More importantly, the existing literature has not yet fully addressed whether the use of AOA leads to any specific adverse effects. Although there are some reports indicating an impact upon gene expression following ICSI combined with AOA, the number of studies is limited, and the sample size involved is low. Moreover, there are very few follow-up investigations on the children born following AOA. In this context, it is worth emphasizing that natural fertilization has a series of control mechanisms which are bypassed by ART in differing extents depending on the method used (i.e., IVF, ICSI, ICSI-AOA). While some biological mechanisms of sperm selection are still present in IVF, such mechanisms are bypassed by ICSI. The extent of this bypass is still higher when AOA is used, as the Ca^{2+}-driven events within the oocyte are not triggered by the sperm presence but rather through a chemical agent which does not interact naturally with the oocyte's internal machinery governing Ca^{2+} homeostasis. In fact, the risk of abortion, miscarriage, and some syndromes associated with imprinting errors is higher with conventional ICSI than with natural conception [220, 221]. It is therefore highly prudent to increase the number of studies addressing these effects and risks in the case of AOA, and the development of other more endogenous, therapeutic strategies would be of significant interest [222]. Although, at present, AOA is the only suitable strategy, the use of a recombinant human PLCζ isoform would inevitably represent a far safer strategy for rescuing oocyte activation deficiency, as discussed in the next section.

The limited amount of data presently available indicate that the use of calcium ionophores appears to be safe and does not cause any detrimental impact upon child health [174, 184, 223, 224]. For example, a study using calcium ionophore A23187 reported a case of major malformation in a baby born using AOA with this chemical agent [216]. However, and according to the authors of this case report, the risk of congenital malformations increases when IVF and ICSI are utilized, so that it is not possible to ascertain whether this case could be explained by the use of ART in general or whether other factors were involved [216]. However, another study observed activation by calcium ionophore A23187 and in almost 80% of cases found no detrimental effects of artificial activation upon chromosome segregation errors during meiotic division, after genotyping and maternal haplotyping these oocytes [225]. Moreover, a retrospective study using data compiled from 2006 to 2014 compared pregnancy and birth defects between ICSI (595 cycles) and ICSI-AOA oocytes (83 cycles) and found no significant differences in the time of delivery, percentage of twin pregnancies, birth defects, type of defects observed (chromosomal and structural abnormalities), and malformations [226].

In the case of ionomycin, comparisons of babies born through ICSI and ICSI, combined with AOA and ionomycin, showed no effects upon chromosomal abnormalities, intrauterine fetal death, preterm delivery, birth weight, growth rate, hospitalization in neonatal intensive care units, abnormal behavior according to age, and the physical and mental health of children born [220].

Finally, although no detrimental effects of strontium chloride have been observed in terms of physical and mental development of children from birth to 60 months [201, 204, 205], a study conducted by Bridges et al. [227] did indentify effects upon gene expression. Briefly, this research compared gene expression in mouse blastocysts produced by IVF, conventional ICSI, and ICSI+AOA with strontium chloride. When conventional ICSI and IVF blastocysts were compared, the expression of 197 genes, involved in cell differentiation, development of the organs and nervous system, cell-cell signaling, transduction pathways, and several metabolic processes, was found to differ. The expression of 132 genes was also found to differ between IVF and ICSI-AOA blastocysts. When comparing ICSI and ICSI-AOA blastocysts, the expression of 65 genes, involved in different developmental, metabolic, and response processes, also differed [227]. These data support the idea that AOA is still an experimental treatment and should only be advised in particular cases until further knowledge about the exact mechanisms by which AOA agents exert their effects is available.

34.6.4 Is AOA Always Useful for Rescuing Fertility?

It is important to consider that artificial oocyte activation may not be effective enough when causes other than oocyte activation deficiency are evident. This is the case of severe globozoospermia, involving mutations/deletions of the *DPY19L2* gene. In such cases, AOA is able to rescue oocyte activation, but due to the fact that sperm chromatin is poorly compacted, presents an aberrant protamine content, and DNA is fragmented, the resultant rates of preimplantation embryo development are low [82].

On the other hand, while research with calcium ionophore A23187 found no effect in terms of sperm source (i.e., ejaculated or epididymal), Borges et al. [228] observed different outcomes when using ionomycin and oocytes from women of different ages. Indeed, the outcomes of AOA with ionomycin using ejaculated, epididymal, and testicular spermatozoa did not differ when the oocytes fertilized originated from women below 36 years of age. However, when AOA with ionomycin was performed with oocytes from women

above this age threshold, the proportion of high-quality embryos was higher with the use of ejaculated and epididymal spermatozoa, and implantation rates were higher with the use of ejaculated spermatozoa [228].

Finally, we should mention that apart from utilizing AOA for severe cases of sperm and oocyte deficiencies, another strategy has proposed the use of this technique with calcium ionophore A23187 to increase fertilization and pregnancy rates of women with a diminished ovarian reserve and whose partners present normal sperm parameters. However, such a strategy has been revealed to be ineffective, as it does not significantly increase fertilization or pregnancy rates [229].

34.6.5 Could Recombinant PLCζ Represent an Effective Agent to Rescue OAD?

This chapter has emphasized the importance of Ca^{2+} homeostasis and that Ca^{2+} oscillations evoked by sperm upon gamete fusion present a characteristic pattern. However, and as previously discussed, Ca^{2+} oscillations triggered following IVF and ICSI differ from those generated when AOA is used (Fig. 34.4) [169]. This has led the scientific community to express concerns about the potential side effects of AOA [169, 230]. One possible strategy to rescue oocyte fertility would be the use of a recombinant PLCζ protein, as Ca^{2+} oscillations evoked by this recombinant sperm-specific protein resemble those observed following conventional fertilization and IVF. This approach has attracted the attention of researchers working in this field. Yoon et al. [48] demonstrated that cRNA encoding PLCζ could rescue fertility in an infertile patient whose sperm were devoid of PLCζ and did not activate the oocyte following ICSI. In addition, Kashir et al. [75] were the first to report the production of a recombinant human PLCζ protein, which was found to be able to elicit the characteristic Ca^{2+} oscillations triggered by sperm after normal fertilization [75]. The species specificity of recombinant PLCζ forms was further demonstrated by Nomikos et al. [45] who showed that the ability of recombinant human PLCζ to initiate embryo development in mice was lower than in humans. Finally, in a study conducted with mouse oocytes, Sanusi et al. [46] compared AOA with recombinant PLCζ, calcium ionophore, and strontium chloride and found that PLCζ gave higher rates of embryo development than calcium ionophore. A more detailed review of the potential use of recombinant PLCζ protein as a more endogenous alternative to AOA agents is beyond the scope of this chapter, but we refer the reader to Amdani et al. [231] for further information. At the time of writing, progress on the clinical translation of recombinant PLCζ protein remains ongoing and is some way from being introduced into clinical practice.

34.7 Conclusions

This chapter has defined the process of oocyte activation and has described the main events that take place during this crucial phenomenon. As oocyte activation is triggered by sperm upon gamete fusion, we have mainly summarized the most relevant research findings pertaining to the identity of the sperm-borne oocyte activation factor (SOAF). Although other candidates have been proposed over the last two decades, mounting evidence now indicates that a sperm-specific phospholipase C, PLCζ, is the primary SOAF candidate. We have also reviewed the molecular pathway triggered by PLCζ and emphasized the crucial role of Ca^{2+} oscillations and Ca^{2+} homeostasis within the oocyte. Finally, we have described how some cases of human infertility relate to OAD and how AOA is increasingly being considered as a strategy to rescue fertility in couples suffering from OAD. Finally, due to concerns being raised about the clinical use of AOA, we have described the limitations of this technique and suggested other potential and safer alternatives.

Conflict of interest The authors declare that there is no conflict of interest with regard to the content of this chapter.

Funding M.Y. was funded by the European Commission, FP7-People Scheme, Marie Curie-IEF (Grant Number: 626061), and the Spanish Ministry of Economy and Competitiveness (Grant Number: RYC-2015-15581). Review Questions

1. What is oocyte activation?
2. Which are the molecular mechanisms underlying that process and what is still unknown?
3. Which is the role of sperm in oocyte activation upon sperm-oocyte membrane fusion?
4. Is there any relationship between sperm devoid of PLCζ and oocyte activation deficiency and total fertilization failure?
5. Are there any means to overcome oocyte activation? Are they safe?

Micromanipulators and Micromanipulation

Contents

Hydraulic Manipulators for ICSI

Hubert Joris

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_35

Learning Objectives

- Overview of micromanipulators and integration to microscopes
- Different components of a hydraulic micromanipulation system
- Alignment of microtools for ICSI
- Maintenance of hydraulic micromanipulation systems

Micromanipulation of cells started more than a century ago. Already in 1859, a description of some kind of microdissector had been made. The first studies on combined micromanipulation of oocytes and embryos appeared around 100 years later. Research on early events of fertilization was the main reason for these studies. In these 100 years between the first description of micromanipulation and the use of this technique for the study of fertilization events, the technological evolution changed our society completely, also improving conditions for such research.

Medical treatments did benefit a lot from scientific progress. Helping infertile couples to conceive was also part of this progress. The birth of Louise Brown in 1978 has been a milestone that changed the world of assisted reproductive technology (ART). The use of IVF evolved rapidly from treatment of female infertility to treatment of male infertility. However, it was obvious that the number, motility, and morphology of the spermatozoa present in the ejaculate largely affected the success rates of IVF. The idea to assist fertilization by bringing sperm cells closer to the egg vestments was already studied in animals in the early 1960s. These techniques have been evaluated and used in humans to assist the fertilization process. This evolution is the subject of other chapters in this book. However, for these studies, the instruments developed over the years to study and manipulate different types of cells showed to be very valuable to manipulate gametes.

Different types of manipulators have been developed and used. The main purpose of this equipment is to bring movements from a macroscale to a microscale without affecting the viability of the material worked with. Transfer of the movement from a macroscale to a microscale can be done in different ways. This can be done mechanically, hydraulically, and electronically. Mechanical and electronic manipulators and their use in ART is the subject of different chapters.

At UZ Brussel, research on assisted fertilization started in the late 1980s aiming for the establishment of a clinical-assisted fertilization program. Assisted fertilization by subzonal insemination (SUZI) in the mouse was successful and demonstrated a correlation between the level of acrosome-reacted sperm cells and fertilization after insertion of a single spermatozoon under the zona pellucida [1]. Micromanipulation of gametes was initially performed with mechanical manipulators (Leica, Wetzlar, Germany). After careful evaluation of different possibilities, they were replaced by a combination of electrical and hydraulic manipulators (Narishige, Japan). This micromanipulation system was used at the start of the clinical-assisted fertilization program. The initial clinical experience by SUZI [2] was soon followed by the first report on intracytoplasmic sperm injection (ICSI) pregnancies [3]. The combination of electrical and hydraulic manipulators showed to be a very successful combination. The aim of this chapter is to describe more in detail the function and characteristics of this micromanipulation system for the ICSI procedure.

35.1 Mounting Micromanipulation Systems on Microscopes

Manipulation of cells smaller than what can be observed by the human eye requires the use of microscopes magnifying the cells to a level allowing proper observation of their characteristics. Manipulation of these cells requires a system that allows a firm, steady movement that successfully executes the required action without damaging the biological material submitted to the manipulations. To visualize human oocytes to a level where morphological details can be observed, a magnification of 200× to 400× is very common. Sperm cells are much smaller, and details cannot easily be observed at that magnification. Movement of tools small enough to manipulate these cells without vibration requires a very steady and firm system. Independent of the way micromanipulators are driven, they need to be mounted so that vibration is minimal. Depending on the microscope available and the choice of the micromanipulation system, manipulators are built on the microscope or on the microscope table or placed next to the microscope. These mounting systems allow a very steady positioning of the manipulators but do not necessarily avoid vibration. Several possibilities of equipment absorbing vibration are available and can be installed at different levels. This can be under the table, under the table surface, or directly under the microscope. However, such antivibration systems have a limited capacity, and certain vibrations will not be absorbed. Avoiding vibration is an important aspect to consider when establishing a new laboratory or when installing a new micromanipulation system.

35.2 Micromanipulation System

Micromanipulators transfer movements from the macrolevel to the microlevel scale. This involves a transition from a movement at the centimeter scale to a movement at the millimeter or micrometer scale. Movements executed with the control units are transferred to the drive units on which tools or tool holders are mounted. For IVF purposes, cells are manipulated by glass tools mounted in a holder, which is then fixed on the drive unit of the manipulator. These tools are usually made from borosilicate glass capillaries. Using a pipette puller, microforge, and if required a grinder allows production of microtools with specific characteristics.

For ICSI purposes, a holding and injection pipette is required. Commercially available products are used mostly

nowadays. The micropipettes are fixed in the holder, and the holder is mounted on the universal joint of the drive unit. Before the actual manipulation can start, the tools have to be positioned and aligned, allowing easy manipulation procedures. The position of the tools before starting the alignment can be considered the *starting position*. Practically, it is important that the tools can easily return to their starting position, for example when dishes are replaced. For this purpose, course manipulators are used. These allow easy movements at the centimeter scale that can be driven mechanically or electrically. Details of the alignment procedure using this manipulator system are described later.

Probably, the most commonly used set of micromanipulators for ICSI is from Narishige. These micromanipulators were initially developed for research purposes and are still commonly used in different areas of research [4]. Different types of manipulators have different ranges in their movements and are used for different applications. As such a system had proven to be successful for ICSI [5, 6], it has been introduced in many IVF clinics all over the world. For use in IVF, a combination of coarse manipulators allowing movements in the centimeter range and fine manipulators with movements at the micrometer scale allowing easy movement covering the microscope field at a magnification of 200× or 400× is adequate (Fig. 35.1). The movement covering the view field at a magnification of 400× is a movement of around 500 µm.

The coarse manipulators allow movements at the centimeter scale. These movements can be driven mechanically or electrically. A possible advantage of a mechanical system is presence of less electrical cables in the laboratory, but it requires significant movements with the arms each time these manipulators are used. The major advantage of the electrical coarse control manipulator is the presence of the joystick next to the microscope. This allows performance of all different manipulation steps within reach and without losing visual control over the biological material visible under the microscope.

Fig. 35.1 Example of setup for ICSI with electrical coarse manipulators and hydraulic manipulators for fine movements. (Courtesy of Nikon, Melville, NY, USA)

35.3 Hydraulic Micromanipulators

Besides the coarse manipulator, a manipulator for fine movements is required. This manipulator is the most important one. The combination presented here uses a hydraulic micromanipulator for fine movements. Similar to the electrical manipulator, a major advantage of such a manipulator is that the joystick can be placed close to the microscope and next to other joystick(s) or injector(s) avoiding excessive movements during the manipulation procedures. The hydraulic manipulator consists of two main parts, namely, the control unit and the drive unit. The control unit (Fig. 35.2) is placed close to the microscope. Its base consists of a magnetic stand, and it is usually fixed on a metal plate by the magnetic switch. In this way, it remains steadily in the same position and allows easy maneuvering of the joystick. The parts of the control unit used during the manipulations are the joystick, allowing movements in two dimensions, and the three rotating knobs, each allowing movement in one dimension. One of the rotating knobs is positioned at the end of the joystick. The two other rotating knobs are positioned above the joystick. The three rotating knobs can be rotated over a certain range. At the 0 level, there is no hydraulic pressure from the system on the moving parts. Rotation of each of the knobs creates movement in one axis. The length of the movement caused by one complete rotation of the knob depends on the characteristics of the manipulator used. Manipulations can be performed using the rotating knobs individually. However, the major advantage of the manipulator used here is that movements in three dimensions can be controlled simultaneously by using the joystick and the rotating knob at the end of the joystick simultaneously. The amplitude of the joystick movement during the manipulations can be regulated using the *movement ratio adjustment ring*. The sensitivity of the movement can be regulated with the *tension adjustment ring*. This three-dimensional movement is an important feature during the different steps of the manipulation procedures performed on human oocytes, embryos, or sperm cells.

Fig. 35.2 Example of control unit of hydraulic manipulator with hanging joystick. (Courtesy of Nikon, Melville, NY, USA)

The joystick can be in a hanging or upright position. In the early 1990s, the hanging joystick could be used only in combination with Nikon microscopes. Later on, this changed. Hanging joysticks are now available for different brands of microscopes. Compared to the joystick in an upright position, the hanging joystick gives important advantages when it comes to ergonomics. Since the embryologist may spend hours at the microscope, this is an important aspect. A hanging joystick allows maintaining the hands at the same level when switching between the electrical course manipulator, the hydraulic manipulator, and the injector and allows supporting with the wrist on the table while working with the hydraulic manipulator.

The second part of the hydraulic manipulator is the drive unit (Fig. 35.3). This is mounted on the coarse manipulator and connected with the control unit by three tubings filled with oil. The tool holder can be fixed in the universal joint that is mounted in the drive unit. As such, movement of the drive unit is transferred directly to the microtool. The movement of the knobs or the joystick creates pressure, and this pressure is transferred by the oil to the moving parts of the drive unit. The pressure created results in an immediate response and causes movement of the drive unit that is in proportion to the amplitude and speed executed on the joystick and/or rotating knobs. It is this movement that is the most crucial in the manipulation process. This direct and proportional transfer of movement performed at the control unit and delivered to the drive unit gives a perception of direct control. This is a very important feeling giving confidence to the operator.

Adjusting the amplitude by the ratio adjustment ring to cover the complete view field at the largest magnification ICSI that is performed at the beginning with the joystick in the neutral position creates a very comfortable working area and allows continuous visual control of the tools during the manipulation steps.

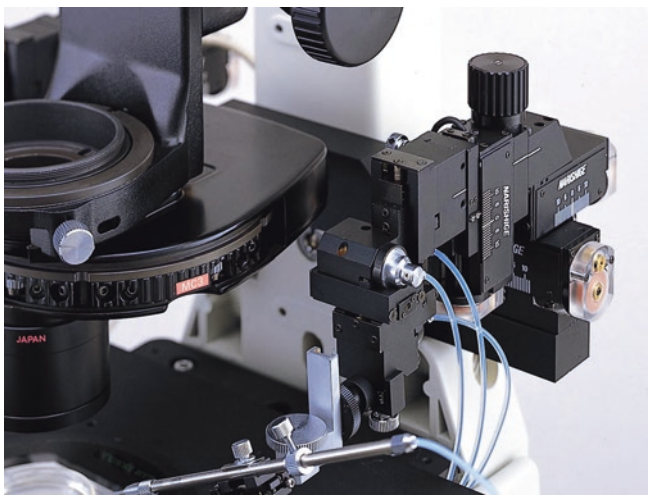

Fig. 35.3 Example of drive unit of hydraulic manipulator (connected to control unit by tubing) mounted on electrical coarse control manipulator and universal joint for mounting of the tool holder. (Courtesy of Nikon, Melville, NY, USA)

35.4 Alignment of Microtools

Proper positioning and alignment of the microtools before starting the injection procedure is crucial for successful ICSI. Although ICSI is considered a routine procedure, it still occurs that micromanipulators are not used optimally and tools are positioned in a way that can affect results. Like certain knowledge about the use and adjustment of CO_2 incubators is required for control of proper functioning during culture, certain minimal knowledge about the characteristics and possibilities of the manipulators is necessary.

Considering the possibilities this equipment has, there is not just one-way positioning and alignment that is performed correctly. The procedure described hereafter is a procedure used during the many years worked in the IVF lab of UZ Brussel.

