patients usually demonstrate high levels of antibodies in the serum and a strongly positive LST [35].

Vaccine Development

Clinical evidence points to the conclusion that recovery from skin infection with *Leishmania* provides lifelong protection against re-infection despite ongoing exposure to sand flies,

suggesting that a vaccine would be of great value in controlling the disease.

For more than 100 years residents of endemic regions in eastern Asia and the Middle East practiced a form of vaccination known as leishmanization, which consisted of the deliberate inoculation of infective material into inconspicuous body areas (especially the buttocks) in the hope of providing protection from a subsequent infection and disfiguring scars on exposed parts of the body. A widescale trial of leishmanization was carried out among soldiers in the Iranian army in the 1990s, with more than a million individuals vaccinated, in this case using live *L. major* promastigotes obtained from cultures. Although the degree of protection initially seemed adequate (less than 3 % of a cohort of the vaccinated group developed a naturally acquired infection, compared with 14 % of unvaccinated volunteers), there was an unacceptable rate of adverse events: 2–3 % of the subjects developed large nonhealing infections at the site of the vaccinations that required treatment [36–38].

Today vaccine trials use killed or live attenuated parasites, genetically modified cells from promastigotes, and DNA encoding recombinant proteins [39–41].

Other vaccine candidates have included those using specific peptides derived from leishmania proteins such as amino acids derived from gp63, administered with certain adjuvants (such as liposomes or complete Freund's adjuvant) [42]. One novel idea was that if components of sand fly saliva were added to a standard mix of antigens, a more effective prophylactic vaccine might result [43].

Although experimental vaccines to control CL have been studied extensively over the past two decades, inoculation with live *L. major* still remains the only successful vaccine in humans [44]. Currently, vaccine development is hampered by an incomplete understanding of the immune process and by concerns about long-term safety.

Onchocerciasis

Onchocerciasis, also known as river blindness, is a neglected tropical infection caused by the filarial nematode *Onchocerca volvulus,* with significant cutaneous manifestations, including pigmentary changes (Fig. 18.4), debilitating itching and subcutaneous nodules. It also causes significant eye damage and is the second (only to trachoma) most common infectious cause of blindness globally. It affects more than 18 million people living in endemic foci mainly of sub-Saharan Africa, but also in Latin America (including Brazil, Ecuador, Guatemala, Mexico, and Venezuela), and Yemen. It is now believed that skin disease is the most important contributor to the burden of onchocerciasis, rather than eye disease [45].

The disease is spread by the bite of black flies of the genus *Simulium* that prefer to breed on fast-running (highly oxygenated) rivers and streams of tropical countries. The female blackflies that transmit the disease need to feed on human blood for ovulation. Feeding on infected individuals results in ingestion of microfilariae of the parasite which then develop into infective larvae, also called third-stage filarial larvae (L3 larvae), inside the blackfly over the course of 2 weeks. Infection of humans occurs when these blackflies deposit L3 larvae while biting for another blood meal. Bites occur during the day time and multiple bites are required for disease transmission. Humans appear to be the primary host, although the gorilla in the Congo and the spider monkey in Mexico may also be naturally infected [46].

Fig. 18.4 Skin depigmentation in a patient with onchocerciasis

Once in the human host, the larvae migrate in the subcutaneous tissue forming nodules and slowly develop into adult worms over a course of about a year. Adult worms may live for 10–15 years and are usually palpable as firm, nontender nodules especially over the bony prominences of the pelvis, or on the scalp. From these sites, after a prepatent period of 3–18 months, fertilized female worms produce thousands of microfilariae daily (millions during a lifetime). The microfilariae (mfs), which can persist for 6–36 months, migrate to

the subcutaneous and ocular tissues usually without provoking symptoms. In the dermis they are accessible to re-ingestion by blackflies, restarting the cycle. In addition to the skin, mfs can also be detected in the blood, urine and sputum. Most of the skin signs and symptoms of onchocerciasis, including severe pruritus and eye damage, are related to the body's inflammatory response to dying and degenerating mfs.

The clinical features that characterize the disease include itching, commonly occurring over the lower trunk and buttocks, and an eczema-like eruption, which includes lichenification and hyperpigmentation, often called "lizard's skin". Individuals who have had the disease for many years may develop lymphedema and postinflammatory depigmentation, often on the anterior tibial surfaces (a sign called "leopard skin"). The prominent change seen on biopsy of affected skin is dermal fibrosis. In time, destruction of elastic tissue occurs, mediated by proteases from the parasites. These changes eventually lead to marked skin atrophy with redundant folds of skin in the inguinal areas, the so-called hanging groin. Two clinical patterns of reaction are evoked once the process is underway: a generalized form, characterized by widespread itching and dermatitis, and a hyperactive form, in which the skin reaction is often intense yet usually localized. The term "sowda" is reserved for severe hyperactive form that dominates one limb. A resistant form of the disease is also found among individuals living in hyperendemic areas and who remain unaffected despite being chronically exposed to the bites of infected flies. Decreased visual acuity is the most serious complication of the disease. The inflammatory reactions within the eye lead to iridocyclitis, choroiditis, and eventually optic atrophy.

The Role of *Wolbachia* Bacteria

The endosymbiotic *Wolbachia* bacteria, living inside both adult worms and mfs of *O. volvulus*, are essential for growth, development, fertility and survival of the parasite [47]. They are now considered to be an important target of the host's inflammatory response [48, 49]. Neutrophil recruitment around the encysted adult worms (onchocercomas) appears to be related to the presence of the bacteria. In patients treated with doxycycline to eliminate the symbionts, the accumulation of neutrophils adjacent to the adult worms was drastically reduced [50]. Antibiotic treatment with doxycycline has also been found to improve skin lesions in hyperergic forms of the disease, and to interrupt embryogenesis of the female adult worms [51].

Immune Responses

Although early in the course of the disease—in the prepatent phase—inflammatory cells react to protein on the surface of the adult worms, the characteristic cutaneous signs and symptoms of the disease (dermatitis and itching) do not develop until mfs are produced by the gravid female worms. The mfs represent an ongoing source of antigen; up to 3000 are released daily by the adult female worm, beginning about 6–10 months after infection [52]. It is now argued that the predominant portion of the skin reaction in onchocerciasis is a reaction not only to the death and degeneration of the mfs but to their accompanying *Wolbachia* as well.

The intensity and type of host immune response gives rise to diverse clinical manifestations with two polar forms. The first, generalized onchocerciasis, occurs in hyporesponsive individuals having palpable nodules under their skin but no strong pathology despite carrying high mf skin loads, and the second, hyperactive form, is when patients exhibit severe inflammatory response with few worms [53].

Early in the course of the infection a polyclonal B-cell activation occurs with the production of parasite-specific immunoglobulins, including IgM, IgG (both IgG1 and IgG4), and IgE. The reaction to the mfs in the dermis and subcutaneous tissue is initiated by antibodies that attach to the surface of the parasites, along with complement. The immune complexes that are formed attract a variety of inflammatory cells, including neutrophils, eosinophils, and later macrophages. Degranulation of eosinophils appears to play the major role in the death of the mfs, but it is likely that proteases secreted by the larvae also add to the tissue damage. In addition to the effect on B cells, parasite antigens also induce substantial reactions from PBMCs. The initial recognition of these antigens, both the infective larvae themselves and their *Wolbachia* cargo, is mediated by TLRs. TLR4 responds to both the larvae of *O. volvulus* as well as to surface protein of the *Wolbachia,* and initiates a Th2 immune response mediated by IL-4 and IL-5 [54]. In addition, TLR2 also responds to surface protein isolated from *Wolbachia,* which mediates the release of TNF-α, IL-12, and IL-8 from PBMCs [55]. The evolution and final expression of the type of immune reaction that develops (Th1 or Th2) has been attributed to the early presence of specific cytokines; for example, the initial presence of IL12 directs the immune response toward a Th1 reaction, while a rapid induction of IL-4 promotes the generation of a dominant Th2-type response [56].

In some individuals an activation of a subset of $CD4^+$ cells known as T regulatory cells (Tr1) occurs, which produce IL-10 and transforming growth factor (TGF), and some IFN [57].

In the usual generalized, chronic form of the disease, where the microfilarial load in the skin is high (up to 500 microfilaria per milligram of skin), the cutaneous reactions tend to be mild to moderate. In this type of onchocerciasis the cellular reactions are downregulated, with a suppression of Th1 and only a moderate Th2 response [58]. High levels

of IL-10 are produced by $CD4^+$ T-regulatory cells (Tr1), which act to inhibit activation of APCs and thus suppress proinflammatory functions. This type of immune response is thought to protect the host from acute skin damage (yet it may also be of benefit to the parasites by protecting them from some of the host's lethal immune responses) [59]. In hyperreactive forms of the disease where the concentration of mfs is low (less than 10 per mg of skin) and the inflammatory reaction of the skin is severe, a strong Th2 response is seen. It is suggested that, in this form of onchocerciasis, inflammatory cells (eosinophils, neutrophils, and macrophages) all combine to kill mfs, under the direction of T cells and APCs.

Up to now HIV infection has been reported to play only a minor role in onchocerciasis, with no significant association with HIV detected in a large case control study [60]. No differences were noted in the density of mfs [61], although antibody response to the parasite was decreased in HIV-infected individuals, and they tended to lose their reactivity to these antigens over time [62].

Mazzotti Reaction

First described in 1948, Mazzotti reaction is a set of adverse reactions following administration of diethylcarbamazine (DEC) in patients with onchocerciasis. It has also been reported with administration of ivermectin and other antihelminths [63]. It is clinically characterized by intensely pruritic rash with or without systemic symptoms. Severity of the reaction correlates with the degree of microfilarial infestation and could at times be life threatening. A complex mechanism involving eosinophil degranulation and release of other mediators following the death of mf is involved in the pathogenesis. Patch testing using DEC is sometimes used to make a diagnosis of onchocerciasis [64].

Vaccine Development

Efforts to conquer onchocerciasis have been directed largely through the control of vectors and the use of community directed mass drug administration. With increasing treat of drug-resistance *O. volvulus*, there are compelling reasons to believe that vaccines will be the main tools for disease control in the future. Protective immunity against *O. volvulus* has been demonstrated in cattle [65] and mice [66]. In one study, 15 recombinant *O. volvulus* antigens out of the 44 screened using the *O. volvulus*-mouse model were found to be protective [67]. Eight of these antigens were produced and tested under controlled conditions, and only three, namely *Ov*-103, *Ov*-RAL-2 and *Ov*-CPI-2M, were able to repeatedly induce protective immunity [68]. Immunization in mice using DNA encoding of selected parasite genes has also shown promise [69]. A new initiative called The Onchocerciasis Vaccine for Africa (TOVA) is currently pursuing development of an onchocerciasis vaccine and has proposed two potential target product profiles, preventive vaccine for children less than 5 years old and therapeutic vaccine for infected individuals, with a plan to perform proof of concept trial for efficacy (phase two trials) at least for one candidate by 2020 [70].

Schistosomiasis

Schistosomiasis, also called bilharzia, is another neglected tropical infection in which schistosomal cercaria that normally parasitizes birds and mammals, including humans, cause skin disease or establish infection in the veins of the urinary or gastrointestinal tract, and occasionally, other organs. More than 260 million people are affected worldwide mainly in the tropical and subtropical regions [71].

The disease is caused by blood flukes of the family *Schistosomatidae*. Exposure to the parasite results from fecal or urinary contamination of freshwater that contains the intermediate host snails and skin contact to the same water by the definite host. Many eggs remain in the mammalian host causing an inflammatory reaction that results in morbidity. Less than half are released through the urine or feces depending on the infecting species. Each egg then releases a free-living stage of the parasite called miracidium that infects the intermediate host snail. Inside the snail miracidia undergo asexual reproduction giving rise to cercaria which are then released back into the water. Contact with contaminated water by the definite host results in penetration of cercaria through the skin that develop to maturity inside the body. When entering non-compatible hosts, parasites do not reproduce and die at various intervals after infection causing allergic reactions only [72].

During penetration and travel into the human skin cercaria transform to schistosomula causing human cercarial dermatitis (CD) or swimmer's itch, represented by a maculopapular skin eruption associated with intense itching that occurs within few hours to days of exposure. Debilitating pruritus and constitutionals symptoms like diarrhea and fever may also occur based on the intensity of infection. Non-human schistosomes like *Trichbilharzia* are known to induce more severe skin reactions than human schistosomes, i.e. *Schistosoma* [72].

Another distinct skin manifestation of schistosmiasis is seen in Katayama syndrome (KS) or acute schistosomiasis. It is the result of immune-complex mediated response to the immature forms of the parasite and is characterized by extensive urticaria with or without angioedema, wheeze, fever, malaise, hepatosplenomegaly and other gastrointestinal symptoms that starts 2–12 weeks after exposure [73].

The pathognomonic features of skin schistosomiasis due to the adult worm is called cutaneous schistosomal granuloma (CSG) and is due to formation of a distinctive granulomatous reaction as a result of trapped eggs that took aberrant routes through the portosystemic anastomoses to the skin. Lesions are typically located in the periumbilcal region, torso, superior dorsal regions, buttock and genitalia and appear as skin colored papules that could progress to tumoral and ulcerative plaques [74].

Immune Response

Different stages of the parasite, cercaria, schistosomula, adult worms and eggs, produce hundreds of antigenic moieties many of which are capable of stimulating both the humoral and cellular wings of the human immune system.

Cercarial penetration to the skin and transformation to schistosomula is accompanied by shedding of the tail, emptying of penetration glands as well as creation of different parasite surface antigens [75]. Mice experiments with *Trichobiliharzia* cercaria showed immediate edema, thickening of the exposure site and an influx of leucocytes including neutrophils, macrophages, CD4+ lymphocytes and mast cells [76]. Mixed cytokine response (IL-1β, IL-6 and IL-12p40), including abundant IFN-γ, and significant elevations of histamine, IL-4 and IL-10 were observed within 1 h post infection. Death of immature parasites in non-competent hosts is believed to induce a severe immune response. It is generally assumed that during initial infection a Th17 -polarized immune response (elevation of IL-4 and IL-5) develops, while experiments in mice re-infected by the cercaria four times showed a Th2-polarized immune response which might characterize the maculopapular rash in human CD [72].

Acute schistosomiasis, KS, is characterized predominantly by a Th1 immune response with high levels of IFN-γ and IL-5 in the first 5 weeks followed by a Th2 shift with IL-4 and IL-5 and low IFN-γ production [77]. Many patients also have circulating immune complexes [78, 79]. The immune response in KS also has been studied with gene-deficient mice. Mice lacking IL-4 production showed severe disease with rapid cachexia and accelerated egg deposition while IL-13-lacking mice showed sufficient Th2 response and enhanced survival [80].

CSG is the result of granulomatous inflammation both in the papillary and reticular dermis elicited by deposition of schistosomal eggs. This granulomatous inflammation consists of an admixture of lymphocytes intermingled with histiocytes and eosinophils around schistosomal eggs. Once egg deposition starts around 6 weeks after infection, there is a dramatic shift towards a Th-2 type inflammatory response with up regulation of IL-13. However, it is generally believed that CSG is formed with the action of Th-1 (IFN- γ) and Th17 (IL-17) cytokines. One study has shown positive immunoreactivity of IFN-γ (Th1 cytokine) and IL-4 (Th2 cytokine) in infiltrating cells around schistosomal eggs in 90 % and 10 % of subjects, respectively [81].

HIV Co-infection

The chronic immune activation induced by helminthic infections like schistosomiasis is known to hasten HIV progression by reducing the cytotoxic effects of CD-8+ lymphocytes. Higher viral loads and accelerated decline in CD4 count has been noticed in untreated schistosomiasis patients with HIV. Untreated schistosomiasis may also be a major contributor for immunologic failure and poorer CD4 gain upon initiation of antiretroviral therapy [82]. Presence of genital schistosomiasis is also known to increase HIV acquisition and susceptibility. It is known that *S. mansoni*-infected individuals displayed higher densities of the HIV chemokine receptors CCR5 and CXCR4 on their CD4+ T cells and monocytes [83]. One study in rural Tanzania showed markedly higher prevalence of HIV among women with schistosomiasis than among women without schistosome infection [84].

Vaccine Development

The critical role that antibodies play in schistosomiasis resistance has been well established in animal models. Schistosoma candidate vaccines are being developed for control of schistosmiasis and are in the process of evaluation [85]. Among many, a recombinant *S. haematobium* 28-kD glutathione S-transferase (Sh28 GST) protein, which is produced in *Saccharomyces cerevisiae* and formulated with alum, is the only vaccine currently in a phase III clinical trial [86]. Numerous novel potential vaccine candidates having a cross-reactivity among *S. hematobium, S. japonicum and S. mansoni* have recently been identified in *S. hematobium*-infected people and monkeys who acquire drug-induced resistance after praziquantel treatment [87]. However, whether vaccination is superior to other means of disease control like mass drug administration and control of the intermediate host remains debatable.

Conclusion

The immunology of cutaneous parasitic infections can be illustrated by leishmaniasis, onchocerciasis, and schistosomiasis. Cell-mediated immunoregulation plays the dominant role in resolving *Leishmania* infections. Most promastigotes deposited in the dermis are opsonized by serum complement and killed by complement-mediated

lysis. The remaining promastigotes are phagocytosed via complement receptors on the macrophage membrane, which bind to gp63 and lipophosphoglycan. Macrophages release chemokines, which attract NK cells, dendritic cells, and more macrophages. *Wolbachia* bacteria living inside *Onchocerca volvulus* are the essential target of the host's inflammatory response in onchocerciasis. The initial reaction in cercarial dermatitis is marked Th-1 response. Understanding these components of the immune response to parasitic infections will potentially lead to better therapies and possibly to vaccines for prevention.

Questions

1. Which human cell type is most responsible for presentation of leishmania antigens to T cells within lymph nodes?
   A. Macrophages
   B. Plasmacytoid dendritic cells
   C. Neutrophils
   D. Langerhans cells

Correct Answer: (D) Langerhans cells

2. Which human cells has been shown to engulf most of the leishmania promastigotes following the bite of an infected sand fly?
   A. Keratinocytes
   B. Macrophages
   C. Mast cells
   D. Langerhans cells

Correct Answer: (B) Macrophages

3. In what disorder may viable leishmania parasites be demonstrated in patients with a history of "resolved" cutaneous leishmaniasis?
   A. Psoriasis
   B. Inflammatory bowel disease
   C. HIV infection
   D. Liver transplantation

Correct Answer: (C) HIV infection

Fungal Infections

19

Jacqueline Guidry, Ramya Kollipara, Christopher Downing, Michael Lee, and Stephen K. Tyring

Abstract

Fungi comprise many species that are associated with a wide spectrum of diseases in humans. The clinical relevance of fungal diseases has increased markedly, mainly because of an increasing population of immunocompromised hosts, including individuals infected with HIV, transplant recipients, and patients with cancer. Fungal infections are classified according to the primary site of infection, as superficial, cutaneous, subcutaneous, and deep or systemic mycosis. Superficial mycosis is limited to the stratum corneum and elicits no or slight inflammation. Cutaneous mycosis involves the integument and its appendages, including hair and nail. Infection of the skin, which is caused by the fungal organisms or its products, may involve stratum corneum or deep layers of the epidermis. Subcutaneous mycosis involves the epidermis and subcutaneous tissues. Subcutaneous mycosis usually follows traumatic inoculation of fungal organisms. The inflammatory response that develops in the subcutaneous tissues usually involves the epidermis. Deep or systemic mycosis usually involves organs such as lung, central nervous system, bones, and abdominal viscera. The portal of entry in deep mycosis is the respiratory tract, gastrointestinal tract, and blood vessels.

Key Points

- The clinical relevance of fungal diseases has increased due to increased populations of immunocompromised patients
- Fungal infections are classified according to the site of the primary infection: superficial, cutaneous, subcutaneous, and deep or systemic
- Dimorphic fungi assume both yeast and hyphal states based on environmental conditions and the hosts' immune response
- Certain fungi can synthesize capsular components, which can affect host immune responses
- The innate response to fungi serves two purposes: a direct antifungal effector activity, and activation and induction of the specific adaptive immune responses
- Understanding the immune responses to fungal infections has led to better diagnostic tests and therapeutic interventions for fungal diseases.

Fungi comprise many species that are associated with a wide spectrum of diseases in humans. The clinical relevance of fungal diseases has increased markedly, mainly because of an increasing population of immunocompromised hosts, including individuals infected with HIV, transplant recipients, and patients with cancer. Fungal infections are classified according to the primary site of infection, as superficial, cutaneous, subcutaneous, and deep or systemic mycosis. Superficial mycosis is limited to the stratum corneum and elicits no or slight inflammation. Cutaneous mycosis involves the integument and its appendages, including hair and nail. Infection of the skin, which is caused by the fungal organisms or its products, may involve stratum corneum or deep layers of the epidermis. Subcutaneous mycosis involves the epidermis and subcutaneous tissues. Subcutaneous mycosis usually follows traumatic inoculation of fungal organisms. The inflammatory response that develops in the subcutaneous tissues usually involves the epidermis. Deep or systemic mycosis usually involves organs such as lung, central nervous system, bones, and abdominal viscera. The portal of entry in deep mycosis is the respiratory tract, gastrointestinal tract, and blood vessels.

Fungi that cause cutaneous, subcutaneous, or disseminated infection with skin involvement exist in a range of morphologic forms that include yeasts and molds. Yeasts (e.g., Malassezia) grow as unicellular round or oval-shaped organisms, whereas molds (e.g., dermatophytes) form long tubular structures termed hyphae that extend into a branch-like network known as a mycelium. Dimorphic fungi (e.g., *Candida albicans, Histoplasma capsulatum, Coccidioides immitis*, *Blastomyces dermatitis*, and *Sporothrix schenckii*) assume both yeast or spherules and hyphal states of growth based on environmental conditions and interactions with the mammalian immune system. Yeasts and molds are bound by a cell wall composed of polysaccharide polymers (chitin, mannans, and glucans) derived from biosynthetic pathways absent in mammalian cells [1, 1a, 2], which inhibits complement-mediated damage to the fungal cell membrane [3]. In addition, certain fungi can synthesize capsular components, melanins, and secondary metabolites that include toxins, for example, gliotoxin and aflatoxin, many of which can affect host immune responses [4–7].

This chapter discusses the general innate and acquired immune responses against fungi, particularly the cellular and molecular pathways of immune defense mechanisms that have significantly contributed to our present understanding of the host response to fungi and have provided a sound framework for development of effective strategies of immunotherapy against some fungal infections. This chapter also discusses host defenses and specific immune responses against certain fungal pathogens causing cutaneous, subcutaneous, and deep mycosis that begins with either cutaneous or subcutaneous diseases and then disseminates to become a systemic disease that involves also the skin.

Innate Immune Responses to Fungal Infection

The host defense mechanisms against fungi are numerous, and range from nonspecific, germline-encoded immunity that presents early in the evolution of microorganisms, to highly specialized and specific adaptive mechanisms that are induced during infection and disease. The relative importance of specific innate and adaptive defense mechanisms differs, depending on the organism and anatomic site of infection (skin, mucosal sites, or disseminated infection). Additionally, the morphotype of the fungal pathogen (yeast or hyphae) determines the type of host immune response. For example, yeasts and spores are often effectively phagocytosed, while the larger size of hyphae prevents effective ingestion. Pathogenic fungi have also developed mechanisms to subvert host defenses, which allow some intracellular fungi to survive within phagocytes, avoid fungal killing, and then disseminate throughout the host.

The innate response to fungi serves two main purposes: (1) a direct antifungal effector activity by mediating nonspecific elimination of pathogens through either a phagocytic process and intracellular killing of internalized pathogens or through the secretion of microbicidal compounds against undigested fungal molecules; and (2) activation and induction of the specific adaptive immune responses via the production of proinflammatory mediators, including chemokines and cytokines, providing

co-stimulatory signals to naive T cells, as well as antigen uptake and presentation to CD4 and CD8 T cells [8]. In addition to the above inducible functions of innate response, the constitutive mechanisms of innate defense that are present in the skin include the barrier function of body surfaces. Figure 19.1 illustrates the link between innate and acquired (cellular and humoral) immune responses against fungal infections of the skin.

Host innate defenses against fungi are mediated by professional phagocytes, including neutrophils, mononuclear leukocytes (monocytes and macrophages), and dendritic cells (DCs), natural killer (NK) cells, and nonhematopoietic cells, such as keratinocytes and epithelial and endothelial cells. The first step in the innate immunity involves fungal recognition and uptake by germline-encoded pattern recognition receptors (PRRs) expressed on the surfaces of several innate immune cells [8–11].

Figure 19.2 illustrates the different PRRs expressed on phagocytic cells such as macrophages and the downstream effector functions resulting from interaction of fungal antigens with these receptors.

The most important classes of PRR are the Toll-like receptors (TLRs) [10, 11], dectin-1 [12], the lectin-like receptors [13, 14], Fc receptors [15], complement receptors, the mannose receptor [16], and integrins [17].

The microbial ligands of these receptors are called pathogen-associated molecular patterns (PAMPs). Fungal structures such as β-1,3/β-1,6 glucans [17], glucuronoxylomannan, phospholipomannan, and galactomannan function as ligands for TLR2, TLR4, and TLR6 [18, 19]. The signaling pathway for mammalian TLR after ligation of PAMPs involves interaction with the adaptor molecule MYD88 (myeloid differentiation primary response gene 88) located in the cytosol [19, 20]. The activation of the MYD88 adaptor culminates in the activation and nuclear translocation of nuclear factor kB (NF-kB), which leads to activation of several cytokine and chemokine genes. Recognition of pathogens by TLR in a Myd88-dependent, and sometimes in a Myd88-independent, manner leads to release of proinflammatory cytokines, chemokines, activation of antibacterial mechanisms, and enhancing the T-cell priming ability of professional antigen presenting cells (APCs) such as dendritic cells. Compared to individual TLRs, Myd88−/− mice had higher levels of fungal growth than control animals [19, 21]. The more severe phenotype of Myd88−/− mice compared with mice deficient in individual TLRs probably reflects the broad function of Myd88 as an adaptor for multiple TLR-dependent responses.

Toll-like receptors discriminate between distinct fungal morphotypes. For example, TLR4 and CD14 expressed on human monocytes appear to recognize Aspergillus hyphae but not Candida hyphae [17, 22].

Similarly, the production of pro-inflammatory and Th1 cytokines such as tumor necrosis factor-α (TNF-α) and interferon-γ (IFN-γ) by macrophages in response to *C. albicans* phospholipomannan expressed on yeast cells depends on TLR2 and TLR4 signaling, whereas hyphal cells trigger these cytokines in a TLR2-dependent manner only [19, 22–24].

In vivo, the role of TLR2 in systemic fungal infection such as systemic candidiasis is less clear: one study reported that TLR2−/− mice are more sensitive to primary infection than control mice [25], while another study reported no difference between TLR2−/− and TLR2+/+ mice, regardless of whether the animals were inoculated with yeast or hyphal forms [26, 27]. TLR2− mediated recognition of Candida has also been shown to expedite differentiation of hematopoietic stem and progenitor cells into macrophages, which likely helps boost the body's innate immune response [28]. In addition to their function in fungal recognition, uptake, and production of pro-inflammatory cytokines, signaling through individual TLR signaling can determine the type of acquired immune responses against fungi. TLR2 ligation by fungal zymosan, and possibly β-glucan, leads to the prevalent production of anti-inflammatory cytokines such as interleukin-10 (IL-10), which can suppress macrophage microbicidal functions and also drive the induction of Th2 response [26, 27, 29, 30].

Lectin receptors are other PRRs on phagocytes that not only play a role in fungal recognition but also mediate distinct downstream intracellular events related to clearance of fungi. Recognition of fungal PAMPs by lectin receptors induces rapid and broad host defense responses such as opsonization, activation of complement, activation of coagulation cascades, phagocytosis, inflammation, and direct microbial killing [31, 32].

Among several lectin-like families, galectin-3 binds to β-1,2-linked oligomannan, an uncommon PAMP present on the surface of *C. albicans* but absent on *Saccharomyces cerevisiae* [33, 34]. The binding of galectin-3 to yeast cell walls of *C. albicans* is inhibited by C. albicans mannans but not by *S. cerevisiae* mannans. More importantly, binding of galectin-3 results in opsonization of Candida expressing different combinations of β-1,2-linked oligomannosides and death of yeast cells [34] and as such gal3−/− mice are more susceptible to infection, have larger fungal burden and die faster than wild type controls [35]. In addition to its direct effects on innate immunity, galectin-3 also plays an important role modulating the Th1 versus Th2 response in infected tissues [36].

Other fungal receptors such as complement receptors (CRs), mannose receptors (MRs), and dectin-1 receptors mediate fungal internalization following binding of various fungal ligands such as complement-associated products, mannosylefucosyl glycoconjugate ligands, and β-glucans, respectively. Internalization through MRs does not lead to effective clearance of fungi in the absence of opsonins. However, MRs expressed by DCs activate specific programs that are relevant to the development of antifungal acquired specific immune

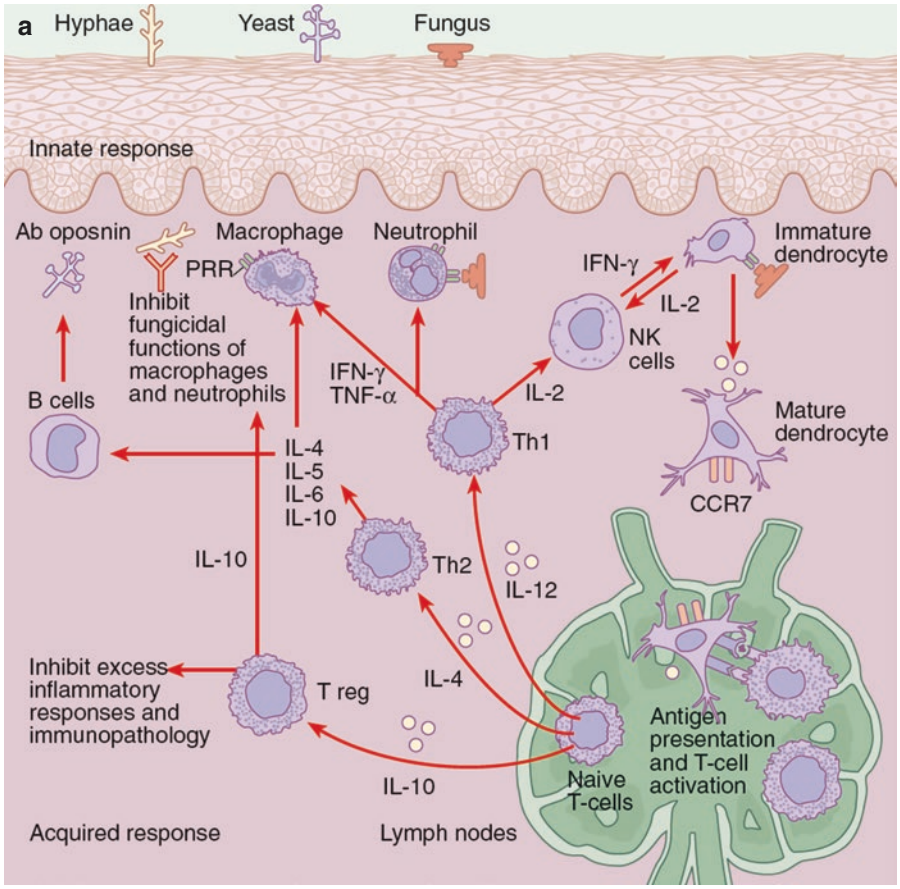

Fig. 19.1 Possible pathways for immunologic responses stimulated by fungi. (**a**) Most fungi are detected and destroyed within hours by innate nonspecific defense mechanisms mediated by phagocytes such as macrophages, neutrophils, immature dendritic cells, and opsonins (antibodies, Ab) through the involvement of distinct pattern-recognition receptors (PRRs). Fungal organisms on the skin surface also release antigens (Ag) that penetrate the skin and are captured by an antigen-presenting cell (APC) such as dendritic cells (DCs). Cross-linking of PRR on the surface of immature DCs by fungal antigen lead to their maturation. In addition, production of inflammatory cytokines such as IFN-γ and TNF-α by other innate cells such as NK cells further enhance activation of microbicidal functions of phagocytic cells as well as maturation of DCs. The DCs sampling fungal antigens from the skin and migrating to secondary lymphoid organs process and present antigens through class I or class II major histocompatibility complex (MHC) molecules to antigen-specific naive T cells endowed with the capacity to recognize the peptide epitopes through specific T-cell receptors (TCRs). This process lead to activation of different antigen-specific T helper (Th) effector cells, regulatory T (Treg) cells and B cells that specifically target the pathogen and induce memory cells. Differentiation of naive CD4+ Th cells in the peripheral lymphoid organs into Th1, Th2, or Treg depend on several factors, among which is the cytokine environment stimulated by different fungal morphotypes. Thus, the production of interleukin-12 (IL-12) by DCs leads to the outgrowth of T-helper-1 (Th1) cells that produce IFN-γ, TNF-α, or both. IFN-γ and TNF-α are required for further activation of fungistatic and fungicidal activities by phagocytes that results in clearance of infection with most, if not all, of these fungal pathogens. The induction of IL-4 (and failure to produce IL-12) by DCs leads to a Th2 response, which blunts the generation of protective immunity. (**b**) Progressive disease in immunodeficient or susceptible hosts is associated with a shift in the balance between Th1 and Th2, toward the Th2 response. The latter is characterized by upregulation in IL-4, IL-5 and IL-10, an increase in tissue eosinophils, antibody isotype switch and production of antigen-specific antibodies including IgG and IgE. The IgE antibodies bind to mast cells (MCs) and upon subsequent encounter with allergens, trigger degranulation leading to inflammation and clinical features of type I hypersensitivity reactions. IL-10 production by mast cells suppresses cell-mediated immune responses in certain cutaneous fungal diseases. Neutralization of IL-4, IL-5, and IL-10 in vivo can sometimes restore protective immunity. Thus, the activation of the appropriate Th-cell subset is critical in the generation of a successful immune response to fungi. Although IL-4 and IL-10 cytokines block the expression of a protective response against fungi, the elaboration of at least some Th2 cytokines also helps to balance the immune response. Finally, induction of T-regulatory (Treg) cells mediated by IL-10 might serve to dampen the excessive inflammatory reactions through cell contact or secretion of immune suppressive cytokines such as IL-10 (**b**)

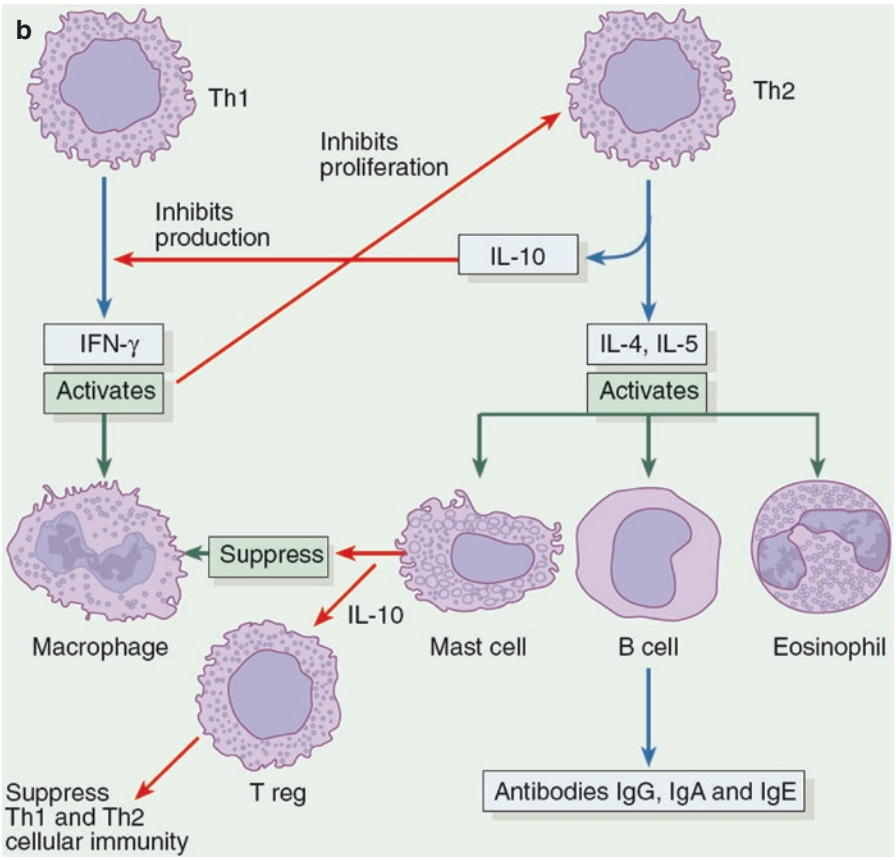

Fig. 28.1 (continued)

responses as will be discussed later. Ligation of CR3 (also known as CD11b/CD18) is one of the most efficient means of engulfing opsonized fungi, but it also has broad recognition capacity for diverse fungal ligands. Interestingly, yeasts such as *Histoplasma capsulatum* establish intracellular fungal parasitism within macrophages when they enter the cells through the CR3. In contrast, a concomitant ligation of both CR3 and FcγIIIR on macrophages triggers an effective phagocytosis and respiratory burst that interferes with fungal infectivity and mediates elimination of fungal pathogens [37, 38].

Neutrophils, macrophages, and monocytes constitute the major cellular effectors of innate immunity against fungal pathogens [39–42]. Following phagocytosis, fungi are killed by intracellular microbicidal effector molecules produced by macrophages and neutrophils, including oxygen-dependent (i.e., nitric oxide, reactive oxygen intermediates, reactive nitrogen intermediates, and peroxynitrite) and oxygen-independent (i.e., release of cationic proteins, lysozyme, and antimicrobial peptides such as defensins, arachidonic acid, myeloperoxidase, and iron sequestration) [42–45]. Enzymes such as the reduced nicotinamide adenine dinucleotide phosphate (NADPH) oxidase and inducible nitric oxide synthase initiate the oxygen-dependent pathways known as respiratory burst that produces toxic reactive oxygen intermediates (ROIs) [43–45]. In retribution, fungi have evolved strategies to selectively inhibit the respiratory burst through the production of specific scavengers of oxidative killing by phagocytes, such as catalase, mannitol and melanin.

Patients with inherited X-linked chronic granulomatous disease, resulting from a deficiency in oxidant formation due to mutations in any of the four genes that encode the subunits of NADPH oxidase, have increased susceptibility to fungal infection, mainly aspergillosis [45]. These patients could be treated effectively with IFN-γ, which increases the non-oxidative as well as the oxidative intracellular microbicidal mechanisms mediated by phagocytic cells such as macrophages and neutrophils. The involvement of neutrophils or macrophages in host defense against fungi depends on the morphotype of the fungi causing infection. For example, neutrophils play a predominant role in phagocytosis of filamentous fungi [40–42, 45], while macrophages play a predominant role in host defense against fungal yeast [39, 46]. In addition to the ability of macrophages to ingest organisms that have been opsonized with antibody, or complement, they are also able to phagocytose unopsonized fungal elements through recognition receptors such as the integrins. Although the main contribution of neutrophils and macrophages resides in their phagocytic and microbicidal functions, they can produce cytokines and chemokines that can modulate the protective immune response. Furthermore, macrophages function also as APCs that activate CD4+ and CD8+ T cells through presentation of fungus-derived peptides in the

Fig. 19.2 Recognition of fungal ligands by different pattern recognition receptors (PRRs) expressed on the surface of macrophages: the role of Toll-like receptors (TLRs) and other receptors as activators of innate and adaptive immunity to fungi. (**a**) Innate cells such as macrophages, monocytes, and dendritic cells express several pattern recognition receptors (PRRs) that recognize various fungal ligands, promote fungal internalization, activate intracellular fungicidal effector mechanisms, and play a role in the induction of the acquired immune response against fungi. Concomitant interaction of antibody and complement-coated fungal cells with Fc receptors (FcRs) and complement receptors (CRs) on host phagocytic cell membranes results in prompt ingestion of the fungal cell, which can lead to the death of the ingested fungal cell. Furthermore, phagocytic cells express several TLRs that bind to specific fungal ligands referred to as pathogen-associated molecular patterns (PAMPs). The signaling pathway for mammalian TLRs after ligation of PAMPs involves interaction with the adaptor molecule MyD88 (myeloid differentiation primary response gene 88) located in the cytosol. The activation of MyD88 results in activation and translocation of nuclear transcription factor $\chi B\,(NF{-}\chi B)\,.\,NF{-}\chi B$ controls the activation of several downstream cytokines and chemokine genes; therefore, its activation is usually linked to production of proinflammatory and antiinflammatory cytokines and chemokines. Although all TLRs signal through MyD88, ligation of certain TLR can result in unique effector functions. For example, TLR2 stimulation leads to production of IL-10, which promotes the expansion and function of immunoregulatory T cells. On the other hand, stimulation of TLR4 or TLR9 leads to the activation of antifungal effector functions in phagocytes, such as respiratory burst and degranulation, and production of interleukin-12p70 (IL-12p70) by dendritic cells. This leads to inflammatory and protective antifungal T-helper-1 (Th1)-cell responses. However, the differential TLR responses could also function by unidentified MyD88–independent pathways (**b**)

context of major histocompatibility complex (MHC) class II and I, respectively as well as providing co-stimulatory signals as illustrated in Fig. 19.3. Nevertheless, for some intracellular fungal pathogens, such as *H. capsulatum*, their intracellular location protects them from host defenses, and these organisms thrive within macrophages [37, 38].

To overcome the fungal immune evasion mechanism within phagocytic cells, other innate immune cells such as NK [46–48], NKT, and γδ T cells [46, 49, 50] play a pivotal role in host defense against fungi. These cells mediate their antifungal response through different mechanisms that include the following: (1) early production of cytokines such as IFN-γ and TNF-α that are important for full activation of macrophage phagocytic and antimicrobial effector functions; (2) direct cytotoxic killing of pathogens or growth inhibition; (3) activation of dendritic cells through either cytokines or cell–cell contact, which in turn mediate activation and differentiation of specific CD4+ and CD8+ T cells as described later. Evidence that supports the protective role of NK, NKT, and γδ T cells in immunity against fungi stems from studies conducted in knockout mice that lack a particular cell subset. These mice are susceptible to various fungal infections, mainly *C. albicans* [48, 49].

Langerhans cells (LCs) and immature dermal DCs are some of the first cells to encounter fungi and play pivotal roles in induction of acquired responses against fungi as well as restriction of fungal growth [51–53]. Immature DCs constantly monitor the epidermal microenvironment by taking up antigen and processing it into fragments that can be recognized by cells of the adaptive immune response. However, receptors on the surface of DCs may be selective for only certain species, or for certain forms within that species, and may explain in part the ability of fungi to survive within the host. Compared to yeasts, hyphae cause DCs to produce cytokines leading to local induction of T regulatory cells (Treg), which serve to limit the immune response [54].

Because of their unique migratory ability, DCs can transport fungal antigen from the epidermis or dermis to regional lymph nodes, where they initiate specific immune responses. Fungal infection provides danger signals, leading to a local production of proinflammatory cytokines that induce local DC maturation [55, 56]. Maturation of DCs is associated with a selective change in chemokine receptor

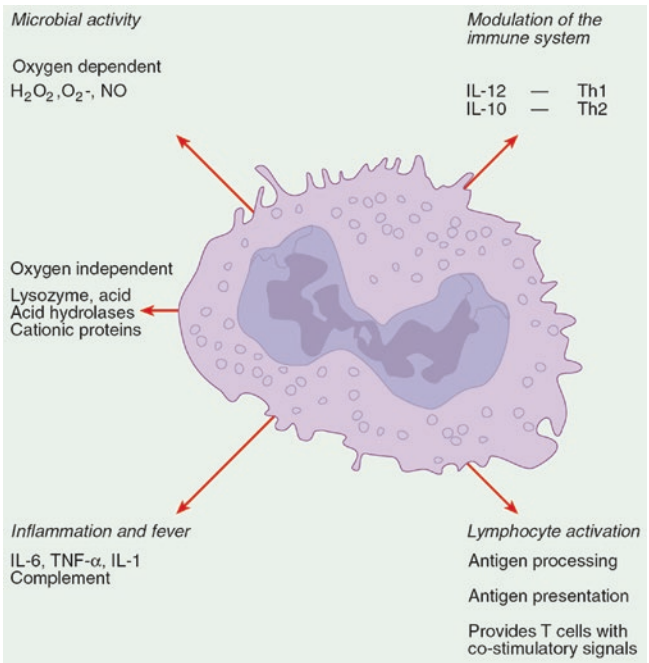

Fig. 19.3 Different functions of macrophages in innate and acquired immune responses against fungal infection. Macrophages play a pivotal role in innate and acquired immune responses against fungal pathogens. Local activation of macrophages at early stages of infection by fungal antigens and later by IFN-γ and TNF-α produced by NK cells or effector CD4+ Th1 cells results in (1) increased oxygen–dependent and independent fungicidal activities; (2) production of proinflammatory cytokines and chemokines that enhance migration of effector immune cells to the skin as well as play a role in activation of T cells. In addition, macrophages can also function as professional antigen presenting cells (APC) that process fungal antigens and present fungus-derived peptides in the context of MHC class II and I to CD4+ and CD8+ T cells, respectively

profile [57–65]. For example, immature DCs express a number of chemokine receptors for inducible chemokines, such as IL-8 (CXCL8), RANTES (regulated on activation, normal T-cell expressed and secreted; CCL5), macrophage inflammatory protein 1α (MIP-1α; CCL3), or monocyte chemoattractant protein 3 (MCP-3; CCL7), by which immature DCs are attracted to the site of inflammation (i.e., skin) [61–63].

Following maturation, DCs downregulate these receptors, which may allow them to leave the inflammatory site (i.e., the site with the highest chemokine concentration). At the same time, maturing DCs upregulate receptors for constitutively expressed chemokines such as the CXC chemokine receptor 4 and CCR7 [62, 63]. Interestingly, the CCR7 ligand secondary lymphoid tissue chemokine (SLC; CCL21) is constitutively expressed by stromal cells in T-cell zones of lymph nodes and by lymphatic endothelial cells in the dermis [61–63]. Thus constitutive expression of SLC by lymphatic endothelium seems to provide the first chemotactic gradient for activated CCR7 positive DCs, leading to a selective recruitment of DCs from the epidermis to the afferent lymphatics [63–65]. Once they enter the lymphatics, they are likely to be transported passively with the lymph to the subcapsular region, where they then encounter an additional chemotactic gradient of SLC that directs their migration into the paracortical T-cell zone of the lymph node where they activate T cells specific for the invading fungal pathogen. In the draining lymph nodes, these DC-capturing antigens initiate T-cell immune responses by virtue of their abilities to present fungal antigens to T cells, provide lymphocytes co-stimulatory molecules, and secrete cytokines. The DCs use distinct receptors to recognize each form of a particular fungus, thereby activating different signaling pathways with distinct functional consequences [55, 65–67].

Finally, the noncellular effectors of innate immunity comprise complement and natural antibodies [68–71]. As described before, these molecules mediate opsonization and therefore promote the ingestion of fungi by phagocytes. However, the fate of opsonized fungi can differ from that of unopsonized organisms, because in phagocytes, opsonized fungi may traffic through a different pathway than do the unopsonized organisms [37, 38].

Adaptive Immunity

For many fungal pathogens, the effective immune response to invasion is a cell-mediated immune response. The role of CD4+ T lymphocytes in protection against fungal infections is underscored by the susceptibility of patients with acquired immunodeficiency syndrome (AIDS) caused by HIV to fungal infections caused by *C. albicans, H. capsulatum, Cryptococcus neoformans*, and *Aspergillus fumigatus*. For all of the pathogenic fungi, a T-helper-1 (Th1) response characterized by production of IL-2 and IFN-γ is the dominant adaptive protective response. The production of IL-12 by DCs leads to expansion and increased number of Th1 cells that produce IFN-γ or TNFα [39, 56, 57, 72, 73]. Interestingly, IL-12 secretion seems to be dependent on the morphologic form of the fungi where the yeast form of *C. albicans* stimulates IL-12 production, while the hyphal form inhibits such production [67, 73]. Interferon-γ production by Th1 cells is essential for optimal activation of phagocytes (e.g., macrophages, neutrophils, and immature DCs) at sites of infection and enhances their fungicidal effector functions [39, 66]. Therefore, deficiency of this cytokine or Th1 response might predispose patients to overwhelming fungal infections, and also favor fungal persistence. On the other hand, the Th2 response characterized by production of Th2 cytokines (IL-4, IL-13, IL-5, and IL-10) is often associated with a subversion of the host response to fungi. Increases in the Th2 cytokines are commonly observed in progressive disease, and neutralizing their activity restores protective immunity [73–77].

The role of Th1/Th2 paradigm in outcome of fungal disease is exemplified in skin infection with *Paracoccidioides brasiliensis* (PCM), which stimulates the formation of granulomatous lesions in the skin [77, 78]. The presence of well-formed granulomas and local Th1 responses in the skin of PCM patients is associated with mild disease, while the presence of poorly formed granulomas and local Th2 responses is associated with progressive and severe disease. These observations suggest that well-organized granulomas and cutaneous Th1 response reflect a better cellular immune response, while the presence of Th2 cells expressing Th2 cytokine such as IL-4 and IL-5 indicate an ineffective response in PCM skin lesions.

More recently, Th17, a distinct CD4+ T cell outside the family of Th1 and Th2 cells, has been discovered and like Th1 cells can confer a protective effect in fungal infections [79]. In the same manner that different fungal pathogens can induce a Th1 versus Th2 immune response, certain fungal PAMPs predominantly activate a Th17 immune response. Thus far, the understanding of Th17 activation pathways relies on the same signaling pathways (e.g. TLR, dectin-1), though further research may elucidate receptors unique to Th17 development [80]. If not regulated, Th17 cells can yield a deleterious effect [54, 80].

Compared to CD4+ T cells, the role of CD8+ T cells during fungal infection has not been defined as clearly [81]. CD8+ T cells mediate protection against fungal infection mainly via the production of IFN-γ. However; the role of CD8+ T lymphocytes in mediating cytotoxic lysis of fungus-infected target cells is not well delineated [82].

Although CD8+ T cell activity against filamentous fungi such as *A. fumigatus* has not been demonstrated in mice, the expansion of cytotoxic, class I–restricted, *A. fumigatus*–specific CD8+ T cell clones from human peripheral blood suggests that CD8+ T cells might contribute to cell-mediated defense [82]. Interestingly, unlike infection with bacteria and viruses, the priming of fungus-specific CD8+ T cells does not appear to require CD4+ T-cell help; in fact, CD8 T-cell responses are enhanced in CD4-knockout mice. In the absence of CD4+ T cells, CD8+ T cells can protect mice from *H. capsulatum* infections by secretion of IFN-γ [83–85].

Although Th1-biased responses to fungal infections are protective, Th2-biased responses are deleterious; an excess or unregulated Th1 response may also generate unnecessary tissue damage. The Th1 response can be downregulated by simultaneous elaboration of Th2 cytokines or suppression of Th1 and Th2 responses that usually are associated with either chronic fungal infection or overwhelming infection, respectively. Thus, the induction of regulatory mechanisms in immunity to fungi is pivotal as they ensure that under physiologic conditions, an effective protective antifungal immunity is generated while avoiding immune pathology. One important immunoregulatory cytokine is IL-10, which is a potent immunosuppressive cytokine, produced in a non–antigen-specific manner by innate cells such as macrophages and DCs or in an antigen (Ag)-specific manner by regulatory CD4+ T cells [86, 87].

Interleukin-10 acts by impairing (1) the antifungal effector functions of phagocytes; (2) the secretion of proinflammatory cytokines such as TNF-α, IL-1, and IL-6; and (3) the production of Th1-promoting cytokines such as IL-12, IFN-γ, and IL-23 [86–89].

The IL-10-mediated suppressive functions would result in defective protective antifungal cell-mediated immunity. Production of IL-10 at early stages of infection suppresses immune responses and enhances susceptibility to fungal infection.

Histopathologic and double immunohistochemical examination of skin lesions from patients with severe PCM infection revealed an increased number of mast cells expressing IL-10 [90, 91]. Early production of IL-10 by mast cells, as part of the innate system, could contribute to an ineffective response against fungal antigens. It is of interest that IL-10 expressing mast cells were detected only in skin lesions characterized by loose granulomas and local Th2 response, but not in lesions that are characterized by compact granulomas and Th1 response. Other studies have shown that patients treated with anti–TNF-α antibodies, which resulted in increases in IL-10 production are susceptible to fungal pneumonia. On the other hand, production of IL-10 at later stages of infection by CD4 T regulatory cells is beneficial by contributing to resolution of excessive inflammatory responses, thus avoiding immune-mediated tissue damage [88–92].

Role of Antibodies in Protective Immunity Against Fungi

Nearly all fungi elicit an antibody response; however, the role of these antibodies in pathogenesis or protective immunity is not completely clear. Initially, the presence of specific antibodies in patients with progressive fungal infections and the lack of increased susceptibility to fungal infections in patients with antibody deficiencies argued against a protective role. However, studies involving opportunistic fungal diseases, mainly candidiasis and aspergillosis, provided evidence that supports a role for antibodies in protective immunity against fungal diseases [96–99]. More recent evidence suggests that the role of fungal antibodies is dependent on the specificity and isotype, which can yield three distinct host responses: protective, non-protective or indifferent, and disease-enhancing [3]. Possible targets for protective antibodies included fungal cell wall polysaccharides of Candida and Aspergillus species, heat shock protein [94], histone-like proteins, and mannoprotein in *C. albicans* [96–100].

Recently, another fungal cell-wall polysaccharide, β-glucan, has been identified as a possible target for the induction of protective antibodies [101]. The conserved structure suggested that β-1,3-glucan could be part of a universal antifungal vaccine. In the light of known inverse relationship between Th1 and Th2 cytokines and immunoregulation of the Th1 and Th2 responses, a role for antibodies in defense against fungal disease might seem to be in conflict with the underlying Th1-directed response that is the most widely accepted explanation for host-acquired specific immunity against fungi. However, some studies show that Th2-derived antibodies have a protective effect by augmenting cell-mediated immunity.

Antibodies can function as opsonins, promoting fungal ingestion and even killing by phagocytes, and several antibodies are directly fungicidal [102–104]. These kinds of activities are complementary, rather than exclusive, to cell-mediated mechanisms. The central importance of granulocytes and macrophages in innate defense against opportunistic fungal pathogens, and of activated neutrophils and macrophages against fungi in general, is consistent with an expectation that opsonic antibodies facilitate host defense. Antifungal antibodies can contribute to the activation of the classic complement system and antibody mediated cytotoxicity by NK cells [105, 106] and can change the gene expression making the fungus more vulnerable to antifungal therapy [3].

Th1-derived antibodies are usually of immunoglobulin G2 (IgG2) isotype, which are excellent opsonins that promote fungal ingestion and even killing by phagocytes. In contrast, the association of antibodies with nonprotective responses or progressive fungal diseases could be due to the possibility that these antibodies are of Th2 isotype (usually IgG1), which are produced by antigen-specific B cells interacting with antigen specific CD4+ Th2 cells producing Th2 cytokines such as IL-4 or IL-10. In that case, Th2-derived antibodies are associated with a Th2 response that causes suppression of protective Th1 and cell-mediated immunity [103, 107].

Cutaneous Fungal Diseases

Cutaneous Candidiasis

Clinical Manifestations and Pathogenesis of Cutaneous Candidiasis

Cutaneous candidiasis is an infection of the skin that is caused by the yeast *C. albicans* and can be either acute or chronic in nature. Cases of cutaneous candidiasis caused by other Candida species such as *C. parapsilosis* or *C. tropicalis* are sometimes seen, but these are rare. *Candida albicans* is part of the normal flora of the gastrointestinal tract rather than of the skin, although it can be found on the skin [108–110]. This organism can grow as either yeast cells or filamentous forms, with mixtures of the two phases generally seen in tissue infections. Acute cutaneous candidiasis may present as lesions with intense erythema, edema, creamy exudate, and satellite pustules within folds of the skin. Other infections may be more chronic, as in the feet, where there can be a thick, white layer of infected stratum corneum overlying the epidermis of the interdigital spaces. Candida paronychia is marked by infections of the periungual skin and the nail itself, resulting in the typical swelling and redness of this type of candida infection. The virulence of *C. albicans* has been attributed to various causes, including its ability to grow at particular temperatures, its ability to produce filamentous forms, its adherence capabilities, and the activity of different enzymes. In some cases superficial *C. albicans* infections may be particularly severe and refractory to treatment, producing the uncommon disorder known as chronic mucocutaneous candidiasis (CMC) [111–113], which consists of persistent and recurrent infections of the mucous membranes, skin, and nails. Oral thrush and Candida vaginitis are fairly common in patients with CMC. There is often infection of the esophagus, although further extension into the viscera is unusual. The typical skin lesions are generally red, raised, and hyperkeratotic but usually are not painful. Epidermal neutrophilic microabscesses, which are common in acute cutaneous candidiasis, are rare in the lesions of CMC. Nail involvement can be severe in this condition, producing marked thickening, distortion, and fragmentation of the nails, with chronic swelling of the distal phalanx.

Immune Responses and Host Defenses Against Candida

The initial events in stimulation of both innate and acquired immune responses against cutaneous Candida infection include recognition of fungal ligands and phagocytosis. The immunoreactive components of *C. albicans* are thought to be the carbohydrate derivatives found on the yeast surface, including glucans, mannans, and chitin. The activation of TLRs by these fungal products presumably contributes to the inflammatory tissue injury seen in mucocutaneous candidiasis by signaling the release of proinflammatory cytokines and by directing the recruitment and activation of other inflammatory cells [114–119]. TLR2, TLR4, TLR6, and TLR9 play a role in host recognition of C. albicans. C-type lectin-like receptors (dectin-1 and 2) also recognize candida infections by binding to β-glucan or mannose, and patients with dectin-1 deficiency appear more susceptible to mucosal candida infections. When both dectin-1 and TLR2 or TLR4 are activated, there appears to be a synergistic effect on the host's proinflammatory response [79].

Recognition of mannan by the mannose receptor on macrophages results in the internalization of Candida. Mannan drives TNF-α production by murine alveolar macrophages in vitro and increases the serum TNF-α level upon intravenous administration in vivo. Earlier studies of the immune response against yeasts have relied heavily on the use of zymosan, an insoluble fungal cell wall preparation, which contains large amounts of β-glucan and mannan [17, 21–27, 29]. It was shown that TLR6 and TLR2 formed heterodimers to coordinate the macrophage activation by zymosan [29, 120]. These findings also suggested that immunity against C. albicans requires the collaboration between receptors responsible for phagocytosis (e.g., mannose or complement receptors) and TLRs designed to induce proinflammatory cytokines. Recent studies highlighted the role of Myd88 [12–19, 121, 122], a signaling molecule for TLR in the phagocytosis of *C. albicans* [19–21]. Macrophages harvested from Myd88–deficient mice and challenged with live *C. albicans* showed a diminished capacity to engulf and kill the yeast, and a diminished capacity to produce TNF-α when compared to wild-type cells [21].

In contrast to immune mechanisms involved in protection against widespread, systemic candidiasis, where cells of the innate immune system, particularly neutrophils, are crucial [17, 38], it has long been recognized, based on both clinical and experimental data, that in the mucocutaneous form of candidiasis, cell-mediated immunity is essential for protection. Chronic mucocutaneous candidiasis

represents a group of syndromes with a variety of predisposing or secondary abnormalities in host defense function. The most common deficiency appears to be one of cell-mediated immune responses against candida antigens, although abnormalities in chemotaxis or phagocytic cell function have also been reported [111–117]. Other host defense mechanisms, such as humoral immunity and the complement system, have generally been found to be normal in these patients [118]. Although treatment of this condition with amphotericin B could be successful in prompt clearance of the cutaneous lesions, relapses usually occurred, presumably because of the underlying immunodeficiency state. HIV infection or severe combined immune deficiencies affecting cell-mediated immunity predispose to mucocutaneous candidiasis. Evidence of impaired cell-mediated immunity to Candida spp. in these patients is represented by negative delayed-type hypersensitivity skin tests, absent or low T-cell proliferation in vitro, and impaired production of leukocyte/macrophage inhibitory factor [123].

Several human and murine studies suggest that impaired clearance of Candida spp. in patients with CMC is due to imbalance between Th1 and Th2 responses with bias toward the Th2 phenotype. Appropriate and timely induction of Th1 responses characterized by production of Th1 cytokines such as IL-2, IFN-γ, TNF-α [124, 125], and IL-12 [39, 66, 126], which activate and recruit effector cells such as macrophages or CD8+ cytotoxic T cells, are of major importance for protection and clearance of the yeast [123, 124]. In contrast, induction of Th2 responses marked by production of Th2 cytokines such as IL-4 and IL-10, which are necessary for mounting an antibody response but also downregulate type 1 cytokine production, had opposite detrimental effects [125]. Neutrophils are thought to be the primary effector cells and their production of either IL-10 or IL-12 likely directs the immune system toward either a Th1 or Th2 response [126]. Recruitment of neutrophils to the site of candida infection is dependent upon recognition of mannans by TLR4 [127].

Peripheral blood mononuclear cells from patients with CMC produce high levels of IL-10, but normal levels of IL-4 and IL-5, upon in vitro stimulation with carbohydrate and mannan fractions of C. albicans. Although Th1 cytokines such as IL-12 and IFN are also decreased in CMC patients, receptors for IL-12 and IFN are shown to be intact [125]. Two possibilities can account for the bias toward Th2 response in CMC patients. The first possibility is that altered cytokine environment caused by interaction of the yeast or hyphal forms of Candida with innate immune cells could inversely influence the induction of CD4+ Th1 cells producing IFN-γ and IL-2. The second possible mechanism could lie more upstream, involving the co-stimulatory functions of APCs such as DCs or macrophages [30, 128].

In support of the first possibility, recent evidence in mice indicates that innate immune cells such as neutrophils and macrophages discriminate between the hyphal and yeast forms of the fungus through binding to different PRRs such as TLR and lectin, being able to produce IL-12 in response to C. albicans yeasts, and IL-10 in response to C. albicans hyphae [30, 66]. The production of IL-12 and IL-10 can thus bias the CD4+ Th response to Th1 or Th2 phenotype, respectively. Th17 cells have also been recently implicated in maintaining a balanced immune response to CMC, which are thought to control fungal growth in the epithelium. Th17 cells produce IL-12, IL-21, and IL-22, cytokines which play a role in neutrophil recruitment, and therefore appropriate recognition, to the area of candida infection [127].

Interestingly, in vitro culture of DCs with the two forms showed that hyphae escaped the phagosome and were lying free in the cytoplasm of the cells, while the yeast form remained within the phagosome. The differences in fungal localization within DCs, therefore, may influence the access of fungal antigens to MHC class I (cytoplasmic) or II (phagosomal) pathways of antigen presentation to CD8+ and CD4+ T cells, respectively, which influences the ability of each fungal form to stimulate CD4+ or CD8+ T cells. Therefore, DCs can influence the type of specific immune response by discriminating between yeast and hyphal forms of the fungus. This can be accomplished through different TLRs, the downstream effect of differential TLR ligation on the cytokine environment, and differential fungal localization within DC.