Before starting the procedure, it is safe to check that both the coarse and the fine manipulator are more or less in a central position. This avoids interruption during the ICSI procedure because one of the manipulators reached the limit of its movement possibility in one of the different directions. The procedure then starts with mounting ICSI and holding pipette in the tool holder and fixing the tool holder on the universal joint. Holding and injection pipette are placed on the left hand side and right hand side, respectively. The tubings connecting the tool holder with the injector as well as the ones between the control unit and the drive unit of the hydraulic manipulator should be free and without any excessive bending that can possibly interfere with correct transfer of the command to the manipulator or microtool.

The design of the universal joint allows positioning of the tool holder in numerous different positions (Fig. 35.3). The older version of the universal joint had two changeable parts, while more recent types have three different parts that can be moved or rotated. As this material was not designed for IVF purposes only, movement in a large spectrum was necessary. However, if ICSI is the only procedure performed, limited adjustments are required once a more or less optimal position is established. Although produced under strictly controlled conditions, individual microtools may vary slightly in certain characteristics that require different settings of the universal joint.

Once the holders are fixed in the universal joint, the tip of the microtool can be moved in the light beam of the microscope. The moving and rotating parts of the universal joint may be used for this if required. Depending on the type of microscope used, it may be useful to do this initial positioning (starting position) high enough above the microscope stage, allowing dishes to be removed and placed under the microtools easily. More recent models of microscopes have a tilting arm on which the manipulators are mounted. By tilting the arm, the complete manipulation system is lifted. This facilitates movements with dishes when microtools are mounted.

For all manipulations related to IVF applications, microtools with similar basic characteristics are used, meaning that capillaries with a diameter of around 1 mm are

formed into tools with different specifications. In the vast majority of the cases, tools are shaped so that the end part of the glass needle is bent to an angle between 20° and 40°. This allows easy positioning of the microtools with the final bent part being positioned almost horizontally once fixed on the universal joint.

Once the two needles are brought in the light beam of the microscope, positioning and alignment controlled via the image in the microscope start. Easiest is to start these steps using the objective with the lowest magnification (often 4×). Without changing the view plane, using the coarse manipulators, the microtools are lowered until they reach the plane where they can be seen clearly (Fig. 35.4a). If required, by rotation of the tool holder, the microtools are rotated until the bent part is positioned in a line going from the 3 o'clock to the 9 o'clock position. Both needles are moved to the center of the image. An ideal alignment brings both microtools in one straight line from the 3 o'clock to the 9 o'clock position (Fig. 35.4b). Further detailed positioning is performed after changing the objective stepwise to 10×, 20×, and finally 40×. Whether the bent part is placed horizontal or deviates from the optimal position (Fig. 35.5) may not be that clear in this image for less experienced operators. When placing the microtools in a medium droplet of a dish, this can be seen more easily. This positioning is performed by using the coarse manipulators for the large movements and the hydraulic manipulators for the fine movements. When using only the rotation knobs of the hydraulic manipulator during these steps, the joystick remains in the neutral position, allowing optimal movement ratio when working at larger magnification.

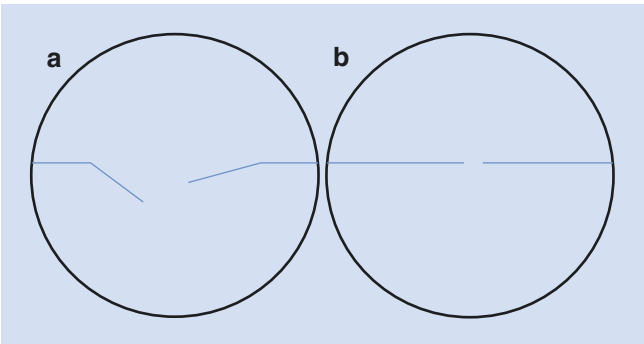

Fig. 35.4 Top view of microtools before initial alignment **a** and after initial alignment **b**. Holding pipette on the left hand side, injection pipette on the right hand side

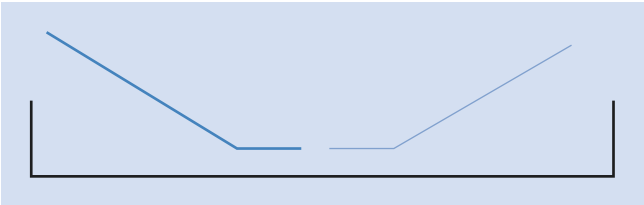

Fig. 35.5 Correct position of microtools at the start of the ICSI procedure. The bent tip is positioned horizontally

The way the drive unit and universal joint are constructed and mounted allows positioning of the tool holder in almost unlimited ways. As mentioned before, slight variation in the angle of individual microtools may require adjustment of the angle for an optimal injection procedure. It is at this stage that modification of the position of the tool holder can easily be performed. After having lifted the tool holders to the starting position, one can easily modify the angle of the tool holder and bring the bent part in a more favorable position. Correct adjustment to place the tools in an optimal position will allow an easy procedure and plays a role in the success rates obtained. In the early days of ICSI, these changes were made by using the different possibilities of the universal joint and required some extra manipulation. Nowadays, improvements in the universal joint allow fine changes in certain axes by simply turning a small screw on the universal joint without additional manipulation of the tool holder (Fig. 35.6).

Ideally, the bent part of the microtools should be in an almost completely horizontal position after alignment (Fig. 35.5). Incorrect positioning of the microtools will affect the manipulation process and can result in positions as shown in Fig. 35.7. Touching the bottom of the dish with the tip of the pipette is not possible when the needle is placed as shown in Fig. 35.7, position 2. This results in difficulties fixing the oocyte in the case of the holding pipette or does not allow aspiration of a sperm cell from the bottom of the dish nor to immobilize a sperm cell with the tip of the needle in case the injection pipette is positioned in this way. In cases where the tip is placed as shown in Fig. 35.7, position 3, one may not have sufficient support of the holding pipette during the penetration of the ICSI pipette in case it is the holding pipette that is placed like this, or one may not make a straightforward movement when injecting a sperm cell into the oocyte. If a tip is aligned as shown in position 3, only the very end of the tip is in focus, while the rest of the pipette cannot be seen sharp in

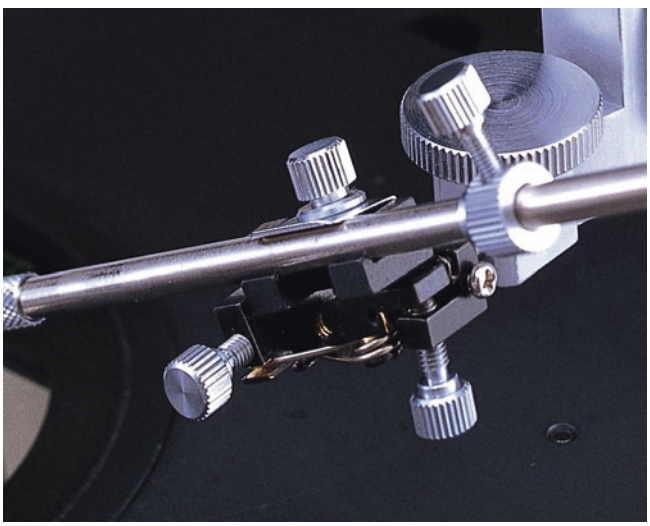

Fig. 35.6 Example of a more recent type of universal joint where changes in position can be made by simple rotation of screws with mounted tool holder. (Courtesy of Nikon, Melville, NY, USA)

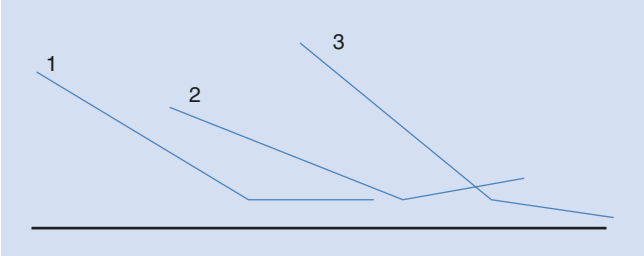

Fig. 35.7 Different positions of microtools: (1) correct position; (2) tip of the pipette cannot reach the bottom of the dish; (3) only the very end of the tip touches the bottom of the dish

the same view plane. When working at the microscope, we have a two-dimensional image while working in three dimensions. Except for the changes in sharpness of the tools when looking at a certain view plane, deviation from the horizontal position of microtools is not visible. However, minimal trauma to the oocyte is created only if the tip of the injection pipette is placed horizontally. It may not be easy to quantify the effect of suboptimal positioning on the microtools. However, like for all other aspects of IVF, attention to detail makes the difference. This is not different when it comes to ICSI. Once microtools are positioned correctly, the ICSI procedure can start.

As for any type of equipment used in the lab, the manipulation system requires maintenance. Maintenance of the moving parts using certain types of grease (performed by technicians trained by the company) results in continuous normal functioning of the manipulators. As the movement from the joystick to the drive unit is a hydraulic system, this part of the system may need to be changed, but only after a very long time of use. It is the author's experience that it took more than 10 years of intensive daily use until the pressure of the hydraulic system became insufficient, and reparation was required in one of the hydraulic manipulators. One can easily significantly increase the life span of the manipulator by turning the three rotating knobs to the 0 (zero) position at the end of each working day. This releases the pressure in the system.

In summary, hydraulic manipulators are usually only part of a complete micromanipulation system. The combination of mechanical or electrical coarse manipulators and hydraulic manipulators for fine movements is used extensively for IVF applications. The combination of the rotating joystick and the rotation knob that are driven together by hand allows easy three-dimensional movement. The hydraulic pressure results in a movement of the microtool that is in proportion to the amplitude and speed executed on the joystick. This gives a sensation of direct control over the manipulation. Furthermore, the way the manipulators and tool holder are designed offers a large scale of possibilities and allows easy adjustment to the type of tool used and kind of manipulation performed.

Acknowledgment The permission of Nikon to use pictures showing different manipulators is greatly acknowledged.

Review Questions

1. Describe the major components of a hydraulic micromanipulator.
2. What is the basic principle of a hydraulic micromanipulator?
3. Describe the two types of joysticks and the functions of the joystick.
4. Describe the steps involved in the alignment of micropipettes in a hydraulic micromanipulator.

Learning Objectives

- To provide an overview of the company and the manufacturing principles underlying Research Instruments equipment
- To describe the basic steps required for the successful installation and operation of Research Instruments micromanipulation systems
- To discuss the various applications of Research Instruments micromanipulation systems within the context of assisted reproduction technology
- To recommend various procedures for overcoming difficulties or problems that may be encountered when using Research Instruments micromanipulation equipment

36.1 The Ethos of Research Instruments

36.1.1 Company History

In response to the requirement for integrated circuit testing by microelectronics companies such as GEC, Research Instruments (RI) was established by Mike Lee and Vince Grispo in 1962. Following an approach by Dr. Simon Fishel during the 1980s, RI adapted their product output in order to meet the needs of assisted reproduction practitioners attempting to perfect new techniques for male factor infertility, such as partial zona dissection (PZD) and subzonal insemination (SUZI).

The company launched the first CE marked micropipette in 1998. The Saturn laser system was designed by David Lansdowne in 1999 and, following the addition of software and firmware capability, became the world's first computer-controlled laser for assisted reproduction technology (ART). The company was bought from Mike Lee, Vince Grispo and Ann Lee by Bill Brown, Justin Retallack and David Lansdowne in 2000 and went on to become an innovative leader within the field of development and manufacture of equipment for ART. In 2016, RI was incorporated into the CooperSurgical group of companies, joining forces with ORIGIO, The Pipette Company (TPC), K-Systems, Genesis Genetics, Recombine, Reprogenetics and Wallace, market leaders in ART.

36.1.2 Research and Development

The earliest purely mechanical micromanipulators manufactured by RI, such as the TCV500 that was released in 1964, featured individual levers with three axes of movement and movement reduction from 100:1 to 500:1. The TLO500 was introduced in the 1980s, incorporating flexural hinges in order to improve stability and reliability. The subsequent development of the classic TDU500 enabled mounting onto an inverted microscope and extremely ergonomic manipulation. Accessory instrumentation, including the 'Sonic Sword', was also introduced at this time to facilitate the penetration of the *zona pellucida* (ZP), primarily for the SUZI technique.

In the early 1990s, following the successful application of intracytoplasmic sperm injection (ICSI) to the human [1], RI modified their micromanipulators to introduce a number of useful features. The first of these allowed rapid raising and lowering of micromanipulators, avoiding accidental damage to the micropipettes and, therefore, was referred to as a 'Home Function'. An innovative feature, laser-guided setting-up device (LASU) launched in 1994, facilitated correct alignment of micropipettes. Other features added during the 1990s were tool holder angle adjustment indicators for more accurate alignment of a range of micropipettes with various known degrees of bend between the tip and the shank. Precisely controlled heated plates were integrated into the mechanical stage in 1999, culminating in a major modification of the TDU500, known as the 'Integra'. RI also introduced semicircular handrests to further improve ergonomics.

36.2 Equipment Installation and Set-Up

36.2.1 Integra Design Features

The current version of the Integra is known as the Integra 3™ (Fig. 36.1).

The Integra 3™ incorporates a mechanical stage, TDU3 micromanipulators, shortcut buttons to link with RI Viewer software, touchscreen four-channel independent control of

Fig. 36.1 The Integra 3™

heated plates, one-touch 'home' function, one-touch micropipette angle adjustment (Fig. 36.2) and a unique touch-screen display with stopwatch and counter (Fig. 36.3). On the Integra 3™, the standard mechanical stages of the 'big four' microscope manufacturers have been replaced by a custom-designed, built-in XY mechanical stage. Each turn of the stage control moves the stage plate 28 mm in either the X or Y plane, with 40 mm full travel. Because the mechanical stage is supplied fitted to the Integra 3™, no set-up is required. The independent four-channel temperature control system is accurately calibrated to within 0.1 °C of the desired set point. One of these channels controls the temperature of the central metal insert in the microscope stage. As an optional upgrade, RI will supply a central glass heated stage. Even better temperature control is provided by the Thermosafe™ warm air system. One channel controls the entire working stage plate. This has been designed for temperature maintenance of microinjection dishes additional to that being worked on at any given time, e.g., in those circumstances where it is necessary to have a testicular sperm preparation in one dish and oocytes ready to be injected in another. The fourth channel can be used to control the temperature of an external heated plate or the heated stage of an adjacent stereo dissecting microscope. The four channels are controlled via a touch-screen panel built into the Integra 3™ (Fig. 36.3). As the heated stages are already installed when supplied, no set-up other than the adjustment of the temperature set points is necessary.

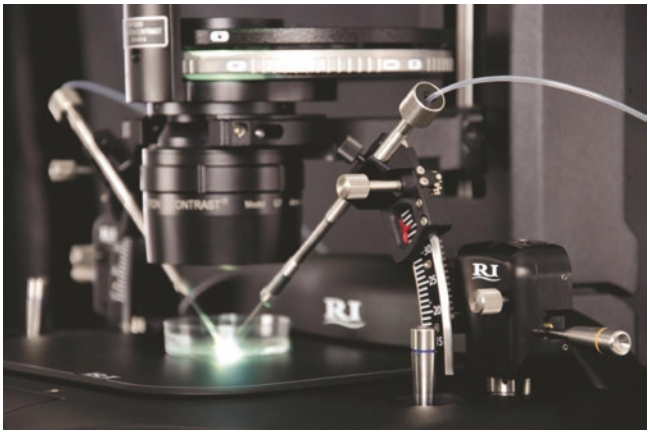

Fig. 36.2 One-touch micropipette angle adjustment

Fig. 36.3 Touch-screen digital display

Compared with that of the previous model, the Integra Ti, the heated stage area of the Integra 3™ has been increased by 40% and is enhanced by an integral monitored and alarmed heating system called Thermosafe™. This system creates a uniform flow of precisely warmed air towards the bottom of the micromanipulation dish, thereby circumventing the known cooling effect of the underlying objective lens which otherwise acts as a heat sink, drawing heat away from the heated stage. Also, the Integra 3™ now benefits from a motion sensor LED light situated below the heated stage which illuminates the objective lenses, making it much easier to visualize the objective lens required for the purpose.

Consistent with the original company policy, the TDU3 micromanipulators remain purely mechanical and are directly controlled, the joysticks providing proportional movement. This policy is based on the principles that direct proportional movement provides greater control and that simple mechanical components are ready to use, are more reliable and are less likely to require routine servicing and maintenance.

36.2.2 Integration with Inverted Microscopes

Installation of the Integra 3™ is extremely simple, quick and straightforward as the system comes largely preassembled in a purpose-built dispatch case. However, it is still necessary to exercise some care when removing the Integra from its dispatch case in order to avoid potential damage to the micromanipulator mechanism from any inadvertent severe shock. An installation manual is available from RI in Adobe Acrobat format. The Integra 3™ can be adapted to a range of inverted microscopes supplied by the 'big four' manufacturers, Leica, Nikon, Olympus and Zeiss using just four screws (Fig. 36.4).

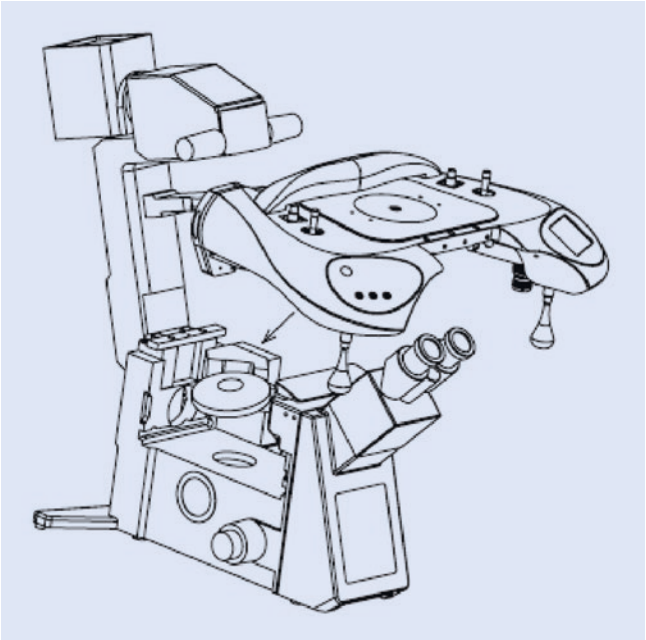

Fig. 36.4 Installation diagram for the Integra 3™ to the Olympus IX73

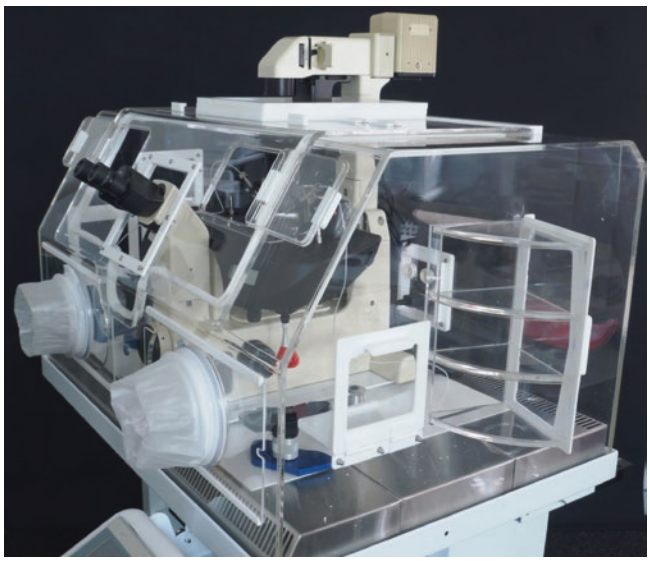

Fig. 36.5 Cell-Tek 3000 IV enclosed chamber for an inverted microscope

36.2.3 Integration with Workstations and Chambers

Since micromanipulation is usually conducted in closed culture under oil using media incorporating buffers (e.g., HEPES and MOPS) that maintain stable pH under atmospheric conditions, it may be performed out in the open on the lab bench. However, there are practitioners who prefer the aseptic conditions offered by a laminar flow cabinet (LFC) or environmentally controlled conditions provided by an enclosed microscope chamber (Fig. 36.5). Such chambers allow micromanipulation to be performed with the assurance that temperature, pH and humidity will remain at optimal levels for the entire duration of the procedure. Some chambers also incorporate inbuilt ultraviolet photocatalytic modules that reduce volatile organic compounds to low parts per billion levels.