Nevertheless, it remains to be identified whether the differential immune responses to different phenotypes of Candida is due to altered responses of immune cells or to expression of different virulent genes that allow evasion of host immune response and persistence. In support of the latter possibility, several studies suggested that phenotypic switching represents a pathogenic strategy for the combinatorial expression of batteries of genes leading to a variety of pathologic states. This conclusion was based on the findings that the process of phenotype switching between yeast and hyphal forms, which is characterized by different colony morphology, regulates the expression of a number of phase-specific genes, including PEP1 (SAP1), SAP3, OP4, CDR3, CDR4, NIK1, WH11, and EFG1 [23, 129, 130]. High-frequency phenotypic switching has also been demonstrated to regulate a number of phenotypic characteristics that have been implicated in pathogenesis, including antigenicity, sensitivity to neutrophils and oxidants, adhesion, and susceptibility to common antifungal agents [130, 131]. Whether similar host-microbial interaction involving putative inherent defects of dendritic cells in terms of different dendritic cell subsets or receptors on the cells or differential gene expression upon phenotype switch exists in CMC patients is not yet known.

Dermatophytosis

Clinical Manifestations and Pathogenesis of Dermatophytosis

The dermatophytes include a group of fungi (ringworm) that under most conditions have the ability to infect and survive only on dead keratin, that is, the top layer of the skin (stratum corneum or keratin layer), the hair, and the nails. Dermatophytes cannot survive on mucosal surfaces such as the mouth or vagina where the keratin layer does not form. Very rarely, dermatophytes undergo deep local invasion and multivisceral dissemination in the immunosuppressed host. Dermatophytes are responsible for the vast majority of skin, nail, and hair fungal infections. These types of infections, termed "dermatophytoses," are widespread and increasing in prevalence on a global scale [132, 133]. Reasons for this increase are not clear, although it may be due, in part, to an aging process. This observation is consistent with the view that changes in the immune response that occur with advancing age lead to disease susceptibility. In keeping with this, fungal nail infections are more frequent in immunocompromised patients such as those who are HIV positive and those who have diabetes [134, 135]. Alternatively, age-related changes in peripheral vasculature may be important in predisposing to infection. In addition to the effects of aging, genetic susceptibility has been proposed to contribute to infection. Although *Trichophyton rubrum* infection has been reported to show a familial pattern of autosomal dominant inheritance, more recent epidemiologic findings challenge this view [135]. Other factors that have been implicated include those associated with a modern lifestyle, including the use of footwear made from synthetic materials and exposure to dermatophytes in communal areas with damp environments that favor fungal growth, such as swimming pools and school gymnasiums [135–137]. Despite the identification of multiple predisposing factors, there is no consensus of opinion regarding a single mechanism to explain the increased incidence of foot disease that has occurred in recent years.

Dermatophytes are classified in several ways. The "ringworm" fungi belong to three genera: Microsporum, Trichophyton, and Epidermophyton. There are several species of Microsporum and Trichophyton, and one species of Epidermophyton. The inflammatory response to dermatophytes varies [133–138]. In general, zoophilic and geophilic dermatophytes elicit a brisk inflammatory response on skin and in hair follicles. The inflammatory response to anthropophilic fungi is usually mild. One very characteristic pattern of inflammation is the active border of infection. The highest numbers of hyphae are located in the active border, and this is the best area to obtain a sample for a potassium hydroxide examination. Typically the active border is scaly, red, and slightly elevated. Vesicles appear at the active border when inflammation is intense. This pattern is present in all locations except the palms and soles. Infections of the feet are particularly troublesome and affect both the skin (athlete's foot) and nails (tinea unguium). Despite the availability of new systemic antifungal therapies, nail infections are difficult to eradicate, with recurrence reported in up to 25 % to 40 % of cases. Since lesions vary in presentation and closely resemble other diseases, laboratory confirmation is often required.

Innate Immune Responses to Dermatophytes

Interaction of dermatophytes with many dermal and epidermal immune cell types including keratinocytes results in a cascade of chemokines and proinflammatory and anti-inflammatory cytokine responses [139–142]. Activation of the alternative complement pathway by dermatophytes such as the case with Trichophyton mentagrophytes also results in production of chemotactic factors. These chemotactic events and inflammatory responses are thus responsible for the observed macroscopic changes associated with dermatophyte infections including scaling, vesicles, pustules, annular dermatitis, and severe inflammatory reactions (kerions). Microscopically, the lesions are characterized by an accumulation of neutrophils in the infected skin of acute infections or a mononuclear cell infiltrate in the dermis of the more chronic ones [139–142]. The acute inflammatory responses may be manifested as epidermal microabscesses, while chronic dermatophyte infection is usually manifested as epidermal hyperkeratosis and parakeratosis [135–139].

Similar to other cutaneous mycosis, neutrophils mediate elimination of dermatophyte infections by a variety of microbicidal processes, including (1) microbicidal oxidants such as superoxide, hydrogen peroxide, hypochlorous acid, and monochloramine; and (2) nonoxidative microbicidal granules such as cathepsins, defensins, lactoferrin, lysozyme, elastase, azurocidin, and a number of other proteins [140]. Furthermore, neutrophils inhibit the growth of dermatophytes through release of large amounts of calcium and zinc-binding protein, called calprotectin that has potent microbiologic static activity against these fungi. This protein is released into inflammatory exudates as neutrophils degranulate at sites of infection [140, 141].

Acquired Immune Responses Against Dermatophytes: Immediate and Delayed-Type Hypersensitivity Reactions

Several of dermatophyte antigens are cross-reactive with airborne molds. These antigens stimulate IgE production, which mediates immediate hypersensitivity (IH) reaction in infected patients, mainly those with chronic dermatophytosis. The IH reaction in these patients is mediated by IgE antibody, and is characterized by a local wheal and flare occurring 5–20 min after injection of antigen into the skin. In this

process, binding of antigen to IgE antibody (Ab) on the surface of mast cells results in cross-linking of IgE Ab, which, in turn, triggers the degranulation of mast cells and release of histamine and other proinflammatory mediators [141, 142].

The IH skin tests to Trichophyton are associated with the presence of serum IgE and IgG Ab to Trichophyton antigens. IgG4 Ab is a major component of the IgG Ab response [136]. Thus, IH reactions to dermatophytes bear the hallmarks of a Th2 response. In this type of response, IL-4 produced by CD4+ Th2 cells induces antibody isotype switching to IgG4 and IgE [142, 143]. A role for fungal antigens (Ags) in allergic disease is strongly supported by the association between chronic dermatophytosis and allergic respiratory symptoms, and the improvement of late-onset asthma after antifungal therapy in patients with IH to Trichophyton.

By contrast, Trichophyton antigens are also able to induce delayed-type hypersensitivity (DTH) responses in some patients [133, 143]. Delayed-type hypersensitivity is a form of cell-mediated immunity in which the ultimate effector cell is the activated macrophage. In the classic DTH reaction, activation of macrophages is mediated by IFN-γ–producing Th1 CD4+ T lymphocytes [142–144]. However more recent studies have shown that both CD4+ and CD8+ T cells can have direct cytotoxicity to *T. mentagrophytes* and *T. rubrum*, although to a lesser extent [145].

These T cells recognize and respond to foreign antigen presented in the form of peptide complexed with MHC class II molecules expressed on the surface of APCs. This cell-mediated response is characterized by induration at the injection site, which is maximal at 48 h. There is considerable evidence that DTH is pivotal in the eradication of dermatophyte infection. This conclusion is based on data showing (1) the development of DTH in association with inflammatory responses in primary infections, (2) the association between acute highly inflamed lesions and DTH, and (3) the failure to develop infection after experimental inoculation when DTH is present. Interestingly, DTH to Trichophyton extract is associated with lower titers of IgG Ab to Trichophyton antigens and no IgE or IgG4 [142, 144, 146]. These observations suggest that humoral response to Trichophyton is less protective. A subset of patients also mounts "dual" skin test responses in which a DTH response follows the IH reaction. Whether this represents a transitional stage in DTH-to-IH conversion (or vice versa) is not known.

Several hypotheses have been proposed to explain the mechanism of induction or suppression of protective DTH responses in different individuals. One study suggested that development of IH suppresses DTH responses in patients with chronic dermatophytosis since most IH responses occur in the absence of DTH [146, 147]. Treatment of chronic dermatophytosis associated with IH responses with the systemic antifungal terbinafine can restore DTH responsiveness to intradermal trichophyton antigen. Another study proposed that prolonged antigen exposure can induce immunologic unresponsiveness, or anergy, by activating suppressor T cells, which then downregulate cell mediated responses. However, several studies have failed to demonstrate diminished T-cell proliferative responses to dermatophyte antigens in patients with IH [143, 146, 148, 149].

An alternative hypothesis was that the properties of the fungus itself may prevent the development of cell-mediated responses. For example, mannans derived from *T. rubrum* have been proposed to inhibit DTH by interfering with antigen-processing pathways required for T-cell activation. However, despite all these data, it is not yet clear whether chronic infection results from a lack of DTH or from the presence of an IH response. Thus, a major question is whether IH is a prerequisite for the development of chronic infection and, if so, whether it reflects a more broad-based immune dysregulation. The answer to this question is complicated by the fact that host factors, such as integrity of the skin barrier as well as immune status of the host, play a central role in determining the outcome of dermatophyte infection. Indeed, it is well recognized that patients with HIV infection or those receiving immunosuppressive therapy are predisposed to develop chronic dermatophytosis and sometimes an invasive disease. This observation is consistent with impairment of cell-mediated immunity associated with these conditions.

Changes in the balance between Th1 and Th2 responses with bias toward Th2 response have been implicated in the progression of several diseases such as HIV infection associated with chronic dermatophytosis [146]. Indeed, this would be consistent with the dogma that Th2 polarization contributes to disease progression in HIV-infected subjects. Similarly, chronic *T. rubrum* infection associated with IH and a markedly elevated total IgE level in the serum was proposed to contribute to the development of severe measles infection by favoring the development of Th2 responses [143, 144, 146, 147]. However, this does not explain the paradoxical association between chronic dermatophytosis and Th1-mediated diseases such as diabetes. Nevertheless, the association between diabetes and dermatophytosis is also complex, as diabetic complications such as peripheral vascular disease could contribute to persistent dermatophyte infection.

Although immune mechanisms involved in the natural resolution of infection have yet to be resolved, recent findings suggest that T cells with a defined specificity for Trichophyton antigens or epitopes are critical for development of DTH or IH responses in different individuals. This conclusion was based on comparison of the T-cell repertoire in subjects with distinct immune responses to a single Ag such as the 29-kd Tri-r-2 derived from *T. rubrum*. Interestingly, the differences in the T-cell repertoire between patients with IH and those with DTH were independent of

human leukocyte antigen (HLA) haplotype [143, 144, 150–152]. The clinical relevance of different T-cell repertoires remains to be determined. However, it is possible that certain antigenic peptides derived from Trichophyton antigens contain an epitope that specifically promotes the development of a DTH response, making progression to chronic dermatophytosis unlikely [150, 151, 153].

Malassezia Infection

Clinical Manifestation and Pathogenesis of Malassezia Infection

Yeasts of the genus Malassezia undergo asexual reproduction by monopolar budding. The yeast cell is actually a phialide that has a small collarette at its apex, which gives it an overall bottle-shaped appearance. Some of the species are able to undergo a phase transition from yeasts to hyphae, although the factors that control this transition are not clearly understood. The genus Malassezia is known to include at least seven species of yeast (M. furfur, M. pachydermatis, M. sympodialis, M. globosa, M. obtusa, M. restricta, and M. slooffiae). Except for M. pachydermatis, the species require an exogenous source of lipid owing to their inability to synthesise C14–C16 saturated fatty acids because of a block in the de novo synthesis of myristic acid [152]. Although Malassezia can be found on normal human skin, it has been implicated in a range of both cutaneous and systemic diseases such as seborrheic dermatitis, dandruff, folliculitis, atopic dermatitis (recently renamed atopic eczema/dermatitis syndrome [AEDS]), psoriasis, confluent reticulate papillomatosis, and seborrheic blepharitis [154–161].

Malassezia is most frequently associated with pityriasis (tinea) versicolor (PV), which is one of the most common disorders of pigmentation seen in dermatologic clinics worldwide [154, 155]. PV is a chronic superficial fungal infection of the skin. The Malassezia species that have been isolated from patients with PV include M. furfur, M. globosa, M. restricta, M. slooffiae, and M. sympodialis, with more than one species of Malassezia being present. PV most often occurs on the trunk, neck, and proximal extremities. It is characterized by scaly hypopigmented or hyperpigmented macules and patches with minimal pruritic reaction [152, 154, 155].

Malassezia folliculitis is characterized by follicular papules and pustules localized to the trunk, upper arms, neck, and, less often, the face [159–161]. These lesions are generally pruritic. Diagnosis is based on clinical signs, cytology, and culture in combination with histopathology. Although it has been suggested that follicular occlusion was the primary cause of Malassezia folliculitis with a secondary overgrowth of Malassezia organisms, colonization of normal pilosebaceous units by these yeasts can also be extensive. The exact role of Malassezia in Malassezia folliculitis, therefore, awaits further elucidation. Therapy for Malassezia folliculitis is similar to that described for PV. As with PV, recurrence tends to be a common problem.

Seborrheic dermatitis and dandruff are other diseases caused by Malassezia. Seborrheic dermatitis is characterized by inflammation and desquamation in areas that are rich in sebaceous glands such as the scalp, face, and upper trunk, whereas dandruff is a noninflammatory scaling condition of the scalp. Dandruff is now generally considered the mildest form or a variant of seborrheic dermatitis [160, 161]. The decreased severity of these diseases upon fungal therapy, the increase in the number of Malassezia organisms, and relapse upon discontinuation of therapy support a role of Malassezia as the etiologic agents in these two conditions. The species that have been isolated from patients with seborrheic dermatitis are similar to those causing PV, with M. furfur and M. globosa being most common. Atopic dermatitis is another chronic, multifactorial, inflammatory allergic skin disease associated with abnormal immunologic regulation and is associated with Malassezia infection [161–163].

Similar to dermatophyte antigens, allergens from Malassezia organisms have been implicated in its pathogenesis [162–164]. For atopic patients with a hypersensitivity response to Malassezia spp., antifungal therapy should be included in the treatment regime. In addition to the diseases described above, Malassezia spp. have also been shown to cause more deep-seated infections, including mastitis, sinusitis, septic arthritis, malignant otitis externa, fungemia, pulmonary vasculitis, peritonitis, and meningitis [159–162].

Immunology of Malassezia-Associated Diseases

There have been large numbers of studies examining the innate and acquired (cellular and humoral) immune responses to Malassezia in patients with many Malassezia-associated diseases [165]. For many of the diseases, the responses reported have varied widely. The innate response against Malassezia involves several components such as complement, phagocytosis, and NK-mediated lysis. Several groups have reported the ability of Malassezia to activate the complement system, via either the alternative pathway or the classic pathway [166–168]. The extent of activation of the alternative pathway was cell concentration and time dependent, reaching a plateau after 30 min. Although the molecule responsible for triggering the

alternative pathway is not well defined, ß-glucan in the cell wall may be involved [168]. The ability to activate complement has been suggested as a mechanism responsible for the inflammation associated with seborrheic dermatitis. Phagocytosis and intracellular killing of the yeast, mainly by neutrophils, is another important innate mechanism by which nonspecific effector cells play a role in host defense against Malassezia [169, 170].

The importance of phagocytosis in protection against fungal infections is highlighted by the increased susceptibility of neutropenic patients to many mycoses. In vitro, neutrophils take up Malassezia in a complement-dependent process. On the other hand, the receptors involved in phagocyte–yeast cell binding have been characterized in a human monocytic cell line as the mannose receptor, ß-glucan receptor, and complement receptor type 3 [171]. Recent studies have shown that when a monocytic cell line, THP1, was stimulated with either live or heat-killed Malassezia, the production of IL-8 was increased, while stimulation of a granulocytic cell line, HL-60, resulted in increased levels of both IL-8 and IL-1β [172]. The effects of IL-1β in host defense against cutaneous fungal organisms include the activation of lymphocytes, chemotaxis, and neutrophils and the induction of inflammation [172–174]. Interleukin-8 also induces chemotaxis and activation of neutrophils and T cells. Therefore, the interaction of Malassezia with phagocytic cells may serve to amplify the inflammatory response and encourage further recruitment of phagocytic cells.

Opsonized live Malassezia yeast cells are more stimulatory than were nonopsonized or heat-killed Malassezia yeast cells. However, the ability of neutrophils to kill Malassezia seems limited compared to efficient killing of *C. albicans* yeast cells and other fungal genera. The mechanism by which Malassezia may resist or prevent phagocytic killing is not completely clear. In addition to escaping phagolysosomal killing, in vitro studies suggested an immunosuppressive effect of Malassezia on activation of different innate effector cells [174, 175]. *M. furfur* was able to invade human keratinocytes and resist phagolysosomal fusion, which allows their survival inside host cells. In addition, culture of yeast cells of *M. furfur* with normal human keratinocytes did not stimulate cytokines or chemokines production.

Low levels of monocyte chemotactic protein 1 (MCP-1), TNF-α, and IL-1β (IL-1β) were found, which were associated with overproduction of immunosuppressive cytokines IL-10 and tumor growth factor-β (TGF-β) [175]. It was further postulated that the suppression of proinflammatory cytokines might allow Malassezia to survive within host cells without causing an inflammatory response. Suppression of IL-1β, IL-6, and TNF-α also has been reported when Malassezia was co-cultured with peripheral blood mononuclear cells (PBMCs), and that the suppression was IL-10 dependent [175]. This correlates with the situation seen in normal healthy skin and also with the limited inflammation seen in PV, despite the large fungal burden seen in the lesions [176, 177]. It is known that the immunosuppressive effects of Malassezia on PBMCs can be reversed by removal of the lipid-rich capsular-like layer around the organism, and it will be interesting to determine if this is also the case with keratinocytes [178].

The role of DC and NK cells in innate and acquired immune responses against Malassezia in atopic and nonatopic individuals has been extensively studied. Uptake of whole M. furfur yeast cells and various allergenic components from the yeast, including M. furfur extracts, recombinant M. furfur allergen 5 (Mal-f-5), and M. furfur mannan by immature monocyte-derived dendritic cells (MDDCs) has been demonstrated in vitro [179, 180].

The internalization of Malassezia was shown to occur via binding to the mannose receptor (other receptors may also be involved) or pinocytosis and is not influenced by IgE. The presence of M. furfur was also shown to induce maturation of immature MDDCs by upregulation of CD83 expression, and also resulted in increased expression of the co-stimulatory molecules CD80 and CD86 [179–181].

The uptake of the yeast by the DCs also induced a significant production of TNF-α, IL-1β, and IL-18, but not IL-10 or IL-12, after 46 h of co-culture. Although immature DCs are highly phagocytic, mature DCs are excellent at presenting antigen-derived peptides on MHC molecules to T cells [182]. Thus, the DCs that had been exposed to Malassezia induced proliferation of autologous T lymphocytes in a dose-dependent way [182–184].

The interaction of Malassezia-infected mature DCs with NK cells in atopic patients also has been examined by comparing the numbers of NK cells in the normal skin of healthy controls with those in the atopic skin of atopic dermatitis or AEDS patients [179, 185]. These studies showed that there were only scanty NK cells in normal skin, but that they were numerous in the atopic skin, and they were in close apposition with DCs. Dendritic cells that had been preincubated with Malassezia for 46 h were less susceptible to NK-mediated lysis, and this resistance to NK lysis was mediated by soluble factors [185–189].

This protection of DCs against NK-mediated lysis, if it were to occur in vivo, would allow the mature dendritic cells to remain in the epidermis, presenting Malassezia antigens to T cells and hence contributing to the maintenance of the inflammatory response in AEDS lesions [188, 189].

The effect of different forms of Malassezia on the responses of DCs has been examined. Similar to that described in immunity against *C. albicans*, the yeast phase

elicits production of IL-12 and priming of Th1 cells, while the hyphal phase inhibits IL-12 and Th1 priming, and induces production of IL-4, a Th2-type cytokine [190–192]. Similar to other fungi, Th1 T-cell–mediated immunity is important in the prevention and recovery from infections. A deficiency in cell-mediated Th1 responses could therefore predispose the host to overgrowth of Malassezia. Atopic patients with specific IgE antibodies against M. furfur were shown to have increased synthesis of the Th2-related cytokines IL-4, IL-5, and IL-10 by Malassezia-stimulated PBMCs [190–192].

In regard to humoral immune responses against Malassezia, it is clear that IgG responses to Malassezia yeasts are common in both healthy individuals and patients with Malassezia-associated diseases. This probably reflects exposure of the immune system to antigens produced by commensal organisms [193]. However, enhanced IgG responses can be seen in humans with atopic dermatitis. The role of this IgG response in the pathogenesis of skin disease is currently unclear. IgG antibodies are known to be able to act as opsonins coating microorganisms and to activate phagocytes, which in turn ingest and destroy extracellular pathogens. This could in theory provide protection for the host. However, as overgrowth with Malassezia does not appear to be a self-resolving condition, it seems likely that these antibodies are not protective [194, 195].

Alternatively, IgG antibodies could activate the complement system, as has been demonstrated with *Pityrosporum ovale* and *P. orbiculare*, and exacerbate the inflammatory response [196]. A final possibility is that IgG responses to the yeast are merely an association and neither contributes to nor inhibits the ongoing disease process [195]. Further studies are therefore required to determine the precise role played by these antibodies in Malassezia-induced skin disease. Using in vitro serologic tests such as enzyme-linked immunosorbent assay (ELISA), the radioallergosorbent test (RAST), and Western immunoblotting, Malassezia-specific IgE has been detected in human atopic patients for over a decade [194, 195].

Stimulation with Malassezia extracts and IL-4 led to a dose-dependent increase in IgE synthesis from PBMCs only in RAST(+) atopic patients, indicating a Th2-type skewed response towards Malassezia in these patients. The Malassezia-specific IgE antibodies in human atopic patients could play a key role in enhancement of immune responses [196–198]. The allergen-specific IgE antibodies could bind to Langerhans cells in the skin, thus enhancing their allergen capturing and presentation capacity upon a second encounter with the allergen. In addition, IgE could mediate mast cell-mediated hypersensitivity responses to Malassezia allergens, and that may be involved in the pathogenesis, and contribute to the clinical signs, in some cases of human atopic dermatitis.

Subcutaneous Mycosis

Chromoblastomycosis

Clinical Manifestations and Pathogenesis of Chromoblastomycosis

Chromoblastomycosis is a term that designates a group of chronic cutaneous and subcutaneous mycoses caused by several species of dematiaceous (darkly pigmented) fungi. As a member of the heterogeneous group of subcutaneous mycoses, chromoblastomycosis commonly presents the following typical features: lesions beginning at the site of a transcutaneous trauma, chronic evolution associated with survival of the fungal agent, and fibrotic reaction [199–201] as seen in Fig. 19.4. In tissues, all agents form thick-walled, dark multiseptate structures—the muriform (sclerotic) cells. It is common worldwide but occurs mostly in tropical and subtropical areas of Africa, Asia, and South America. Chromoblastomycosis is considered an occupational disease in many tropical and temperate countries (Madagascar, northern Venezuela, and the Amazon region of Brazil) [202–204].

The disease is caused by a large number of fungi that exist in the soil, plants, flowers, and wood. The most common agents are *Fonsecaea pedrosoi* and *Cladophialophora carrionii*. The latter is considered to be the most important etiologic agent in deserts in South Africa and Australia [202–204]. Less frequently, the disease is caused by *Phialophora verrucosa, Rhinocladiella aquaspersa*, as well as *Wangiella* or *Exophlaia* dermatitidis. Other etiologic agents that were discovered recently are *Exophiala jeanselmei* and *Exophiala spinifera. Fonsecaea compacta* has also been observed in lesions of chromoblastomycosis. The etiologic agents enter the host through cutaneous puncture wounds, usually on a thorn or a splinter. Other kinds of trauma such as animal-associated trauma (insect bite or sting) are identified as the portal of entry of the fungus.

A primary lesion is represented by a papule that slowly enlarges over time and can ulcerate. The primary lesion can progress to polymorphic skin lesions, including nodular and verrucous lesions. Sometimes the lesions can heal as sclerotic plaques, scars, or keloid formations [199–204]. The most frequent clinical presentation is a cauliflower-like lesion that develops at the site of inoculation, and satellite lesions gradually arise from scratching, autoinoculation and spread via the lymphatic system. Secondary lymphedema and pruritus are common findings, but the disease remains confined to the subcutaneous tissue and does not invade underlying muscles and bone, except in immunosuppressed patients such as those on high-dose corticosteroids. The lower limb is the most common site followed by the upper limb, ear pinna, and nose [199–204]. The diagnosis can be

Fig. 19.4 Leg of a patient with chromoblastomycosis

made by detection of multiform cells, referred to as sclerotic bodies, from tissue biopsies or from fungal culture. Hydrogen peroxide and hematoxylin and eosin (H&E) are recommended stains for elucidation of the sclerotic bodies in tissues [204, 205]. The hyphae and budding cells are usually seen in the surface of the lesion, while the muriform cells are often seen in the deep part of the lesion. The treatment of chromoblastomycosis is difficult due to its limited response to oral antifungal therapy [206, 207]. Medical treatment usually includes combined use of antifungal drugs such as itraconazole with terbinafine. Other treatment strategies include a combination of cryotherapy, 5-fluorocytosine, and amphotericin B. Surgical treatment is the ultimate effective therapy, which involves surgical removal of lesions, electrodesiccation, and cryosurgery.

Immunology of Chromoblastomycosis

The host defense mechanism in chromoblastomycosis has not been extensively investigated. The first line of defense utilizes HLA-DR and costimulatory molecules, like CD86, TNF-α, IL-10, and IL-12, to activate dendritic cells. Although melanin produced by *F. pedrosoi* has been suggested to play a role in immune evasion, other research suggests that melanin stimulates the immune response by helping to activate TLR4 leading to the production of IL-8, increasing fungal internalization and amplifying oxidative burst. Mannose in the cell wall may also contribute to this immune reaction [208].

Some studies have focused on fungus–host interactions, showing a predominantly cell-mediated immune response, with activated macrophages involved in fungus phagocytosis [209–211]. The highly organized inflammatory reaction and chronic nature of chromoblastomycosis is characterized by the presence of a granulomatous reaction in association with neutrophil-rich, purulent abscesses. This granulomatous reaction shows extensive phagocytosis of brown thick-wall fungal cells, which is considered the main factor explaining the chronic and inflammatory nature of the disease [204, 212]. However, the degree of phagocytosis and cytotoxicity depends on the fungal species causing infection. *P. verrucosa* and *R. aquaspersa* rely on complement-mediated phagocytosis and macrophages are only cytotoxic on *R. aquaspersa* [208].

Macrophages (referred to as epithelioid or giant cells) are highly activated as marked by higher expression of TNF-α and their enhanced in vitro antifungal activities marked by H2O2 and NO production [213, 214]. Inhibition of macrophage synthesis of NO by fungus-derived melanin has been proposed as an immune evasion mechanism that prevents the host from clearing *F. pedrosoi*, leading to a chronic disease [215]. CD4+ Th1 cells and type 1 response are important for host defense against causative agents of chromoblastomycosis [216]. Patients with a mild form of the disease have predominant production of IFN-γ, low levels of IL-10, and efficient T-cell proliferation, consistent with a type 1 response, while patients with the severe form of the disease have predominant production of IL-10, low levels of IFN-γ, and inefficient T-cell proliferation, consistent with an immunosuppression rather than Th2 response [216, 217] Histopathologic and immunohistochemical staining of skin tissues from patients with the verrucous form of the disease has identified CD4+ T lymphocytes at the periphery of the granulomas, with immunostaining for IL-10. These findings suggest that either a Th2 phenotype or immunosuppression is linked to severe or verrucous forms.

Furthermore, patients with chromoblastomycosis produce specific IgM, IgG, and IgA antibodies [209] and levels may correlate with disease chronicity [208]. Several cell wall and secreted immunoreactive antigens of *F. pedrosoi* have been identified. Antifungal antibodies specific to secreted melanin inhibit fungal development, support fungal internalization, and enhance macrophage functions as marked by greater degrees of oxidative burst [52]. Sera from infected human patients also reacted with secreted melanins, suggesting that

F. pedrosoi synthesizes melanin in vivo [52]. Antibodies against melanin purified from patients' sera also reacted with sclerotic cells from patients' lesions as well as with sclerotic bodies cultivated in vitro—conidia, mycelium, and digested residues [218].

Taken together, these results indicate that melanin from *F. pedrosoi* is an immunologically active fungal structure that activates humoral and cellular responses that could help the control of chromoblastomycosis. Glucosylceramide (GlcCer) is another immunoreactive conserved lipid component in the cell wall of many fungi including dark fungi. Antifungal antibodies specific to GalCer directly inhibit fungal development, which supported the use of monoclonal antibodies to GlcCer as potential tools in antifungal immunotherapy [219, 220]. However, unlike the clear correlation between mild disease and cell- mediated type 1 response, there is inconclusive evidence to support a protective role of the humoral immune response in host defense against chromoblastomycosis.

Mycetoma

Clinical Manifestation and Pathogenesis of Mycetoma Infection

Mycetoma is a chronic granulomatous infection caused by fungi (eumycetoma) or actinomycetes (actinomycetoma). The first description of a case of mycetoma is usually attributed to Dr. John Gill, who reported "Madura foot" in a report of the Madras Medical Service of the British Army in India in 1842 [221–224]. The mycetoma lesion is characterized by a subcutaneous mass and multiple sinuses draining pus, blood, and fungal grains as seen in Fig. 19.5. The morphologic characteristics and color of the grains provide clues about the species of the agents. The mycetoma infection has a prolonged and indolent course. The mycetoma lesion might ultimately extend to deeper tissues and bones, leading to deformity of the affected site and subsequent disability for the patient. This disease has been reported in many countries including Sudan, Somalia, Senegal, Mauritania, Kenya, Niger, Nigeria, Ethiopia, Chad, Cameroon, Djibouti, India, Yemen, Mexico, Venezuela, Columbia, and Argentina [221–225].

Mycetoma infection is not self-limited and, if untreated, leads to massive lesions, which in the end necessitate surgical amputation. Mycetoma initially presents as a slowly progressive and painless subcutaneous swelling, sometimes in combination with a history of preceding trauma [225–227]. However, the incubation time before classic signs develop is not well defined because in many cases the patients usually present at later stages of disease when most early clinical symptoms have disappeared.

Fig. 19.5 Clinical example of Madura foot from mycetoma infection

The duration of the disease, the type of causative organism, the site of the infection, and the immune response of the host can all affect the clinical presentation of mycetoma. However, patients with a short disease history might present with massive lesions and severe destruction of deep tissues and even of bones. The subcutaneous swelling is usually firm and rounded but it can also be soft and lobular. It is rarely cystic and is often movable. The subcutaneous nodule increases in size, and secondary nodules might evolve as well. The nodules might suppurate and drain through multiple sinus tracts, which can close transiently after discharge during the active phase of the disease. The disease process involves opening of fresh adjacent sinuses while the old ones heal completely. The nodules are connected to the skin surface and to each other through deep sterile abscesses.

Mycetoma can affect any part of the body. Most cases are usually seen in the feet, followed by the hands, legs, and knee joints. Rarely, the chest and abdominal walls, facial bones, paranasal sinuses, eyelid, orbit, scrotum, and old surgical incisions might also be affected [224–228]. Mycetoma

spreads locally or through the lymphatic system, and, rarely, through the bloodstream. Compared to actinomycetoma where secondary nodules that represent lymphatic metastasis, are common, eumycetoma is rarely associated with secondary nodules [229].