Most horizontal and vertical LFCs provide sufficient space within which to house an inverted microscope fitted with a micromanipulation rig. However, some will need to be specially adapted for this purpose so that the eyepieces of the microscope project through an aperture in the front window. The microscope will impede the laminar flow to some extent but, nevertheless, an LFC will provide more aseptic conditions than the open lab bench. To minimize vibration during micromanipulation, it is advisable to use a low vibration LFC and to place an anti-vibration plate between the base of the microscope and the floor of the LFC. Similar anti-vibration measures have to be taken if opting to house a micromanipulation system within a microscope chamber, such as the inbuilt anti-vibration pad that accommodates any microscope configuration within the chamber available from Tek-Event.

36.2.4 Micromanipulators

The micromanipulators on the Integra 3™ incorporate both fine and coarse controls in one compact unit. Both fine and coarse control levers should be set to their vertical positions before making further adjustments. In common with the classic TDU500 micromanipulator, the joysticks of the TDU3 also extend downwards, but now from within the microscope stage of the Integra (Figs. 36.1 and 36.3). Rotation of the fine control knob actuates up to 5 mm of movement within the z-axis so, in order to avoid running out of travel mid-procedure, it is recommended to set its travel of movement at the midpoint prior to use. As a guide to determining the midpoint of micromanipulator travel, green electronic height indicators (Fig. 36.3) enable precise setting of the manipulators on each side and provide an audible warning alarm just before the end of the travel has been reached.

36.2.5 Tool Holders and Micropipettes

RI's PL3 tool holders are supplied with the Integra 3™ and are calibrated and actuated using a single screw to enable accurate adjustment to a range of micropipette bend angles, from 16° to 43° (Fig. 36.2). This is important to ensure an optimal angle at which a micropipette is employed respective to the procedure being undertaken so as to achieve effective manipulation while minimizing shear stress. A unique feature of the PL3 tool holder is that the tip of the micropipette does not move when the angle is changed, allowing alterations of the pipette angle to be made 'on the fly'. Once the angle of the tool holder has been set to correspond to the bend angle of the micropipette to be used, RI's MPH microtool holders can be clipped into place onto the PL3 tool

holders (Fig. 36.2). Once fitted to each other, vertical, axial and rotational movement of the micropipette is possible, allowing a rapid set-up.

36.2.6 Setting Up and Aligning Micropipettes

When adjusted using an additional objective lens and spacer (supplied by RI), micropipettes can be aligned 14 mm above the microscope stage, minimizing the likelihood of damaging them. A one-off initial set-up of the tool holder is achieved as follows: A scratch or mark is made on the inner surface of a Petri dish and the dish is placed onto the microscope stage of the Integra 3™. Using the 4× objective lens, the scratch is brought into focus to establish the set focal length for tool holder set-up, and is not adjusted further. A holding micropipette is fitted to the microtool holder and, with the vertical lever of the tool holder in the fully raised position, the objective lens is changed over to the RI 4× objective lens with spacer which allows the micropipette to be brought into focus in this raised position. Check that the micromanipulator is set to the middle of its vertical travel and that both fine and coarse control levers are positioned in their vertical axes. Drive the MPH microtool holder forward until the tip of the micropipette is directly above the objective lens. Rotate the microtool holder until the micropipette vertically bisects the objective lightpath, as viewed with the naked eye, and then tighten the bottom securing screw of the PL3 tool holder (Fig. 36.6). This adjustment effectively sets the detent position of the microtool holder to its central position.

For routine micropipette set-up, next use the axial drive mechanism of the PL30 tool holder to position the micropipette within the centre of the field of view and rotate it axially using the rotating wheel at the distal end of the MPH microtool holder to obtain a perfectly vertical orientation of the micropipette (Fig. 36.2) – precise alignment is best achieved with the aid of the inverted microscope, viewing the micropipette using the 4× or 10× objective lens and using the fine control lever to bring its tip into focus. If necessary, move the 4× objective lens back into place and fully lower the vertical lever on the PL3 tool holder – the scratch or mark on the Petri dish should still be in focus. Because the micropipette is positioned slightly above the surface of the Petri dish, it will now appear slightly out of focus. If desired, the distance between the tip of the micropipette and the surface of the microinjection dish can be minimized by increasing the distance travelled when lowering the vertical lever on the PL3 tool holder. This adjustment is achieved using the lowered position adjustment screw located on the top of the PL3 tool holder (Fig. 36.6). These steps are repeated when setting up the injection, zona drilling or biopsy micropipette on the opposite side of the micromanipulation rig. As an optional extra for those wishing to biopsy embryos for the purpose of

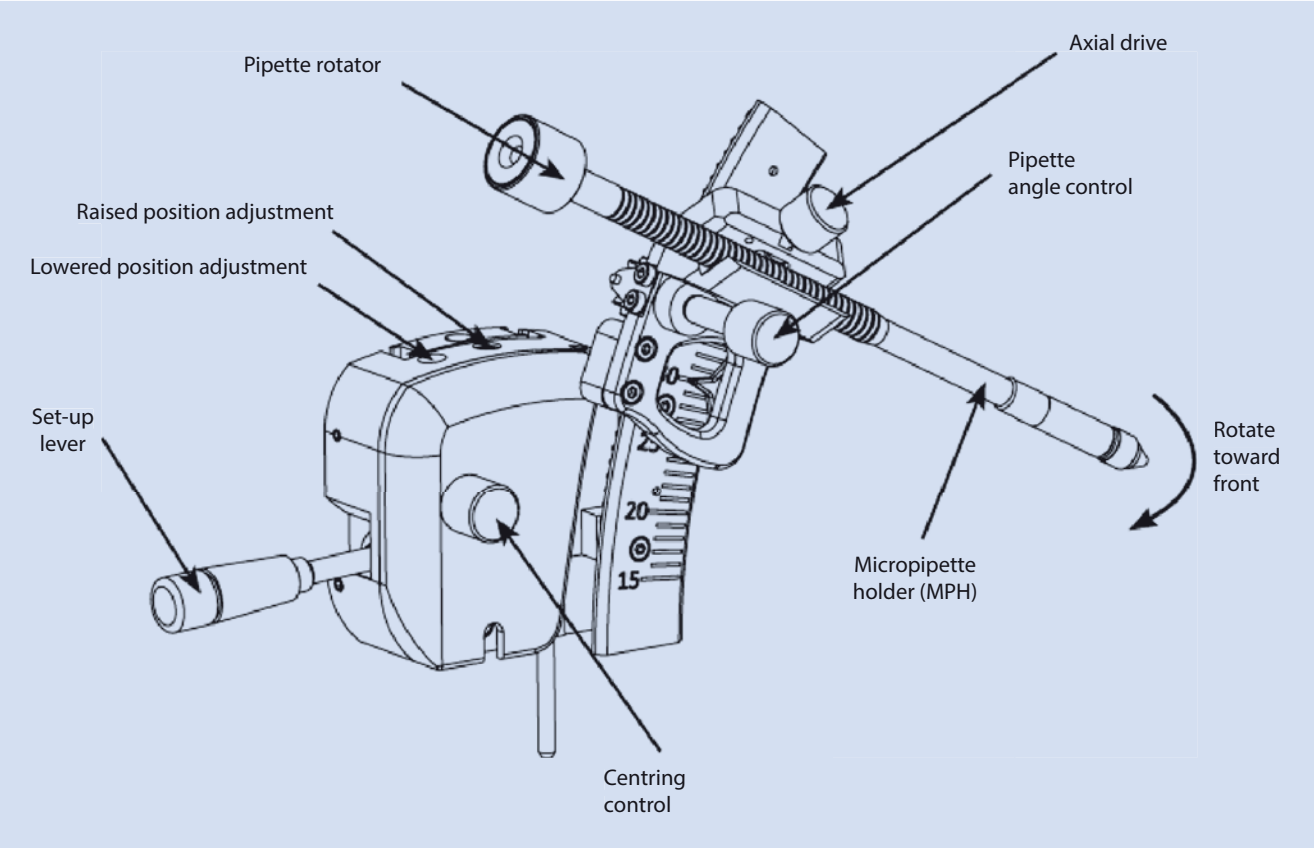

Fig. 36.6 PL3 tool holder

pre-implantation genetic testing (PGT), a double tool holder that enables independent movement of two micropipettes on the one tool holder is available from RI. However, with the advent of laser systems such as RI's Saturn 5 Active™ laser, most practitioners have now moved away from the use of double tool holders.

36.2.7 Microinjectors

The RI screw-actuated syringes (SAS) supplied as standard with the Integra 3™ are air-assisted microinjectors that are sometimes referred to as 'mushrooms' due to their inverted mushroom-shaped design (Fig. 36.7). By virtue of their heavy circular base, they are very stable, yet they occupy a relatively small footprint. With a capacity of 2 ml, they can generate high aspiration and pressure. The SAS air injector also benefits from incorporating a pressure release button situated on top of the screw control that enables rapid equilibration of internal and external pressure (Fig. 36.7). This feature is particularly useful for stabilizing capillary flow and for rapid cessation of aspiration pressure applied to rupture the oolemma during ICSI. An extra-smooth chrome special edition of the SAS microinjector is available from RI as an optional extra. For those who prefer to use an oil microinjector, RI will supply a micrometer-actuated sealed oil syringe (SOS) mounted on a sturdy, non-slip base.

The SAS microinjectors are supplied with hard polythene tubing for connecting them to the MPH microtool holders. It is a simple procedure to attach the tubing at one end to the metal nozzle underneath the SAS microinjector and, at the other end, to the proximal end of the MPH microtool holder. Once the tubing has been connected and a micropipette fitted to the MPH microtool holder, the micropipettes must be primed with media and the SAS microinjectors equilibrated prior to use. For the holding micropipette, this procedure simply requires the micropipette to be lowered into a drop of micromanipulation medium and the SAS to be rotated slowly anticlockwise until media rushes in, at which point the pressure release button can be pressed down in order to equilibrate the pressure inside and outside of the micropipette, thereby halting the influx of the medium. Priming and equilibrating an injection micropipette is a slightly longer process. Firstly, the SAS needs to be rotated fully clockwise to its lowest position and the pressure release button pressed. Then, the micropipette can be lowered into a drop of micromanipulation medium or a 7–10% polyvinylpyrrolidone (PVP) solution and the SAS rotated several turns anticlockwise, approximately 50% of its travel upwards. It may then be necessary to wait for up to 5 min in order for the media to be aspirated into the micropipette until it almost reaches the unpulled shank. At this point, the pressure release button can be pressed down to ensure the equilibration of the pressure, preventing unwanted drift of media up or down the micropipette. For those using older SAS models that do not incorporate a pressure relief button, it is necessary to disconnect and reconnect the tubing at the SAS microinjector in order to achieve equilibration during priming of micropipettes.

36.3 Clinical Applications

36.3.1 Zona Drilling and Assisted Hatching

Zona drilling is the technique of creating a hole in the ZP surrounding the oocyte or preimplantation embryo, originally described in 1986 [2]. Although less frequently used these days, the most widely used application of zona drilling in assisted reproduction, termed 'assisted hatching', is based on the assumption that the blastocyst will 'hatch' more readily from the ZP if previously breached by drilling a hole or cutting a slit in it. A variety of factors, including excessive thickness of the ZP and zona hardening following embryo culture, were originally proposed as one cause of recurrent implantation failure, due to the inability of blastocysts to 'hatch' [3]. Various means have been used to achieve 'assisted hatching' including the use of acids, enzymes and lasers to dissolve the ZP, no single method proving universally better

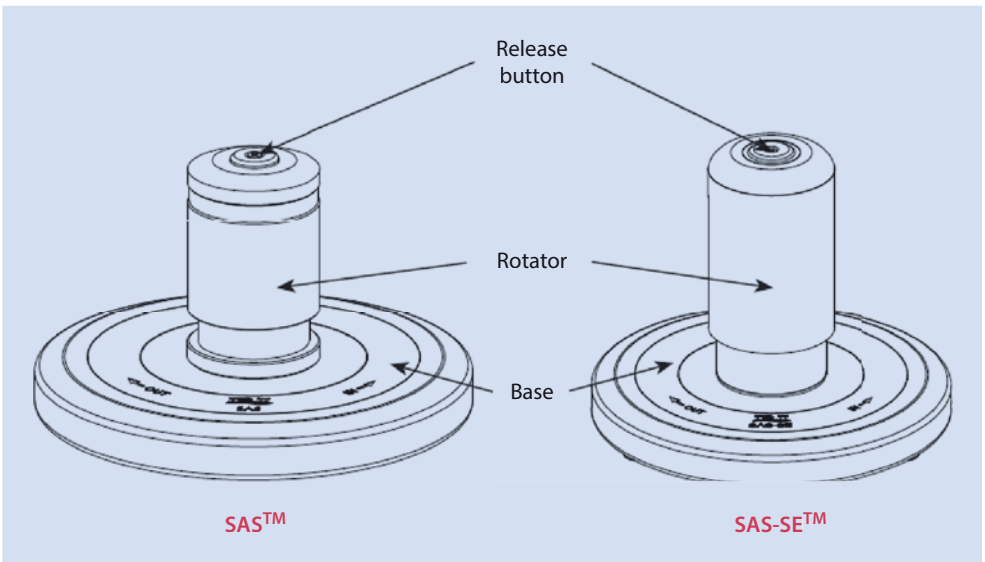

Fig. 36.7 SAS™ and SAS-SE™ air injector with equilibration button

than another [4]. It can be achieved by chemical means through controlled and directed application of acidified Tyrode's solution (pH 2.3–2.5) or pronase, using a drilling micropipette attached to a microinjector. For the flow of acidified or enzymatic media to be precisely controlled, a drilling micropipette should be fire-polished to an internal diameter of 5–10 µm, which is much smaller than the internal diameter of a holding micropipette. Contact and non-contact lasers, operating in either the ultraviolet or infrared spectrum, may also be applied to the ZP at a single point or at several adjacent points, depending on the length of hole desired. Lasers dissolve the ZP by generating heat, so non-contact lasers, especially those operating within the infrared spectrum, are generally considered safer for use with human oocytes and embryos. Zona drilling has also been used for other applications such as fragment removal from early cleavage-stage embryos and embryo biopsy for PGT.

36.3.2 Partial Zona Dissection

One of the earliest applications of zona 'drilling' in the human, termed 'zona tearing' or PZD, was to create a conduit for access to the oocyte by spermatozoa deemed incapable of binding to and penetrating the ZP [5, 6]. In this approach, micropipettes are used to physically cut a slitlike hole in the ZP while holding the oocyte firmly onto a holding micropipette.

36.3.3 Subzonal Insemination

At around the same time that PZD was developed, the PZD technique was being combined with the use of large microinjection pipettes in order to introduce spermatozoa directly into the subzonal perivitelline space [7, 8]. Originally termed 'microinjection sperm transfer' (MIST), the technique later became known as 'subzonal insemination' (SUZI). Once the manufacture of fine, sharp microinjection pipettes had been perfected, PZD became redundant for the purposes of SUZI.

36.3.4 Intracytoplasmic Sperm Injection

The technique known as intracytoplasmic sperm injection (ICSI) represents the ultimate evolution of experimental methods to alleviate male factor infertility, such as PZD and SUZI [1, 9]. The vastly superior efficiency of ICSI in achieving monospermic fertilization of the oocyte resulted in its rapid replacement of the SUZI technique. Successful application of ICSI depends on an appreciation that it must mimic the latter stages of fertilization that occur in vivo [10]. As with gamete fusion, the sperm plasmalemma and oolemma have to be temporarily breached. Hence, the microinjection pipette should be set up at such an angle that the sperm plasmalemma can be ruptured using the tip of the pipette, illustrated by a permanent kink in the sperm tail. Likewise, the tip of the microinjection pipette must be sharp enough that the oolemma ruptures when aspirated onto it using a microinjector, as evident by sudden free-flow of ooplasm into the microinjection pipette. Modifications of ICSI, such as laser-assisted ICSI [11], could feasibly result in improvements to the technique, though their relative benefits and risks need to be considered further.

36.3.5 Oocyte, Embryo and Blastocyst Biopsy

Following zona drilling, cells can be removed from the oocyte, early cleavage-stage embryo and blastocyst as biopsy material for the purposes of PGT, this technique having been pioneered soon after that of 'assisted hatching' [12]. Since the majority of aneuploidies occur during oocyte maturation [13], the first polar body (PB) represents a useful source of material for PGT, so methods have been developed to perfect PB biopsy. However, since postzygotic aneuploidy is also possible, although less common, blastomere biopsy of early cleavage embryos at the eight-cell stage has tended to be the approach preferred by those testing for sex-linked disease and other genetic mutations. More recently, partly because of the possibility of misdiagnosis due to mosaicism in the early cleavage-stage embryo, trophectoderm biopsy of the blastocyst has assumed greater importance.

Biopsy micropipettes should have an internal diameter of 40–50 µm. If a laser is not available for zona drilling, it will be necessary to fit drilling and biopsy micropipettes to a double tool holder that allows rapid interchange between the two during a biopsy procedure. For the purposes of blastomere biopsy, the optimal size hole to be drilled in the ZP should be only just large enough to allow a biopsy micropipette to enter the perivitelline space. One or two blastomeres may be removed from a seven- or eight-cell embryo, two blastomeres providing greater control for the potential for a misdiagnosis. With trophectoderm biopsy of the blastocyst, a commonly applied method is to allow a small portion of trophectoderm to herniate from the ZP following previous zona drilling on day 3 of development, and then to use a laser to help separate the extruded trophoblast.

36.3.6 Cytoplasmic and Mitochondrial Transfer

Some patients, particularly those of advanced maternal age, may remain infertile due to poor oocyte quality, yet may prefer to have their own biological children rather than resort to oocyte donation. Hence, cytoplasmic transfer was introduced as a potential means of rectifying perceived deficiencies or defects within the oocytes of patients experiencing repeated implantation failure [14]. Cytoplasmic transfer may be achieved by electrofusion or micromanipulation, the latter being the simplest approach. The micromanipulation technique requires aspiration of cytoplasm containing various nucleic acids, proteins, mitochondria and other cellular organelles from donor oocytes (usually from younger women) and

its deposition into the oocytes of the patient during ICSI. An alternative approach is transfer of the patient's germinal vesicle (GV) to an enucleated immature donor oocyte [15]. Amid concerns over the safety of cytoplasmic transfer [16], and following the birth of three children exhibiting developmental disorders (Turner's syndrome in two and an autism spectrum disorder in the other), the US Food and Drug Administration (FDA) effectively banned such treatment in 2001 until such time that its safety could be clinically proven.

Similar to cytoplasmic transfer, mitochondrial replacement therapy (MRT) has been recently introduced to alleviate the maternal inheritance of mitochondrial disease [17]. The objective of MRT is to transfer genetic material from a patient's oocyte into an enucleated donor oocyte, devoid of mitochondrial genetic mutations. There are various ways in which this might be achieved including polar body transfer (PBT), maternal spindle transfer (MST) and pronuclear transfer (PNT), MST and PNT having recently been approved for MRT by the Human Fertilisation and Embryology Authority in the UK.

36.4 Troubleshooting

36.4.1 Micromanipulators

If it proves impossible to bring the injection micropipette into focus at the surface of the microinjection dish, the most likely reason for this is that the angle of alignment of the micropipette is too obtuse, causing it to be 'heel-down' and pushing the pipette tip upwards and out of the microscope's focal range at high magnification. NB. Attempting to raise the focal plane will bend the micropipette further until it eventually snaps. The remedy for this problem is to lower the focal plane until the micropipette is clear of the surface of the microinjection dish and then use the angle compensation screw of the PL30 tool holder (Fig. 36.2) to adjust the pitch angle to a steeper position.

If the micropipette fails to move smoothly in either the X or Y plane, the most likely reason for this is that its tip is scraping along the surface of the microinjection dish, resulting in a juddering movement. This is simply remedied by raising the micropipette off the surface of the microinjection dish using the fine control lever of the micromanipulator (Fig. 36.3).

If there is no movement in the Z plane in response to rotation of the fine control lever of the micromanipulator, the most likely reason for this is that the control lever has reached the limit of its travel. This is simply remedied by resetting the fine control lever to its mid-point by rotating it in the opposite direction in order to free the locked movement.

If the fine or coarse control levers are too stiff or loose, the most likely reason for this is that the ball joint is out of adjustment. The remedy for this is to loosen or tighten the screws in the plate that retains the ball joint in place (Fig. 36.8) using the appropriately sized hexagonal wrench supplied with the Integra3™.

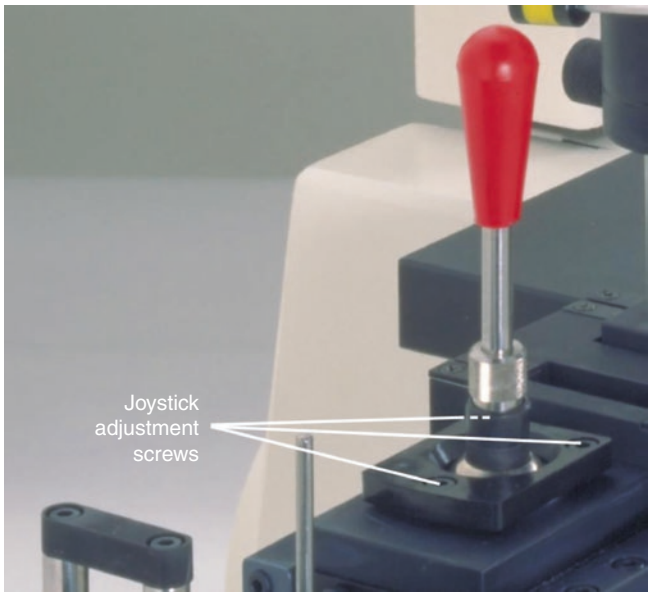

Fig. 36.8 Joystick ball joint retaining plate adjustment screws

36.4.2 Microinjectors

Should it prove impossible to control the sperm's position within the injection micropipette, the most likely cause of this is incorrect priming and equilibration of the micropipette. In this event, it will be necessary to repeat the steps described in the 'Equipment installation and set-up' section above.

Should there be drifting of the sperm's position following correct priming and equilibration of the injection micropipette, then the most likely cause of this is an air leak. In this case, check the tightness of both the MPH microtool holder and microinjector seals. If necessary, cut a 10 mm length off the end of the polythene tubing and reconnect it to create a fresh seal. If this fails to resolve the problem, remove the top of the SAS microinjector and replace the O-ring inside the barrel, and lubricate the O-ring using the special lubricant supplied by RI.

Review Questions

1. Can you list at least three micromanipulation techniques that are possible to be performed using RI micromanipulation systems?

2. What is the likely cause for a micropipette failing to move smoothly in either the X or Y plane of movement?

3. What are the indications that the sperm plasmalemma has been ruptured prior to microinjection, and why is rupture of the sperm plasmalemma biologically relevant?

4. Which checks should be performed in the event that there is drifting of the sperm's position following correct priming and equilibration of the injection micropipette?

5. Can you list at least three reasons why trophectoderm biopsy of blastocysts is preferable to blastomere biopsy of cleavage-stage embryos?

Eppendorf Micromanipulator: Setup and Operation of Electronic Micromanipulators

Laszlo Nanassy

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_37

Learning Objectives

- To describe the Eppendorf manipulator system and its history
- To highlight the main differences between the Eppendorf manipulator and other systems
- To provide detailed information about assembling and setting up the Eppendorf system
- To provide useful tips on how to operate the Eppendorf micromanipulation system efficiently

37.1 Eppendorf as a Company

The roots of today's Eppendorf AG can be traced back to Dr. Heinrich Netheler and Dr. Hans Hinz, who formed "Dr. Netheler's work group" in 1945 in a building on what was then the campus of University Medical Center Hamburg-Eppendorf. The workshop was established under the supervision of both scientists in order to return the hospital to a functioning state after the war. The team succeeded in repairing many devices and invented new ones like Thermorapid and Eppendorf photometer. Since then, Eppendorf AG, Hamburg, Germany, has created many devices and tools which are now considered breakthroughs in the field of laboratory applications. Today Eppendorf is a leading life science company that develops and sells instruments, consumables, and services for liquid handling, sample handling, and cell handling in laboratories worldwide. Its product range includes pipettes and automated pipetting systems, dispensers, centrifuges, mixers, spectrometers, and DNA amplification equipment as well as ultralow-temperature freezers, fermenters, bioreactors, CO_2 incubators, shakers, and cell manipulation systems. Consumables such as pipette tips, test tubes, microliter plates, and single-use bioreactor vessels complement the range of highest-quality premium products.

Eppendorf products are most broadly used in academic and commercial research laboratories, for example in companies from the pharmaceutical and biotechnological as well as the chemical and food industries. They are also aimed at clinical and environmental analysis laboratories, forensics, and at industrial laboratories performing process analysis, production, and quality assurance. Eppendorf has about 3000 employees worldwide. The company has subsidiaries in 25 countries and is represented in all other markets by distributors.

37.2 The History of the TransferMan

Eppendorf has a long history of micromanipulation equipment that started in 1982 when the company received a letter from the European Molecular Biology Laboratory (EMBL) in Heidelberg, Germany, requesting for a "device for injection of very small (approx. 10^{-15} L) volumes, which (they) employ with great success in the needle microinjection into living cells." After testing the first prototypes in 1984, the microinjector 5242 was launched replacing the barely reproducible and laborious manual work with a glass syringe. With the help of joystick-controlled stepper motors, a very precise positioning was possible when in 1988 the successor model was launched. A revolution was the coordinated process of manipulation and injection which was enabled by a communication protocol of both devices. In 1996, the first TransferMan was introduced. It was already equipped with specialized features for different working fields. An advanced version of the TransferMan was the TransferMan NK (1999) that was equipped with a proportional joystick instead of a dynamic which simplified IVF workflows. Its first successful application of intracytoplasmic sperm injection (ICSI) [1] showed its effectiveness [2] and had been adopted by many scientists. A micromanipulator's main usage in ART was for assisted fertilization, but many other procedures could be performed with it such as assisted hatching [3] or embryo biopsy [4], especially operations requiring proportional movement like ICSI. The newest manipulator generation, the TransferMan 4 model, launched in 2014, combines an intuitive user interface with an unprecedented movement control.

37.3 Description

37.3.1 Components

The Eppendorf TransferMan 4m (Fig. 37.1) is composed of two main components: the motor module unit (Fig. 37.2) and the control board (Fig. 37.3). The control board is mechanically separated from the motor module.

37.3.2 Motor Module Unit

The motor module unit can be fixed on any side of a microscope. For best results, especially for ICSI procedures or any cell surgery, the motor modules are mounted via a microscope-specific adapter. The motor module is made up

Fig. 37.1 The Eppendorf micromanipulator is composed of two main components: motor module unit and control board

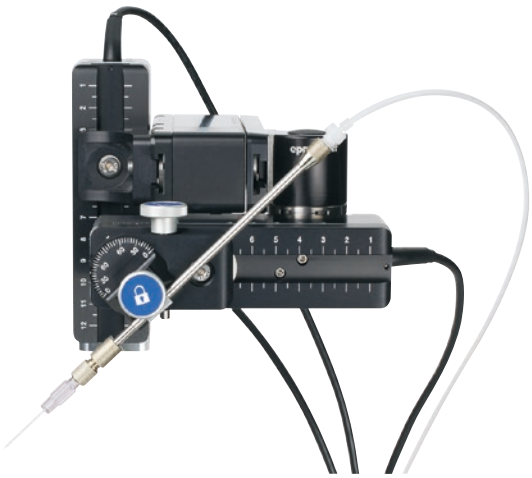

Fig. 37.2 Mounted motor module with attached capillary holder

Fig. 37.3 Control board of Eppendorf TransferMan 4

of three modules for the x-, y- and z-directions. The capillary can therefore be moved in all three spatial axes. The x-module with the capillary can be swung out of the working range using the swivel joint. This allows an easy capillary exchange. The injection angle of the capillary can be set on the angle head.

37.3.3 Control Board

The upper part of the control board contains the joystick which enables the user to make horizontal and vertical movements in a proportional and dynamic way. This unique DualSpeed™ movement gives precise, instantaneous control and positioning using different speed modes. The position can be changed to another saved position by pressing the button twice. The working range can be chosen between coarse and x-fine mode depending on the needed travel distance of the capillary. The speed is adjusted accordingly. One of the main advantages of the Eppendorf micromanipulator is that it is user-friendly even for new users. It can save certain positions and allows for rapid changing between them. In addition, a z-limit can be programmed, limiting pipette movements downward and maintaining the distance to the Petri dish. The position feature is not found in other brands of micromanipulators used in IVF and greatly reduces the risk of pipette breakage by inexperienced and experienced users. The "home" button allows fast withdrawal of the pipettes from the stage, allowing for changing the sample or pipette. Pressing the "home" button again returns the pipettes to the previous position. The display illustrates the axis coordinates and the options chosen. The multifunctional keypad gives the desired function when the button is pressed or released and allows multiple positions to be saved. With the selection dial on the side, the working range can be easily adjusted. In the rear part of the control board, the connections for the motor modules and external devices are located. Also, the power connection is located there.

37.4 System for Micromanipulation

Micromanipulators are one of the main components of a manipulation workstation. Therefore, they have to be carefully chosen to ensure the best possible results. In addition, it is important to choose appropriate optics for embryo manipulation for the inverted microscope. Also, careful consideration is needed when a heating stage is chosen. It has to be reliable and keep temperature within a range that is not damaging the cells and provides a uniform heat distribution. It is also highly recommended to use an anti-vibration table or alternative solution (e.g., anti-vibration pads) in order to avoid unnecessary damage during manipulation.

The location of the workstation within the laboratory is also worth considering. It is recommended to place it close to the biosafety cabinet and incubators and far from air ventilation systems if possible. The ergonomics of the station is also important as long hours of work are expected on the manipulation station.

37.5 Setting Up the Hardware

Before setting up, as always, it is advisable to read the manual of the equipment. Usually, the manufacturer assembles the manipulator in the laboratory and sets up working units, but fine alignment is the responsibility of the user.

The first step with the Eppendorf system is to center the x- and y-motors and to drive the z-motor down by 80%. Then, with capillaries inserted into the injection holders, both modules should be positioned resulting in needles being in the middle of the field of view. In order to make sure that we have the tips of the needles at the same position or nearby at every setup, the depth of the needles can be fixed with the adjustable clamp on the injection holder. It has to be noted that the needles are needed to be pushed into the holders to the endpoint in order to be able to reproduce the setup every time.

Obviously, the angle of the needles needed to be set up based on the choice of needles. The final step is to save the centered set up that can be recalled when needed. Before every manipulation, only fine alignment is necessary; thus, a fast setup can be accomplished.

37.6 Setting Up the Software

As mentioned previously, in the case of the software, it is also worth studying the manual as it can make the operator's life easier. There are different applications preprogrammed based on the purpose of the procedure. We can find an application for ICSI where there are two main functions preset, the Y off and the Z-axis limit options. Also, there is a possibility to add other user-specific applications since additional spaces are available in the software. Other predefined applications such as "cell transfer" and "DNA injection" can be chosen and further fine-tuned based on the operator's preferences. Another option is to choose "My application" which is a fully programmable application.

37.7 Training on TransferMan

Like with all manipulators, operators need some training to be able to work efficiently on the Eppendorf units.

Motors are strong enough not to feel any resistance if we reach the bottom of the dish and needles can be broken. In case of other manipulators, this phenomenon could be more obvious. It needs to be visually checked when dealing with the depth of the capillaries.

The working range can be changed, which is the amount of movement of the needles that is translated by the movement of the joystick. This is solely based on the preference of the operator but needs some practice to work out the most optimal setting. There are three main options (coarse, fine, and extra fine), each of which can be changed using the selection dial on the left side of the control panel. Another feature that is different from other manipulators is that the TransferMan 4 allows for proportional and dynamic movement. When the joystick is pressed against the rim on the side, the pipette moves continuously. This function can be disabled based on the operator's preference. It is useful when needles need to be centered.

Also, joysticks can be centered without moving needles. This is a useful tool when fine alignment of the capillaries is needed in the middle of a procedure. Uncoupling the joystick from the motor module is accomplished by pushing and holding the button on the top.

In order to be able to acquire movement only for one direction, the "Y off" function can be enabled. This function is similar to what the Narishige system is capable of when only rotating one knob, for example for injecting the spermatozoon into the egg. This function is preset when the ICSI application is chosen on the Eppendorf system.

A vertical limit of the capillary movement can be set. For this option, when the desired lowest point is reached, the "Z-axis limit" function should be enabled. Although this is a useful option, it should be noted that dishes used for ICSI are not always plain enough to be able to take advantage of the function.

One simple feature that can fasten procedures on Eppendorf manipulators is the double click on the joystick button. This allows the user to switch between saved positions (e.g., inside and above the injection droplet of the ICSI dish).

37.8 Everyday Work

It is the responsibility of every operator of the ICSI station to maintain the proper functionality of the equipment. For efficient manipulation work, it is crucial to properly set up our system. When the instrument is turned on, the centered setup can be recalled if it was saved as one of the positions. If not, all motors can be centered from the main menu (menu/function/executing center motors). It is advisable to set the microscope to the lowest magnification. Before mounting pipettes, both manipulator arms can be lifted by pressing the "home" buttons. The X-module can be swiveled out, allowing for an easier access to inserting the capillary. After inserting capillaries on both sides, the manipulator arms can be set to the previous position by pressing the "home" buttons again. If the adjustable clamp on the injection holder is set to the right depth, the injection holder can be slid down gently to its endpoint. We should have a more or less centered position of capillaries in the plain, and only fine adjustment should be necessary. Then the alignment should be checked at the magnification at which the actual work will be carried out. After finalizing the alignment of the pipettes, this position can be also saved by pressing and holding the "Pos" button. This should be saved in a different position than zero or centered setup. With this, we can recall this setup any time during the manipulation procedure if it becomes necessary. Between patients, the centered setup can be recalled, and after fine alignment, the setup can be saved again. Both manipulator arms can be lifted by simply pushing the "home" button, and the dish can be placed on the microscope stage to start the procedure.

37.8.1 Priming of Capillaries

Eppendorf offers two types of injectors (air and oil) that can be used on both the holding and the injection side. Injectors from all other manufacturers are also compatible with the Eppendorf system. Thus, operators with certain injector preferences can use this system as well.

Oil-based injectors are able to offer a very fine control. In these injectors, the tubes are filled with oil that cannot be compressed, which translates the movements to the tip of the needles. Before capillaries are inserted, oil should be pushed through the pipette holder to make sure that there is no air in

the system. The transparent cylinder of oil-based injectors should be visually checked prior to work every day if it is free of any air bubbles. It is also critical to ensure there is enough oil in the system and to refill if necessary. For this, the filling screw should be unscrewed from the filling bore and a syringe filled with oil attached and cylinder filled with oil while the injector is held vertically.

Priming of capillaries is simple; the medium can be withdrawn to a point that still can be observed under the microscope at a lower magnification. Suction should be stopped by turning the knob in the opposite direction, and basically priming of the capillaries is done.

A similarly fine control of samples can be obtained using air-based injectors as well, but priming of capillaries needs to be done differently. Usually, for the holding side, the capillary action is enough to prime. The capillary needs to be submerged into the medium and equilibrated for a couple of minutes. The level of the medium should be in the vicinity of the middle of the pipette. For embryo biopsies, this should be sufficient to prime the injection side as well depending on the diameter of the biopsy pipette. If it is narrow, a little suction can be applied, and waiting a little is recommended because of slower equilibration. For ICSI, first priming is needed with the medium applying suction and waiting a couple of minutes. Then, priming is needed with PVP or any other medium that is used for slowing down sperm.

Less attention is needed when working with air-based injectors. It is worth checking the injectors before manipulation if there is enough room in the cylinder for priming and performing the actual procedure.

37.8.2 ICSI, Embryo Biopsy, and Other Techniques

The detailed description of executing ICSI, embryo biopsy, or other manipulation techniques is beyond the scope of this chapter.

Probably, the most common manipulation procedure is still the intracytoplasmic sperm injection. For ICSI, on the injection side, it can be helpful to set the angle a bit steeper to obtain easier sperm handling. The angle can be easily changed with the knob on the top of the angle head.

37.9 Maintenance

Eppendorf does not specify certain time frames for service. Service is needed only if problems arise. Similar to every precision instrument, service needs to be done by professional Eppendorf technicians.

Review Questions

1. How is the Eppendorf manipulator system different compared with other systems?
2. What are the specific functions of the Eppendorf system that are most helpful for operators during the manipulation of oocytes and embryos?

Oocyte Treatment and Preparation for Microinjection

Thomas Ebner

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_38

Learning Objectives

- To learn how to score cumulus-oocyte complexes
- To learn how to avoid lethal stress during the denudation process
- To realize the potential of cumulus cells as predictors of oocyte quality
- To keep in mind the physiological way of sperm processing and selection
- To learn how to perform ICSI in the presence of immotile sperm
- To learn how to deal with cases of ICSI fertilization failure
- To learn when a modified ICSI technique is useful

It must be emphasized in advance that two major problems must be solved in preparation for ICSI. First of all, it has to be ensured that temperature is constantly kept at physiological ranges (approx. 35–37.5 °C) throughout the whole process of oocyte collection, denudation, and injection. For this purpose, the temperature of all laboratory devices involved (e.g., heating plate, transportable container, microscope stage, incubator), has to be set higher than the requested temperature in the prevailing incubation medium. The required difference has to be tested individually for each laboratory set up and will be closely related to the volumes of culture medium and/or mineral oil used.

The second prerequisite for an optimal ICSI performance is a well-calculated time schedule. The period between oocyte collection and subsequent ICSI should never exceed 6 hours [1, 2] in order to avoid in vitro aging of the oocytes. In this respect, it seems irrelevant whether the cumulus-oocyte complexes (COC) are denuded immediately after collection leaving denuded eggs in culture for later ICSI or if the manipulation is performed directly prior to ICSI after a resting period of several hours [1]. However, since oocytes may develop osmotic problems, e.g., an unwanted influx of culture medium, after a prolonged period without cumulus cells attached (unpublished data), and cumulus cells play an important role in maturation of the oocyte, it is recommended to perform processing of the COCs close to the time of injection.

38.1 Processing of the Cumulus-Oocyte Complex

Harvested COCs are traditionally evaluated by their appearance and by the expansion of the corona radiata and the cumulus complex. Based on these criteria oocytes within cumulus matrix are roughly categorized as either mature (metaphase II) or immature (pro- and metaphase I). In detail, an expanded and luteinized cumulus complex and a radiant corona radiata suggest completion of nuclear maturation, while the absence of expanded cumulus or corona cells is associated with immaturity [3]. This is in contrast to more recent data which show that nuclear maturation and oocyte quality cannot be predicted adequately by scoring the COCs [4, 5].