Mycetoma is usually painless, and the mycetoma lesion has been suggested to produce substances that have an anesthetic effect. At a late stage of the disease, the absence of pain might be due to nerve damage by the tense fibrous tissue reaction or endarteritis obliterans, or alternatively, poor vascularization of the nerves. In the final stages of the disease, pain might be due to invasion of the bone or to secondary bacterial infection. As the mycetoma granuloma increases in size, the skin may become smooth and shiny, and areas of hypopigmentation or hyperpigmentation can develop [226–230].

Diagnosis of mycetoma is based on the presence of subcutaneous masses, sinuses, and granular discharge in patients from an endemic area. Madurella species, the causative agents for eumycetoma, in general are slow-growing fungi that produce dark colonies composed of a dense, melanized, and mostly sterile mycelium. Madurella species are well-known agents of black-grain mycetoma. Two species are recognized, *M. mycetomatis* and *M. grisea.*

In different culture media, *M. mycetomatis* strains show various colonies and moderate growth rate. The colonies, which are white and woolly at first, becoming olivaceous, yellow, or brown, and produce a brownish, diffusing pigment. Colonies are mostly sterile, composed of dense melanized mycelium. No efficient sporulation has ever been seen [231, 232].

However, phialides with minute conidia in balls and collarettes may be seen. Species-differentiation of *M. mycetomatis* and *M. grisea* can be made by differences in sugar assimilation and optimal growth temperature. *M. mycetomatis* assimilates lactose but not sucrose, whereas *M. grisea* assimilates sucrose but not lactose. *M. mycetomatis* grows well at 37 °C, while *M. grisea* does not grow at 37 °C (growth is seen at 30 °C). This finding might also explain the observed difference in virulence.

Molecular tests have recently been developed and have significantly improved the diagnosis. The polymerase chain reaction (PCR) test is useful for detection and identification of *M. mycetomatis* in patients [233]. The test showed that a wide range of agents can actually cause eumycetoma. When different isolates of *M. mycetomatis* derived from patients originating from endemic areas were genetically compared, they did not show major differences, despite differences in phenotypes seen when cultured [231–233]. The diverse clinical presentations thus seem to be due to differences in host susceptibility rather than gross genetic differences among the fungal strains involved. In addition to culture, biochemical, and molecular identification of the fungal etiologic agents of mycetoma, other diagnostic tests are important in developing an appropriate plan of treatment [234–236]. Magnetic resonance imaging has been shown to be valuable in the detection and even identification of fungal grains and for the assessment of therapeutic success [236]. Furthermore, radiology helps in clinical diagnostics, especially in the follow-up of disease progression, development of a surgical strategy, and assessing the clinical cure. At the level of the fungus, direct examination of grains might be useful in determining the type of mycetoma [234, 235]. The large numbers of causative organisms and the poor in-vitro differentiation of fungi that cause mycetoma complicate the identification process. Histopathologic examination is generally not useful for differentiation of fungi, although some of the pigmented fungi may be categorized to a certain extent [237]. Fine-needle aspiration cytologic methods for mycetoma have also been described and are considered to be useful. Finally, serodiagnosis also can be helpful in identification of the etiologic agent [238–242]. The common serologic tests are immunodiffusion and ELISA; however, due to possible cross-reactivity between some species, the specificity of these assays is compromised [229, 238–242].

In tissues, *M. mycetomatis* forms numerous black sclerotia (grains). Grains are vegetative aggregates of the fungal mycelium embedded in a hard brown matrix, which consists of extracellular cement that seems to be 1,8-dihydroxynaphthalene melanin in combination with host tissue debris. This rigid matrix might act as a barrier protecting the fungus from the natural immunity of the host and antifungal agents. Melanins are thought to be protective in cases of host-induced oxidative stress. Two types of grains have been identified: filamentous and, less commonly, vesicular. Triple-layered tissue reaction zones have been described around the grains. An inner neutrophil zone immediately around the grain, an intermediate zone containing mainly macrophages, and an outer zone consisting of lymphocytes and plasma cells mainly can be seen under the microscope [234, 235, 237]. The medical treatment of eumycetoma is difficult, as the in vivo activity of azoles is often poor especially in late, advanced cases, but lesions of patients under ketoconazole treatment remain localized and well encapsulated. Thus, long-term treatment with itraconazole seems to be the best therapeutic regimen at present. Treatment of advanced cases usually implies amputation of the infected limb.

Immune Responses in Mycetoma

In 1964, Mahgoub [238] was able to demonstrate that eumycetoma patients developed Abs against *M. mycetomatis*. Counterimmunoelectrophoresis, immunodiffusion, and ELISA were developed to detect Abs raised against different mycetoma causative agents, using crude culture extracts as

Ag [239–241]. However patients without mycetoma infection who live in endemic areas also have elevated Ab levels, yet do not develop disease. In mouse models, mycetoma only developed when introduced with an adjuvant, which led to a Th2-dominant response [243].

It was not until the second half of the 1980s, that it was demonstrated that the cytoplasm, organelles, and, predominantly, the cell wall of *M. mycetomatis* were antigenic. About the same time it was also determined that IgM and IgG were the dominant immunoglobulins resulting from mycetoma. In 1991, the first attempts were made to characterize the nature of the epitopes present in the crude extracts used for the initial experiments. Cytoplasmic proteins were extracted from several eumycetoma agents, and, although the different *M. mycetomatis* isolates had very heterogeneous protein profiles by sodium dodecyl sulfate–polyacrylamide gel (SDS-PAGE), the antigenic makeup was quite similar within the species [242]. However, information about the individual immunoreactive Ags was not examined in this study [239–242].

A recent study identified the first immunogenic Ag, a protein homologous to the translational controlled tumor protein (TCTP), a well-conserved histamine release factor in a range of eukaryotes [244]. The gene for this Ag was demonstrated to be present in two variants in *M. mycetomatis*, with 13 % amino acid difference between the two proteins encoded. In vitro, TCTP was secreted into the culture medium. In vivo, this protein was found to be expressed on hyphae present in developing stages of the eumycetoma-characteristic black grain. Significant IgG and IgM immune responses, against the whole protein and selected *M. mycetomatis*–specific peptides, were detected. The Ab levels correlated with lesion size and disease duration. Overall, the patients with the largest lesions had the highest Ab level, which lowered with decreasing size of the lesion. Similarly, prolonged duration of the disease was associated with the highest Ab levels. Whether these TCTP-specific antibodies are markers of progressive and chronic disease or whether they play a protective role in host defenses against *M. mycetomatis* infection is not yet known. Nevertheless, this TCTP is considered to be the first well-characterized immunogenic Ag that can be used as a monomolecular vaccine candidate against *M. mycetomatis*.

Dimorphic Fungi with Cutaneous Involvement

Sporotrichosis

Clinical Manifestations and Pathogenesis of Sporotrichosis

Sporotrichosis is caused by a thermo-dependent dimorphic fungus, *Sporothrix schenckii*. The hyphal form that is present in the normal environment consists of both conidia and hyphae, while the yeast form develops at 37 °C [245]. The conidia or hyphae enter the body through either traumatic implantation or inhalation. However, *S. schenckii* is observed only as the yeast form in biopsies or excised specimens. Such conversion from hyphal to yeast form seems to occur in both the implantation and inhalation sites. Clinical manifestations of sporotrichosis are variable [245–249].

Fig. 19.6 Sporotrichoid lesions on the upper extremity

The major clinical manifestations occur in the skin and present primarily as either fixed cutaneous or lymphocutaneous forms. The lymphocutaneous form is depicted in Fig. 19.6. However, cases of disseminated cutaneous or visceral forms in immunosuppressed patients have reportedly increased.

Immune Responses in Cutaneous and Visceral Sporotrichosis

Both virulence factors of the individual *S. schenckii* strains and the immunologic status of the host determine the clinical manifestations of sporotrichosis [250, 251]. From the host perspective, cell-mediated immunity to *S. schenckii* antigen is a key immunologic defense mechanism that controls infection with *S. schenckii* [250, 251]. Both CD4+ Th1 cells producing IFN-γ and macrophages are required for the development of granuloma formation, which is a critical and essential component of normal host defense against the pathogens. Interferon-γ messenger RNA (mRNA) is detected in the granulomatous skin lesions of sporotrichosis [252], and immunohistochemical analysis demonstrated the existence of IFN-γ–producing CD4+ T cells in the periphery of such lesions [253]. The Th1 response activates macrophages to kill intracellular *S. schenckii*. Other studies demonstrated a CD83+ DC subpopulation in the granulation tissue of sporotrichosis, which indicates that activated DCs that express co-stimulatory molecules such as CD83 may play important roles in the Th1 immune response against *S. schenckii* [254].

From the fungal pathogen perspective, infection with different strains of *S. schenckii* possessing special virulence factors is a critical factor that contributes to different clinical manifestations of individual *S. schenckii* strains (cutaneous

versus visceral strains) [255, 256]. *S. schenckii* of cutaneous origin and yeast forms are more potent at activating DCs to induce subsequently stronger Th1-prone immune responses than those of visceral origin as evidenced by (1) higher expressions of HLA-DR and costimulatory molecules such as OX40L on DC and (2) higher induction of Th1 cytokines (IFN-γ and TNF-α). In contrast, *S. schenckii* of visceral origin positively induced a Th2 cytokine environment as evidenced by significantly higher IL-4 production and the inability to induce strong Th1 immune responses. Thus, similar to immune responses generated against other fungi described in this chapter, the Th1/Th2 balance may explain the differential clinical manifestations observed in cutaneous versus systemic or visceral sporotrichosis [55, 255–257].

Although the exact mechanism that accounts for differential Th1/Th2 responses following cutaneous and visceral sporotrichosis is not known, two possibilities are postulated: (1) different efficacies for the internalization of individual *S. schenckii* strains may affect the immunostimulatory response of DCs; and (2) differential expressions of surface molecules on *S. schenckii* could contribute to differential abilities of these strains to stimulate DCs via TLR or other PRRs such as lectin [258–260]. Examination of fungal internalization reveals no difference between the cutaneous and visceral strains. Therefore, the second possibility involving differential interaction of different strains with different PRRs on various APCs is the most likely mechanism that accounts for different clinical manifestations between the two strains of Sporothrix [121, 261–263]. The PRRs that recognize *S. schenckii* have not yet been identified in humans; however, TLR2 and TLR4 appear to be plausible because many fungi such as *C. albicans*, *Aspergillus* spp., and *S. cerevisiae* are recognized through TLR2 and TLR4. However, recent murine models of sporotrichosis implicate TLR4 in the induction of the oxidative burst [264].

Recognition of fungi via TLR2 and TLR4 activates several signaling molecules including JNK, ERK, p38 MAPK, and NF-kB pathways. While TLR induces release of proinflammatory cytokines such as IL-6 and TNF-α, TLR2 signals mediate anti-inflammatory effect by release of IL-10 that shifts the immune responses toward the Th2 phenotype. Since IL-10 was not detected in studies involving interaction of *S. schenckii* with DCs, these studies suggested that TLR4, but not TLR2, might be the receptor to recognize *S. schenckii* of cutaneous, but not visceral, origin, which induces a strong Th1 immune response. In conclusion, *S. schenckii* of cutaneous, but not visceral, origin may be localized to the skin due to stimulation of protective Th1 responses [121, 261–263, 265]. Nevertheless, the immune status of the host might be another contributing factor that accounts for the limited versus disseminated disease in cutaneous and visceral sporotrichosis, respectively.

Coccidioidomycosis

Clinical Manifestations and Pathogenesis of Cutaneous and Systemic Disease

Coccidioidomycosis (San Joaquin Valley fever) is a mycotic disease caused by *Coccidioides immitis* and the newly proposed phylogenetic species *C. posadasii*. The fungus propagates in soil in the regions of the southwestern United States, Mexico, and Central and South America, in a region corresponding to the Lower Sonoran Life Zone [266]. The saprobic phase is characterized by mycelia that give rise to infectious arthroconidia, which become aerosolized when the soil is disturbed. Humans acquire the infection by inhalation of the arthroconidia, which differentiate into large, endosporulating spherules once they are in the host. The disease presents a diverse clinical spectrum that includes inapparent infection, primary respiratory disease (usually with uncomplicated resolution), stabilized or progressive chronic pulmonary disease, and extrapulmonary dissemination involving skin, which can be acute, chronic, or progressive. The degree of severity varies considerably within each category and depends, in part, on the dose of inhaled arthroconidia, the genetic predisposition of the host, and the host's immunologic status [266–270]. Cutaneous infection with Coccidioides can also be acquired via a percutaneous route. Most percutaneous infections occur in laboratory workers as a result of a hypodermic injection of Coccidioides. Primary cutaneous coccidioidomycosis is characterized by a painful suppurative lesion at the site of inoculation, often with regional lymphadenopathy. Most of the cutaneous coccidioidomycosis acquired via this route is self-limited, and most cases have remained localized [266–270].

Immune Response Against Cutaneous and Systemic Coccidioides

Recognition of coccidioides spherules is dependent upon macrophages, TLR2, and dectin. TLR4 is not involved in recognition of infection, but is necessary in preventing dissemination of disease [271]. Polymorphonuclear leukocytes (PMNLs) comprise the earliest cellular influx to be arthroconidia. Ingestion of the arthroconidia is followed by a respiratory burst. However, fewer than 20 % of the arthroconidia are killed by this mechanism, and some studies suggest that PMNL may promote the maturation of arthroconidia into endosporulating spherules. Transformation of arthroconidia into spherules renders the latter impervious to phagocytosis and killing by PMNLs [272, 273]. Rupture of the spherules and release of the endospores triggers an influx of PMNLs. Ingestion of the endospores triggers an oxidative burst, and the level of intracellular killing is less effective compared to that observed in the killing of arthroconidia by PMNLs [272]. Both arthroconidia and endospores are phagocytosed by

monocytes/macrophages, but less than 1 % of the phagocytosed cells are killed. One mechanism that Coccidioides might use to survive intracellularly is the inhibition of phagosome-lysosome fusion, a strategy used by many intracellular pathogens to evade the antimicrobial effects of phagocytes. Co-incubation of monocytes/macrophages with immune T lymphocytes or IFN-γ significantly enhanced their anticoccidioidal activity [272–274].

Natural killer (NK) cells are a major component of innate immunity against Coccidioides. On activation, NK cells secrete cytokines, notably IFN-γ, and chemokines that induce inflammatory responses and control the activation of monocytes and granulocytes. Before adaptive immunity has fully developed, NK cells are thought to the main source of IFN-γ, in response to macrophage-derived IL-12 and IL-18 [275]. In addition, some studies suggest a direct cytotoxicity of NK cells to Coccidioides. Dendritic cells also play a pivotal role in innate immunity and adaptive immunity against Coccidioides by producing IL-12 [271]. As described before, DCs are sentinel cells that trigger T-cell responses against several fungi. A study has shown the potential immunotherapeutic use of DCs when the anergy demonstrated by peripheral blood lymphocytes from patients with disseminated coccidioidomycosis could be reversed by the addition of DCs pulsed with coccidioidal antigen [276]. Although the study was conducted in vitro, additional studies of the restoration of immunity by DC immunotherapy in animal models could reveal a new avenue for adjunctive therapy in severe coccidioidomycosis [277, 278].

Pro-inflammatory and Th1 cytokines play a dominant protective role in antifungal host defense. It has been reported that heat-killed spherules and arthroconidia of Coccidioides induced the production of TNF-α by adherent mononuclear cells from healthy human donors. TNF-α has several biologic functions, including its ability to activate neutrophils, enhance the cytolytic activity of macrophages, augment NK-cell activity, and promote T and B-cell proliferation. TNF-α has also been implicated as a major component in host-mediated destruction of host tissue. Similarly, IFN-γ production is associated with protection against Coccidioides infection, and significantly lower levels of IFN-γ are detected more frequently in patients with disseminated disease than in healthy, skin test–positive persons. Incubation of the monocytes with recombinant human IFN-γ or recombinant TNF-α augmented the fungicidal capabilities of the monocytes via increases in phagosome-lysosome fusion [274–276, 279, 280]. The mechanism by which IFN-γ or TNF-α activates human monocytes to kill Coccidioides is not known, but in studies with other intracellular pathogens such as those examining responses of human alveolar macrophages from tuberculosis patients, IFN-γ and TNF-α activate the macrophages to generate nitric oxide and related reactive nitrogen intermediates via nitric oxide synthase, using l-arginine as the substrate.

Recently, Th2 and Th17 immune responses have also been found to play a protective role against coccidioidal infection. Eosinophilia is a common finding in patients with coccidioidomycosis and cytokines IL-5 and eotaxin (CCL11), which are chemoattractants for eosinophils may also serve as stimulators of the Th2 response. In recent vaccine studies, it has been suggested that the Th17 response may be the most vital reaction to coccidiodial infection and lack of this response, as demonstrated by a mouse model with no IL-17 receptor on lymphocytes, may lead to increased mortality [281].

Different profiles of adaptive immune responses in persons with various clinical forms of coccidioidomycosis have been characterized. Persons with primary, asymptomatic, or benign disease characteristically have strong skin test reactivity to coccidioidin (the classic antigen preparation that was used in the early skin test and serologic studies), and low or nondemonstrable levels of anti-Coccidioides complement fixation (CF) antibody [279, 280, 282]. The converse pattern develops in patients who develop severe, chronic, or progressive pulmonary or disseminated disease. Typically, these persons, in particular those with disease involving two or more organ systems, are hyporesponsive or show anergy to coccidioidal skin testing but have high levels of anti-Coccidioides IgG to the CF antigen. Recovery from active disease, either spontaneous or in response to antifungal therapy, is in many patients associated with a reacquisition of T-cell reactivity to Coccidioides antigens and decreased CF antibody titers [279, 280, 282].

Chronic or progressive coccidioidomycosis is associated with a polyclonal B-lymphocyte activation, as evidenced by elevated levels of IgG, IgA, and IgE in serum. Antibodies reactive with coccidioidal antigens have been demonstrated within each of these Ig classes [2285-286,291]. Two separate antibody classes are involved, coccidioidomycosis-tube precipitins (TP) and complement fixing (CF) antibodies. The latter tends to be associated with IgG, while the former is usually associated with IgM [271]. Serum IgG levels directly correlate with disease involvement, being highest in patients with multifocal involvement. High CF titers often indicate significant disease severity and therefore suggests that a robust humoral response may be detrimental in patients with coccidioidomycosis. However, more likely, this indicates that antibodies to certain antigens are protective while antibodies to others are not [271]. The serum IgA level is elevated in approximately 20 % of patients, being manifested most often in patients with chronic pulmonary disease. Hyperproduction of IgE would be consistent with a Th2 response and has been demonstrated in approximately 23 % of patients with active disease, with the highest incidence occurring in patients with disseminated disease and, within

this group, in patients who have disease involving two or more organ systems [280, 282, 283].

Longitudinal studies of coccidioidomycosis patients with excessive IgE levels revealed that, in most patients, IgE production diminished to normal or near-normal levels after clinical remission, suggesting that IgE hyperproduction is a consequence of the disease [282]. This interpretation is countered, however, by the report that atopic persons are at greater risk of developing symptomatic coccidioidomycosis than are persons who are nonatopic [284]. Binding of circulating immune complex complement products has been detected in sera from coccidioidomycosis patients and has been shown to correlate with disease severity. Whereas 33 % of sera from patients with disease involving a single organ system had elevated immune complex levels, 67 % of sera from patients with disseminated multifocal disease showed circulating immune complexes. The role, if any, of immune complexes in the immunopathogenesis of coccidioidomycosis is not known.

Investigators reported suppression of lymphocyte proliferation responses when lymphocytes from healthy coccidioidin skin test–positive persons were assayed in the presence of patient sera and, conversely, augmentation of the responses of patient lymphocytes when assayed in sera from healthy subjects (versus autologous serum). However, addition of immune complexes formed in vitro (by the addition of coccidioidin to a serum sample with high levels of anti-Coccidioides IgG) to cultured mononuclear cells from healthy, coccidioidin skin test–positive persons did not suppress their proliferation response to coccidioidin. These results, taken together, argue against suppression by immune complexes and raise the question of whether the suppression observed with patient sera was merely attributable to the neutralization of coccidioidin in such a manner that it was not available to stimulate lymphocytes [277, 278, 284].

Cutaneous Histoplasmosis

Clinical Manifestations and Pathogenesis of Cutaneous and Systemic Histoplasmosis

Histoplasmosis, caused by the dimorphic fungus *Histoplasma capsulatum*, is a deep mycosis endemic to regions in the Western Hemisphere, including southern Mexico and some areas of the southeastern United States. The infection is acquired by the inhalation of spores from soil contaminated by bird and bat excreta. *Histoplasma capsulatum* is an opportunistic pathogen residing in the macrophage phagolysosome. Histoplasma infection commonly results in mild or inapparent clinical symptoms in immune-competent individuals [285–287]. However, in immune-compromised individuals deficient in CD4+ T-cell function, failure of adequate granuloma formation allows the fungus to disseminate systemically and can lead to a life-threatening disease. Thus, in endemic areas, histoplasmosis affects a susceptible population of patients with secondary immune defects due to HIV infection, immune suppression after transplantation, or anti–TNF-α immunotherapy

Three forms of histoplasmosis in susceptible individuals, including acute pulmonary, chronic cavitary, and disseminated histoplasmosis, have been described. In the pre-AIDS era, disseminated histoplasmosis was rare and the cutaneous manifestations were reported infrequently, mainly in patients at the extremes of age and in those with decreased cell immunity secondary to inborn errors of immunity, malignancies, and cytotoxic or steroid therapy. Whether HIV-associated disseminated histoplasmosis is a manifestation of progressive primary infection or whether it represents reactivation of old infection, is currently unknown. The cutaneous manifestations of histoplasmosis are reported to occur in 10–25 % of AIDS patients with disseminated histoplasmosis [288, 289]. Clinical manifestation of cutaneous histoplasmosis varies depending on the stage of the disease and immune status of the host. The cutaneous lesions usually have not only different morphologic appearances in different patients but also varying morphology in the same patient. The cutaneous histopathologic spectrum comprises necrotizing tuberculoid and nonnecrotizing granulomatous inflammation with focal organisms, diffuse dermal histiocytosis (DDH), and diffuse dermal karyorrhexis (DDK) characterized by the presence of sheets of heavily parasitized histiocytes [288–291]. Clumps of H. capsulatum var. capsulatum, released from disintegrating macrophages, are identified predominantly extracellularly in an interstitial location in DDK, while a dense infiltrate of heavily parasitized histiocytes is identified in biopsies demonstrating DDH. Exfoliative dermatitis and cutaneous vasculitis have not been documented in AIDS patients with disseminated histoplasmosis. The lesions are usually painless unless they ulcerate. The skin lesions are widely disseminated, but they are common on the trunk, face, and upper limbs. In the majority of patients, cutaneous histoplasmosis is accompanied by disseminated histoplasmosis involving lung, bone marrow, esophagus, duodenum, and liver [288–291].

Since the clinical lesions of histoplasmosis are nondiagnostic and the morphologic spectrum is shared by a range of infective and noninfective diseases that are common in AIDS patients, the gold standard for differentiating disseminated cutaneous histoplasmosis (DCH) from other processes is the identification and isolation of the infective agent in tissue sections and in fungal cultures, respectively [292–296]. Cutaneous histoplasmosis entails disease caused by two morphologically different forms of the fungus, *H. capsulatum var. capsulatum* and *H. capsulatum var. duboisii*. *H. capsulatum var. duboisii* infection causes a relatively indolent form of histoplasmosis with skin, bone, and lymph node involvement,

and rarely fatal disseminated disease, while *H. capsulatum var. capsulatum* causes widespread visceral (including pulmonary) involvement that is commonly fatal. However, the cutaneous clinical spectrum of *H. capsulatum var. capsulatum* is similar to that caused by *H. capsulatum var. duboisii* infection in some features including isolated or disseminated papules, nodules, plaques, or large subcutaneous nodules. The most important distinguishing feature is the larger size of *H. capsulatum var. duboisii* yeasts (i.e., 8–15 μm) and their predominant location within foreign body giant cells. *H. capsulatum var. capsulatum*, 2–4 μm in diameter, is located predominantly within histiocytes and less commonly in giant cells. Under special circumstances, *H. capsulatum var. capsulatum* is known to transform to a larger size that mimics *H. capsulatum var. duboisii.* Both organisms may be identified extracellularly. Round and oval configuration of the yeasts is common to both variants [292–296].

The yeast forms of *Blastomyces dermatitidis* may resemble *H. capsulatum var. capsulatum*; however, the former forms are multinucleate and demonstrate broad-based budding, while *H. capsulatum var. capsulatum* is uninucleate with narrow-necked budding. Other fungal pathogens with similar morphology are encapsulated and nonencapsulated *Crytococcus neoformans* that stains black or dark brown with the Fontana–Masson stain, while *H. capsulatum var. capsulatum* is characteristically negative. Intracellular small yeast forms have also been documented in sporotrichosis. *S. schenckii*, however, grows easily in cultures as dark brown colonies at 25 °C within 5 days [292–296]. Furthermore, identification of *Sporothrix schenckii* within microabscesses is facilitated when a Splendore–Hoeppli phenomenon is present. The presence of pseudohyphae, and intercellular location of the yeast cells in tissues allow the differentiation of Candida species that have a comparable size range to *H. capsulatum var. capsulatum*. Finally, *H. capsulatum var. capsulatum* must be distinguished from Leishmania species, which may be difficult on low-power examination, as both organisms share a 2–4-μm size range, round and oval morphology, and intracellular location. High power examination, however, demonstrates the kinetoplast of *Leishmania amastigotes*, which on Giemsa-stained sections appears red and is not seen in *H. capsulatum var. capsulatum* [296].

Immune Response Against Histoplasma Capsulatum

Histopathologic examination of skin biopsies from HIV patients with disseminated cutaneous histoplasmosis demonstrated granulomatous inflammation with a histiocytic palisade bordering central necrosis. Although intracellular organisms were identified focally within histiocytes and giant cells, they were not numerous as in the biopsies that lacked a granulomatous component [73, 297]. The granuloma is a form of delayed-type hypersensitivity. Localized inflammatory lesions composed of infected macrophages and fused giant cells can subsequently form granulomata with the help of CD4+ T lymphocytes. CD4+ T cells are very important for initiating and regulating granuloma function, but macrophages are the dominant cell type. A Th1 immune response, in particular, is necessary for control of the infection and is stimulated by IL-12 production as depicted in Fig. 19.7. Similar to other fungal infections, Th17 cells have also been shown to play a proinflammatory role in histoplasmosis infection. However, it seems that Th17 activity is driven more by IL-21 than IL-6 in *H. capsulatum* [298].

The benefit of granuloma formation for the host is that it isolates the inflammation, protects the surrounding healthy tissue, controls the growth of pathogens, and prevents systemic dissemination. At the same time, the microorganism may also benefit from localization to the granuloma. As an isolated microenvironment, granulomas presents a special environment for the pathogen in the host [73, 297, 299]. The chronic granulomatous lesion may be the reservoir from which surviving pathogens emerge to reactivate the infection after a long term latency is broken by a compromised immune system. Thus, granulomata formed in response to macrophages infected by Histoplasma are most likely a dominant component of the highly effective antifungal immune response. Conversely, the progressive, disseminated histoplasmosis observed in immune-compromised persons arises in large part from failures of established granulomas and failure to form new inflammatory lesions in response to recently infected macrophages. While there is growing knowledge about the nature of systemic immunity during the course of histoplasmosis, there is little known about local immune responses within granulomas despite these lesions representing the main interaction between the fungi and the host. A recent study in mice isolated *H. capsulatum*–induced granulomas in order to determine the cellular composition and cytokine milieu of granuloma-infiltrating cells during the course of disseminated infection that involves multiple organs [289].

The average granuloma size reaches a maximum at day 10 of the infection and subsequently declines. Furthermore, this study shows that IL-10 and TGF-β were elevated in the Histoplasma granuloma, mainly at early stages of granuloma formation. The main source of TGF-β was macrophages. In addition to production of IL-10, the decreased granuloma size in this animal model of histoplasmosis was postulated to be due to fungal clearance leading to decreased antigenic stimuli, inflammatory agents, chemoattractants, and attenuated cellular recruitment. Although the new granuloma formation was detected after clearance of the yeast, it is not completely clear whether granulomatous protection is completely sterilizing. However, it is possible that very low

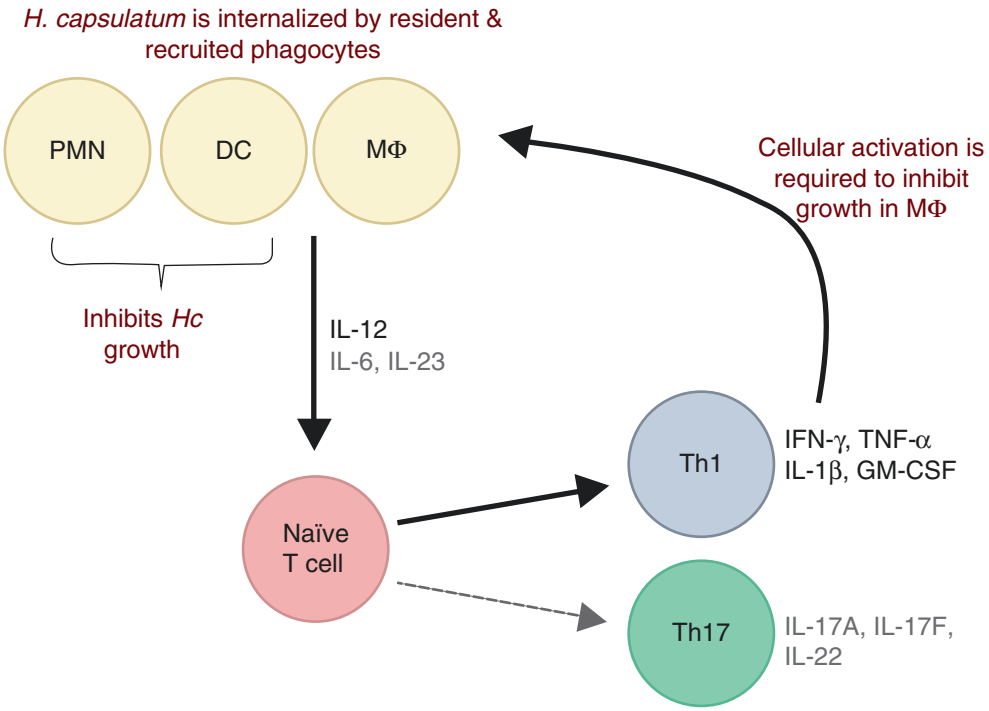

Fig. 19.7 *H. capsulatum* induces a proinflammatory response. Upon inhalation, the H. capsulatum is internalized by host phagocytes. Whereas polymorphonuclear (PMN) and DCs inhibit fungal growth, the organism replicates within macrophages (MΦ) prior to cellular activation. Cytokines such as IL-12, IL-6, and IL-23 are produced during the innate response and are involved in the polarization of naïve T cells. Th1 cells, characterized by IFN- γ, are the predominant T cell population during infection. A smaller population of Th17 population emerges, but only plays a minor role in resolving infection. In addition to IFN- γ, other Th1 cytokines including TNF-a, IL-1b, and GM-CSF activate macrophages to prevent intracellular growth (Reprinted from Cytokine, 58, Kroetz and Deepe [298], with permission from Elsevier)

numbers of yeast survive within granulomas similar to *Mycobacterium tuberculosis* and serve as a source for reactivation during immune deficiency.