Frequently, blood clots or other amorphous clumps [5, 6] are present in the cumulus matrix. Embryologists tend to cut off these areas with the help of two needles. Apart from the fact that this is mechanical stress to the oocyte, particularly if the dysmorphic cells are close to the corona radiata, it is of no use. On the one hand, amorphous clumps, considered to be a sign of postmaturity, did not have any effect on preimplantation outcome, and on the other, COCs showing blood clots have already been harmed during folliculogenesis and, thus, their developmental capacity may not be retained by cutting off the blood clots mechanically [5].

38.2 Denudation of the Oocyte

For successful ICSI it is critical that cumulus cells are adequately removed from the oocyte. Apart from the fact that oocyte maturity and/or quality need to be checked prior to injection, some technical problems could occur. Theoretically, it could happen that the oocyte cannot be manipulated adequately with the holding pipette if these nutritive cells block the 9 o'clock position. In addition, there is a certain risk to accidentally bring in foreign somatic DNA into the egg if cumulus cells are still attached at the site of injection [7].

It has been established that any denudation process consists of two steps, an initial enzymatic digestion followed by mechanical precision work. Since it has been shown that a dislocation between the first polar body and the meiotic spindle could occur if the mechanical part is performed inadequately, e.g., using pipettes of an inappropriate inner diameter (<140 μm), it is recommended to prolong the enzymatic incubation period. This would definitely help to minimize the mechanical denudation part, in particular to reduce shear stress [8].

Usually, commercially available hyaluronidase is used to start the denudation process. Hyaluronidase is an enzyme degrading hyaluronic acid which is a major component of the extracellular matrix of the oocyte. Most of the commercially available hyaluronidases have a concentration of 80 IU/l, which is only a tenth of the critical threshold above which parthenogenetic activation might occur [9]. For reducing the theoretical risk of harming the oocyte even further, incubation time could be shortened (30 seconds) or the dilution could be changed to 40 IU/l (1:1 mixture with culture medium). Ultimately, it seems to be sufficient to put few drops of hyaluronidase in the well containing the COCs, but in such a case, the exposure time will naturally need to be prolonged to approximately 10–15 minutes (P. Vanderzwalmen, personal communication).

Alternatively, plant (CoronaseTM, Bio-Media, Boussens, France) or recombinant human products (ICSI Cumulase™, Origio, Måløv, Denmark) could be applied [10]. It has been argued that due to the reduced toxicity of these enzymes, exposure time is not critical anymore.

The question remains if it is at all necessary to completely denude the female gametes. Our study group could demonstrate that coculture using homologous cumulus cells in situ

(partial denudation) is associated with an enhanced rate of in vitro maturation, embryo quality, and blastocyst formation [11]. Obviously, leaving numerous cumulus cells attached to the zona pellucida mimics the in vivo situation and utilizes the stimulatory effect of the somatic cells during the first days of preimplantation development. However, due to their varying stage of maturity oocytes do not present a standardized pattern of cumulus cell attachment. Younger oocytes (from the time of ovulation induction) show a more homogeneous pattern with cumulus cells involving the whole surface of the gamete, which makes ICSI somewhat difficult since there is almost no cumulus cell-free access to the zona. Indeed, it has been suggested that incomplete denudation of oocytes might increase degeneration rate under certain circumstances [12].

38.3 Cumulus Cells as Noninvasive Predictors of Oocyte Quality

It should be emphasized in this context that the detached somatic cells could be used for both adequate prognosis of the quality of the associated oocyte and treatment outcome. All techniques available, e.g., analysis of apoptotic phenomena [13], evaluation of telomere length [14], or cumulus cell gene expression [15], are based on the hypothesis that a healthy follicle gives birth to good-quality gametes and granulosa cells. Female gametes are further thought to protect the associated cumulus cells since inside-out gradients in gene expression of bone morphogenetic proteins 6, 7, and 15 [16] and DNA-integrity [17] have been observed.

38.4 Catching of the Spermatozoa

In parallel to the processing of the COCs, the ejaculate produced under sterile conditions has to be processed for further usage. This can either be done using a centrifuge combined with a swim-up procedure (e.g., Percoll, density gradient, Sephadex columns, glass wool column) or sperm isolation without centrifugal stress (Zech-Selector, microfluidics).

Since in most of the patients a certain proportion of sperm is motile, embryologists are faced with the problem of catching these gametes prior to immobilization and injection. This procedure can be performed in three different milieus: culture medium, polyvinylpyrrolidone (PVP), or a more physiological viscous solution.

Naturally, catching sperm in the same balanced culture medium in which the oocytes are cultured (different drop) would be the most natural approach. Loading a processed sperm sample into medium drops on an ICSI dish has the benefit that motile sperms will automatically separate from immotile gametes, somatic cells, and other debris by their motility. This makes the purity of the whole drop much higher and minimizes theoretical contamination. However, this mode of catching sperms has the drawback that without a viscous solution covering the inner surface of the injection pipette sperm manipulation during injection is not a smooth process but much rather a jerky one. This problem cannot be overcome, but it can be reduced by either washing the ICSI tool with PVP or by slightly changing the injection technique [18]. It is recommended that a minimum volume of medium is placed in the ICSI pipette (border between medium and oil/air should be below the knee of the pipette) and that the sperm is placed in the foremost third of the visible part of the glass tool. These precautions will facilitate stabilization of the sperm and help further manipulation. Embryologists using this setup often tend to aspirate the sperm with its head first since this is much easier and less time-consuming than trying to aspirate a hypermotile sperm from its tail end. Although ICSI in reverse has been found to be of similar outcome [19], there is a much higher risk of artificially creating vacuoles at zygote stage [20] since the larger volume (as compared to sperm head-first ICSI) of medium entering the oocyte frequently becomes encapsulated (Fig. 38.1).

For these reasons, most embryologists regularly use a viscous water-soluble polymer (PVP) of the monomer N-vinyl pyrrolidone to facilitate manipulation of sperms (and to coat the injection pipette). In contrast to the usage of culture medium, PVP that enters the oocyte cannot be actively removed through membrane channels due to its rather high molecular weight (between 40,000 and 360,000). Thus, larger volumes of PVP could alter intracytoplasmic pressure and/or osmotic behavior of the oocyte. It has to be mentioned that PVP per se is not toxic at all, e.g., it is used in personal care products such as toothpaste, contact lens solutions, and shampoo. However, there is no denying the fact that it is an unphysiological liquid.

This circumstance led several companies to introduce more physiological solutions for sperm manipulations. Currently, two such products are on the market, SpermSlow™ (Origio, Måløv, Denmark) and SpermCatch™ (Nidacon, Mölndal, Sweden). Both are based on the finding that a

Fig. 38.1 Artificially created vacuole (V) after ICSI (day 1) resulting in a monopronuclear (Pn) zygote. Please note that sperm is located within the vacuole

naturally occurring major component of the cumulus cell matrix called hyaluronate (polymeric chain of glycoseaminoglycans) slows down the movement of spermatozoa and could act as a natural alternative to PVP [21]. Hyaluronate has a relatively high negative charge and a high hydration capacity that allows for the preparation of solutions with adequate viscosity for ICSI. It has been reported that its effect on sperm motility is reversible, and its use does not affect the outcome of the treatment cycles in terms of fertilization, pregnancy, and live birth rates [22]. However, it has to be noted that hyaluronate-based products do not have the same effect on the ease of sperm modulation as PVP probably due to its rather low content of hyaluronate (approx. 1%).

38.5 Immobilization of the Spermatozoon

Once the spermatozoon is caught, it appears necessary to immobilize it prior to injection [23]. Regardless of the fact that under normal in vivo conditions no sperm tail enters the oocyte, immobilization of the sperm has two beneficial effects: on the one hand, any possible damage to the cytoskeleton caused by motile sperms is theoretically negligible, and on the other, permeabilization of the sperm membrane will ensure that a soluble oocyte-activating factor (phospholipase C zeta) immediately enters the ooplasm [24].

Sperm immobilization is usually performed toward the end of the tail (back half); however, permeabilizing alternative sites is also possible. Yong et al. [25] successfully damaged the head membrane of porcine spermatozoa. This is also possible in the human since sperm chromatin is tightly complexed to protamines (approx. 85%) and histones (approx. 15%) and further stabilized by the formation of intra-intermolecular disulfide cross-links between the cysteine residues of the protamine molecules [26]. Thus, any suggested mechanical harm to sperm DNA is only of theoretical nature, e.g., laser shots directed at the sperm head did not cause DNS strand breaks (unpublished observations).

However, sperm immobilization can be performed using four different methods. The most common approach would be a mechanical one, e.g., pressing the tail of the spermatozoon to the bottom of the ICSI dish by use of the injection pipette [23]. This is in line with the work of Palermo et al. [27] who found a more aggressive mechanical immobilization process in epididymal sperms helpful in order to increase fertilization rate from 48% to 82%.

Sometimes the angle of the ICSI pipette is suboptimal, permitting no adequate manipulation of the spermatozoon. In such cases, repeated aspiration in and out the injection pipette is found to be helpful to immobilize sperms. However, only 16% of the corresponding oocytes showed 2Pn as compared to conventional mechanical breakage (90%) of the sperm membrane [23].

Montag et al. [28] introduced laser-assisted permeabilization of the sperm membrane into the field of assisted reproduction. Our study group [29, 30] successfully used this mode of immobilization as a routine procedure. In detail, spermatozoa were immobilized with a noncontact diode laser (1.48 µm wavelength) applying a double shot strategy. Two successive laser irradiations were applied per spermatozoon, the first aimed near the middle of the tail (1.5 mJ) and the second directly at the end of the tail (1.0 mJ). This strategy minimized the total energy dose male gametes were exposed to. In addition, laser shots were placed far from the head, which made laser application for immobilization a presumably safe process.

A fourth alternative is piezoelectric manipulation of the motile sperm [31]. The same authors [32] published that the piezo method shows the most rapid onset of Ca^{2+} oscillations of all techniques (except laser immobilization) and, thus, may have caused the most damage to the sperm membrane. The method of sperm immobilization may be important for the rapid release of sperm factors that initiate oocyte activation.

38.6 Selection of Spermatozoa

Whatever method appears convenient, special care should be taken to select spermatozoa with best prognosis in terms of fertilization and further preimplantation development. Optimal selection of male gametes is a prerequisite for a successful ICSI program and should at least be performed at a magnification of ×400 if not at much higher magnification [33]. Not only should embryologists accurately evaluate normal sperm morphology [34, 35] in order to use gametes of optimal prognosis, but it is also of utmost importance that these cells reveal a high grade of maturity and genetic stability.

Huszar et al. [36] reported that a hyaluronate receptor is expressed in mature spermatozoa only after plasma membrane remodelling during spermiogenesis, and that hyaluronate is an ideal medium for sperm selection for ICSI. Thus, hyaluronic acid (HA) has recently been used as "physiologic selector" for spermatozoa prior to intracytoplasmic sperm injection as a convergence to a more physiological fertilization [22, 37, 38]. Spermatozoa bound to HA show a significant reduction in DNA fragmentation and a significant improvement in nucleus normalcy compared with spermatozoa immersed in PVP. Furthermore, injection of HA-bound spermatozoa significantly improved embryo quality and development [22], whereas zygote score was unaffected [37].

It should be noted that HA-ICSI requires special preparation of the ICSI dish. In detail, a small (e.g., 2 µl) droplet with suspension of spermatozoa has to be connected with a pipette tip to a slightly larger (e.g., 5 µl) droplet of HA-containing medium and allowed to incubate for 15 minutes at 37 °C under oil. Thereafter, spermatozoa bound to HA in the junction zone of the two droplets can be detected, easily detached by the injection pipette, and subsequently used for injection.

A similar mode of selection aiming toward more mature spermatozoa utilizes spermatozoa previously bound to the zona pellucida of an immature egg [39]. This specific binding induces the acrosome reaction and, theoretically, should

provide for better ICSI outcome. Indeed, embryo quality was found to be increased, although fertilization rate was unaffected [39].

In practice, it has been suggested [39] that a processed sperm sample (ca. 1×10^6 motile spermatozoa per ml) should be incubated with one MI-oocyte in buffered culture medium. After a 2-h incubation period, the eggs should be carefully washed to dislodge sperms loosely adhering to the surface of the zona pellucida. Spermatozoa bound to the MI-oocyte zona pellucida are presumed to be mature and can be removed with a microinjection needle for subsequent ICSI. However, since MI-gametes did not finish either nuclear or cytoplasmic maturation, it is questionable whether immature eggs express a zona pellucida selecting for the same male gametes as a MII-oocyte. Another technical limitation is the rather strong binding between sperm head and zona. Anyone having tried to detach bound sperm from the outer shell of an ovum will have realized that this requires rather strong suction forces by the ICSI pipette. Moreover, the sperm tail is still intensely motile since this step has to be performed in culture medium and not in viscous solutions.

Although both methods, using zona- or HA-bound spermatozoa for ICSI, will increase the percentage of genetically intact spermatozoa, there is currently no way to completely remove DNA strand break-free from a given processed sperm sample. Recently, our study group [40, 41] evaluated the efficiency of a particular sperm selection chamber (ZechSelector™, AssTIC Medizintechnik GmbH, Leutasch, Austria) with respect to its selection properties in terms of DNA damage. Interestingly, it turned out that these glass or polyethylene chambers exclusively accumulate strand break-free spermatozoa, which for the first time ensures elective usage of DNA-intact sperms for ICSI. Since the ZechSelector™ strictly separates spermatozoa according to their motility/velocity without exposure to centrifugation stress [42], these parameters should be of utmost importance during sperm selection. Obviously, once DNA damage has occurred, both nuclear and mitochondrial DNA will be affected. Any impact on the latter could reduce ATP production and as a consequence sperm motility.

38.7 Immotile Sperm

This selection criterion can of course not be applied if all spermatozoa of an ejaculate are immotile (e.g., Kartagener syndrome, cryopreserved sperm, TESE-material). In this particular case, embryologists have to be aware that it is of serious consequence if they cannot distinguish between immotile and viable sperms, although immotility does not preclude viability. Theoretically, one has four options to solve this tricky problem.

Commonly, the most reasonable approach would be to use the ICSI pipette in order to test the elasticity of the sperm tail [43]. A spermatozoon showing an elastic tail (once being manipulated with a glass tool) is presumed to be more viable than those with more rigid ones. Typically, these nonviable sperms show incapacity to resume the initial tail position once touched by the pipette from the side, and they show a characteristic "rolling" motion when touched from above. However, in the final analysis there is no guarantee that more elastic sperms are viable, e.g., being an osmotically intact cell.

For confirming osmotic capacity sperms can be incubated in a hypoosmotic swelling solution, e.g., a 150 mOsm NaCl solution [44, 45]. Gametes with a functional membrane will undergo swelling of the cytoplasmic space and the sperm tail fibers will curl, whereas those gametes with damaged or osmotically inactive membranes do not show these phenomena. It is important to consider that swollen and curled sperms have to be moved to an isoosmotic culture medium prior to injection in order to facilitate original state and osmotic status.

Recently, a third alternative was introduced [46] suggesting usage of a diode laser in order to assess viability in cases of complete asthenozoospermia. Applying a single laser pulse (1.2 ms) at the very end of the sperm tail (direct method) caused a characteristic curling of the tail end. Since nonviable sperm did not show this phenomenon, this new technique helped to identify spermatozoa with functional integrity of its membrane.

The fourth strategy is the only one allowing for partial restoration of original motility [47]. Pentoxifylline and other caffeine derivates such as theophylline (Spermmobil™, Gynemed, Lensahn, Germany) are inhibitors of phosphodiesterase activity, which enhance motility in spermatozoa. Using this ready-to-use compound Ebner et al. could successfully treat patients suffering from crypto- and azoospermia [48] as well as in a case of retrograde ejaculation and absolute asthenozoospermia [49].

These agents show maximum activity after 10 minutes and an activity phase of less than 2 hours [50]. Because of this immediate and short-term effect, direct addition into the droplet containing the immotile sperms is recommended.

38.8 Intracytoplasmic Sperm Injection

Regardless of whether a motile or immotile sperm is available, ICSI should be performed according to a standardized procedure. To perform ICSI, the oocyte is held in place with a holding pipette at 9 o'clock. The first polar body usually is located on the 6 or 12 o'clock position. As soon as the equatorial plane of the oocyte is focused, the ICSI pipette has to be pressed against the zona pellucida creating a characteristic funnel at 3 o'clock. After penetrating both the zona and the oolemma, a small volume of cytoplasm should be aspirated into the glass tool to activate the egg and to ensure entering of the ooplasm [51]. The single immotile spermatozoa should then be gently placed near the horizontal axis. Withdrawal has to be done carefully to prevent the oocyte from leakage.

Placing the first polar body farthest from the path of the injection needle was thought to protect the meiotic spindle, which is considered to be located in the periphery of the egg subjacent to the first polar body, against mechanical damage

Fig. 38.2 Suboptimal pronuclear formation close to the periphery of the oocyte

[52]. Meanwhile, it has been published that due to the manipulation during denudation, the first polar body is a rather inaccurate marker of the spindle position [53] and that it is almost impossible to harm the dense microtubule structure of the spindle apparatus.

This finding is further supported by data of Blake et al. [54] who analyzed fertilization and embryo development resulting from varying distances between the injected sperm and the polar body associated with the presumed area of the spindle. Among the orientations examined in this paper, depositions of the sperm in the vicinity of a polar body at 9 o'clock resulted in significantly fewer normally fertilized oocytes and significantly more unfertilized and digynic oocytes. All other locations gave similar rates of fertilization and embryo qualities. It appears to be crucial that the immobilized spermatozoon is placed in the very center of the female gamete. Since decondensation of the sperm head and formation of the male pronucleus takes place at the site of sperm deposition [55], any deviation from this optimal place, e.g., close to the periphery of the egg, would result in suboptimal pronuclear formation (Fig. 38.2). This scenario is most likely associated with cleavage anomalies or developmental arrest [56].

38.9 ICSI Failure

Since intracytoplasmic sperm injection is more invasive than other micromanipulation techniques, there is a higher risk of irreversibly damaging the injected oocyte (lysis, shrinkage, and/or tanning of the egg). The rate of degenerated oocytes after ICSI should be around 1% and not exceed 3%. Though most embryologists have made the experience that a suboptimal injection technique may influence ICSI outcome as they progressed on their learning curve with micromanipulation, only few studies deal with degeneration of oocytes [57]. The main problems found were as follows: (i) spermatozoon remained attached to the ICSI pipette while being released, (ii) insufficient immobilization of the spermatozoon (as assessed by subsequent movement of the tail after injection), (iii) rejection of spermatozoon into perivitelline space after ICSI (as assessed by the sperm's tail protruding out of the oolemma/zona pellucida), and (iv) difficult breakage of oolemma. None of the abovementioned deviations from a presumed optimal injection procedure are significantly correlated with oocyte survival except the latter one.

During ICSI, different responses of the zona pellucida and the membrane to the injection pipette can be observed. In contrast to the very frequent normal response, showing a distinct injection funnel prior to rupture, two rather rare breakage patterns are considered as abnormal [27], namely, sudden breakage without any invagination during injection and difficult breakage characterized by delayed rupture of the oolemma. Recently, it could be shown that the characterization of an injection funnel during ICSI reflects cytoplasmic maturity of the oocyte [58], in a way that the more immature an oocyte is, the smaller is the injection funnel, and consequently the ooplasmic viscosity.