Identification of the type of cells infiltrating the granuloma indicates that macrophages are the dominant cell type in the lesion reaching up to 70% of the granuloma. The local expressions of IFN-γ and TNF-α in the lesion indicate that most of infiltrating macrophages are activated. The main cellular source of IFN-γ in the granulomas is CD4+ and CD8+ T cells. Interferon-γ plays a central role in the immunity against H. capsulatum as marked by findings that IFN-γ–deficient animals are killed by H. capsulatum infection [300]. Local IFN-γ activates macrophages to produce reactive radicals crucial to control of the yeast and directly prevents the yeast from replicating by limiting the amount of available minerals (iron, zinc) [298]. The primary cellular source of TNF-α is the macrophage, and T cells contribute little if any to local TNF-α levels. Therapeutic anti-TNF-α treatments induced reactivation of latent *H. capsulatum* infection in some patients, emphasizing the role of this mediator in control of the yeast and preventing dissemination [301]. The H&E-stained sections suggest that most lesions have few, if any, neutrophils, and flow cytometry analysis indicates that only a low percentage of granuloma-infiltrating cells express a dendritic cell phenotype (CD11c+DEC205+) [289]. The latter could be due to the fact that DCs are professional APCs that sample antigens from peripheral sites of infection, and migrate to lymph nodes where they stimulate T cells.

The presence of DCs may provide a local reactivation for the recruited effector T cells and raises the possibility that they sample granuloma Ags and may carry them to draining lymph nodes. The idea that Ags in granulomas might prime systemic T cells needs further investigation. Both effector CD25 low CD4+ and CD8+ T cells are recruited to the lesions. At early stages, there was more CD4+ T cells present, but later the ratio was close to 1:1. This temporal change in the CD4/CD8 T-cell ratio likely reflects the somewhat earlier systemic activation of CD4+ T cells relative to activation of CD8+ T cells. Interestingly, in HIV patients with disseminated cutaneous histoplasmosis, a predominant infiltration of CD8+ T cells was detected in biopsy samples from skin lesions [289]. Both T cells contribute to the cytokine milieu of the granulomas.

In contrast to high infiltration with CD4+ CD25 low T cells, CD25 high CD4+ T cells, thought to be regulatory T cells, are present at much lower levels in the granuloma relative to both infected spleen and naive spleen, suggesting an exclusion of those cells from the local inflammatory site. Thus, the role of regulatory T cells in Histoplasma-induced granuloma formation warrants more investigation since these cells are reported to regulate Leishmania and Schistosoma-induced lesions.

However, due to the limitation of regulatory T-cell classification based on CD25 expression alone, additional phenotypic and functional characterization will be needed in further studies of regulatory T cells in Histoplasma infection. The level of γδ T cells was also lower in granulomas compared with systemic sites; γδ T cells have been reported in granulomas affecting granuloma size during the chronic stage of infection. A low level of B cells was also present having a conventional B cell phenotype (CD5−, Mac-1−) characteristic of peripheral blood [289]. The local Ab production in the granuloma could be potentially important since there are reports that Abs can protect against intracellular yeasts. Taken altogether, local granuloma responses in histoplasmosis at infection site(s) are similar to systemic responses represented by the spleen where responses against Histoplasma infection are dominated by CD4+ Th1 cell responses and require IFN-γ and TNF-α for activation of macrophages.

Conclusion

Due to the increased populations of immunocompromised patients, the clinical relevance of fungal infections has risen in the last three decades. Fungal diseases are classed according to the site of the primary infection: superficial, cutaneous, subcutaneous, and deep or systemic. Dimorphic fungi assume both yeast and hyphal states based on environmental conditions and the hosts' immune response. Certain fungi can synthesize capsular components, which can affect host immune responses. The innate response to fungi serves both a direct antifungal effector activity and an activation and induction of the specific adaptive immune responses. Understanding the immune response to fungal infections has led to better diagnostic tests and therapeutic interventions for fungal diseases. In the future, it is hoped that this knowledge will lead to vaccines for their prevention.

Q&A

1. Which of the following is not a fungal structure that acts as a ligand for toll-like receptors?
   A. β-1,3/β-1,6 glucans
   B. glucuronoxylomannan
   C. cholesterol*
   D. phospholipomannan
   E. galactomannan

2. Which of the following is true regarding the immunoregulatory functions of interleukin 10?
   A. It is produced in a non-antigen specific manner by macrophages*
   B. It is produced in an antigen specific manner by dendritic cells
   C. It is produced in a non-antigen specific manner by regulatory CD4+ cells
   D. It activates the antifungal effector function of phagocytes
   E. It enhances the secretion of proinflammatory cytokines

3. Which toll-like receptor (TLR) is not known to play a role in host recognition of *Candida albicans*?
   A. TLR2
   B. TLR4
   C. TLR6
   D. TLR8*
   E. TLR9

4. Which of the following are thought to be the primary effector cells against Candida spp. that direct the immune system toward either a Th1 or Th2 response via production of either IL10 or IL-12?
   A. CD4+ cells
   B. CD8+ cells
   C. neutrophils*
   D. CD17+ cells
   E. monocytes

5. Which component of the immune response to coccidioides spherules is not involved in recognition of infection, but is necessary in preventing dissemination of disease?
   A. Macrophages
   B. Polymorphonuclear leukocytes
   C. Dectin
   D. TLR2
   E. TLR4*

HIV/Opportunistic Infections

20

Kemunto Mokaya and Toby Maurer

Abstract

HIV adversely affects the immune system via destruction of T cells, macrophages and related effector cells. Clinical manifestations include a spectrum of opportunistic infections, neoplasms and inflammatory conditions. Control of HIV replication involves combination of drugs from two or more classes that significantly lower the viral load and allow increases in immune effector cells. They extend the length and quality of life of HIV patients. These drugs, however, are very expensive and can be associated with resistance and to a number of adverse events. Although effective use of these drugs can reduce transmission of HIV, they do not produce a cure. The best hope for control of the pandemic of HIV is the development of a safe and effective preventative vaccine.

Keywords

HIV • AIDS • cART • IRIS • Opportunistic infections • Viral load

Key Points

- The two major glycoprotein subunits on the HIV envelope that interact with target cell surface receptors are gp120 and gp41.
- CD4, as well as co-receptors, on the target cell surface interacts with gp120 to initiate infection. The co-receptor used by HIV on T cell targets is primarily CXCR4 while the co-receptor used by HIV on macrophage targets is primarily CCR5.
- Mucocutaneous manifestations of HIV affect up to 90% of infected individuals and are due to opportunistic infections, neoplasms and inflammatory dermatoses. Cutaneous findings in individuals often correlate with their immune status.
- Antiretroviral therapy (ART) includes inhibitors of viral reverse transcriptase, protease, and integrase, as well as blockers of fusion and co-receptors (e.g., CCR5).
- ART has prolonged the life of HIV positive individuals, but complications of treatment include various drug reactions and toxicities, and the immune reconstitution inflammatory syndrome (IRIS).

Introduction

Human immunodeficiency virus (HIV) infection continues to be a major global pandemic. Since AIDS was first described in 1981, about 78 million people have contracted HIV, and over half of these have died from AIDS-related causes. Over 35 million people are currently living with HIV [1]. In 2013, an estimated 2.1 million people became newly infected with

the virus, while about 1.5 million people died from AIDS. Despite these sobering statistics, some progress has been made globally to reduce HIV infection, with a 33% decline in new infections since 2001, and a decline in the number of annual AIDS-related deaths since the late 1990s [2]. This progress can be attributed to preventive interventions (such as prevention of mother-to-child transmission efforts, male circumcision, global educational campaigns) and to increased access to healthcare and the use of combined antiretroviral therapy (cART). Since AZT was approved as the first drug to treat AIDS in 1987 and combination anti-retroviral treatments were shown to be highly effective against HIV in 1996, there has been a robust pipeline of new effective antiretroviral therapies. To date, 26 individual HIV drugs have been approved by the United States Food and Drug Administration [3]. These drugs effectively suppress viral load below detectable levels, however, they are unable to eliminate HIV from the body. The successes of cART are tempered by the need for lifelong treatment to suppress the virus – which is costly, drug toxicities, drug resistance, and chronic immune activation, which predisposes HIV-infected individuals to other non-AIDS disorders. There is also a treatment access gap, and it is estimated that just about 13 million individuals (37% of the total HIV-infected population) have access to antiretroviral therapy [4]. To combat the HIV/AIDS pandemic, more efforts are needed to reduce the rates of new HIV infection and to increase access to life-saving cART. The ultimate hope in the war against the virus lies in finding a cure for it – whether this comes in the form of a vaccine, gene therapy or a drug. Therefore, understanding basic virologic and immunologic mechanisms in the pathogenesis of HIV disease continues to be of critical importance.

The HIV Life Cycle

Human immunodeficiency virus (HIV) is a retrovirus. This means that the basic genetic material encoded by HIV is RNA, and that the virus contains an enzyme, reverse transcriptase, which is able to convert viral RNA to viral DNA. Double-stranded viral RNA is contained within the core of the virus, and is immediately surrounded by the viral capsid, which is surrounded by the viral envelope. The viral envelope gene encodes a precursor protein, gp160 which is cleaved into the two major glycoprotein subunits of the viral envelope: gp120 and gp41. These glycoproteins are trimeric, consisting of three gp120 molecules (surface unit), and three gp41 molecules (transmembrane region). The gp 120/41 trimers on the viral envelope interact with cell-surface receptors on target cells to initiate infection [5, 6]. The number of gp120/41 trimers on each virion ranges from 10 to 100 depending on the isolate [7].

The life cycle of HIV begins with viral entry into a new target cell and ends with release of new virions from the infected cell. The first event involves binding of gp120, the major envelope protein of HIV, with the molecule CD4 on the surface of target cells. CD4 extends from the cell membrane, and it is believed that CD4–gp120 interactions induce conformational changes that bring virus close to the cell membrane, and subsequently allow for another region of gp120 to interact with and bind to a HIV co-receptor embedded in the cell membrane [8]. HIV co-receptors are seven-transmembrane–domain molecules, members of the G-protein-coupled receptor family, and normally function as chemokine receptors, helping to mediate chemotaxis during inflammatory processes. The two major HIV co- receptors for HIV are CCR5 [9–11], and CXCR4, [12] although several other minor HIV co-receptors with similar structure and function have also been described [13]. Viruses that are predominantly macrophage-tropic use CCR5 for entry (labeled R5 viruses), whereas viruses that are predominantly T-cell-tropic use CXCR4 for entry (labeled X4 viruses). Viruses that use both receptors are termed R5X4. Determination for co-receptor usage is dictated by the amino acid sequence in the co-receptor binding region of gp120. Recent studies reveal that different R5 viruses prevail during the chronic phase of infection, while X4 viruses are associated with pathologic disease progression [14].

Binding of gp120 to an HIV co-receptor then leads to activation of gp41, the other major envelope glycoprotein, causing conformational changes that lead to fusion of the viral envelope with the cell membrane [8, 15]. Following fusion, viral RNA is released into the cytoplasm of the cell. Detailed knowledge of these events has been greatly facilitated by the discoveries of HIV co-receptors and by identification of the crystal structures of gp41 and gp120 [16, 17]. Importantly, these advances in basic research allow for better understanding of HIV disease pathogenesis and have led to design of new therapeutic strategies aimed at blocking viral entry.

Viral RNA is reverse transcribed to DNA in the cytoplasm by the viral enzyme reverse transcriptase. Much of the genetic variability and the development of drug-resistant HIV strains can be attributed to errors introduced into the viral genome during reverse transcription. Proviral DNA is then transported to the nucleus, where it becomes incorporated into the host genome with the aid of the viral enzyme integrase. Host cellular machinery, in combination with the viral proteins Tat and Rev and transcription factors such as P-TEFb (human positive transcription elongation factor), drive viral transcription [18]. In cytoplasm, viral messenger RNA (mRNA) is then translated into viral proteins, and viral capsids form around paired strands of viral RNA. Capsids obtain outer envelopes upon budding from cell membranes, which are studded with the viral glycoproteins gp120 and gp41. The viral protease enzyme orchestrates release of virions from infected cell membranes. Currently available antiretroviral drugs were designed to specifically inhibit these various steps in the HIV life cycle (see Fig. 20.1).

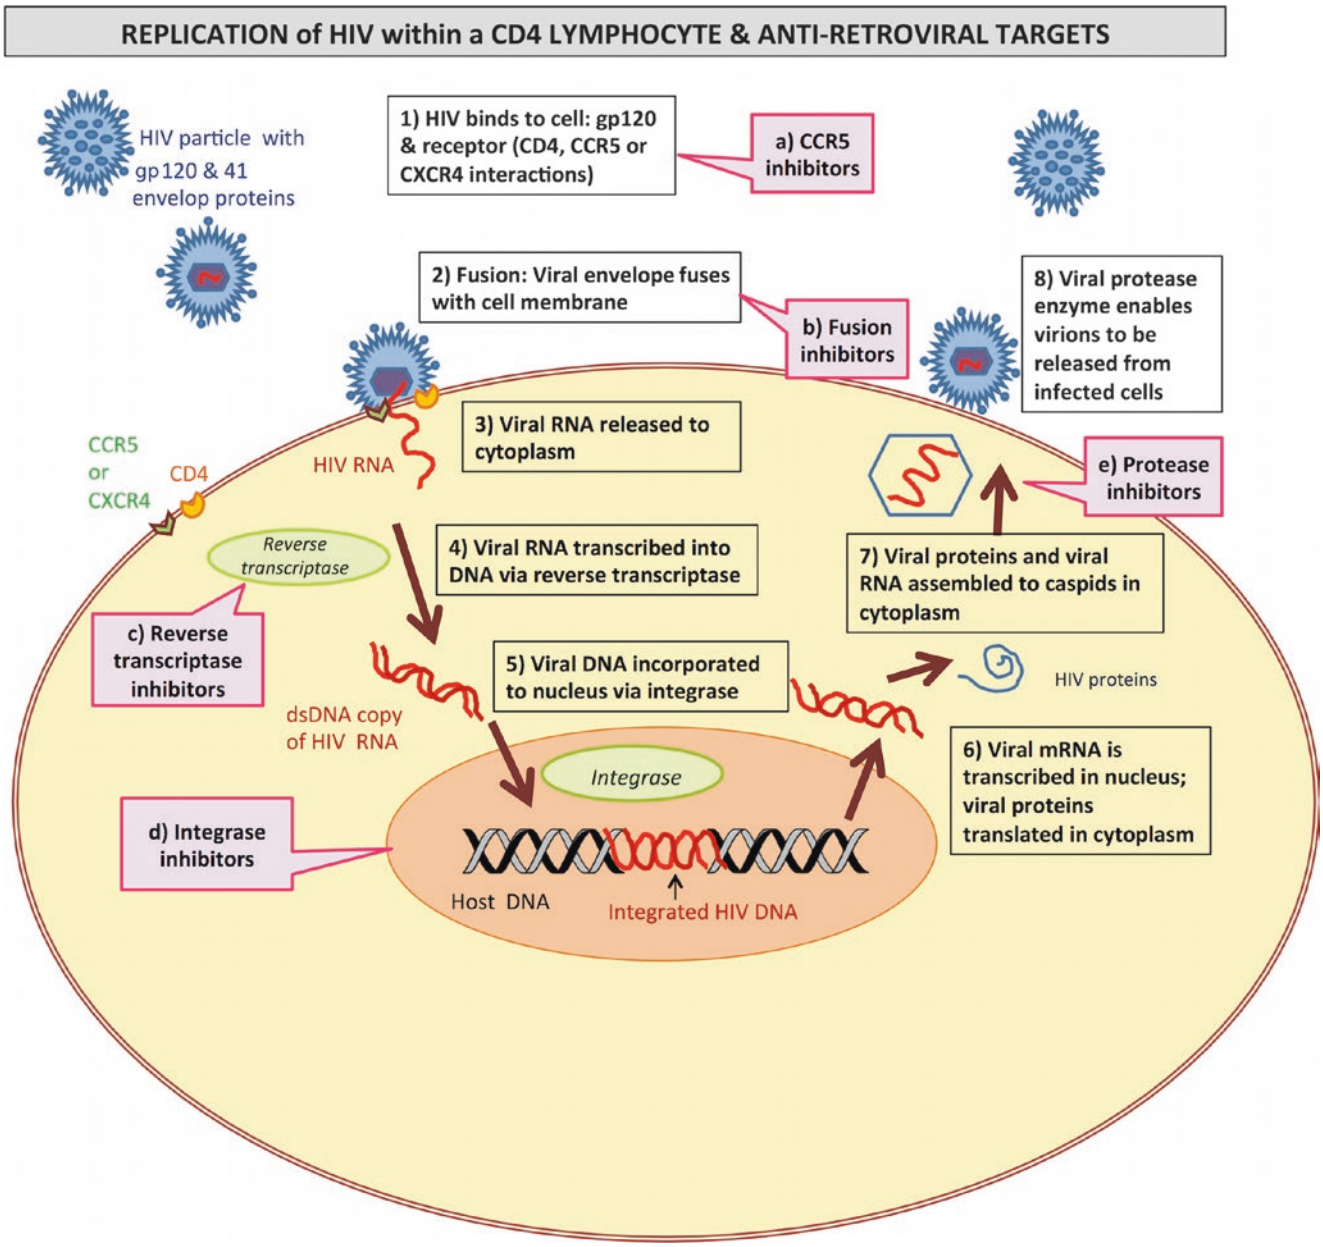

Fig. 20.1 Represents the major steps in the infection of a CD4 lympocyte with HIV. Anti-retroviral drugs have been developed to target various steps in the replication of HIV

Virologic, Immunologic, and Clinical Features of HIV Disease

Early-Stage HIV Disease

Langerhans Cells as Initial Targets for HIV Following Sexual Exposure to Virus

Most HIV infections are transmitted through the mucosa. Most adults acquire the virus via vaginal, penile and rectal transmission, while most pediatric HIV infections occur through the oral ingestion of maternal fluids [19].

Langerhans cells are antigen-presenting cells found within skin and in oral, vaginal, cervical, and anal epithelial layers, and normally function as outposts of the immune system within these tissues [20–23]. Here, they capture surface antigens and emigrate from the epithelium to draining lymph nodes via afferent lymphatics. Langerhans cells then present processed antigenic peptides to T cells, thereby leading to antigen-specific T-cell activation. Intraepithelial Langerhans' cells have been shown to be the first cells infected following vaginal exposure to simian immunodeficiency virus (SIV) in a rhesus macaque model of primary HIV infection [24].

Following infection, Langerhans' cells are believed to migrate from mucosal surfaces to draining lymph nodes via afferent lymphatics, where they transmit HIV to paracortical activated CD4+ T cells, thus establishing infection within the lymph node compartment [25, 26].

In situ, immature Langerhans cells express CD4 and are CCR5+CXCR4− [27–29]. Epithelial cells are CD4− and HIV co-receptor negative and are thus not predicted to be easily infected by HIV. However, they express HLA-DR, CD1a and some mannose dependent C-type lectin receptors (MCLRs) that can function as viral attachment factors [30]. The differential surface expression of CCR5 and CXCR4 may explain why macrophage-tropic, or R5 type, viruses are the dominant type of HIV to be sexually transmitted (90–95 % of cases) [31, 32]. In vitro, human immature Langerhans cells are much more easily infected by R5 viruses when compared to X4 viruses, and cells can be completely protected from infection by blocking CCR5 [33–36]. The importance of CCR5 in initiating primary HIV infection is underscored by the fact that individuals who have homozygous deletion of their CCR5 gene are relatively protected from becoming infected by HIV despite numerous exposures [37–40].

Development of Topical Microbicides to Prevent Sexual Transmission of HIV

In the absence of a prophylactic vaccine against HIV, health measures designed to limit the numbers of new cases of sexually transmitted HIV infection have included abstinence and condom use. Unfortunately, these methods can be impractical in certain countries and social situations where women are not empowered to influence decisions regarding sexual intercourse [41]. Thus, additional means to block sexual transmission of HIV are urgently needed. The use of topical microbicides, drugs or compounds that can be applied to genital tissue prior to sexual intercourse and potentially block sexual transmission of HIV, is being actively investigated [42]. Microbicide acceptability studies in populations of at-risk women have suggested that an effective topical microbicide would likely be used by women [43, 44], potentially making a major impact on improving world health.

In the past decade, several potential microbicides have been developed, many of which have reached Phase III human clinical trials. These include Nonoxynol-9 and cellulose sulfate, which failed due to inducing damage in vaginal epithelia of users thereby increasing HIV infection; and Carraguard, which failed due to lack of efficacy [45–47].

A promising microbicide currently undergoing Phase III clinical trials is tenofovir 1 % gel. In the CAPRISA 004 Phase IIb clinical trial, this gel demonstrated prophylactic efficacy against HIV acquisition [48]. Should it demonstrate efficacy, tenofovir 1 % gel will be the first, successful gel microbicide. Another highly promising potential microbicide that is currently undergoing phase III clinical trials is the dapivirine vaginal ring. Its advantages include its long-acting nature (for a month or longer), its convenient use and discrete nature, its durability and high acceptability among potential users [49]. Other new microbicides in the pipeline include vaginal tablets of tenofovir and emtricitabine [50]. Many other compounds are in the development pipeline, and the future of effective microbicides in multiple formulations to empower at-risk women to prevent themselves from acquiring HIV is promising.

Immunologic Features and Cutaneous Manifestations of Acute Primary HIV Infection

The clinical syndrome in acute HIV infection often develops within 2–4 weeks following exposure and can range from asymptomatic to a severe illness, lasting from a few days to several weeks. 50–90 % of acutely infected patients are symptomatic, often with fevers, lymphadenopathy and the nonspecific flu-like signs and symptoms outlined in Table 20.1 [51, 52]. Rash occurs in a relatively high percentage of patients (50–75 %). Lesions are described as non-pruritic erythematous macules and papules, with a predilection for the upper trunk, head, and neck (Fig. 20.2). The cutaneous eruption is probably caused by infiltration of anti–HIV-specific CD8+ cytotoxic lymphocytes, as has been shown in the skin of rhesus macaques during acute infection with SIV [53]. Painful

Table 20.1 Signs and symptoms of primary HIV infection

Common	Uncommon
Fever (95 %)[a]	Diarrhea (30 %)
Lymphadenopathy (75 %)	Headache (30 %)
Pharyngitis (70 %)	Nausea/vomiting (25 %)
Rash/oral ulcers (70 %)	Hepatosplenomegaly (15 %)
Myalgia/arthralgia (55 %)	Thrush (10 %)
Neurologic symptoms (10 %)	

[a]Approximate incidence

Fig. 20.2 Rash of primary HIV infection. Lesions are characteristically erythematous macules involving the head, neck, and upper trunk. Oral ulcers are also common

oral ulcers are also common in primary HIV infection. Because of the nonspecific nature of these signs and symptoms, clinical diagnosis of acute HIV infection requires a high index of suspicion. Accordingly, it is now suggested that all individuals with known or suspected risk factors for acquiring HIV, who present with rash and fever, should be questioned in detail about possible HIV exposures and have laboratory tests to investigate this possibility [54].

Characteristically, HIV plasma viremia is high during this acute syndrome, with plasma usually containing >100,000 copies of HIV RNA/mL as measured by standard viral load assays, whereas routine HIV antibody tests are negative (Fig. 20.3). The combination of a high viral load and no HIV-specific antibodies confirms the diagnosis of primary HIV infection. Signs and symptoms resolve and plasma viremia gradually drops as cellular and humoral immune responses are initiated to control initial infection. HIV antibody tests usually become positive within 3 months following infection, although this interval may be prolonged in unusual cases.

Most clinicians and HIV researchers promote the widespread use of antiretroviral therapy at the earliest possible time point following diagnosis of acute HIV infection [55, 56]. There are several pieces of data that support this recommendation. First, early use of cART (defined as the use of three or more HIV medications from at least two different drug classes) most likely decreases the "viral set point"—the level of plasma viremia following resolution of acute HIV infection. This level of plasma viremia is linked with the ultimate prognosis for a given HIV-infected individual [57]. Second, cART has been shown to preserve both number and function of anti–HIV-specific CD4+ and CD8+ T cells, believed to be critical in the partial, albeit incomplete, control of HIV replication. Third, early cART likely blunts loss of antigen-specific memory T cells, which are preferentially lost in early HIV disease [58]. Preservation of cellular immunity to common antigens would be predicted to prevent opportunistic infections. Fourth, early initiation of cART reduces plasma HIV-1 concentrations, and has been shown to decrease the risk of viral transmission to others [59, 60]. The drawbacks of treatment with cART in early HIV disease include the possible emergence of drug-resistant strains of HIV, the high cost of medications, drug-related side effects and chronic immune activation resulting in increased risk of several non-AIDS disorders [61, 62].

Middle Stage HIV Disease

Virologic and Immunologic Features That Determine Progression to AIDS

Following resolution of acute infection, HIV-infected individuals often go into a prolonged period without clinical symptoms of HIV disease. This is the clinical latency period. Although plasma viremia is usually low or undetectable during this asymptomatic stage, viral replication continually occurs unabated within lymph nodes and there is gradual damage to the architecture of lymph nodes and other lymphoid tissues [63]. During middle stage HIV disease, CD4+ T cell counts range between 200 and 500/μL, with a slow gradual decline often observed (Fig. 20.3).

As mentioned earlier, three strains of HIV can be classified based on their cellular tropism: (1) macrophage-tropic (R5) strains that preferentially infect peripheral mononuclear cells, monocytes and macrophages via the co-receptor CCR5; (2) T-cell line tropic (X4) strains that preferentially infect T cell lines via the CXCR4 co-receptor; and (3) Dual-tropic (R5X4) strains that infect macrophage and T cell lines using both receptors. R5 strains are present in all stages of HIV. During the middle stage of HIV, there is a gradual increase of X4 strains, which are more cytopathic to CD4+ T cells leading to their gradual decline in numbers.

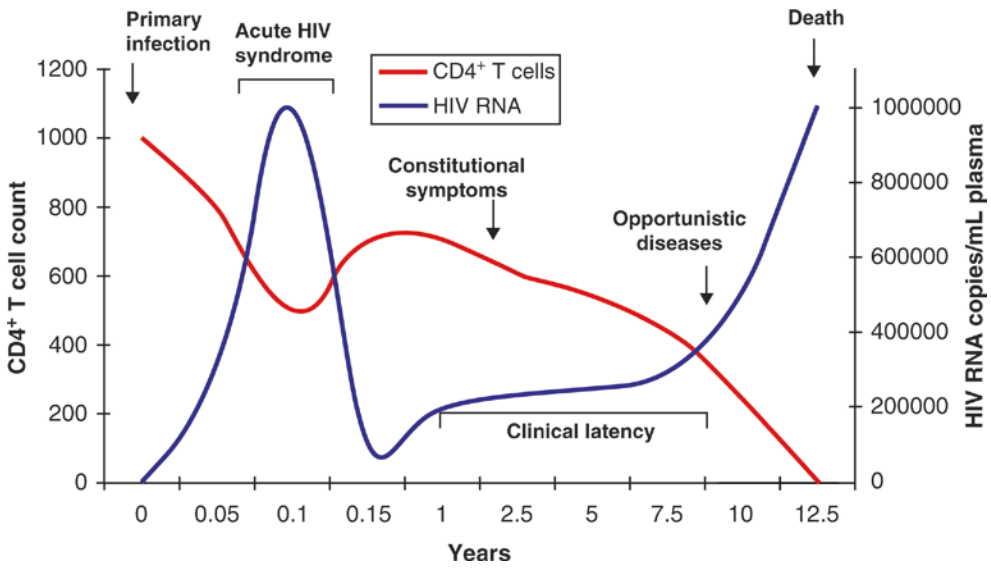

Fig. 20.3 Natural course of HIV disease. Potent highly active antiretroviral therapy (HAART) has a strong influence on this course by prolonging life for HIV-infected individuals

The V3 loop of the gp120 viral protein determines the viral phenotype (R5, X4 or R5X4). It is thought that mutations in gp120 lead to more X4 viruses, which in turn deplete CD4+ T causing the progression to AIDS [64]. However, it should be noted that even individuals with predominant R5 or R5X4 strains still develop AIDS; only at a much slower rate, since the R5 strains are still able to deplete T cells [65].

Deletions or polymorphisms in genes encoding HIV co-receptors (i.e., chemokine receptors) and their ligands (i.e., chemokines) have been associated with delayed HIV disease progression. For example, individuals with a particular polymorphism in their SDF-1 gene, the gene that encodes for the natural chemokine ligand of CXCR4, progress to AIDS less quickly than individuals without this particular polymorphism [66]. Functional studies on the two forms of SDF-1 protein suggest that the variant form is degraded less rapidly than the wild-type form, and would therefore be predicted to have more prolonged binding periods with CXCR4. In addition, heterozygous mutations of the CCR5 gene or its promoters as well as gene duplications in CCR5 ligands prolong the onset of AIDS, presumably by limiting infection and spread of macrophage-tropic viruses early in HIV disease [67–69].

Cutaneous Manifestations of Middle-Stage HIV Disease

Human immunodeficiency virus–infected individuals with CD4+ T-cell counts in the 200 to 500/μL range are mostly asymptomatic, although this certainly is not always true. Signs and symptoms that belie underlying HIV infection often manifest as cutaneous diseases during this phase [70]. In particular, herpes zoster and treatment-resistant seborrheic dermatitis in young persons should alert clinicians to the possibility of coexisting HIV infection and lead to questioning about known HIV risk factors. Zoster involving multiple dermatomes, zoster involving the head and neck, and prolonged healing of lesions are distinct clues to possible underlying immunosuppression, and thus are more common in HIV-infected individuals [71]. Subtle loss of antigen-specific cell-mediated immunity is believed to be the mechanism by which these diseases occur. Although not limited to patients with particular CD4+ T-cell counts, diagnosis of any sexually transmitted disease (syphilis, condyloma, herpes simplex, etc.) should also prompt questioning about possible concomitant HIV infection. Additionally, there is an increase in Staphylococcus aureus colonization and infections in HIV infected people, especially in the middle and late stages of the disease [72].

Acute illnesses, such as herpes simplex reactivation and herpes zoster, lead to tissue inflammation, immune activation, and increases in HIV plasma viremia. The basis for increased plasma viremia is most likely multifactorial. Inflammatory cytokines released during acute inflammation or infection can directly lead to enhanced viral replication within HIV-infected cells. As well, immune activation and cytokine production can stimulate HIV infection of previously uninfected CD4+ T cells. Thus, there is a strong basis for both preventing and aggressively treating all acute infections and illnesses in HIV-infected individuals. Of note, immunizations, which lead to transient activation of the immune system, also trigger transient increases in HIV plasma viremia [73]. The benefits, however, of protecting against future illnesses accorded by immunizations outweigh any potential harm caused by them.

Late Stage HIV Disease, or AIDS

Virologic and Immunologic Features of AIDS

Viruses of all types (T-cell-tropic, macrophage-tropic, dual-tropic) can be isolated from most AIDS patients [64]. Plasma viremia is also usually high in untreated patients (Fig. 20.3). In addition, destruction of lymph node architecture also contributes to high viral loads in blood. This occurs because many infectious HIV virions previously trapped by follicular dendritic cells are released into blood following breakdown of lymphoid tissue [63]. Viral loads can drop dramatically in AIDS patients who are placed on cART for the first time, although it can be difficult for AIDS patients to get to the point where plasma viremia is undetectable [74].

Immune defects in advanced-stage HIV disease are profound. Due to chronic immune activation from persistent viral antigens, both the innate and adaptive immune systems develop immune exhaustion: a state of relative unresponsiveness to the persistent pathogen [75]. T cell exhaustion is weak or absent virus-specific T cell reactivity characterized by impaired cytokine production (such as the loss of interleukin-2 production, a key cytokine involved in normal T-cell function), decreased T cell proliferation, poor effector cytotoxic activity, and sustained expression of inhibitory receptors – such as PD-1, LAG-3, CTLA4, and Tim-3 [76, 77]. Eventually, this results in apoptosis of T cells – preferentially the memory subset of T cells – leads to AIDS. By definition, patients with AIDS have CD4+ T-cell counts less than 200/μL.

B cell exhaustion is also seen in AIDS, characterized by hypergammaglobulinemia, decreased sub-populations of memory B cells, over-representation of exhausted B cells that have decreased capacity to proliferate in response to de novo stimuli, and increased numbers of aberrant naïve B cell subsets – many of which express increased inhibitory receptors [78, 79]. Macrophages also demonstrate numerous defects in AIDS and may also display immune exhaustion, although the mechanism of this is less well understood. Surprisingly, most studies show that dendritic cell function, including epidermal Langerhans cell function, remains relatively intact, even in late-stage AIDS patients [33, 80, 81].

In conclusion, due to immune exhaustion, HIV-infected individuals develop loss of antigen-specific cell-mediated immunity and are susceptible to opportunistic infections. Early initiation of cART is important in reducing viral loads and preventing T-cell exhaustion. Use of cART often leads to increases in CD4+ T-cell counts for AIDS patients [82]. Additionally, new approaches to combating immune exhaustion are being

explored such as the development of molecules that block inhibitory ligand-receptor interactions, leading to the rescue of exhausted T cells. Immunotherapy targeting the inhibition of inhibitory receptors (PD-1, CTLA-4, Tim-3, LAG-3) is not only being studied in chronic viral infections such as Hepatitis C and HIV, but also in fields like oncology in which PD-1 blockage has been used to target tumors in humans [83].

Cutaneous Manifestations of AIDS

In patients with AIDS, especially those that are not on anti-retroviral therapy, the most cutaneous manifestations of their disease are opportunistic infections, which can be viral, bacterial, fungal, parasitic and ectoparasitic (infestations). Additionally, they develop neoplasms such as Kaposi's Sarcoma, lymphomas, non-melanoma skin cancers, and other cutaneous neoplasms. They also develop forms of non-infectious dermatoses such as papular pruritic eruption of AIDS and severe ichthyosis. They are susceptible to many severe drug-reactions such as toxic epidermal necrolysis. Due to AIDS and the initiation of anti-retroviral drugs, they develop metabolic changes such as HIV/ART-associated lipodystrophy. Finally, patients with AIDS who then receive anti-retroviral therapy may develop the immune reconstitution inflammatory syndrome (IRIS), which is the paradoxical worsening of pre-existing infections after initiation of cART due to inflammatory sequelae that result when the immune response to those pathogens is enhanced [84]. These cutaneous manifestations of AIDS are discussed in more detail below.

Kaposi's Sarcoma

Kaposi's sarcoma (KS) is the most common neoplasm in HIV-infected individuals [85]. However, due to more widespread use of anti-retroviral therapy, its incidence is declining, except in resource-poor settings where cART is not readily available. Most investigators now believe KS is not a true malignancy, but rather a multicentric proliferative process driven by inflammation and immune dysregulation. In a landmark study from 1994, the KS-associated herpesvirus (KSHV) – now more commonly referred to as human herpesvirus 8 (HHV-8) – was discovered within lesions of AIDS-associated KS [86]. HHV-8 is transmitted sexually and also through saliva and blood, and it infects endothelial and spindle cells [87]. Factors that play a role in the pathogenesis of KS include loss of HHV-8-specific cell-mediated immune immunity and inflammatory cytokines [88]. Only a small number of cells (<2%) within KS tumors are productively infected with HHV-8 and produce virions. The remaining cells are latently infected with virus [89]. It is thought that the viral genes expressed in latently infected cells contribute to the abnormal spindle cell growth observed in KS lesions [90, 91].

Clinically, KS patients present with violaceous lesions ranging from small papules to large plaques and ulcerated nodules. It typically affects the upper body, usually along the skin-lines. It has a predilection for the face, especially around the nose and oral mucosa. KS can also affect internal organs such as the lymph nodes, gastrointestinal tract and lungs. Multiple treatments exist for KS depending on the stage of HIV, extent of KS and other patient comorbidities. Most patients on cART note regression of their disease: most likely due to improved HHV-8-specific immune function and decreases in HIV-associated inflammatory cytokines that directly stimulate KS spindle cell growth [92]. However, patients on cART may develop KS flares due to immune reconstitution inflammatory syndrome (IRIS). Other options include local destruction (for example cryotherapy), laser therapy, topical alitretinoin, radiotherapy, and intralesional chemotherapy (for example vinblastine). Systemic therapies for disseminated KS include IV liposomally encapsulated doxorubicin, duanorubicin and paclitaxel [93].

Other Viral Infections

Loss of cell-mediated immunity predisposes to viral infections. Infection with herpes simplex virus types 1 and 2 in AIDS patients often results in slow-healing, painful cutaneous ulcerations in the perianal region, genitalia and tongue. These lesions can get large and verrucous, and often take longer to respond to treatment. Varicella zoster virus (VZV) in AIDS patients is usually multidermatomal, and lesions can be chronic, verrucous, ulcerative and widely disseminated with systemic involvement [70]. Treatment and prophylaxis with acyclovir or one of its derivatives is indicated, although clinicians should be wary of the development of acyclovir-resistant strains of both HSV and VZV in the setting of AIDS.

Lytic replication of Epstein-Barr virus within lingual epithelial cells produces oral hairy leukoplakia. This manifests as white corrugated adherent plaques on the lateral aspects of the tongue. CMV viremia can rarely lead to cutaneous diseases, such as ulcers in the anogenital area [94]. Human papillomavirus and molluscum contagiosum virus infections can be particularly aggressive and treatment-resistant in individuals with AIDS. Giant mollusca are seen, and the lesions of HPV can also be quite extensive. Of note, anogenital cancer, like cervical cancer, has been linked to human papilloma virus infection and occurs more commonly in HIV- infected persons compared to the general population [95].

Cutaneous viral infections, like all other cutaneous manifestations of HIV disease, are best treated by first ensuring that patients are on proper cART, which completely suppresses HIV plasma viremia. Second, specific treatment as dictated by the clinical disease, biopsy findings, and culture results should be instituted. As learned in the era prior to cART, specific treatment of AIDS- associated dermatoses is unlikely to be optimally effective in face of uncontrolled HIV plasma viremia and continued destruction of the immune system.

Fungal Infections

Loss of cell-mediated immunity also predisposes to fungal infections. Candidiasis is the most common mucocutaneous manifestation of AIDS, often presenting as friable non-adherent white plaques within oral and vaginal mucosa. Esophageal candidiasis is a particularly painful complication and can lead to impaired swallowing. Treatment and prophylaxis with systemic antifungals is often indicated. Dermatophytosis can also be particularly widespread and difficult to treat.

Systemic fungal infections are also seen in AIDS, with the most common being cryptococcosis and histoplasmosis, where up to 10–15% of patients have cutaneous involvement. Cutaneous cryptococcosis in AIDS usually presents as papules and nodules with central umbilication (i.e., molluscum-like) or necrosis. Histoplasmosis can present with acneiform papules and pustules, which often involve the face. Other systemic fungal diseases that can affect the skin when they are disseminated include coccidioidomycosis, blastomycosis, paracoccidioidomycosis, sporotrichosis, penicilliosis and aspergillosis [96]. Fungal infections in AIDS are best managed by optimizing cART, making accurate diagnoses, and instituting specific antifungal therapy.

Bacterial Infections

Bacillary angiomatosis is caused by gram-negative *Bartonella* bacteria (specifically *B. henselae* and *B. quintana* species), and is thought to be a reactive, vasoproliferative condition. Lesions affect any body site and present as red-purple vascular papules, nodules and ulcers. Staphylococcal infections in AIDS present as impetigo, folliculitis, furunculosis, botryomycosis and cellulitis and tend to be more refractory to therapy. Mycobacterial infections such as cutaneous tuberculosis are seen in AIDS. Other mycobacteria that produce cutaneous lesions include: *Mycobacterium avium* complex, *M. kansasii*, *M. haemophilum* and *M. fortuitum*.

Parasitic and Ectoparasitic Infestations

Scabies, caused by infestation with the *Sarcoptes scabiei* var. *hominis* mite is the most common ectoparasitic skin infestation patients with AIDS. Lesions range from the usual burrows, vesicles and papules – to a widespread dermatitis of thickened, dry, scaly hyperkeratotic eruption called crusted scabies in which thousands to millions of mites may be present on an individual. Demodicosis is also frequent in AIDS. Parasites such as leishmaniasis, acanthamebiasis and strongyloidiasis are also seen in AIDS. In patients with disseminated strongyloidiasis, thumb-print purpura on the lower trunk may be seen.

Neoplastic Cutaneous Disorders in AIDS

In addition to Kaposi's Sarcoma (which is considered both infectious and neoplastic), other neoplastic disorders that may develop in AIDS include lymphomas such as non-Hodgkin B-cell and T cell lymphomas. The lymphomas usually present as violaceous papules and nodules that sometimes ulcerate and resemble panniculitis. Roughly half of non-Hodgkin lymphomas in HIV are associated with EBV infection. Cutaneous T cell lymphomas, squamous cell carcinomas and basal cell carcinomas are also seen in not only AIDS, but also patients with higher CD4 counts. HPV-induced genital SCCs – such as vaginal, cervical, penile and anal SCC – occur at increased frequency and with more rapid progression in HIV-infected individuals.

Other Cutaneous Diseases

Eosinophilic folliculitis is an extremely common cutaneous manifestation of AIDS. Patients present with intensely pruritic urticarial papules surmounted by tiny central vesicles usually on the face and upper trunk [97]. This morphology may not be preserved at the time of presentation due to scratching of lesions, in which case the lesions appear as excoriated papules or small round scars (Fig. 20.4). Lesions are distributed on the face,

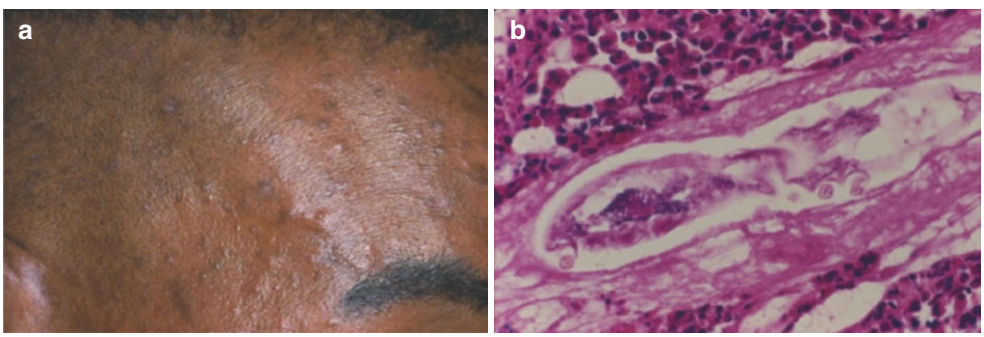

Fig. 20.4 (**a**) Typical urticarial papules of eosinophilic folliculitis. (**b**) High-power histologic view of an early lesion of eosinophilic folliculitis. Demodex mites are characteristically seen within centers of affected hair follicles surrounded by sheets of eosinophils. Excoriated or older lesions show a mixed infiltrate and will not demonstrate mites

neck, and upper chest and back. In early nonexcoriated lesions, Demodex mites are observed within hair follicles at the center of heavy eosinophilic infiltrates [81]. Eosinophilic folliculitis is thought to be an aberrant immune response directed against Demodex mites or *Malassezia* yeast. Treatment options for eosinophilic folliculitis – which is often refractory to therapy – include topical permethrin, topical corticosteroids, topical tacrolimus, UVB phototherapy, systemic antibiotics, itraconazole, dapsone and oral retinoids [98]. Papular pruritic eruption (PPE) of AIDS is believed to be in the same spectrum of pruritic disorders as eosinophilic folliculitis. It primarily affects the extremities more than the trunk and face [99].

Other non-infectious cutaneous disorders seen in AIDS include an acquired ichthyosis with generalized dryness and scaling of skin, refractory seborrheic dermatitis, severe psoriasis, development of refractory oral aphthae, and photosensitive dermatoses such as chronic actinic dermatitis and generalized UV light sensitivity (often with a photolichenoid reaction) [100].

Drug Reactions in AIDS

Drug reactions are common in advanced- stage HIV disease, particularly severe reactions, like Stevens-Johnson syndrome (SJS) and Toxic Epidermal Necrosis (TEN), which occur with increased frequency in these patients [101]. The most common drug eruptions in AIDS are morbilliform eruptions. Others include urticarial eruptions, vasculitis, exfoliative erythrodermas, photodermatitis and SJS/TEN. Common triggers of AIDS-associated drug reactions include medications like trimethoprim-sulfamethoxazole and the antiretroviral drug nevirapine. Up to 8 % of patients treated with nevirapine develop Steven Johnson's syndrome [102]. Additionally, patients taking protease inhibitors may develop a syndrome with clinical features resembling Cushing's disease. These individuals have central fat deposition ("buffalo humps," protuberant abdomens, gynecomastia), wasting of facial fat and peripheral fat of the arms and legs, hypertriglyceridemia, glucose intolerance, and increased risk for myocardial infarction (Fig. 22.6) [103]. Unlike in Cushing's disease, the pituitary axis is unaffected. Facial wasting may be treated by switching drug regimens that have less lipodystrophic effects and by injection of filler substances [104, 105]. Other cART-associated cutaneous drug reactions have also been reported, including abacavir hypersensitivity, zidovudine-associated hyperpigmentation of the nails, and retinoid-like effects due to protease inhibitors (Table 20.2) [106]. The pathogenic basis for all of these drug reactions occurring in HIV-infected individuals is unclear (Figs. 20.5 and 20.6).

Table 20.2 Major adverse cutaneous manifestations of cART

Hyperpigmentation due to zidovudine
Hypersensitivity due to abacavir
Stevens-Johnson syndrome due to nevirapine
Lipodystrophy due to indinavir, ritonavir, stavudine, or zidovudine
Retinoid-like effects due to indinavir
Injection site reactions to enfuvirtide
Morbilliform eruptions to most drugs

Fig. 20.5 Nevirapine-induced Stevens-Johnson syndrome. This side effect occurs in approximately 8 % of individuals treated with this drug

Fig. 20.6 Protease inhibitor-induced lipodystrophy. "Buffalo hump" along with other fat accumulations centrally (i.e., in breast and abdomen) occurs in combination with loss of fat on the face and extremities

Immune Reconstitution Inflammatory Syndrome (IRIS)

The immune reconstitution inflammatory syndrome (IRIS) is the paradoxical worsening or unmasking of pre-existing infections after initiation of cART due to inflammatory sequelae that result when the immune response to those pathogens is enhanced. This clinical deterioration of patients on cART typically presents within the first weeks to months of cART, especially when CD4+ cell counts increase by at least two-fold from low pre-treatment levels. An estimated 10–25 % of patients on cART develop IRIS [107]. The mechanism of IRIS is not fully understood; proposed mechanisms include the uncoupling of the innate and acquired immune responses, restoration of pathogen-specific immune responses and defective regulatory responses [108]. Examples of cutaneous diseases that can flare due to IRIS include: mycobacterial infections (*m. tuberculosis*, *m. leprum*, *m. avium* complex), cryptococcus, VZV and HSV, cytomegalovirus, Kaposi's Sarcoma and many others. Strategies to prevent IRIS include initiation of cART before the CD4+ T cell count drops below 100 cells/mm^3, delaying cART initiation until an opportunist infection resolves, starting cART with prophylaxis against suspected infections, and the use of corticosteroids and nonsteroidal anti-inflammatory drugs [109].

Conclusion

Basic science advances in immunology and virology have led to key advances in the care and management of HIV-infected individuals. For instance, knowledge of the structure and function of the viral proteins and life cycle of HIV has led to the development of novel antiretroviral medications. As well, increased understanding of the initial and later stages of HIV disease through epidemiologic, clinical, immunologic, and genetic studies has provided a solid basis for using these medications in a proper manner. As has been consistently demonstrated in the past, therapeutic advances to combat HIV disease in the future are likely to be based on discoveries in basic virology, biology, and immunology. As evidenced by numerous cutaneous manifestations that can occur throughout the course of HIV disease, the dermatologist remains an important member of the team caring for infected individuals.

Questions

1. **What are the steps required in the life cycle of the HIV virus: from infection of a target cell to the production of virions?**
   Answer: See Fig. 20.1. Binding of HIV to target (gp120 binds CD4 and co-receptors (CCR5 or CXCR4) → Fusion of HIV to target cell → Release of viral RNA to cytoplasm → Transcription of viral RNA to viral DNA (via reverse transcriptase) → Integration of viral DNA to human genome → Transcription of viral mRNA → Translation of viral mRNA to viral proteins in cytoplasm → Assembly of viral proteins into capsids in cytoplasm → Release of virions from infected cells

2. **What are the 5 major classes of currently available anti-retroviral drugs? Describe how they target the HIV life cycle**
   Answer: See Figure 1:
   A. CCR5 inhibitors that try to prevent viral interactions with co-receptor
   B. Fusion inhibitors that prevent HIV from fusing to target cell
   C. Reverse transcriptase inhibitors that block the virus reverse transcriptase. Of 2 types: nucleoside reverse-transcriptase inhibitors (NRTIs) and non-nucleoside reverse-transcriptase inhibitors (NNRTIs)
   D. Integrase inhibitors that inhibit integration of viral DNA to human genome
   E. Protease inhibitors

3. **A HIV positive patient who you normally see for psoriasis has been increasing the frequency of his visits because his scalp lesions are increasingly difficult to control. He presented last month with thrush, and today, comes in with worsened psoriasis and a painful vesicular eruption affecting 4 dermatomes on his left chest and back. Based on his clinical presentation, what do you estimate his CD4+ T cell count is? What other findings would you expect in someone with a similar CD4+ T cell count?**
   Answer: CD4 count is below 500 cells/mm^3. See Table 20.2 for other findings

4. **What is the immune reconstitution inflammatory syndrome (IRIS)? List some conditions where IRIS has been noted**
   Answer: IRIS is the paradoxical worsening or unmasking of pre-existing infections after initiation of cART due to inflammatory sequelae that result when the immune response to those pathogens is enhanced. It has been seen in Kaposi Sarcoma, mycobacterial infections, Cryptococcus, etc

5. **What are some common side effects of anti-retroviral medications?**
   Answer: Lipodystrophy → Morbilliform reactions to most drugs, retinoid-like effects, lipodystropyhy, SJS/TEN, hyperpigmentation, abacavir hypersensitivity

6. **What is immune exhaustion in T cells and B cells, and what are some strategies to prevent/ delay it?**

Answer: Immune exhaustion is a state of relative unresponsiveness of the innate/ adaptive immune system due to chronic immune activation from persistent viral antigens. Leads to impaired cytokine production by T cells, decreased T cell proliferation, poor effector cytotoxic activity, and sustained expression of inhibitory receptors in T cells. In B cells, it is characterized by hypergammaglobulinemia, decreased sub-populations of memory B cells, over-representation of exhausted B cells that have decreased capacity to proliferate in response to de novo stimuli

– Strategies to prevent it include early initiation of antiretroviral therapy; and new immunotherapy agents in development that target inhibitory receptors on B/T cells

Immunopathogenesis of Psoriasis

21

Paola Di Meglio and Frank O. Nestle

Abstract

Psoriasis is a common, complex, inflammatory skin disease resulting from the interplay of genetic, environmental and immunological factors. In the last four decades, advances in understanding psoriasis etiopathogenesis have resulted from pivotal genetics studies, as well as, the integration of clinical and experimental models of disease. This has resulted in the identification of several psoriasis susceptibility genes as well as cellular and molecular mediators, with some of these findings already translated in novel targeted therapies. Here we review the psoriasis literature, describing the elucidation of key pathogenic mechanisms and their translation into effective drugs. Moreover, we describe how the stratified medicine approaches being developed in psoriasis and the quest for psoriasis biomarkers are poised to predict individual susceptibility to disease, detect the onset of disease at the very earliest stages pre-empting its progression, and to develop and prescribe safe and effective medicines to each patient.

Skin • Genetics • T cells • Keratinocytes • Targeted therapies • Biomarker • Stratified medicine

Introduction

Psoriasis is a complex disease, resulting from the interaction of genetic, environmental, and immunological factors [1, 2]. The complexity of its etiopathogenesis is mirrored by a spectrum of clinical phenotypes, which often associates with comorbidities that are also multi-factorial and possibly feed back onto the primary disease. Being one of the most common skin conditions, psoriasis has received a great deal of attention from clinicians and basic scientists alike in the past four decades, becoming a model to study chronic skin inflammation. This joint effort has resulted in the elucidation of many underlying pathogenic mechanisms and, more importantly, has been translated in novel therapeutic strategies. Here, we review recent advances in understanding the complex genetic, environmental and immunological basis of psoriasis, identify research gaps which need to be filled in, describe how some of the more recent findings have resulted in novel targeted therapies already available in the clinic or in advanced stages of clinical trials, and highlight how stratified medicine approaches and the quest for psoriasis biomarkers has begun in earnest to further improve patients' life.

Epidemiology, Clinical Subtypes and Histological Features

Psoriasis is a common disease, affecting 2–4 % of the population in western countries, with prevalence rates influenced by age, geographic location and genetic background [3]. Prevalence is higher in adults (from 0.91 to 8.5 %) as

A.A. Gaspari et al. (eds.), *Clinical and Basic Immunodermatology*, DOI 10.1007/978-3-319-29785-9_21

compared to children (from 0 to 2.1 %) with a dual peak of incidence: an early onset, before the age of 40, which is often associated with familiar disease history and showing high association with the human leukocyte antigen (HLA)-Cw0602 allele (type I psoriasis), and a late onset, after the age of 40 (type II psoriasis). Geographical patterns of prevalence suggest lower prevalence in countries closer to the equator, in keeping with the beneficial effects of UV radiation exposure [4]. Prevalence is higher in individuals of European descent (from 0.73 to 2.9 %) as compared to those of African and Asiatic background (from 0 to <0.5 %).

Psoriasis has traditionally been considered to affect both genders equally; however recent data about age stratification within gender shows a higher incidence in females <18 years old, and conversely a higher incidence in males ≥18 years old [5, 6].

The term psoriasis (from the Greek word *psora*, to itch) encompasses a number of distinct clinical phenotypes [7]. This heterogeneity often represents a dynamic, anatomical or qualitative spectrum of the same disease (e.g. large and small plaque-psoriasis), while in other cases most likely pins down the existence of quite different disease entities (e.g. generalized pustular psoriasis, GPP). According to the International Psoriasis Council, there are four main forms of psoriasis: plaque-type, guttate, GPP, erythroderma, plus several further sub-phenotypes defined based on different parameters; i.e. the distribution, anatomical localization, size and thickness of plaques, onset and disease activity [8].

Plaque-type psoriasis, occurring in 85–90 % of affected patients is the most common form of psoriasis, the most studied and also the one usually targeted in randomized controlled clinical trials. Plaque-type psoriasis is characterized by oval- or irregularly-shaped, red, sharply demarcated, raised plaques, covered by silvery scales [1, 7] (Fig. 21.1). Plaques occur mainly on the extensor surface of elbows and knees, on the scalp and in the lower back, but can affect every area of the body, often with a symmetrical distribution. Key histological features of psoriasis are epidermal thickening (acanthosis), incomplete keratinocyte terminal differentiation with retention of the nucleus by corneocytes (parakeratosis) and thickening of the *statum corneum* (hyperkeratosis), elongation of the rete ridges extending downward between dermal papillae (papillomatosis), together with blood vessel dilation and immune cell infiltration into the skin. In the epidermis, neutrophils accumulate into the parakeratotic scales in the *stratum corneum* forming Munro microabscesses while lymphocytes, mainly CD8 + T cells, are interspersed between keratinocytes. The dermis is heavily infiltrated by T cells (mainly CD4+) and dendritic cells (DC).

Psoriasis is a dynamic disease: newly formed lesions evolve into an advanced plaque that can slowly enlarge (active lesion) or remain static (stable lesion) [8]. Resolving lesions after therapy can be encased by a distinctive rim of blanching (Woronoff's ring), predictive of clearing, and are histologically characterized by orthokeratosis, that is thickening of the *stratum corneum* without parakeratosis and restoration of the *stratum granulosum*.

Guttate psoriasis, from the Latin "*gutta*" for tear drop, is characterized by multiple small scaly plaques, commonly occurring around the trunk and upper arms and thighs. The rash has often abrupt onset, usually within 2–4 weeks after streptococcal pharyngitis in children and young adults and is therefore associated with type I psoriasis [8]. Guttate psoriasis can either completely clear spontaneously or following topical treatment, become chronic, or worsen into the plaque-type.

Generalized pustular psoriasis (*GPP*), also known as von Zumbush psoriasis, is a rare but potentially life-threatening disease characterized by episodic, widespread skin and systemic inflammation. A typical histological feature of GPP is the presence of conspicuous aggregates of neutrophils infiltrating the *stratum spinosum* (spongiform pustules of Kogoj) and giving rise to sterile cutaneous pustules [7]. Acute attacks can occur during pregnancy and may be triggered by infection, exposure to or withdrawal of drugs. GPP is frequently associated with plaque type psoriasis and/or palmoplantar pustular psoriasis (PPP). Although still classified as a variant of psoriasis, the salient clinical and histological feature of GPP have long suggested that is a disease of distinct aetiology.

Recent genetic data lend further support to this hypothesis suggesting that, at least in certain cases, GPP is inherited as an autosomal recessive trait, due to mutations in the *IL36RN* gene encoding the anti-inflammatory IL-36-receptor antagonist, IL-36Ra [9, 10]. IL-36Ra blocks the pro-inflammatory cytokines IL-36α/β/γ: when *IL36RN* is mutated, IL-36 signaling is unrestrained, with enhanced production of further pro-inflammatory cytokines [10]. However, IL36RN mutations only occur in a minority of patients [11], thus more genetic determinants are likely to be involved. Interestingly, a *de novo* mutation in the epidermal NF-kB activator *CARD14* [12] has been described to underlay a sporadic case of severe GPP, suggesting that keratinocytes dysfunction is likely to play a predominant role in this disease phenotype.

Erythrodermic psoriasis is characterized by diffuse erythema, with or without scaling, involving more than 75 % of the skin surface. It represents the most severe, albeit rare, psoriasis phenotype. Systemic manifestations such as hypothermia and limb oedema might occur, due to the generalized vasodilation underlying the erythema, as well as myalgia, fatigue and fever. Both administration and abrupt withdrawals of systemic corticosteroids or methotrexate, sunburn and emotional stress have been suggested as possible triggering factors [13].

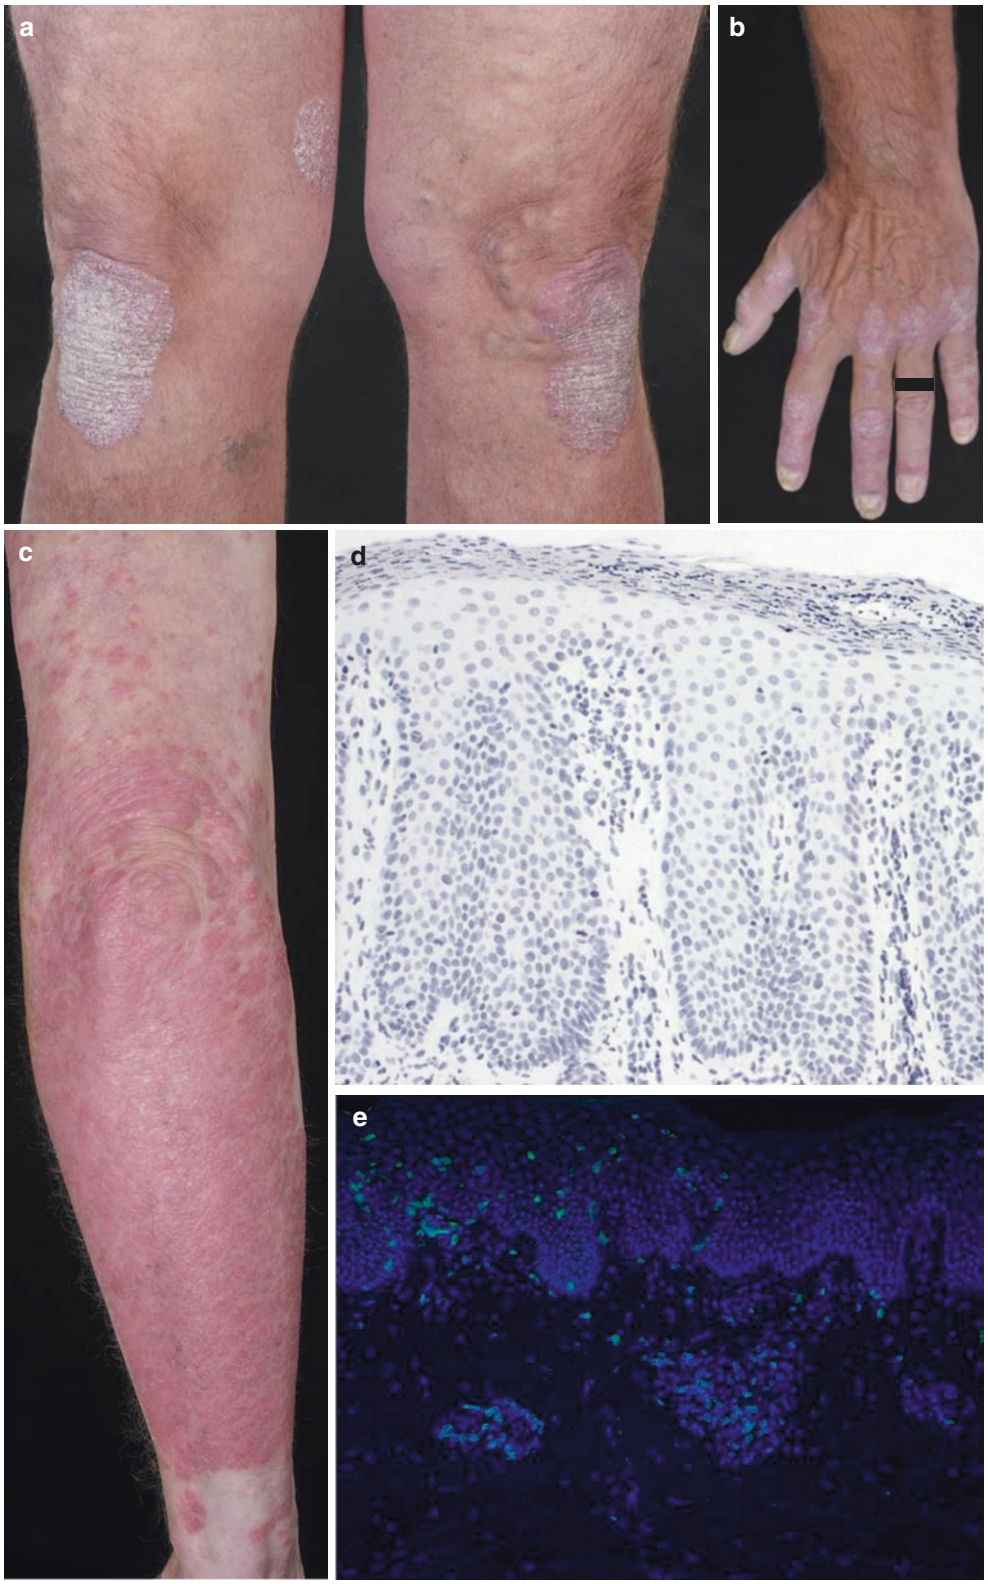

Fig. 21.1 Clinical and histoimmunological features of psoriasis- (**a**–**c**) clinical photographs of chronic plaque-psoriasis, note nail involvement in (**b**). (**d**) Hematoxylin-stained skin section from chronic plaque-psoriasis showing acanthosis, papillomatosis, parakeratosis, as well as Munro abscess. (**e**) Immunofluorescence staining of chronic plaque-psoriasis showing skin-infiltrating CD3+ T cells in green (Reproduced with permission from: Di Meglio et al. [242])

Added together, these last three forms of psoriasis represent 10–15 % of psoriasis cases. Both their relative infrequency as compared to the plaque-type form, and their peculiar epidemiological and clinical features (e.g. high prevalence in children and young adults for the guttate form or the extremely severe systemic manifestation for GPP and erythrodermic psoriasis) have hampered so far a thorough investigation of the genetic determinants and molecular and cellular mechanisms underlying their pathogenesis, which might diverge from that of plaque-psoriasis. Moreover, very few or no randomized controlled clinical studies have been specifically conducted with these forms of psoriasis thus far, leaving open only the option for off label use of approved therapy for plaque-type psoriasis which might or might not be effective. Thus, a concerted effort by the wide international scientific community is requested to fill both these gaps in the near future.