It has been shown that additional manipulation in MII oocytes showing difficult oolemma breakage may cause an increase in degeneration rate [59]. In order to avoid this scenario, a modified injection technique has been suggested [52] combining a pressing and a sucking phase, thus keeping oocyte survival rate at an adequate level.

38.10 Laser-Assisted ICSI

To overcome this high risk for degeneration in such oocytes, an alternative laser-assisted intracytoplasmic sperm injection has recently been suggested [60] and successfully applied in patients with diminished oocyte survival in previous cycles [60, 61]. This method involves injection of the oocyte through a small laser-created hole (5–10 μm) in the zona, which facilitates penetration of all anatomical structures. As a consequence, oocyte survival is increased significantly, as demonstrated in a larger number of cases [62].

However, none of the abovementioned studies took into account a major problem of laser-assisted ICSI, namely, the impossibility to localize the laser-generated hole at later developmental stages [62]. This phenomenon is particularly evident at the blastocyst stage, when the embryo expands and the zona pellucida gets thinner prior to hatching. Thus, if assisted hatching is applied in such embryos, as recommended in embryos derived from oocytes with difficult penetration of the oolemma [63], an additional opening is unintentionally created, which might impair the hatching process per se and/or result in monozygotic twinning [64].

In order to avoid this possible dilemma, Moser et al. [65] decided not to perform ICSI through a relatively small opening but through a zona pellucida area on which laser zona thinning [66] was applied. This approach allows for accurate location of the manipulated zona area at later developmental stages and, theoretically, should combine two advantages, namely, minimal mechanical stress to the oocyte during ICSI (e.g., increased oocyte survival) and assisted hatching.

Laser-assisted ICSI suggests that difficult penetration during ICSI is always caused by the zona pellucida and never by the structure of the oolemma. As in zona-free ICSI no injection funnel forms in laser-assisted approaches and immediate penetration is observed.

38.11 Modified ICSI

Considering the complexity of the fertilization process may help to understand its susceptibility to disturbances potentially causing complete fertilization failure (in spite of the presence of a presumably normal spermatozoon). The frequency of total fertilization failure cycles is up to 3% with most of them being the result of impaired semen characteristics or a very low number of eggs collected. In such cases, repeated ICSI treatment proved useful [67]; however, some patients will have to face repeated fertilization failure in spite of normal sperm parameters and good ovarian response.

In order to rescue such cycles, Tesarik and coworkers [68] reported a modified intracytoplasmic sperm injection technique mainly based on a repeated dislocation of central ooplasm to the periphery, thus increasing the intracellular concentration of free calcium by either creating an influx of calcium ions or a considerable release of calcium stored in cell organelles.

Taking into account a possible negative effect of this rather vigorous injection technique on further preimplantation development, another modified ICSI version was developed [69], which is based on the hypothetical accumulation of high-polarized mitochondria, e.g., showing a high inner mitochondrial membrane potential [70], from pericortical regions (9 o'clock) to the center of the oocyte, thus supplying more energy (ATP) directly to the place where the spermatozoon is normally injected. In this respect, it proved helpful that aggregation patterns of mitochondria correspond well to the light-microscopical appearance of the oocyte [71]. In 17 cases of complete fertilization failure after ICSI, we [69] could achieve a 54% fertilization rate and a 33% clinical pregnancy rate, respectively. However, it must be emphasized that the positive effect of our modified ICSI that could be shown in cases of previous fertilization failure after standard ICSI could not be demonstrated in cases without this problem since fertilization rate and further development were comparable. This implies that a minimum baseline of functionally active mitochondria must have been present in oocytes without impaired fertilizability [72].

More recently, an additional modified ICSI technique has been suggested [73], namely, increasing the effectiveness of ICSI by piezoelectric activation. In 50 patients with more than one previous total fertilization failure after ICSI, as many as 48% eggs could be fertilized resulting in a 44% clinical pregnancy rate.

Since all these techniques to overcome fertilization failure after ICSI are either rather invasive or require certain technical skills or equipment, usage of a calcium ionophore, e.g., Calcimycin (CULTactive™, Gynemed, Lensahn, Germany), can be recommended in such patients [74]. This ready-to-use solution (Ca^{2+}-ionophore in DMSO and culture medium) opens membrane channels and facilitates entrance of extracellular Ca^{2+} from the culture medium, which is a prerequisite for oocyte activation and fertilization. In fact, it proved useful in cases of complete fertilization failure or reduced fertilization after ICSI [75], severe male factor infertility [76], and developmental problems/arrest/delay [77].

In practice, immediately after ICSI (since the ionophore might alter the constitution of the zona), injected oocytes are incubated in a bath of ionophore (approx. 15 minutes), whereafter the ionophore has to be removed by carefully washing the ova several times.

38.12 Conclusion

ICSI is undoubtedly one of the most severe manipulation techniques in IVF laboratories. Not only does it require a certain learning curve, but it is also particularly dependent on oocyte quality, which is governed by individual patient response and other stimulation details. It is a fact that suboptimal ICSI results in an impaired oocyte survival and reduced preimplantation development [57, 78]. It is a prerequisite to use ICSI pipettes of standardized quality that show a relative sharp spike (Gynemed, Lensahn, Germany; Humagen, Charlottesville, VA, USA). These tools combined with the individual skills of the embryologist will maximize fertilization rate and outcome, particularly if only a limited number of female gametes is available. In difficult ICSIs, spontaneous change of the injection technique can rescue the cycle or optimize the results. Additional help may come from the usage of theofylline, Ca^{2+}-ionophore, and (in the case of TESE) collagenase (Gynemed, Lensahn, Germany). To conclude, there is a general tendency toward the application of a more physiological ICSI using PVP substitutes (Origio, Måløv, Denmark; Nidacon, Mölndal, Sweden) and more mature and strand break-free spermatozoa.

Review Questions

1. What are the potential pitfalls in oocyte denudation?
2. Which techniques can be applied to cumulus cells in order to predict the health of the associated oocyte?
3. Which different milieus would facilitate sperm processing?
4. Which sperm immobilization techniques are reported in literature?
5. How can spermatozoa be selected physiologically?
6. How can immotile sperm be treated in order to restore motility?

7. What should be avoided in ICSI?
8. How can ICSI failures be overcome?
9. In which situations are modified ICSI techniques recommended?

Piezo-ICSI

Kenichiro Hiraoka, Kiyotaka Kawai, Tatsuya Harada, and Tomonori Ishikawa

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_39

Learning Objectives

- To review the current techniques for intracytoplasmic sperm injection (ICSI) in human oocytes
- To clarify the problems in the current ICSI technique (Conventional-ICSI)
- To introduce a new technology of ICSI (Piezo-ICSI) to improve the survival and fertilization rates for injected oocytes
- To survey how Piezo-ICSI can contribute to the human assisted reproductive technology field

Key Points

- In the Conventional-ICSI technique, the cytoplasm is aspirated into the micropipette to break the membrane.
- The volume of cytoplasm aspirated into the micropipette at the membrane breakage point affects the fertilization rate after ICSI.
- In the Piezo-ICSI technique, the cytoplasm is not aspirated into the micropipette.
- Piezo-ICSI results in higher survival and fertilization rates than Conventional-ICSI.
- The micropipette wall thickness used for Piezo-ICSI affects the survival and fertilization rates after ICSI.
- Piezo-ICSI can contribute to shortening the training period for ICSI for junior embryologists.

39.1 Introduction

39.1.1 Brief History of Intracytoplasmic Sperm Injection (ICSI)

The first four pregnancies achieved by ICSI were reported by Palermo in 1992 [1], and ICSI is now an essential technique in human assisted reproductive technology (ART). ICSI uses beveled and spiked micropipettes (Fig. 39.1a) for mechanical penetration of the zona pellucida and the membrane as well as aspiration of the cytoplasm into the micropipette to break the membrane. After membrane breakage, the sperm is injected into the cytoplasm (Conventional-ICSI). However, the survival rate of mouse oocytes (oocyte diameter 80 μm) was as low as 16% (8% fertilization rate) after Conventional-ICSI [2].

Kimura and Yanagimachi performed membrane breakage by applying a piezo pulse, which produced ultrafast submicron forward momentum using uniquely shaped flat-tipped micropipettes with no bevel or spike (Fig. 39.1b) (Piezo-ICSI), in 1995 for mouse oocytes [2]. The survival rate of mouse oocytes was dramatically improved to 80% (78% fertilization rate) by using Piezo-ICSI [2]. Therefore, the Piezo-ICSI may be a less invasive method also for human oocytes (oocyte diameter 160 μm). However, to the best of our knowledge, only four reports detail the application of Piezo-ICSI to human oocytes, and little information is available regarding its clinical efficiency [3–6].

The goal of this chapter is to compare Conventional-ICSI and Piezo-ICSI techniques and to show the superiority of the Piezo-ICSI technique.

39.1.1.1 Conventional-ICSI Method

We used commercially available ICSI micropipettes with a beveled and spiked tip (Fig. 39.1a) (K-MPIP-1035, Cook Ireland Ltd., Ireland). The micropipette inner diameter was 5 μm, and the wall thickness was 1 μm. The micropipette was connected to a pneumatic injector (IM-9C, NARISHIGE Inc., Japan). The micropipette preparation was as follows. First, HEPES-buffered medium (SYDNEY IVF GAMETE BUFFER, Cook Australia Pty Ltd., Australia) was aspirated into the micropipette by capillary action for 1 min. Next, 7% polyvinylpyrrolidone (PVP) (7% PVP solution, Irvine Scientific, USA) was aspirated via negative pressure using an air injector. A motile sperm was immobilized by crushing the tail with the micropipette tip and aspirated tail-first into the micropipette in a 10 μl drop of 7% PVP. With the polar body at 12 o'clock, the micropipette was inserted through the zona pellucida into the oocyte (~90% of the oocyte diameter) to stretch the membrane (Fig. 39.2a–c). The membrane breakage procedure was performed as follows. Air was aspirated into the micropipette using an air injector to create negative pressure and suction on the membrane. The membrane was slowly aspirated into the micropipette (Fig. 39.2d) until a sudden flow of cytoplasm into the micropipette occurred (Fig. 39.2e), which was considered to be the moment of membrane breakage. After membrane breakage, positive air pressure was quickly provided to stop the flow of cytoplasm into the micropipette, and the sperm was injected into the oocyte (Fig. 39.2f).

39.1.1.2 Piezo-ICSI Method

Characteristics of Piezo-ICSI

In Piezo-ICSI, membrane breakage is performed by applying a piezo pulse that produces ultrafast submicron forward momentum using uniquely shaped flat-tipped micropipettes with no bevel or spike (Piezo-ICSI) (Fig. 39.1b) [2]. During zona penetration, the injection pipette can penetrate the zona without zona or oocyte deformation, and during membrane breakage, no cytoplasm is aspirated into the micropipette.

Procedure for Piezo-ICSI

We used commercially available Piezo-ICSI micropipettes with a flat tip (PIN07-20FT, PRIME TECH Ltd., Japan). Fluorinert (6.25 µl, FC-770, 3 M) was aspirated to the middle of the micropipette (Fig. 39.3). Fluorinert is a clear, colorless, fully fluorinated liquid, which is nontoxic and water insoluble. The micropipette was inserted and clamped into the micropipette holder, which was then connected to the oil injector (HDJ-M3, PRIME TECH Ltd.). The piezo-micromanipulator drive unit (MB-S, PRIME TECH Ltd.) was attached to the micropipette holder

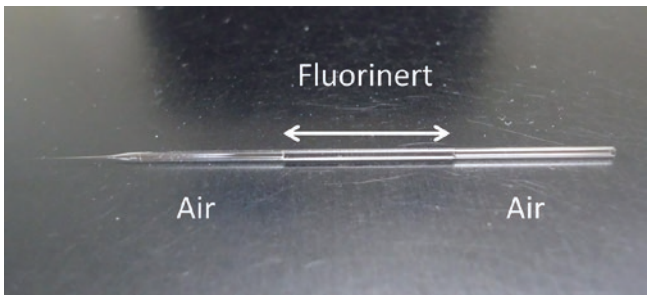

Fig. 39.3 Fluorinert placed in the middle of the micropipette for Piezo-ICSI

(Fig. 39.4). The piezo drive unit was driven by a controller (PMAS-ET150, PRIME TECH Ltd.). After Fluorinert was pushed to the micropipette tip, 6–12 pl of 7% PVP was aspirated into the micropipette. The sperm was then immobilized, as was done for Conventional-ICSI, and aspirated tail-first into the micropipette. Without oocyte deformation, the micropipette was placed gently against the zona pellucida while piezo pulses were applied to allow the pipette to break through the zona pellucida and not the membrane (Fig. 39.5a–c). The broken piece of the zona was expelled, and the sperm was advanced

Fig. 39.4 Piezo-micromanipulator drive unit for Piezo-ICSI

until the sperm head was near the micropipette tip (Fig. 39.5d). The micropipette was advanced forward (to ~90% of the oocyte diameter) to stretch the membrane (Fig. 39.5e, f). The membrane break was performed by applying one piezo pulse without aspirating the cytoplasm into the micropipette (Fig. 39.5g), and the sperm was injected into the oocyte (Fig. 39.5h).

Mechanism of Piezo-ICSI

Figure 39.6 shows the mechanism of zona pellucida opening or membrane breakage by piezo pulse. The Fluorinert is placed in the middle of the micropipette (Fig. 39.6a). The piezo pulse is applied producing an ultrafast submicron

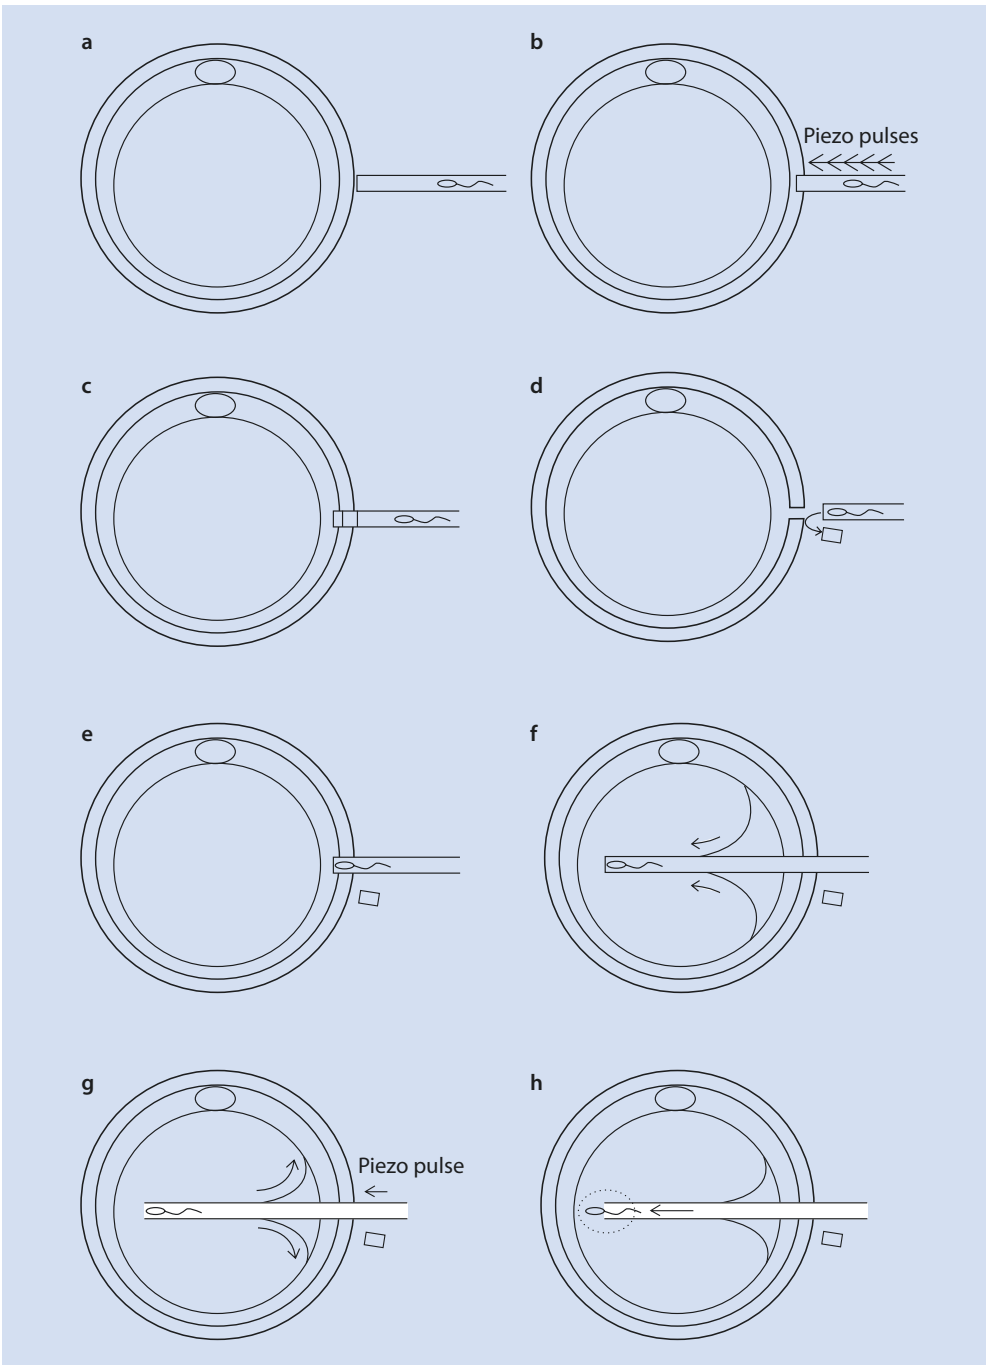

Fig. 39.5 Piezo-ICSI Before zona drilling **a**, during zona drilling **b**, after zona drilling **c**, expelling the broken piece of the zona **d**, during insertion of the micropipette tip through the drilled hole **e**, during stretching the membrane **f**, membrane breakage by applying the piezo pulse **g,** and sperm injection **h**

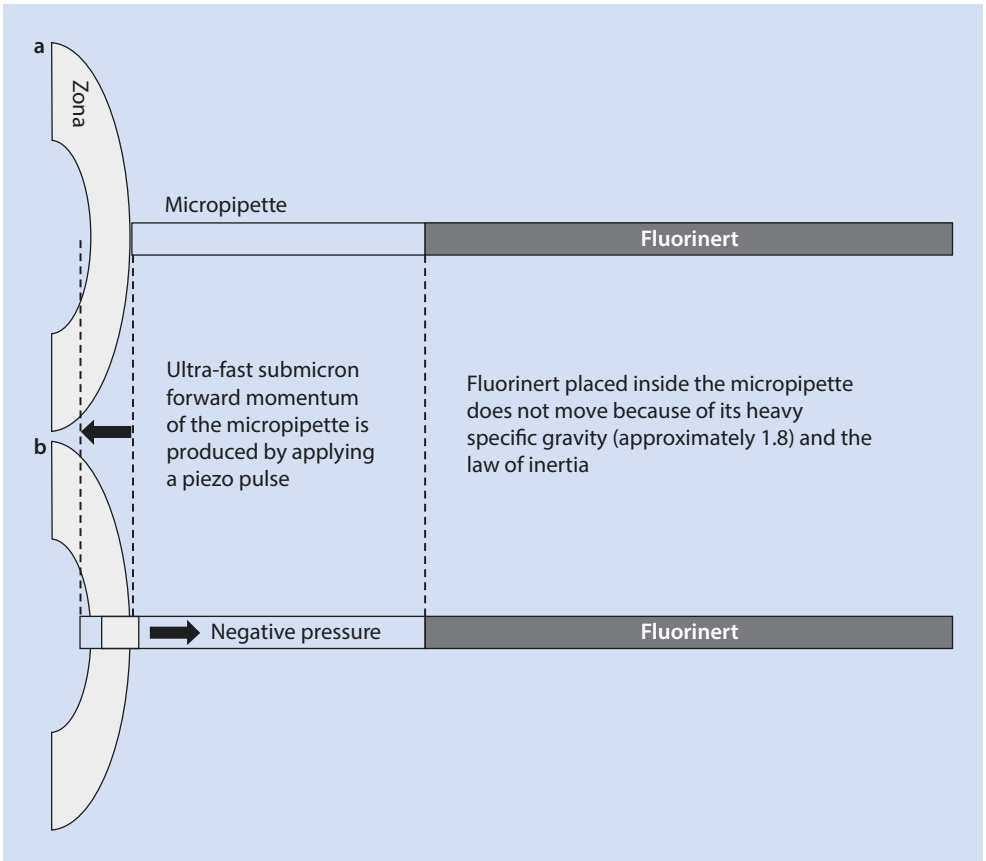

Fig. 39.6 Mechanism of Piezo-ICSI Before applying a piezo pulse **a** and during applying a piezo pulse **b**