Co-morbidities

Psoriatic Arthritis

About 20–30 % of psoriasis patients develop psoriatic arthritis (PsA), a seronegative, chronic inflammatory muscoskeletal disorder, occurring in most cases about a decade after the appearance of psoriasis [14].

PsA has a complex aetiology mirrored in a wide spectrum of clinical disease presentation, expression and clinical course [15]. PsA can affect different tissues (synovium, cartilage, bone, entheses, tendons); it presents common involvement of distal joints, asymmetric articular distribution, erythema over affected joints, spinal involvement and enthesitis [14] and eventually leads to erosion and loss of function of the affected areas.

Since about 80 % of the patients develop PsA following psoriasis [16], PsA is sometimes considered as a disease within a disease with the skin manifestation being the parent disease [17]. PsA has a stronger genetic component than psoriasis (sibling recurrence risk (λ_s) of 27–47 for PsA v [18] *vs.* 4–11 for Ps [19]), however it is not as well defined as that of psoriasis due to phenotypic heterogeneity, disease overlap and smaller number of patients analyzed. Several PsA susceptibility genes, such as *HLA-C*, *IL12B*, *IL23R*, *TNIP1*, overlap with psoriasis [16, 20, 21]. On the other hand, differences in the genetic background of the two conditions do exist and unique genetic determinants have been identified, although not at a genome-wide significant level [21]. Nevertheless, PsA shares several key cellular and molecular mediators with psoriasis, such as lymphocytes infiltrating the inflamed skin or joint [22] and the pro-inflammatory cytokines TNF, IL-23, and IL17. TNF is a critical disease player and about 70 % patients successfully respond to anti-TNF therapy in terms of signs and symptoms improvement, and, in some cases also by radiographic progression [15]. Moreover, clinical trials showed efficacy for the anti IL-12/IL23p40 antibody ustekinumab [23–25] or anti-IL17 secukinumab [26] in the treatment of PsA.

Other Co-morbidities

The association of psoriasis with physical and psycho-social co-morbidities, such as cardiovascular disease (CVD, i.e. myocardial infarction (MI) and stroke), metabolic disorders (obesity, non-alcoholic fatty liver disease, dyslipidaemia and diabetes), depression and Crohn's disease (CD), is increasingly being appreciated and results in a more modern definition of the disease as a systemic inflammatory disorder in which the chronic nature of the skin inflammation is likely to contribute to the development of associated co-morbidities [27]. In analogy with that occurring in atopic dermatitis, the concept of "psoriatic march" has been proposed to describe the synergistic interplay of psoriasis and its co-morbidities in the establishment of systemic inflammation [28].

Moreover, in analogy to hypertension being called the "silent killer", psoriasis has been recently dubbed the "visible killer" [29] as patients with severe psoriasis have a 6-year reduction in life expectancy, mainly due to excess risk of CV death [30, 31]. The association between psoriasis and CVD has attracted considerable interest since a significant increased risk of death from CVD for psoriasis patients requiring hospital admission was reported in 2004 [32]. Nevertheless, it has been long known that psoriasis patients have a higher prevalence of traditional cardiovascular risk factors such as diabetes, hypertension, dyslipidaemia, obesity, and metabolic syndrome compared to the general population [33–35] that might account for some or all of the increased CVD risk. Therefore, a number of population-based epidemiological studies have been performed in the last decade to address this issue. Unfortunately, these studies are often heterogeneous in their data collection methods, outcomes, sample size and thus in statistical power, and display variable degrees of control for confounding factors [29, 36, 37]. This heterogeneity is likely to account for some conflicting results [38–40].

Nevertheless, a growing body of epidemiologic literature suggests that severe psoriasis (defined in most of the studies as affecting >10 % body surface area or requiring systemic treatment or phototherapy) confers a clinically significantly increased risk of CVD and cardiovascular mortality that is independent of conventional risk factors [39, 41]. A recent meta-analysis, including 14 previous epidemiological studies of which ten were population-based, showed increased risk of CVD in patients with severe disease, with OR relative

to the general population of 1.37 for CVD mortality, 3.04 for myocardial infarction (MI) and 1.59 for stroke [42]. Thus, psoriasis has been included as an independent risk factor for CVD in recent guidelines for CVD prevention (Fifth Joint Task Force of the European Society of Cardiology, 2012).

Moreover, severe psoriasis has been shown to be an independent risk factor for atherosclerotic CV disease, as defined by outcomes such as imaging of coronary and carotid arteries, and measurements of endothelial function and arterial stiffness [43–45].

As mentioned earlier, high prevalence of metabolic syndrome has been reported among psoriasis patients, with more than two-fold increased odds ratio (OR) in psoriasis patients, compared to matched healthy controls [46]. In particular, the association of type 2 diabetes with psoriasis is stronger in patients with severe disease (OR = 1.97) as compared to those with mild disease (OR = 1.53).

Clinical data and a better understanding of psoriasis immunopathogenesis also support these epidemiological observations. Elevated levels of nonspecific inflammation markers (e.g. as C-reactive protein), pro-inflammatory cytokines (such as TNF and IFN-γ) and immune cells (such as T helper type 1 (Th1) and Th17) in the circulation of psoriasis patients [47, 48], and the fact that most of these inflammatory markers are also increased in the skin lesions [49], strongly support that psoriasis is not only *skin deep*. Indeed, psoriasis patients have high levels of lipids and lipid peroxidation, altered adipokine function [50, 51] as well as abnormal coagulation profile [52, 53].

Despite a definitive biological link between co-morbidities and psoriasis has yet to be identified, it is reasonable to infer that the systemic inflammation and dyslipidaemia present in patients may predispose to impaired glucose tolerance and cardiovascular damage [27]. It has been suggested that the pro-inflammatory molecules produced by the skin could be released into the systemic circulation; in fact several genes differentially regulated in psoriasis are linked to functional pathways associated with metabolic diseases/diabetes and cardiovascular risk [49]. For instance renin, an enzyme involved in the renin–angiotensin pathway ultimately regulating blood pressure, is over-expressed in psoriatic skin, suggesting a functional link between expression profile at the skin level and peripheral functions. The presence of IL-17A/IL-17 F and CD4+ cells expressing IL-17 and IFN-γ in atherosclerotic lesions [54, 55], and risk alleles shared between psoriasis and its metabolic and cardiovascular co-morbidities [56], also lend support to the association between psoriasis and these diseases.

Epidemiological [57–59] and genetic [60, 61] studies support a close relationship between psoriasis and inflammatory bowel diseases (IBDs). Increased occurrence of psoriasis has been reported in patients with CD (8.9 %) yielding an aggregate relative risk of 7.1 ($\chi^2 = 139$, $P < 1 \times 10^{-9}$) [62]. Conversely, Li et al recently reported that women with psoriasis have a significantly increased risk of CD (relative risk (RR), 3.86, 95 % CI 2.23–6.67), but not ulcerative colitis (UC) (RR, 1.17, 95 % CI 0.41–3.36) [58].

Remarkably, psoriasis and IBDs share a number of common genetic determinants such as *IL23R* [60, 61].

Finally, psoriasis carries a severe psychosocial burden with anxiety, depression and perceived stress appearing at higher rate in psoriasis patients [63]. The impact of psoriasis on health-related quality of life is similar to that of other major medical diseases, including cancer, arthritis, hypertension, heart disease, diabetes, and depression [64]. Psoriasis patients find it hard to adapt to the chronic yet variable and unpredictable nature of the disease. Another major component of psychological distress is the anticipated negative reactions of others which can be of shame or stigmatization. Coping mechanisms include avoidance and seclusion which in turn affect their quality of life.

Changes in cognitive processing of facial expressions of disgust have been identified in psoriasis patients, who display smaller signal responses to disgusted faces to protect them from stressful emotional responses [65].

Depression, which is one of the stronger predictors of suicidal ideation, has been observed in more than 60 % of patients [66], and higher prevalence of suicidal ideation has been detected in psoriasis patients as compared to healthy controls and patients affected by other skin disease [67, 68].

Taken together, clinicians are presented with the challenging task of managing a multifaceted and lifelong disease which, although apparently not lethal, can severely affect patients' quality of life and, in some cases, life expectancy.

Thus, the current focus is not to only treat but to manage psoriasis patients [69]. A multidisciplinary approach is needed, particularly in cases of severe psoriasis with multiple comorbidities or cardiovascular disease with dermatologists alerted to detect and react to early indications of cardiovascular risk factors and comorbidities in psoriasis patients. While all patients should be encouraged to correct their modifiable cardiovascular risk factors, particularly obesity and smoking, and to adopt healthy lifestyle behaviours, patients with moderate to severe psoriasis are to be recognized and managed as being at intermediate risk of CVD with appropriate counselling and treatment [70].

Moreover, a patient-centred therapeutic approach, undertaken early in the psoriasis treatment pathway ("early intervention") aimed at complete clearance, has been advocated to improve control of cutaneous symptoms and modify disease course and burden [71].

A number of outstanding questions arise from the study of psoriasis and its comorbidities, including what is the effect of systemic therapy for psoriasis on CVD and diabetes [42, 72] and whether an association exists between specific subtypes of psoriasis and co-morbidities.

Etiopathogenesis

Psoriasis is a complex disease occurring in genetically predisposed individuals, in which a dysregulated immune response takes place following exposure to certain environmental triggers.

Genetics

Genetic predisposition to psoriasis is supported by population and family studies, as well as, higher concordance rates in monozygotic twins, compared with dizygotic twins (up to 73 vs. 20 %, depending on the population studied) [73–76]. Lack of complete concordance between monozygotic twins and familial occurrence of disease not following a clear inheritance pattern, support the definition of psoriasis as a complex genetic trait, resulting from gene–gene and gene–environment interactions [77, 78]. Large efforts to understand the genetic architecture of psoriasis have resulted in the identification of a number of psoriasis genetic determinants. The psoriasis genetic landscape emerging from recent genome-wide association studies (GWAS) and their meta-analysis [20, 60, 79–86], as of mid-2014, includes 36 independent psoriasis-associated genetic regions in individuals of European ancestry (Table 21.1), plus five more uniquely associated in the Chinese population [87]. Psoriasis- susceptibility genes encompass skin and immune-related genes, with the latter belonging to either the innate or the adaptive immunity, as well as bridging the two arms of the immune system. SNPs and Copy Number Variation (CNV) [85, 86] in genes of the late cornified envelope (LCE) family within the epidermal cell differentiation complex, a cluster of genes involved in skin barrier formation, support a critical role for skin-specific genes in psoriasis susceptibility. Among immune genes, the over-representation of four pivotal immunological processes and pathways strongly points towards their critical contribution to disease susceptibility: antigen presentation (*HLA-C* and *ERAP1*), NF-kb signalling (e.g. *TNFAIP3*, *TNIP1*, *TRAF3IP2*, *CARD14*), type I IFN pathway (e.g. *IL28RA* and *RNF114*), and IL-23/IL-17 axis (e.g. *IL23A*, *IL12B*, and *IL23R*) [77]. Psoriasis susceptibility region 1 (PSORS1) within the major histocompatibility complex is the strongest susceptibility locus [88, 89] and the HLA- Cw*0602 allele of the MHC class I molecule HLA-C is considered to be the primary associated allele, as confirmed by early sequence and haplotype analysis [90], and more recently by GWASs [81, 82, 86], and analysis of high density SNP data [91]. The HLA-C association has not only the greatest statistical significance observed in GWAS studies [86] but also accounts for about 6 % of the total genetic variance [92], which is at least ten fold more than that explained by any other known psoriasis susceptibility locus [86]. The expression pattern of MHC class I molecule on all nucleated cells makes HLA-C capable of regulating both innate and adaptive responses [93]. Nevertheless, despite the strong genetic evidences and the obvious immunological function of HLA-C, functional studies addressing the precise mechanism by which -Cw*0602 alleles predispose to psoriasis are still missing and no -Cw*0602 specific antigen or interacting protein has been identified to date. Among genes of the innate immunity, more than half belong to the NF-kB pathway, which has a pivotal role in amplifying and sustaining chronic inflammation. Two recent studies have identified and evaluated the functional consequences of rare and common gene variants [86, 94] and missense mutations [12] in CARD14, an activator of NF-kB primarily expressed in skin epidermis. Genes belonging to the type I IFN pathway support clinical and experimental findings indicating an important role for antiviral responses in psoriasis [95, 96]. Finally, several susceptibility genes belong to the IL-23/IL17 pathway, whose critical involvement in disease pathogenesis has been extensively documented by a wealth of studies showing a pivotal role for IL-23-induced and IL-17-mediated responses in psoriasis [97]. Moreover, the genetic association with *IL23R* is one of the very few supported by functional evidence with reduced IL-17 responses in carriers of the protective Arg381Gln *IL23R* allele [98, 99]. Interestingly, some genes from the above pathways influence multiple phenotypic traits, in particular other immune-mediated conditions such as Crohn's disease (CD), celiac disease and ankylosing spondylitis [86], thus confirming the presence of a shared genetic basis among immune-mediated inflammatory diseases.

The signals identified in the European population collectively account for approximately 20 % of estimated psoriasis heritability, and the gene variants identified have only modest- effect size [86]. It has been hypothesized that rare variants with bigger effects may explain this "missing heritability" [100]. However, two recent re-sequencing studies in individuals of European or Chinese descent, have shown that rare variants at known immune-related loci have a negligible role in psoriasis genetic susceptibility [101, 102], suggesting that the estimated missing heritability either results from the co-existence of many common variants of weak effect, or has been overestimated, owing to the existence of gene-gene and gene-environment interactions [103].

Environmental Factors

In contrast to the fast-growing list of psoriasis susceptibility genes, the environmental component concurring in initiating the disease is still ill-defined. Among known environmental triggers of psoriasis there are drugs, infections, physical trauma, smoking, alcohol and stress.

Table 21.1 Psoriasis susceptibility genes

Chr	Gene(s)	Class	Protein function	Pathway	Reference
1	LCE3B/3C/3D	Skin-related	Keratinocyte structural protein	Skin barrier formation	[80, 84, 85]
1	IL28RA	Immunity	IL-29 receptor subunit	IFN signaling	[82]
1	IL23R	Immunity	Unique subunit of IL-23 receptor complex	IL-23/IL17 axis	[79–82, 86]
1	RUNX3	Immunity	Transcription factor	Tbet pathway	[86]
1	TNFRSF9*	Immunity	Adaptor molecules involved in T cell biology	T cell differentiation	[16, 86]
2	REL	Immunity	NF-kB subunit	NF-kb signaling	[82]
2	IFIH1	Immunity	Innate antiviral receptor	IFN signaling	[82]
2	B3GNT2	Other	Enzyme	Carbohydrate metabolism	[86]
5	TNIP1	Immunity	Inhibitor of TNF-induced NF-kB activation	NF-kb signaling	[81, 82, 87]
5	IL12B	Immunity	Shared subunit of IL-12/IL-23	IL-23/IL17 axis	[79–81, 84, 86]
5	ERAP1	Immunity	Enzyme processing MHC class I ligands	Antigen presentation	[82, 83]
5	IL4/IL13	Immunity	IL-4 and IL-13 cytokines	IL-4/IL-13signaling	[81]
6	TNFAIP3	Immunity	Inhibitor of TNF-induced NF-kB activation	NF-kb signaling	[81, 82]
6	TRAF3IP3	Immunity	Adaptor molecule mediating IL-17-induced NF-kb activation	IL-23/IL17 axis, NF-kB signaling	[20, 80, 82]
6	IRF4*	Immunity	Transcription factor	IL 17 signaling	[86]
6	HLA-C	Immunity	MHC class I antigen	Antigen presentation	[79–82, 84, 86]
6	TAGAP	Immunity	RhoGTPase-activating protein	T cell activation	[86]
7	ELMO1	Immunity	Involved in TLR-mediated IFN-a signaling	IFN signaling	[86]
9	KLF4	Skin-related/ immune	Transcription factor	Skin barrier formation, IL 17 signaling	[86]
9	DDX58	Immunity	Innate antiviral receptor	IFN signaling	[86]
10	ZMIZ1	Immunity	Protein inhibitor of activated STAT(PIAS) family of proteins	TGF-β signaling	[16, 86]
11	PRDX5	Other	Antioxidant enzyme	Intracellular redox signaling	[16, 86]
11	ETS1	Immunity	Transcription factor	Unknown	[86]
11	ZC3H12C	Other	Zinc finger protein with putative RNase function	Unknown	[86]
12	IL23A	Immunity	Unique subunit of IL-23	IL-23/IL17 axis	[81, 82]
14	NFKBIA	Immunity	Inhibitor of NF-kB activation	NF-kb signaling	[82, 83]
16	FBXL19	Immunity	Putative inhibitor of NF-kB activation	NF-kb signaling	[83]
16	SOCS1	Immunity	Suppressor of cytokine signaling	Type II IFN signaling	[86]
17	CARD14	Immunity	Activator of NF-kB pathway	NF-kb signaling	[12, 86, 94]
17	NOS2	Immunity	Induced nitric oxide synthase	Inflammation	[83]
17	STAT3*		Transcription factor	IL-23/IL17 axis	[86]
18	MBD2*	Other	Transcriptional repressor	Unknown	[86]
19	CARM1*	Immunity	Transcriptional co-activator of NF-kB	NF-kb signaling	[86]
19	TYK2	Immunity	Tyrosine kinase associated with cytokines receptors	IL-23/IL17 axis, IFN signaling	[82]
20	RNF114	Immunity	E3 ubiquitin ligase	IFN signaling	[79, 81–83]
22	UBE2L3*	Immunity	Ubiquitin conjugating enzyme	NFkb signaling	[83, 86]

* denotes more then one gene in the locus; the most plausible one is reported

Drugs, such as the anti-viral and anti-proliferative agent imiquimod, anti-depressants (lithium), anti-hypertensives (beta-blockers), cytokines (IFN-α) and anti-cytokine therapies (anti-TNF) have all been clinically associated with initiation, exacerbation and worsening of psoriasis [104]. Imiquimod, a Toll Like Receptor (TLR) 7/8 agonist used to treat genital warts and non-melanoma skin tumours, represents one of the best investigated examples of psoriasis triggers so far. The initial clinical observation of a case of psoriasis exacerbated by topical treatment with imiquimod [105] has prompted research into plasmacytoid DC (pDC) and type I IFN pathway, which is downstream of TLR7/8 signaling [95]. Moreover, it has also been translated into the imiquimod-induced psoriasiform skin inflammation mouse model, which faithfully reproduces most of the features of the human disease and has quickly become one of the most widely used experimental models to study psoriasis [106].

An association between preceding streptococcal throat infection and psoriasis [107] has been reported, mainly with guttate psoriasis [108] and homologous T cell clones have been found in both the tonsils and skin lesions of plaque-type psoriasis patients [109].

Tattoos and surgical incisions give rise to the Koebner phenomenon with psoriasis plaques appearing at the site of the trauma [110].

The association of modifiable behavioural risk factors, such as smoking and alcohol consumption, as well as comorbidites such as stress, are traditionally more difficult to investigate. Although a number of studies have offered evidence linking stress and smoking with psoriasis [33, 111, 112] there is no consensus on whether these factors do actually cause or aggravate psoriasis [113].

While more often included among risk factors, environmental cues can also have a protective role against disease. We have recently uncovered an unexpected protective role in psoriasis for the ligand-activated transcription factor Aryl hydrocarbon receptor (AhR) [114], an environmental sensor which responds to a wide range of stimuli including environmental pollutants (e.g. dioxin), but also more physiological ones (e.g. tryptophan metabolites of dietary or light-exposure origin), by inducing detoxifying enzymes belonging to the cytochrome P450 family. In particular, physiological ligands are believed to mediate the beneficial effect exerted by AhR, via short-term activation of the receptor in contrast to the prolonged and deleterious activation sustained by dioxin and tobacco smoke [115]. By combining data from the imiquimod model of psoriasis-like skin inflammation in mice lacking AHR, with the analysis of human psoriasis skin biopsies treated *ex vivo* with AhR ligands we found that absence of AhR signalling results in an exacerbation of psoriasis [114]. In particular AhR exerts its beneficial effect in keratinocytes as in its absence they become over-reactive to pro-inflammatory stimuli and release a greater amount of cytokines and chemokines, thus instigating an excessive inflammatory reaction. Thus, physiological AhR activation acts as an immunological brake that prevents dysregulation of the inflammatory response. Based on this data it is tempting to speculate that psoriasis patients might have impaired activation of the AhR pathway, possibly due to genetic variants in genes of the AhR pathway or perhaps shortage of physiological ligands, and ongoing studies are addressing these hypotheses.

Immunopathogenesis

The contribution of the immune system to psoriasis is not less complex than the overall disease pathogenesis, with a variety of innate and adaptive immune cells and pro- inflammatory mediators involved, possibly at different stages of the disease.

The recent integration of findings drawn from studies of clinical samples, xenotransplant models in which human skin is transplanted onto immuno-compromised hosts, and experimental mouse model of psoriasis-like skin inflammation, has contributed and accelerated a better understanding of disease pathogenesis. It is worth highlighting that, although no mouse model can fully recapitulate the development and features of a disease only occurring in humans [116], lessons from a number of animal models, exhibiting most of the crucial clinical traits and molecular signatures of psoriasis [117], should not be discarded as they can provide valuable insights to dissect pathogenic mechanisms.

The question of whether psoriasis is primarily an epithelial- or immune-mediated disease has recurred for several decades in the scientific community, with researchers torn between the prominent changes in the skin and the increasingly recognized importance of immunological pathways. Not surprisingly, given the macroscopic alterations occurring in psoriatic skin, the focus has initially been on keratinocytes and the accelerated and aberrant terminal differentiation program they undertake in psoriasis. Following the unexpected efficacy of serendipitously administered immunosuppressive agents, immune cells have attracted attention and have been almost the exclusive focus of clinical and experimental studies for two decades. These efforts have elucidated many of the pathogenic immune mechanisms and highlighted the critical contribution of tissue resident T cells and TNF, leading to effective anti-T cell and anti-cytokine targeted therapies. Nevertheless, KC, equipped with innate immune receptors and actively taking part in inflammatory skin responses, are nowadays considered non-hematopoietic

immune cells and gained the status of skin sentinel cells [118, 119], thus prompting a re-evaluation of their role in psoriasis.

The current view of psoriasis pathogenesis implies that the aberrant immune and epidermal response seen in psoriasis is sustained by a pathogenic cross-talk between epithelial and immune cells [120, 121]. This interplay is primarily driven by the critical pro-inflammatory molecules, TNF, IL-23 and IL-17, whose direct therapeutic targeting has proven to be clinically effective, with other mediators, such as IFN-α, IFN-γ and IL-22 possibly contributing to the initiation, amplification and maintenance of the disease.

One of the best characterized initiation mechanisms, leading to dysregulated skin immune responses, involves damaged skin KC releasing the cationic antimicrobial peptide (AMP) LL-37, following physical trauma or infection. LL37 binds to self-DNA/RNA fragments forming LL-37/self-DNA/RNA complexes [122–124] that activate TLR7/9-bearing pDC. pDC are a subset of circulatory DC normally absent in human healthy skin but highly infiltrating developing psoriasis lesions [95], and once activated, specialize in releasing type I IFN which is thought to play important roles in the early phases of psoriasis development. In the AGR129 xenotransplantation model, where human non-lesional psoriatic skin is transplanted onto AGR129 mice lacking T/B cells and having severely impaired NK activity, Type I IFN triggers activation and expansion of autoimmune T cells present in the transplant, leading to full-fledged psoriasis plaque formation [95]. Moreover, self-RNA-LL-37 complexes, and pro-inflammatory cytokines IL 1β, IL 6, TNF and IFNα activate myeloid DC. Psoriatic skin lesions have a 30-fold increase in myeloid dermal DC (DDC) [125] and harbour both "classical" CD11c + CD1c + DDC, also found in healthy skin, and a distinct population of "inflammatory" CD1c- DC [126] producing TNF, iNOS, IL-20 and IL-23 [127–129]. DDC are thought to migrate to skin-draining lymph nodes to present an as-yet elusive antigen (either of self or of microbial origin) to naïve T cells. T cells, particularly those residing in the skin as tissue-resident memory T (T_{RM}) cells, are critical players in the initiation phase of disease. T_{RM} are memory cells which do not circulate but are strategically positioned as the first-line defence in the tissue [130, 131] and have been implicated in long term peripheral immunity [132, 133]. One of the very first evidences of their existence came from the AGR xeno- transplantion model of human non-lesional psoriatic skin onto immunodeficient mice. In this model development of full-fledged psoriatic lesions occurs in the absence of T-cell recruitment from blood [134] and depends on the ability of locally activated skin T_{RM} cells, present in the initial graft, to migrate into the epidermis [135].

Activation of DDC and their interaction with T cells is central to plaque progression as it creates an IL-23/IL-17 inflammatory environment in which DC and macrophages-derived IL-23 promotes an IL-17-rich pro-inflammatory environment sustained by Th17 cells, [48, 121], Tc17 [136–138], γδ-T cells [139, 140], NCR+ group 3 Innate lymphocytes (ILC3) [141–143] and possibly neutrophils, mast cells [122] and regulatory T cells [144]. The initial definition of psoriasis as Th1 and IFN-γ-driven disease, based on a strong type II IFN transcriptomic signature and the high frequency of Th1 and Tc1 cells in both psoriasis plaques and peripheral blood [145–147], has been challenged by the discovery of IL-23 and Th17 cells and a wealth of genetic, clinical and experimental findings indicating a key role for the IL-23/IL-17 axis in psoriasis [97].

IL-17A and IL-17 F, sharing high structural and functional homology, activate keratinocytes to produce an array of molecules with chemoattractant properties, including neutrophil- (CXCL1, CXCL2, CXCL5, CXCL8) and T cell- (CCL20) recruiting chemokines and AMP (LL37, S100A7/8/9/15) [148, 149]. Moreover, another IL-17 family member, IL-17C induces an autocrine pro-inflammatory loop in KC [150, 151] and IL-22, produced by Th, Tc and NCR+ ILC3, which mediates most of the epidermal hyperplasia by impairing KC differentiation [152, 153]. Finally, a recent study has identified IL-9-producing Th cells FOXP3+ in psoriatic lesions although their pathogenic relevance has not been established to date [154].

Taken together, a pathogenic cross-talk between KC, DCs and T cells, sustained by TNF, IL-23 and IL-17 and supported by other immune cell players and further pro-inflammatory molecules, underlie the dysregulated immune response observed in psoriasis (Fig. 21.2).

Targeted Therapy

No definitive cure is available for psoriasis and current treatments are aimed at decreasing disease activity and improving symptoms. Therapies are administered according to disease severity, assessed by the Psoriasis Area and Severity Index (PASI, ranging from 0 to 72), which takes in account appearance and extension of the lesions. Most psoriasis patients present with a mild form of disease which is usually treated with topical agents, with local anti-inflammatory and/or anti-proliferative action. However, moderate and severe disease cases require systemic treatment. Systemic treatment usually comes after unsuccessful topical strategies, in a two-tiered approach where systemic therapy is used as a second-line treatment of moderate to severe psoriasis. Traditional systemic therapies aim at general immunosuppression and include the use of cyclosporine and/or methotrexate (MTX). In the past decade, a

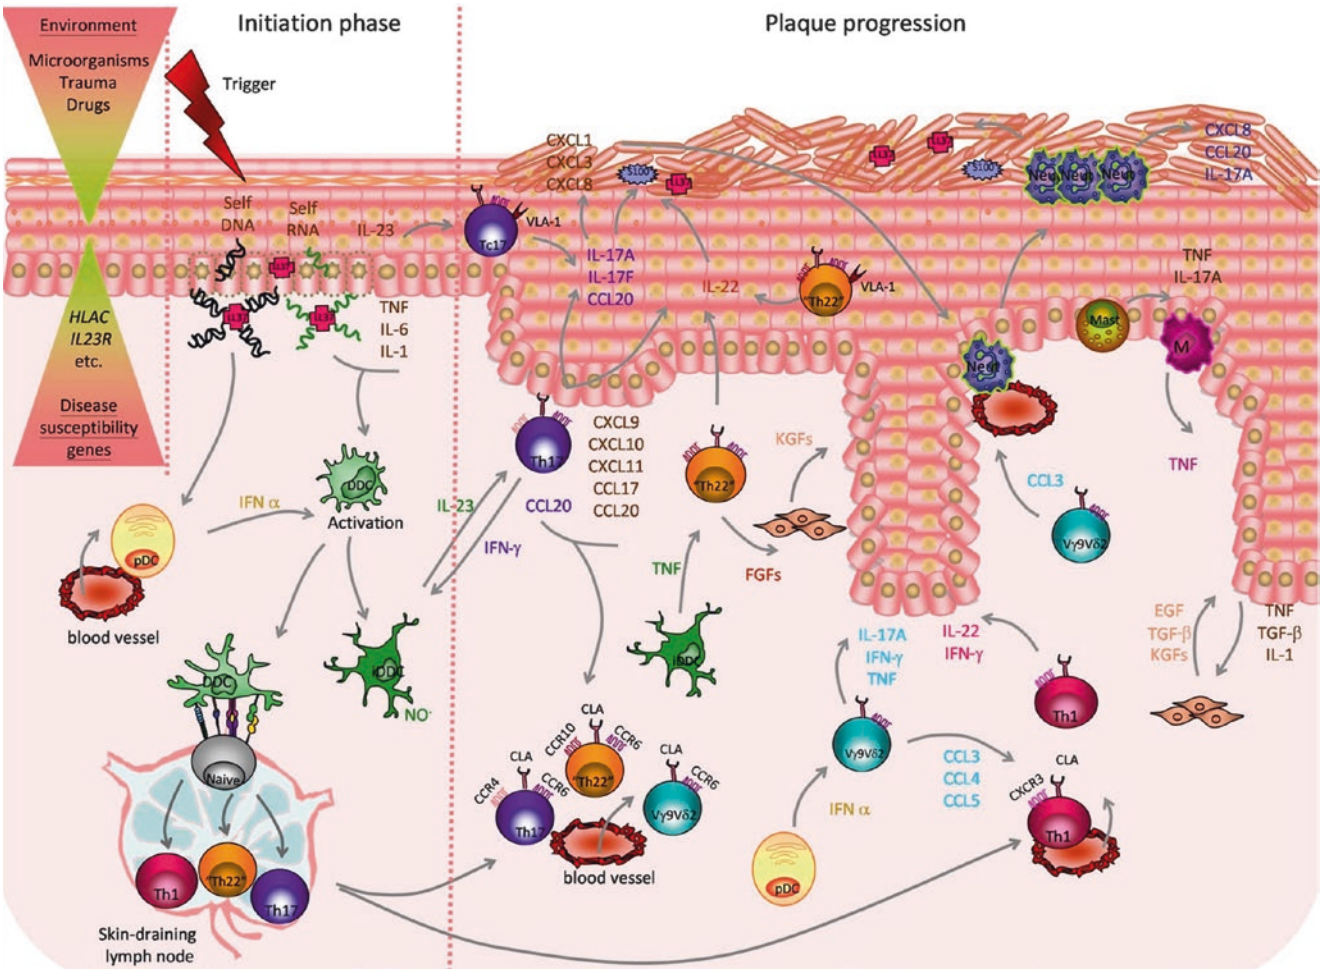

Fig. 21.2 Psoriasis etiopathogenesis- The combination of environmental factors with psoriasis susceptibility genes triggers a cascade of pathogenic events leading to disease initiation and plaque formation. In the initiation phase, pro-inflammatory cross-talk between damaged keratinocytes (KCs), releasing self-nucleic acids and LL-37, recruited plasmacytoid dendritic cells (pDCs), activated dermal DC (DDCs) and inflammatory DDC (iDDCs), producing IL-23, TNF and nitric oxide radicals (NO.), promote the activation of skin resident and newly recruited T cells that lead to plaque formation. IL-23 stimulates T helper 17 (Th17) and T cytotoxic 17 (Tc17) cells, expressing cutaneous leukocyte antigen (CLA), CCR6 and CCR4, plus very late antigen (VLA)-1 in the epidermis, to release IL-17A, IL-17 F, IL-22 and IFN-γ. IL-17A and IL-17 F act on KCs promoting production of T cells and neutrophils-attracting chemokines (CXCL1,3,8-11;CCL17-20) and antimicrobial peptides (AMPs): S100 proteins and LL-37. IL-22, produced by Th17 cells, as well as Th1 cells, expressing CXCR3 and skin-homing marker CLA, and "Th22"/"Tc22" cells, expressing CCR6, CCR10 and CLA, induces epidermal hyperplasia by impairing KC terminal differentiation. Recruited unconventional V 9v 2 T cells, expressing CLA and CCR6, are activated by pDCs-derived IFN-and release further pro-inflammatory cytokines and chemokines (CCL3-5) attracting neutrophils (Neut) and Th-1. Infiltrating Neut, mast cells and macrophages (M) contribute to the pro-inflammatory environment producing cytokines (IL-17A, TNF), AMPs (S100 proteins, LL-37) and chemokines. Cross-talk between keratinocytes producing IL-1, TNF and transforming growth factor beta (TGFβ), and fibroblasts, which in turn release keratinocyte growth factor (KGF), epidermal growth factor (EGF) and TGFβ, and possibly Th22 cells releasing fibroblast growth factor (FGFs), contribute to tissue reorganization (Reproduced with permission from Di Meglio et al. [120])

better understanding of disease immunopathogenesis has been successfully translated into new drugs, known as *biologics*, targeting key inflammatory mediators and currently representing an effective third-line therapy in moderate-to-severe psoriasis patients, unresponsive to non-biologic systemic agents. As of mid-2014, there are five biologics approved for the treatment of psoriasis, targeting either T cells or cytokines such as TNF or IL-12/IL-23 (see also Chap. 43) [155] (Table 21.2).