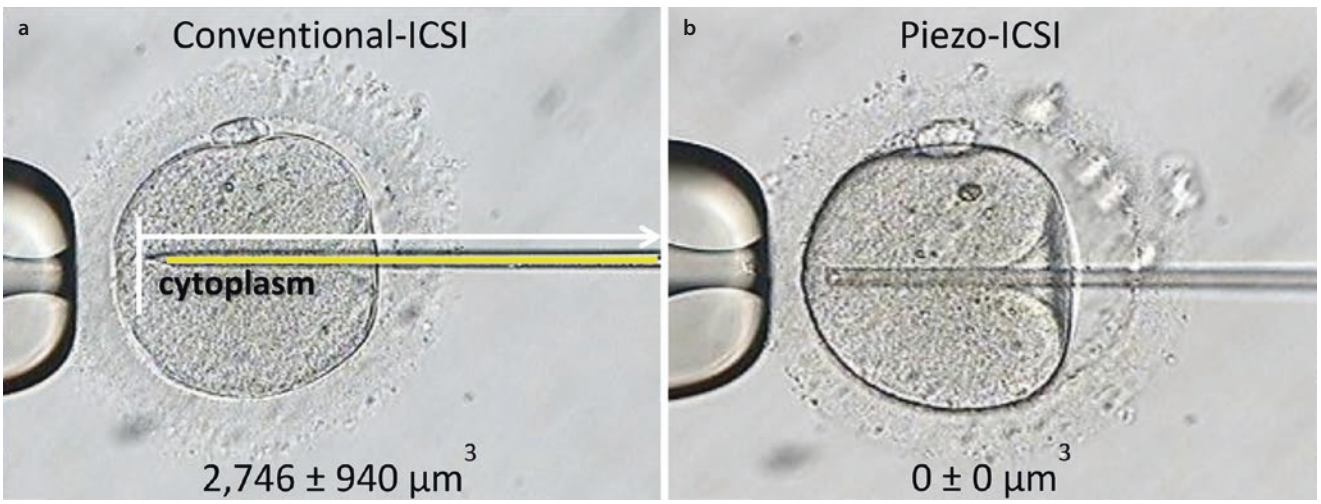

Fig. 39.7 Mean volume of cytoplasm aspirated into the micropipette at the point of membrane breakage from Conventional-ICSI **a** and Piezo-ICSI **b**

forward momentum of the micropipette. By applying a piezo pulse, only the micropipette is advanced forward, whereas the Fluorinert inside the micropipette does not move because of its heavy specific gravity (approximately 1.8) and the law of inertia. As a result, ultrafast submicron negative pressure is produced inside the micropipette tip. This ultrafast submicron negative pressure produces ultrafast submicron aspiration at the micropipette tip. This ultrafast aspiration induces the opening of the zona pellucida or membrane breakage (Fig. 39.6b). However, if the power of the piezo pulse is stronger, the zona or membrane can be destroyed, so the mechanism of Piezo-ICSI is still unclear.

39.1.1.3 Comparison Between Conventional-ICSI and Piezo-ICSI

In our previous analysis of 1341 oocytes from 286 patients, the calculated mean volume of cytoplasm aspirated into the micropipette with Conventional-ICSI (2746 ± 940 µm^3) (Fig. 39.7a)

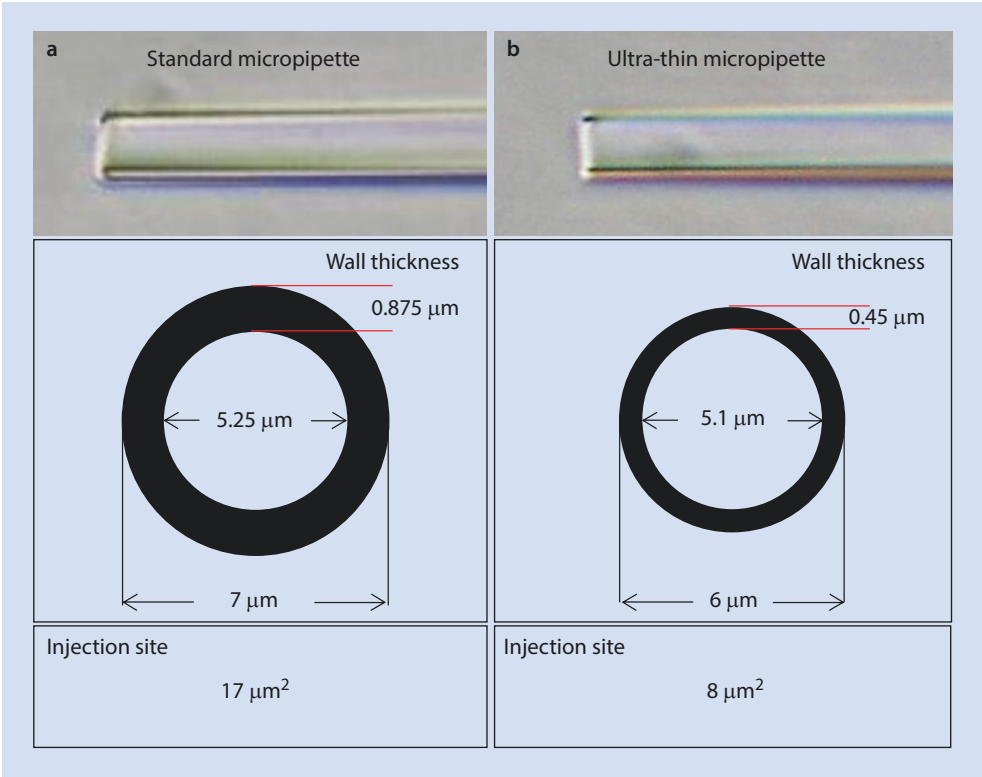

Fig. 39.8 Wall thickness, inside diameter, and injection site in the membrane for a standard micropipette **a** and an ultrathin micropipette **b**

was significantly higher than with Piezo-ICSI (0 ± 0 μm^3) (Fig. 39.7b) ($P < 0.05$) [6]. In addition, significantly higher survival and fertilization rates were observed when using Piezo-ICSI (717 oocytes from 166 patients) compared to Conventional-ICSI (624 oocytes from 120 patients) (survival rates 95% vs. 90%, fertilization rates 75% vs. 68%) ($P < 0.05$) [6]. When using the Conventional-ICSI method, the injection site in the membrane was larger due to the procedure of aspirating the cytoplasm into the micropipette during membrane breakage, which is avoided when using Piezo-ICSI. Moreover, Conventional-ICSI might also increase physical damage to the oocyte. As a result, the survival and fertilization rates using Conventional-ICSI were significantly lower than when using Piezo-ICSI. However, no significant differences were observed in embryo quality and pregnancy, implantation, or live birth rates between Conventional-ICSI and Piezo-ICSI. These results suggest that Piezo-ICSI can increase survival and fertilization rates without detrimental effects on embryo quality, implantation ability, or live birth potential.

39.1.1.4 Improvement in the Piezo-ICSI Technique

Standard Micropipette Versus Ultrathin Micropipette

We evaluated two micropipette wall thicknesses to determine the effect on the rates of survival, fertilization, good-quality day 3 embryos, pregnancy, implantation, and live birth during Piezo-ICSI. The standard micropipette had a wall thickness of 0.875 μm (Fig. 39.8a), and the ultrathin micropipette had a wall thickness of 0.45 μm (Fig. 39.8b). The membrane injection sites for the standard micropipette and ultrathin micropipette were 17 μm^2 and 8 μm^2, respectively (Fig. 39.8a, b) [6]. In our previous analysis of 1396 oocytes from 317 patients, significantly higher rates for survival (99% vs. 95%), fertilization (89% vs. 75%), good-quality day 3 embryos (55% vs. 43%), pregnancy (31% vs. 21%), implantation (31% vs.21%), and live births (25% vs.16%) were obtained when using the ultrathin micropipette (679 oocytes from 151 patients) than when using the standard micropipette (717 oocytes from 166 patients) for Piezo-ICSI ($P < 0.05$) [6]. The physical damage to the oocyte was reduced by creating a smaller injection site (17 μm^2 vs. 8 μm^2), which could partially explain the increased survival and fertilization rates. Consequently, we suggest that the combination of Piezo-ICSI and the ultrathin micropipette can significantly improve the effective utilization rate of injected oocytes and can increase live birth rates.

Oil Injector Versus Air Injector

In preparation for Piezo-ICSI, we aspirated approximately 1–2 cm of Fluorinert to the middle of the micropipette (Fig. 39.3). Next, this micropipette was inserted into the micropipette holder of the oil injector filled with mineral oil. The mineral oil flows inside the micropipette, pushing the air and Fluorinert forward to the micropipette tip. Figure 39.9a shows a good example of micropipette preparation. However, if air bubbles occur in the mineral oil (Fig. 39.9b) while inserting the micropipette into the micropipette holder, Piezo-ICSI does not work. A hole does not open in the zona, and the membrane does not break. In this case, this micropipette is discarded. Because

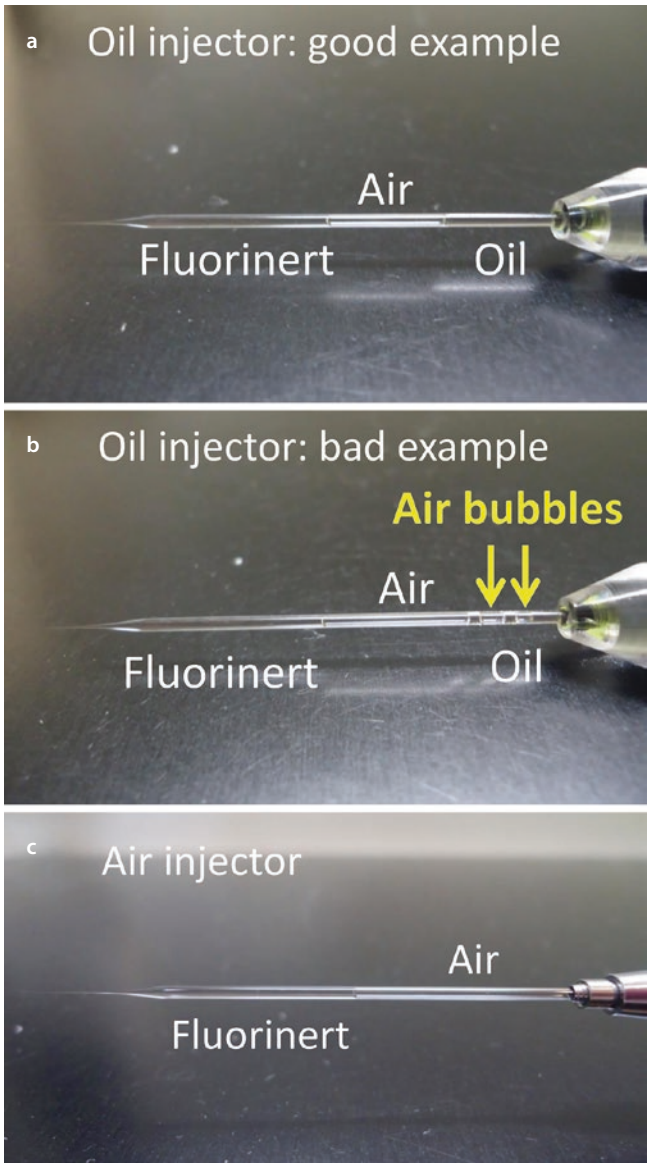

Fig. 39.9 Preparation of Piezo-ICSI using an oil injector (**a**: good example, **b**: bad example) and air injector **c**

the oil injector is sticky from the mineral oil, micropipette preparation takes time. Therefore, if an air injector for Piezo-ICSI can be used, the number of wasted micropipettes and preparation time should be reduced. However, little information is available regarding the clinical efficacy of Piezo-ICSI with an air injector. Therefore, we assessed the clinical efficiency and safety of Piezo-ICSI with an air injector. In our previous analysis of 780 oocytes from 180 patients, we measured the time for micropipette preparation with the oil injector (409 oocytes from 90 patients) and air injector (371 oocytes from 90 patients). The average time for the oil injector was 233 s, whereas the average time was significantly reduced to 106 s with the air injector ($P < 0.05$) [7]. We also counted the number of wasted micropipettes due to air bubbles. The average number of wasted micropipettes from the oil injector per patient was 0.28 ± 0.56. However, when using the air injector, which was free from mineral oil and thus air bubbles were not possible (Fig. 39.9c), no micropipettes were wasted [7]. No significant differences were found between the oil and air injectors in the survival (99% vs. 99%), fertilization (89% vs. 90%), or good-quality day 3 embryo (61% vs. 61%) rates [7]. During this study, an extra 3.2 h and 25 micropipettes were used for the oil injector group (90 patients) compared to the air injector group (90 patients) [7]. Our results indicate that the air injector dramatically reduced the waste of time and micropipettes occurring with the oil injector and did not impair the survival, fertilization, or good-quality day 3 embryo rates. Therefore, Piezo-ICSI with an air injector is clinically efficient and safe.

Head-First Injection Versus Tail-First Injection

In human oocyte ICSI, a sperm is injected head-first into the cytoplasm during fertilization because sperm internalization into the cytoplasm is initiated from the sperm head in natural fertilization. However, ICSI procedures bypass hyperactivation, zona pellucida penetration, and internalization of the sperm head into the cytoplasm. Because the sperms are injected directly into the cytoplasm, the oocytes could be fertilized if injected tail-first. However, little information is available regarding the effect of the sperm direction during injection into the cytoplasm for Piezo-ICSI results and embryo development. In order to inject sperm head-first into the cytoplasm, the sperm is aspirated from the tail into the micropipette. This procedure is technically difficult owing to the small tail size. Head-first sperm aspiration into the micropipette would be easier and faster. Therefore, we assessed the effects of sperm direction (head-first or tail-first) during injection into the cytoplasm on oocyte survival, fertilization, and embryo development. For head-first injection, the sperm was aspirated into the micropipette tail-first and injected into the oocyte head-first (Fig. 39.10a); for tail-first injection, the sperm was aspirated into the micropipette head-first and injected into the oocyte tail-first (Fig. 39.10b). In our previous analysis of 632 oocytes from 152 patients, we calculated the duration of sperm manipulation (from starting sperm immobilization to aspiration of the sperm into the micropipette). The average time for sperm manipulation during head-first injections (342 oocytes from 75 patients) was 10.5 ± 1.6 s, whereas with the tail-first injections (290 oocytes from 77 patients), the time was significantly reduced to 8.6 ± 1.8 s ($P < 0.05$) [8]. No significant difference was found between the head- and tail-first injections in the survival rates (99% vs. 99%), fertilization rates (86% vs. 90%), or good-quality day 3 embryo rates (69% vs. 68%) [8]. Our results indicate that the sperm direction during cytoplasmic injection does not affect oocyte survival, fertilization, and subsequent embryo development (good-quality day 3 embryo rate) with Piezo-ICSI. However, aspiration of sperm into the micropipette is easier and faster using sperm tail-first instead of head-first. Consequently, we recommend injecting the sperm into the cytoplasm tail-first during Piezo-ICSI.

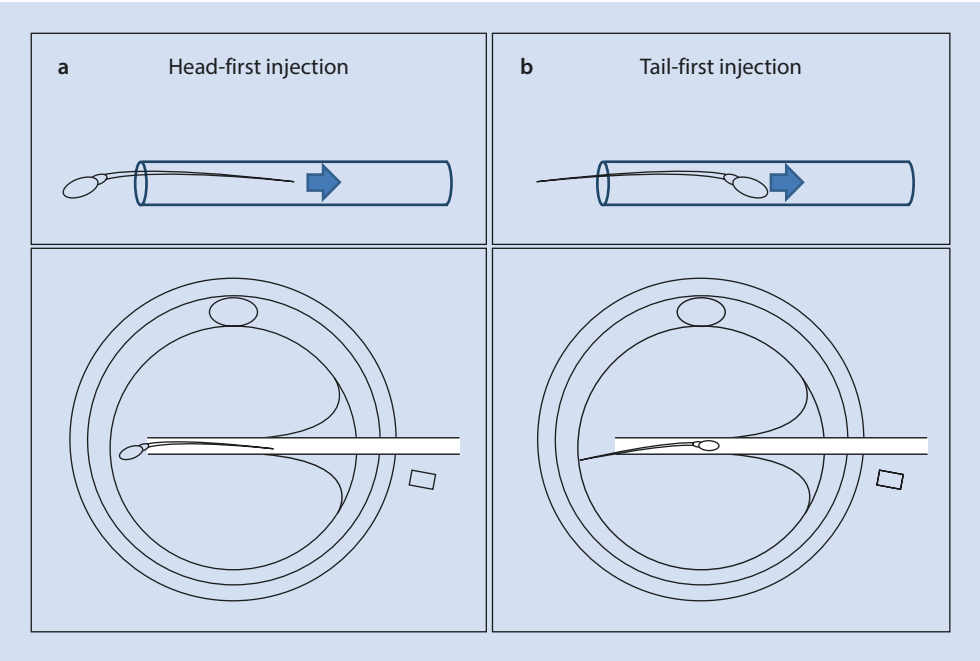

Fig. 39.10 Head-first injection **a** and tail-first injection **b** during Piezo-ICSI

39.1.1.5 Advantages of Piezo-ICSI

Improvement in Fertilization Rate and Reduced ICSI Training Period

The fertilization rates for Conventional-ICSI published in the 2000s were 62–77% [9–13]. Similarly, the fertilization rate for Conventional-ICSI performed by three junior embryologists at our hospital, Kameda Medical Center (Kamogawa City, Chiba, Japan), was 66%. We sought to improve this fertilization rate using Piezo-ICSI. However, little information was available regarding if Piezo-ICSI improves the fertilization rate for procedures performed by junior embryologists and, if so, how many procedures are needed to improve the rate. We assessed whether introduction of Piezo-ICSI could improve the fertilization rates and, if so, the number of procedures needed to see improvement. The study subjects were three junior embryologists. They had performed Conventional-ICSI for 5, 5, and 1 year, respectively. They received Piezo-ICSI training from a senior embryologist who had performed Conventional-ICSI for 11 years and Piezo-ICSI for 4 years. The fertilization rate for the procedures performed by the senior embryologist at Kameda Medical Center was 83%. The fertilization rate for the senior embryologist per 20 oocytes (120 oocytes in total) was more than 80%. Thus, we considered our junior embryologists proficient in performing Piezo-ICSI when their fertilization rate improved to ≥80% per 20 oocytes. In our previous analysis of 1373 oocytes, the fertilization rate for Conventional-ICSI (between February 2014 and September 2014) performed by the three junior embryologists was 66%, whereas the fertilization rate with Piezo-ICSI (between October 2014 and June 2015) significantly improved to 82% ($P < 0.05$) (Fig. 39.11). The fertilization rates for Conventional-ICSI performed by junior embryologists I, II, and III were 60%, 74%, and 64%, respectively. The fertilization rates for Piezo-ICSI performed by junior embryologists I, II, and III were 80%, 83%, and 83%, respectively. The fertilization rates in the case of each junior embryologist using Piezo-ICSI were significantly higher than that for Conventional-ICSI ($P < 0.05$). After 20 procedures, the fertilization rates from the junior embryologists using Piezo-ICSI reached ≥80% per 20 oocytes (unpublished data). Our results indicate that Piezo-ICSI significantly improved the fertilization rates for the procedures performed by three junior embryologists from 66% to 82%, and they became proficient after 20 procedures.