Anti T-Cell and Anti-cytokines Biologic Drugs

The first biologics to be approved for psoriasis treatment were anti-T cell therapies targeting T cell adhesion or activation.

The first biologic to be approved was alefacept in 2003, a LFA-3/IgG1 fusion protein binding CD2 on T cells and thus, selectively inducing apoptosis of CD2(+) human memory-effector T cells [156]. Clinical efficacy was shown in phase

Table 21.2 Targeted therapy for Psoriasis in 2014

Mechanism of action	Name	Molecular target	Phase	Formulation	Administration route	Company	Reference
Anti-Tcells	Alefacept	CD2	Approved 2003 (US)	Human LFA-3/ IgG1 fusion protein	IM or IV	Biogen	[157, 158]
Anti-cytokine	Etanercept	TNF	Approved 2004 (US and EU)	Human TNF-R(p75)-lgG1 fusion protein	SC	Amgen	[169–171]
	Infliximab	TNF	Approved 2006 (US and EU)	Mouse-human IgG1 chimeric monoclonal antibody	IV	Janssen Biotech	[172–174]
	Adalimumab	TNF	Approved 2007 (EU) 2008 (US)	Human IgG1 monoclonal antibody	SC	Abbott	[175, 176]
	Ustekinumab	IL12p40 (IL-12,IL-23)	Approved 2009 (US and EU)	Human IgG1 monoclonal antibody	SC	Janssen Biotech	[179, 180]

III studies with 40 % of patients achieving a PASI75 response (75 % reduction of the PASI) [157] and more that 50 % achieving PASI 50 (50 % reduction of the PASI) [158]. A further antibody, anti-T cell strategy was approved in 2003 and consisted in a humanized antibody (efalizumab) binding and blocking CD11a, a key molecule for T-cell activation and migration through the circulation into the skin [159]. Despite a good efficacy profile, [160–166], efalizumab has been withdrawn from the market in 2009, due to three cases of progressive multifocal leukoencephalopathy [167], highlighting the importance of carefully monitoring the long-term safety of immunomodulatory therapies.

An alternative strategy to anti-T cell targeting aims at interfering with the psoriasis cytokine network using anti-cytokine biologic drugs. TNF blockade was serendipitously found to ameliorate psoriasis in a patient with IBD treated with the anti-TNF drug infliximab and had concomitant psoriasis [168]. Currently there are three anti-TNF biologics approved for psoriasis: etanercept, a human p75 TNF receptor fusion protein (approved in 2004), infliximab, a humanized chimeric anti-TNF monoclonal antibody (approved in 2006), and adalimumab, a fully human monoclonal antibody (approved in 2008). The efficacy of TNF inhibitors has been tested in phase III clinical trials, showing up to 80 % of treated patients achieving PASI75 within 10–12 weeks of treatment [169–176]. TNF neutralization causes early down- modulation of myeloid cell-related genes, with decrease of Th17 cell products and downstream molecules in just 2 weeks after commencing therapy [125, 177, 178]. The latest biologic to be approved for psoriasis in 2009, ustekinumab, is a monoclonal antibody simultaneously blocking the heterodimeric proteins IL-12 and IL- 23 via its binding to the shared subunit p40. Its efficacy is quite high, with 67 % of patients achieving PASI75 at 12 weeks of treatment [179, 180].

Some serious adverse events, such as opportunistic infections and reactivation of latent tuberculosis, have been reported for these monoclonal antibodies [181]. Long term safety data (up to 4 and 5 year treatment) are now available for etanercept and ustekinumab [169–171, 182, 183], suggesting a safe use of these drugs.

Emerging New Drugs: Biologics and Small Molecules in Clinical Trials

A number of other biologic drugs is currently being investigated in clinical trials, as of mid-2014 (see also Chap. 43) (Table 21.3). In line with the prominent role of IL-23/IL-17 axis in psoriasis, there are three antibodies (BI655066, tildrakizumab, and guselkumab) specifically targeting the IL-23p19 subunit which are currently being tested in phase II [184], III [185] or have recently completed phase II [186] clinical trials, respectively. Data from a small phase 1 study showed between 50 (10 mg) and 100 % (300 mg) of guselkumab-treated patients achieving PASI75, with improvements generally maintained through week 24 and rate of adverse event similar to placebo-treated patients [187]. Preliminary phase IIb data presented at the American Academy of Dermatology (AAD) meeting 2014 showed up to 81 % of patients receiving the highest dose achieving PASI75 response [188]. Phase 3 data for tildrakizumab presented at AAD 2013 showed PASI75 response rates of 64–74 % [189].

Monoclonal antibodies blocking either IL-17A (ixekizumab and secukinumab) [190–192] or IL-17R brodalumab [193], have shown remarkable efficacy in phase 2 clinical trials with more than 70 % of patients achieving PASI 75, and more than half achieving a striking PASI 90. While phase 3 clinical trials are currently ongoing, initial molecular data

Table 21.3 Emerging drugs in clinical trials as of 2014

Type	Mechanism of action	Name	Molecular target	Phase	Formulation	Administration route	Company	Reference
Biologics	Anti-cytokine	Tildrakizumab (MK-3222)	IL-23p19	Phase III	Humanized IgG1 monoclonal antibody	SC	Merck	[185, 189]
		Guselkumab (CNTO 1959)	IL-23p19	Phase II	Human IgG1 monoclonal antibody	SC	Janssen Biotech	[186–188]
		BI655066	IL-23p19	Phase II	Humanized IgG1 monoclonal antibody	SC	Boehringer Ingelheim	[184]
		Brodalumab (AMG 827)	IL-17R	Phase III	Human IgG2 monoclonal antibody	SC	Amgen	[193]
		Ixekizumab (LY2439821)	IL-17	Phase III	Humanized IgG4 monoclonal antibody	SC	Eli Lilly	[190]
		Secukinumab (AIN457)	IL-17	Phase III	Human IgG1 monoclonal antibody	SC or IV	Novartis	[191, 192]
	PDE4 inhibitor	Apremilast (CC-10004)	PDE4	Phase III	N/A	Oral	Celgene	[201, 202]
Small molecule	JAK inhibitor	Tofacitinib (CP-690,550)	JAK1 and JAK3	Phase II	N/A	Oral	Pfizer	[199, 200]
		Tofacitinib (CP-690,550)	JAK1 and JAK3	Phase II	N/A	Topical	Pfizer	[198]

showed that the effect of IL-17 blockade on expression of genes synergistically regulated by IL-17 and TNF is greater than in previous studies with anti-TNF therapy [194].

Notwithstanding the efficacy of the biologic drugs currently available in the clinic, at least one third of patients do not respond to biologic therapy [195] or lose initial responsiveness, due to the development of anti-drug antibodies (ADA), which causes decreased drug efficacy and/or induction of adverse events [196, 197]. Moreover, biologic drugs pose a considerable economic burden due to their cost of about £10 k per patient/per year. Finally, a sizable number of patients with mild-to-moderate psoriasis still rely only on traditional topical treatments to manage their disease. Thus, other therapeutic options are being explored, such as small molecules, i.e. low molecular weight organic compounds targeting key molecules involved in cellular signalling. Based on the importance of cytokine- driven inflammatory pathways in psoriasis, the most promising small molecules currently under testing are targeting key cellular components in cytokine signalling, such as Janus kinases (JAK), as well as enzymes involved in cytokine production. Among JAK inhibitors, tofacitinib, which specifically inhibits JAK1 and 3 and is approved for RA treatment, has showed good efficacy in phase II trials for both its oral and topical formulation [198, 199] with 66.7 % of patients treated with the highest dose of oral tofacitinib reaching PASI 75 at 12 weeks in a phase 2b study [200]. Apremilast, a phosphodiesterase four inhibitor which inhibits an enzyme involved in the breakdown of cAMP, thus suppressing the production of pro-inflammatory cytokines is also been tested in Phase IIb clinical trials [201, 202] showing 41 % of patients achieving PASI75 at week 16 with the highest dose. A cheaper manufacturing process, a route of administration (oral or topical vs injectable) which ensures high patient compliance and an overall good safety profile, makes the use of these small molecules in mild-to-moderate psoriasis foreseeable

Novel Integrative Approaches for Stratified Medicine in Psoriasis

Stratified medicine, that is tailoring medicine to the individual characteristics of each patient, aims at predicting individual susceptibility to disease, detecting the onset of disease at the very earliest stages, predicting and pre-empting disease progression, developing novel targeted therapies, and prescribing safe and effective medicines to each patient.

At the heart of stratified medicine is patient stratification, or the classification of individuals into sub-populations that differ in their susceptibility to a particular disease, or the

natural history of their disease or their response to a specific treatment. To this end, stratified medicine encompasses the entire spectrum of molecular medicine (including the genome, proteome, metabolome and epigenome) and relies on recently developed technologies allowing deep analysis of biological samples available in limited quantity, in a high-throughput manner.

The psoriasis research community has embraced these innovative tools with enthusiasm, not only to better understand disease mechanisms but, ultimately, to overcome patients' heterogeneity and improve disease diagnosis, prognosis and therapy, by implementing stratified medicine approaches.

For instance, high-throughput genotyping has enabled the identification of 36 psoriasis susceptibility genes by means of GWAS in which common genetic variation such as SNPs are examined in patients and control individuals to identify association with the disease [86]. Moreover, next-generation sequencing (NGS) that parallelize the sequencing process, producing millions of sequences concurrently and at a fraction of the initial costs, have enabled the refining of the psoriasis transcriptome via RNA-sequencing [203, 204], building upon initial array-based analysis [205–207]. Array-based technologies have also been used for DNA methylation profiling resulting in the detection of different methylation profiles between lesional and non lesional psoriatic skin [208]. Other powerful techniques allowing multiparameter analysis of samples at the cellular level are multiparameter flow cytometry with the use of lyoplates, (pre-formatted plates containing lyophilized cocktails of antibodies) to increase reproducibility, standardization and medium throughput processing of the samples [141, 209].

Not only all the aforementioned technologies each generate a vast amount of data, but they are often used in combination to analyse the same biological sample, thus resulting in an escalating amount of data which require powerful bioinformatics tools not only to analyse but also to integrate, handle, manage, and store these "omics" data [210]. Computational analysis approaches applied to the analysis of large data in psoriasis has already proven successful in a number of studies, especially taking advantage of the large amount of publicly available gene expression data from psoriasis skin. Integrative approaches have been used to combine the results of five microarray datasets obtaining the Meta-Analysis Derived (MAD) psoriasis transcriptome [205]. The over-representation of atherosclerosis signaling and fatty acid metabolism pathways in lesional skin, supports the close relationship between psoriasis and systemic manifestations [205]. A set of 20 "classifier" genes clearly separating lesional from non lesional psoriasis skin has also been identified, to contain many genes that were part of the residual disease genomic profile, or "molecular scar', still present in psoriasis skin after successful treatment [211]. Moreover, by integrating differentially expressed genes with altered expression in psoriasis lesions, as well as candidate genes near susceptibility loci from psoriasis GWAS studies and candidate cell types for genes near susceptibility loci, a recent study has prioritized SNPs at which susceptibility variants are predicted to influence transcription factor binding [212]. This has resulted in the identification of potentially causal non-coding SNPs for which susceptibility variants influence binding of key pro-inflammatory transcription factors, such as AP-1, NF-kB, IRF1, STAT3 and STAT4. From skin gene expression data, ensembles of decision tree predictors were used to cluster psoriatic samples and the analysis revealed distinct molecular sub-groups within the clinical phenotype of plaque psoriasis [213]. In another study, cytokines and cell-type specific signatures were identified according to differentially expressed genes in the lesions, uncovering a range of inflammatory- and cytokine- associated gene expression patterns able to differentiate between etanercept responders and non-responders [207]. Data from human samples can also be integrated with data from in vivo models to overcome the translational gap in the development of new targeted therapies. For example, the role of the cytokine IL-22 in psoriasis has been recently evaluated by comparing the publicly available psoriasis transcriptome with the transcriptome derived from humanized mouse models of disease (i.e. IL-22 injection into xenografts of normal human skin) for inhibition of disease (i.e. antibody-mediated blockade of IL-22 into xenografts of psoriasis human skin). Mapping the in vivo experimental data over the psoriasis transcriptome, resulted in the identification of PIM1, a serine/threonine kinase, subsequently validated as a critical checkpoint for human skin inflammation and potential future therapeutic target in psoriasis [214]. Finally, a systems biology approach has been used to model and quantify immune cell interactions contributing to skin inflammation via cytokine signalling [215].

The Quest for Psoriasis Biomarkers

Critical to the implementation of stratified and personalized medicine approaches are biomarkers, or biological characteristics that are measured and evaluated objectively as indicators of normal biological processes, pathogenic responses or to pharmacological responses to therapeutic intervention [216]. Biomarkers can be classified according to their function in diagnostic biomarkers, indicating the existence of disease; prognostic biomarkers, able to forecast disease progression, with or without treatment, and predictive or theranostic biomarkers, able to predict the probable response to a particular treatment. A further

alternative classification, according to the NIH Biomarkers Definitions Working Group, distinguish biomarkers in three categories: type 0 biomarkers, correlating longitudinally with the severity of disease; type 1 biomarkers, reflecting the effect of an intervention according to the mechanism of action of therapy itself (or drug endotype), and type 2 biomarkers which are surrogate endpoints for a therapy [217].

Examples of stratified medicine approaches are already in clinical practice in oncology, where a number of reliable biomarkers aiding in patients stratification have been identified and implemented (e.g. human epidermal growth factor receptor (Her2) in breast cancer tissue [218]. Following in these steps, large efforts aimed at the identification of psoriasis biomarkers are ongoing [216].

Psoriasis is in most of the cases diagnosed by clinical assessment by a dermatologist, with rare cases of histological confirmation of the disease. However, in patients difficult to diagnose, e.g. those with other skin diseases, such as atopic dermatitis, a molecular signature may be useful. Using patients simultaneously affected by both psoriasis and non-atopic or atopic dermatitis, a recent study has developed a disease classifier consisting of NOS2 and CCL27 which was able to identify initially misdiagnosed or clinically undifferentiated patients [219].

Prognostic biomarkers indicating disease severity progression or the onset of comorbidities would be extremely useful for better patient management. Moreover, biomarkers for early diagnosis are an unmet need in psoriatic arthritis, where the large disease heterogeneity often hampers proper diagnosis and the progressive course of the disease also calls for prognostic biomarkers. Finally, despite the growing number of therapeutic alternatives to treat psoriasis, not all patients respond to the same treatment and a recent survey has indicated that more than 50 % of patients polled are dissatisfied by the management of their disease [220]. The current therapeutic approach to treat psoriasis, especially in its moderate-to-severe forms, contemplates the use of different treatments, in an empirical attempt to find the most effective one. Patients are therefore likely to experience one or more ineffective therapies with relative associated side-effects. Moreover, this approach also results in increased public health costs which are especially relevant in the case of expensive biologic drugs. Thus, biomarkers for better disease management are both a clinical and a public health need which would benefit both patients and the healthcare system (Fig. 21.3).

Despite large efforts in the quest for psoriasis biomarkers, none of those identified so far have entered into clinical use for disease diagnosis, prognosis or for predicting therapy response [216]. Here, we describe them according the type 0, 1 and 2 classification and discuss their potential use in stratified medicine approaches in psoriasis.

Type 0 Psoriasis Biomarkers: Markers of Disease Severity

Type 0 biomarkers, correlating with the severity of psoriasis, include genetic, as well as, tissue and systemic biomarkers. It is known that HLA-Cw*0602- positive patients have more severe disease and early onset (Type I Psoriasis) compared to HLA-Cw*0602- negative patients [221]; while HLA-Cw*0602- positive PsA patients have a less severe clinical course [222].

The aberrant skin architecture of psoriatic plaques is reflected by the altered expression of tissue-specific molecules, such as keratins, as well as pro-inflammatory molecules in the tissue. Keratins associated with cell proliferation such as K6 and K16 are upregulated in psoriatic skin, while K1 and K10, indicating keratinocyte terminal differentiation, are decreased [223].

Moreover, being psoriasis is “more than skin deep”, it is not surprising that alteration of inflammatory mediators, both at the tissue and peripheral level, correlate with disease status. Pro-inflammatory cytokines such as TNF, IFN, IL-6 and IL-8 and IL-12 [47, 224] are increased in psoriatic skin and in the circulation of psoriatic patients, as compared to healthy individuals, and their expression rapidly reduces after successful anti-TNF treatment [177]. Inflammatory cytokines increased in psoriatic serum are also increased in the skin, suggesting that peripheral blood can mirror the skin [49]. The study of circulating markers has been extensively investigated due to the easy access to patients’ peripheral blood samples. IL-22 serum levels are increased in psoriasis patients and positively correlate with PASI [225, 226]. Th17 cells and cytokines are associated with psoriasis severity. IL23, IL23R and Th17 cytokines are increased in lesional psoriatic skin [227] and IL23R is overexpressed in circulating T cells [228]. However, it is not clear yet whether IL-17A serum levels are altered in psoriatic disease as inconsistent results have been found in different studies, possibly due to low levels and sensitivity issues of the detection assays used [47, 49, 225, 226, 229]. Nevertheless, high IL17-A serum levels, together with high IL1RA, correlate with the eruptive inflammatory form of the disease and not with chronic and stable psoriasis [230]. Increased frequency of T cells subsets such as Th1, Th17 and Th22 cells is detected in both the circulation of psoriasis patients as well as in the tissue [48, 231, 232]. Interestingly, also innate cells involved in the production of IL-17 and IL-22 such as ILC3 are increased in the skin and blood of psoriasis patients, and decrease in the circulation after successful anti- TNF treatment [141–143]. Finally, psoriasis patients have high levels of generic inflammation markers (e.g. CRP, haptoglobin and platelet P-selectin), shared with other inflammatory conditions [233], as well as lipids and oxidative status alterations [234, 235], shared with metabolic diseases.

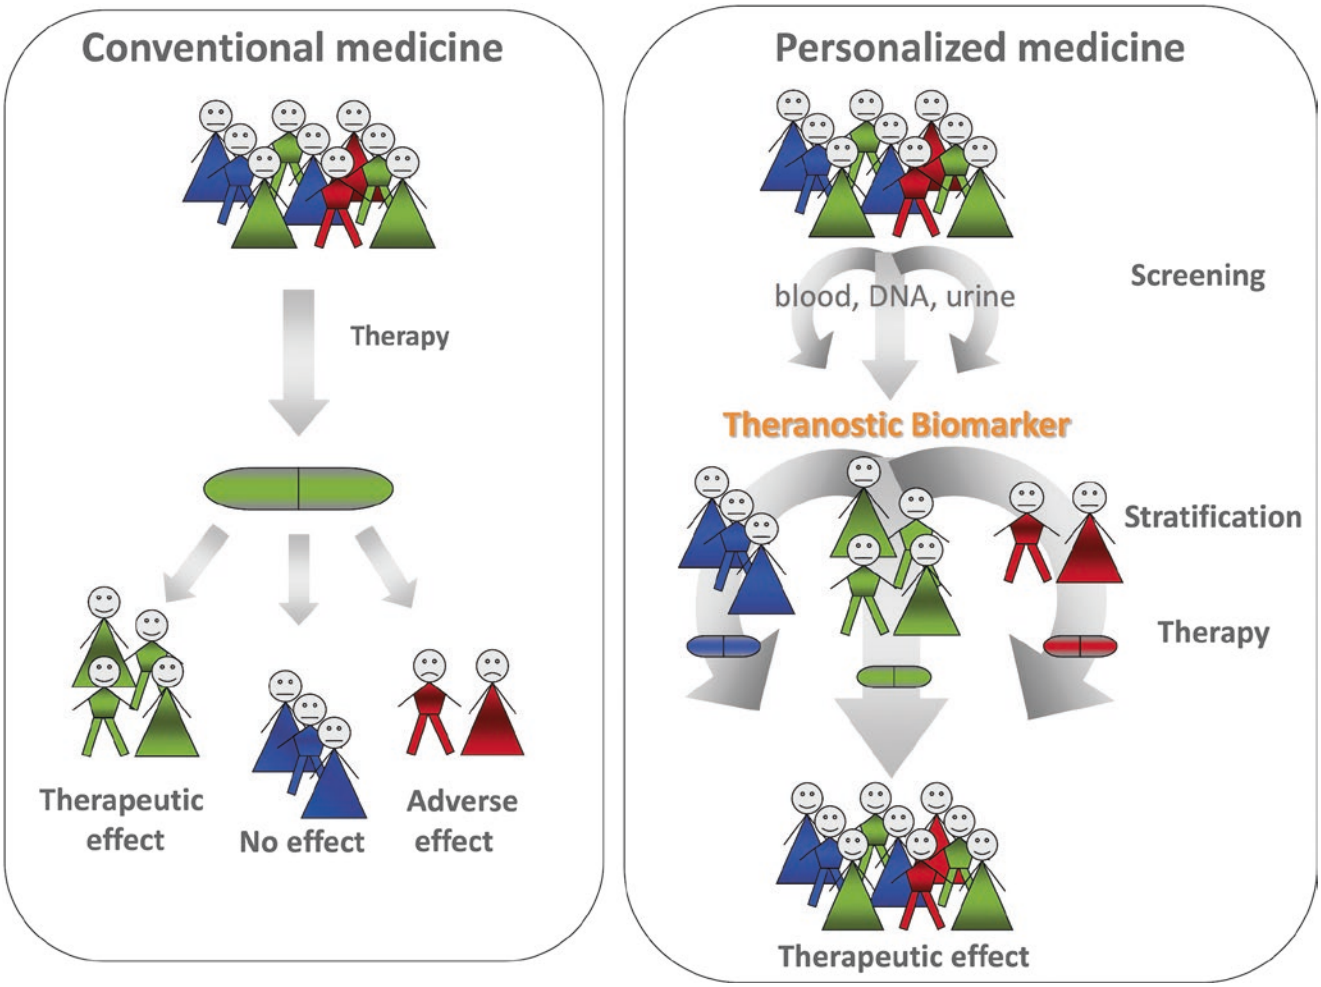

Fig. 21.3 Conventional versus stratified medicine- In conventional medicine approaches (*left*) patients receive the same drug which will have a therapeutic effect on the majority of them but will be ineffective in some and cause adverse events in others. In personalized medicine approaches, patients undergo screening using biological materials (DNA, urine, blood) to identify theranostic biomarkers allowing their stratification to receive the most appropriate and effective drug for each individual (Reproduced modified with permission from: Targeted therapies and biomarkers for personalized treatment of psoriasis (Villanova et al. 2014, submitted) in: Personalized Treatment Options in Dermatology -Springer)

Type 1 Psoriasis Biomarkers: Drug Endotype

Type 1 biomarkers, reflecting the effect of an intervention according to the mechanism of action of therapy itself, are being identified as results of targeted therapies aimed at restoring specific immune circuits which are dysregulated in psoriasis. In particular, anti-IL12/23 and anti-IL17 biologics act on the central IL23/IL17 axis in psoriasis. The molecules directly targeted by these drugs can potentially be used as prognostic or theranostic biomarkers to monitor the actual suppression of the targeted pathway and the associated clinical improvements.

Blockade of IL-17 with ixekizumab results in reduced IL-17, IFN-γ, and IL-22 in the tissue, as well as in the downregulation of IL-17-regulated molecules (LL37, beta defensin 2, S100A7, S100A8) in epidermal keratinocytes, within 2 weeks of treatment. This in turn leads to decreased infiltration of lymphocytes and DC, as well as, normalization of keratinocyte structural and activation markers within 6 weeks of treatment. These cellular and molecular changes correlate with the rapid clinical improvements suggesting that IL-17 is a key marker whose regulation is sufficient to normalize many other deregulated circuits in psoriatic skin [194]. Downregulation of IL17 and its immediate regulated genes is also necessary for positive response to the anti-TNF biologic etanercept [125, 236], suggesting that the efficacy of TNF blockade is ultimately down to the inhibition of IL17 signaling.

Type 2 Biomarkers: Predictive or Theranostic Biomarkers

Type 2 biomarkers, which are surrogate endpoints for therapy, have predictive value and theranostic use.

The identification, validation and implementation of this type of biomarker is the most urgently needed in psoriasis. Soluble, circulatory or genetic markers associated with therapeutic response would be ideal theranostic biomarkers in psoriasis, being not or minimally invasive.

In a small study, a disease response classifier including 23 genes using gene expression of PBMCs has been obtained to accurately predict response to alefacept [237]. The relative frequency of specific immune cell populations within the first few weeks of treatment has been shown to correlate with more long-term therapy response. In particular, an increase in T regulatory cells within 8 weeks of anti-TNF therapy predicts good therapeutic response [238], while the expression of cutaneous lymphocyte-associate antigen (CLA) on lymphocytes negatively correlates with PASI at 6 weeks [239]. Among genetics biomarkers, psoriasis susceptibility genes identified by GWASs represent a potential gold mine for the identification of theranostic biomarkers. SNPs in TNAFAIP3, encoding for a zinc finger protein (A20) that is a negative regulator of TNF-induced pathways, are associated with improved response to anti-TNF agents [240] Moreover, a small cohort of HLA-Cw06+ patients have been shown to respond better and faster to ustekinumab [241]. An obvious potential candidate to probe is the *IL23R* R381Q SNP in IL-23R, given its functional role in down-regulating IL-23 responses in psoriasis patients [99].

Conclusions and Future Perspectives

The complex pathogenesis of psoriasis has been untangled in the last 40 years, resulting in an increase of effective therapeutic options available to patients. Future directions call for a refinement of the current knowledge using novel integrative approaches. Psoriasis susceptibility genes identified so far clearly point towards critical pathogenic pathways warranting further studies. More genetic studies are required to identify the so called "missing heritability" while functional investigation of genetic determinants is needed to better exploit them in a clinical setting, e.g as theranostic biomarkers. The integration of different types of large datasets, obtained through high-throughput platforms and powerful analytical tools, will aid in the discovery of disease biomarkers with multiple applications in patient stratification, treatment of co-morbidites and new drug discovery. Taken together, these efforts hold the promise to further benefit psoriasis patients.

Acknowledgements We are indebted to psoriasis patients and healthy volunteers for their courage, trust and generosity in donating clinical specimens to make psoriasis research possible. We thank F.O.N. laboratory members for their contribution over the years to the work cited in this review. We acknowledge support by the following grant bodies: Wellcome Trust Programme GR078173MA (F.O.N.) and National Institute for Health Research (NIHR) Biomedical Research Centre based at Guy's and St Thomas' NHS Foundation Trust and King's College London. The views expressed are those of the authors and not necessarily those of the NHS, the NIHR or the Department of Health. FON has been a consultant for companies producing targeted therapies for treatment of patients with psoriasis. PDM has been an educational speaker for a company producing a targeted therapy for treatment of patients with psoriasis.

Questions

1. Which is the **correct** definition for psoriasis:
   A. Psoriasis is a chonic skin disease due solely to an alteration of the immune system
   B. Psoriasis is a infectous skin disease
   C. Psoriasis is a chonic skin disease due to the interplay of genetic and environmental factors resulting in altered immune system and aberrant skin differentiation
   D. Psoriasis is a monogenic skin disease

2. What **are** the clinical features of plaque-type psoriasis:
   A. Infected, white pustules
   B. Inflamed, sharply demarcated, raised plaques, covered by silvery scales
   C. Diffuse erythema, with or without scaling, involving more than 75 % of the skin surface
   D. Violaceous or pinkish papules

3. Which signaling pathway below is **not** involved in the pathogenesis of psoriasis
   A. Type I Interferon
   B. NF-kB
   C. IL-23/IL-17
   D. Sonic/Hedgehog

4. Which statement below about T helper 17 (Th17) cells **is correct**:
   A. Th17 cells are innate immune cells and protect against infections
   B. Th17 cells are key players in the pathogenesis of psoriasis and an important therapeutic target
   C. Th17 cells have a minor role in psoriasis, which is insted a Th1-mediated disease
   D. Th17 cells produce esclusively IL-17, hence their name

5. Which statement below about therapy of psoriasis is **not correct**:
   A. Biologics drugs used in psoriasis target key inflammatory mediators such as IFN-γ
   B. Systemic therapy is used as a second-line treatment of moderate to severe psoriasis

C. The first wave of biologics to be approved for psoriasis treatment were anti-T cell therapies targeting T cell adhesion or activation
D. Apremilast, which inhibits an enzyme involved in the breakdown of cyclic AMP, is in clinical trials for psoriasis

Answers

1. C
2. B
3. D
4. B
5. A