39.2 Summary

The rates of survival and fertilization using Piezo-ICSI with standard micropipettes in our previous results (survival rate 95%, fertilization rate 75%) are not superior to those recently reported using Conventional-ICSI (survival rate 89–93%, fertilization rate 62–77%) [9–13], suggesting that Piezo-ICSI with a standard micropipette may not be optimized for human oocytes. However, Piezo-ICSI with ultrathin micropipettes resulted in significantly higher survival and fertilization rates than with standard micropipettes (survival rates 99% vs. 95%, fertilization rates 89% vs. 75%) [6]. Furthermore, as shown in this chapter, we designed a new Piezo-ICSI methodology using an air injector and tail-first injection for a more user-friendly Piezo-ICSI technique. By using this modified Piezo-ICSI, we significantly improved the ICSI fertilization rate performed by our junior embryologists from 66% to 82% after 20 procedures. We believe that Piezo-ICSI can not only improve the ICSI fertilization rate but also shorten the training period for ICSI practitioners. Further study is needed to assess whether Piezo-ICSI can improve the fertilization rate and shorten the training period for ICSI at other ART institutions.

Fig. 39.11 Monthly and total fertilization rates of Conventional-ICSI (between February 2014 and September 2014) and Piezo-ICSI (between October 2014 and June 2015) for three junior embryologists at Kameda Medical Center

Review Questions

1. What kind of characteristic does the current ICSI technique (Conventional-ICSI) have during membrane breakage?
2. What kind of characteristic does a new technology of ICSI (Piezo-ICSI) have during membrane breakage?
3. How can Piezo-ICSI contribute to the training period for ICSI for junior embryologists?

Traditional Embryo Morphology Evaluation: From the Zygote to the Blastocyst Stage

Jonathan Kort and Barry Behr

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_40

Learning Objectives

- Understand the importance and limitations of morphological assessments at each key stage of preimplantation embryo development.
- Understand methods for fertilization check and apply pronuclear scoring systems.
- Understand methods for cleavage-stage embryo assessments, including assessments of multinucleation, cell number, and fragmentation.
- Apply grading systems for blastocyst evaluation.

40.1 Introduction

After in vitro fertilization, providers are repeatedly tasked with assessing embryos at various stages in order to make critical, time-sensitive patient care decisions at each stage of embryo culture using morphological assessments. At the zygote stage, assessment of normal fertilization must occur just before the brief window in which pronuclei are visible closes in order to determine which embryos are suitable to continue in culture. Cleavage-stage assessments must determine whether a patient should transfer early or pursue blastocyst culture before transfer or cryopreservation. Finally, blastocyst morphology assessments must be made to determine if and when embryos are optimally ready for trophectoderm biopsy for cases undergoing genetic screening, if and when embryos are optimally ready for cryopreservation, and, most importantly, which embryos are most likely to become a healthy pregnancy when selecting an embryo for transfer. To compensate for imperfect embryo selection methods, clinicians in the US transfer multiple embryos in 67–89% of cases [1] leading inevitably to multiple gestation pregnancies and their inherently high risk of prematurity and other complications [2]. Due to health, legal, and financial consequences of multiple gestation pregnancies, single embryo transfer remains the ideal for IVF patients and providers and, in some countries, has already been mandated for these reasons with a consequent reduction in multiple gestation pregnancies and perinatal morbidity [3].While molecular and biochemical methods to assess human gamete and embryo reproductive potential have been described and are increasingly utilized, these methods are still relatively complex, time-consuming, and expensive for most ART laboratories. Hence, the assessment of morphology has been, and will remain, the most widely employed method for embryo selection as it is quick and inexpensive and, although not without faults, has consistently been shown to have predictive value.

Most morphological methods of embryo assessment rely on a single static observation of the embryos, whereas the embryo itself, after fertilization, is on a precise set of clocks governing the division and initiation of key events from gene activation through compaction and blastulation. Each stage of the complex developmental process is dependent upon the successful completion of the previous one. Consequently, the optimal evaluation of an embryo's potential would require multiple, dynamic assessments of the embryo at each developmental checkpoint as it makes its complex transition from a single-celled zygote to a blastocyst. A comprehensive morphological evaluation should assess the end result at each checkpoint but also the path taken to reach that point. An embryo that does not meet a selection criterion at one point may meet it at another but perhaps should be avoided or at least flagged and deprioritized, as early deviation from optimal development may indicate inherent abnormalities within the embryo. Performing assessments in a systematic, cumulative fashion should provide the most predictive information regarding embryo quality. This chapter will outline the various morphological and morphokinetic criteria that are currently available for selection within the framework of a continuous model from the zygote through to the blastocyst. No one selection criterion is better, but if possible a combination of one, two, or even three selection points should lead to the most accurate selection [4].

Apparent in this chapter will be arguments in the literature regarding the utility of particular morphological assessments. The lack of standardization regarding assessment timing, techniques employed in culture such as hatching, and heterogeneous inclusion criteria among the literature make it difficult to achieve consensus regarding the application of many of the methods described. Additionally, given new research regarding the importance of synchrony between the embryo and endometrium and the effect of ovarian hyperstimulation on endometrial receptivity [5, 6], many of the ideal morphological characteristics that were determined in studies utilizing fresh embryo transfers will need to be revisited in studies employing frozen embryo transfers to ensure characteristics deemed unfavorable are not merely out-of-sync in a fresh cycle rather than reflective of reduced embryo viability.

40.2 Zygote Quality Day 1: Pronuclear Scoring Systems

The fertilization check, occurring 16–18 hours after conventional insemination or intra-cytoplasmic sperm injection (ICSI), offers the opportunity to confirm normal fertilization by the presence of two pronuclei but also subjectively assess the pronuclei using any of a number of systems designed to offer insight into the overall viability of the embryo based on the symmetry, position, and number of pronuclei and nucleoli [7]. All pronuclear scoring systems discussed here [8–11] attempt to classify zygotes based on the following characteristics of the two pronuclei: symmetry (equal vs. unequal), position (in apposition vs. at a distance), and location (central vs. noncentral). The nucleoli are scored based on number [3–7], symmetry (equal vs. unequal sizes), and location (polarized or aligned vs. nonpolarized or nonaligned).

At the fertilization check, visualization of the pronuclei should be attempted using an inverted microscope with Hoffman modulation optics [12]. Zygotes should be rolled during observation and positioned with simultaneous visualization of the polar bodies and pronuclei if present. While normal fertilization is traditionally confirmed by the presence of two pronuclei, it has been demonstrated that healthy babies can develop from monopronuclear [13] or even zero-pronuclear zygotes [14]. While primarily thought to indicate parthenogenetic activation of the oocyte, a single pronuclei may actually only demonstrate the asynchrony in pronuclei formation, which has been observed in over one-third of zygotes [15] and more commonly after conventional insemination than ICSI [16] or result from pronuclear fusion [17] during syngamy and should be continued in culture, particularly after conventional insemination, in case no 2-pronuclei derived embryos are available for transfer. Similarly, 0-pronuclei zygotes may actually represent normally fertilized embryos with an accelerated cell cycle and breakdown of pronuclear membranes with no visible pronuclei at the time of fertilization check [18]. These embryos can also be continued in culture for selection if no 2-pronuclei embryos are available. Zygotes with >2 pronuclei are a result of polyspermy, usually after IVF, in which there are three or more pronuclei but also two polar bodies or failure to extrude the second polar body in which there are three pronuclei and one polar body (digynic) [19]. After IVF ≥3 pronuclei is indicative of a high incidence of mosaicism, and after ICSI digyny conveys a high incidence of polyploidy. Due to the limitations of most molecular diagnostic methods of preimplantation genetic screening not being capable to detect polyploidy, zygotes with ≥3 pronuclei should not be continued in culture, although healthy offspring have been reported without verification by neonatal karyotyping [20].

For zygotes with 2-pronuclei at the time of transfer, pronuclei scoring systems can potentially be employed. The initial pronuclei scoring of Scott et al. was based on parameters such as pronuclear size and alignment, alignment of nucleoli within the pronuclei, and cytoplasmic morphology such as appearance of cytoplasm, presence of a halo, timing of nuclear membrane breakdown, and early cell division [8]. The total score ranged from 7 to 25 with an optimal score ≥15. Their revised score included only parameters that could be assessed at the time of fertilization assessment (17–18 hours post-insemination), classifying the zygotes by five characteristics including the presence of a halo, the orientation of the nuclei relative to the polar bodies, and the size, number and pattern of distribution of nuclear precursor bodies (NPB) in the nuclei. According to this system, the ideal pronuclei should be symmetric and centrally located aligned onto the polar axis for the completion of mitotic division. Additionally, the intracellular movement required to achieve this alignment results in the favorably observed halo. NPBs are ideally equal in number and size and aligned between the two pronuclei although nonalignment is preferable to asymmetry. Scott's group demonstrated that employing a composite pronuclei score, denoted as the Z-score, significantly increased pregnancy and implantation rates during cleavage stage and blastocyst transfers [8, 10]. Tesarik and Greco also claimed pronuclei assessment could predict embryo development; however, they focused their assessment on the number, distribution, and synchrony of NPB progression within each pronucleus [11, 21]. These authors considered interpronuclear synchrony, evaluated at 12–20 hours after IVI/ICSI, to be more important than the actual NPB polarity at the site of pronuclear apposition as they assumed that polarization of nucleoli was a dynamic process and may not be evident from the beginning of pronuclei formation. Using this assessment system, Tesarik and Greco were able to retrospectively demonstrate that zygotes with more favorable NPB assessments had higher rates of embryo development with better morphology and higher implantation rates.

Despite initial promise for the predictive value of pronuclei assessment, subsequent studies have been inconsistent. Multiple other groups failed to demonstrate correlation between pronuclear assessments and pregnancy rates [15, 22–24]. Similarly, no consensus exists regarding the utility of using the presence of a halo as a marker of embryo potential with studies demonstrating its presence as having a positive [9, 22, 25, 26] effect, but another found that having an excessive halo was also a negative prognostic [27] for blastocyst development.

Zygote pronuclei assessments are limited by the static nature of assessments and dynamic nature of pronuclear morphology, a range of biological variation within normal development, particularly as a result of heterogeneous lab techniques such as ICSI [16] or oocyte cryopreservation and embryo characteristics [28]. Consequently, no clear consensus regarding the utility of zygote grading has been reached. Additionally, accurate assessment of the three-dimensional disposition and number of NPBs is technically difficult while avoiding prolonged exposure of the zygote to light, temperature, and pH shifts. With the advent of incubator time-lapse imaging systems with improved optics, this topic may be revisited in the near future.

40.3 Timing and Result of the Initial Cleavage

The LH surge, or trigger injection for patients undergoing IVF, starts the clock which dictates the timing of events as the oocyte progresses through the completion of meiosis [29]; however, many of the assessments performed in clinical labs are based on the timing of insemination or ICSI. With any time-based embryo assessment, it is critical to standardize the reference point from which the clock is started to ensure genuine comparisons. While the use of time-lapse imaging for embryo selection has received increasing attention more recently, researches have been interested in the timing of the first cell division as a prognostic marker for embryo viability for almost 20 years [30, 31], when it was noted that embryos undergoing "early cleavage" (<25 hours post-insemination) had higher implantation rates than those that did not.

Typically, embryos enter the 2-cell stage 20–36 hours post-insemination [32, 33]; however, numerous studies have demonstrated that embryos that undergo initial cleavage earlier in that spectrum have improved blastocyst formation rates, pregnancy rates, and even higher rates of euploidy [10, 30, 31, 34–41]. Again lab technique can significantly influence downstream events, as embryos fertilized by ICSI have been observed to undergo cleavage earlier than those undergoing conventional insemination [39], affirming the importance of standardizing comparisons whether clinically or for research. More recent studies employing time-lapse imaging have demonstrated the limitations of a single static assessment of a dynamic process, and it is likely our interpretation of the fluid events involved in early embryo development will be more refined with increasing use of this technology [33].

In addition to the timing of the initial cleavage, the result of the initial cleavage has important prognostic implications. In multiple time-lapse studies, embryos that proceed directly from the 1-cell stage to ≥3-cell stage have significantly reduced, if not nonexistent, implantation rates [42, 43] as do embryos with marked blastomere asymmetry at the 2-cell stage. These findings support the potential benefit of using dynamic morphological assessments (i.e., time-lapse imaging) to augment morphological embryo assessments and expose the limitations of single static assessments at each stage.

40.4 Cleavage-Stage Embryo Assessments

Most clinical IVF programs have now incorporated blastocyst culture to some extent into their practice. By culturing embryos beyond the cleavage stage, it identifies embryos without a development block at the cleavage stage identifying those with the greatest reproductive potential [44] and facilitates other embryo selection methods such as preimplantation genetic screening. Some question the utility of cleavage-stage assessments, particularly for patients committed to blastocyst culture. To the contrary, some studies suggest cleavage-stage enhanced blastocyst selection [45], and there are still sufficient poor prognosis patients with few embryos pursuing IVF that need to decide whether to transfer at cleavage stage or pursue blastocyst culture.

After evaluating transfers with high implantation rates, researchers have been able to develop multiple scoring systems to assess cleavage embryos on days 2 and 3. Most focus on the presence/absence of multinucleation, fragmentation, and blastomere number, size, and morphology as these parameters have been found to be most predictive of subsequent development and favorable transfer outcomes [46, 47].

40.5 Multinucleation

The presence of ≥2 interphase nuclei within a single blastomere qualifies an embryo to be multinucleated, a common characteristic present in at least one embryo in roughly 75% of IVF cycles [48, 49]. This phenomenon can be a result of chromosome segregation errors in the first cleavage. Mitotic replication without the first cytokinesis explains instances when multinucleated and sibling mononucleated blastomeres have the same genetic composition. Nuclei fragmentation into multiple nuclei would result in a different instance in which a multinucleated blastomere would have the sum total chromosomes as found in mononucleated sibling blastomeres. Finally, defective mitotic spindles and consequent segregation errors are theorized to explain instances where the number of a particular chromosome was double, triple, or quadruple the copy number of mononucleated cells, and the replicates of this same chromosome were randomly distributed among the multiple nuclei [32, 50]. Multinucleation can be identified on either day 2 or day 3 of embryo culture, although its prevalence may be higher on day 2. It is unclear to what extent this observation is due to optical factors including the larger dimensions of cells and less obstruction from fewer overlapping cells on day 2. Alternatively, this may be indicative of the biologically transient nature of multinucleation [48, 51] which may result from embryos' repair mechanisms [52] as blastocysts have been observed to have a far lower incidence of nuclear abnormalities than cleavage-stage embryos [53].

Multinucleation has been deemed an unfavorable characteristic due to its correlation with higher rates of embryo aneuploidy, impaired cleavage and development, and poorer implantation rates [46, 50, 53–59]. Some have proposed that stimulation-specific factors such as shorter duration of stimulation and use of higher gonadotropin doses influence the incidence of multinucleation [48], although others have attributed other factors such as lab environment [60], although many of these contributing factors and subsequent observations likely confound each other due to the high coincidence of multinucleation with poorer embryo quality, poorer patient population, and higher rates of fragmentation and lower cleavage rate and cell number. Better resolution imaging and innovative staining techniques will likely lead to additional investigation of the cleavage-stage nucleus and the association of morphologic abnormalities with embryo development and reproductive potential [53].

40.6 Cell Number

Many studies have reported observations of an optimal cleavage pattern, citing higher pregnancy rates after transfer of former day 2 4-cell embryos than those at the 2- or 3-cell stage [61–63]. Additionally, the path to the 4-cell stage appears to be as, if not more, important than the end result. The 2-cell embryo proceeds through an intermediate 3-cell stage before quickly cleaving again to form a 4-cell tetrahedron embryo [64, 65]. An embryo which is an even-sized 3-cell that is not progressing rapidly to the 3-cell stage is likely abnormal, demonstrating cytokinetic delays, which, in some studies, have been predictive of a zero live birth rate [66]. While delays in reaching the 4-cell stage have prognostic

value for poor subsequent development, Guerif and others have observed that too rapid cleavage (5–8 cells at day 2) was also predictive of lower blastocyst formation rates [67–69]. Possible hypotheses to explain this phenomenon include that some blastomeres may actually be large anucleate fragments or that accelerated early cell division may indicate developmental instabilities and have higher rates of aneuploidy [62, 70]. While Guerif did find a correlation between day 2 development and blastocyst formation, after controlling for blastocyst morphology and other confounders, they did not find day 2 morphology predictive of blastocyst implantation [67].

Day 3 blastomere number has also shown value in predicting subsequent development, albeit with a wider acceptable range of cell number. Various studies have shown a positive correlation of the number of cells in day 3 embryos (up to 8) with implantation rates following day 3 transfer [71, 72], rate of blastocyst formation [73], and pregnancy rates [73, 74] when compared to embryos with less than eight cells. Consistent with these findings, Alikani also observed that embryos with 7–9 cells on day 3 converted to blastocysts at a significantly higher rate than day 3 embryos with <7 cells or >9 cells [63], and further refining this ideal range, Racowsky et al. observed that embryos with exactly eight cells on day 3 had the highest implantation rates [75].

40.7 Fragmentation

Embryo fragmentation is a result of the expulsion of anucleate, membrane-bound cytoplasm that occurs during embryo cleavage and is associated with aberrant cell division [32, 71, 76, 77]. These fragments have been argued to be both by-products and catalysts of apoptosis [78, 79] or an indicator of the irregular loss of synchrony between nuclear and cytoplasmic cell division. While it is difficult to demonstrate whether this is a consequence or precursor of fragmentation, surviving blastomeres may be depleted of critical organelles, substrates, or signal ligands [80–83] as a result of excessive fragmentation affecting future development and reproductive potential.

Assessment of fragmentation is typically quantified as the percentage of the embryo the fragments occupy [84], although the timing pattern of fragmentation has also been demonstrated to be associated with genetic abnormalities when applied with other morphokinetic parameters [85]. One scoring system simply assigns values based on the volume occupied by fragments (score 0 = 0%, score 1 = <10%, score 2 = 10–25%, score 3 = >25%) [86], while others have proposed a more detailed classification taking into account the size and location of fragments relative to the size and position of nucleated cells [76]. Regardless of the system used, increasing fragmentation on day 2 of culture has been associated with poorer blastocyst formation rates, possibly due to the association with genetic abnormalities [63, 67, 87–89]. It is unclear if the fragments are a cause or coincidental result with poorer outcomes. Some postulate that the fragments physically impede cell-cell interactions and interfere with blastulation, while others hypothesize the fragments release substances toxic to continued development [76, 90], supporting the case for microsurgical removal which has been performed with mixed results [91, 92].

More recently, with the advent of time-lapse imaging, fragment reabsorption and the presence of chromosomes within fragments have been demonstrated [32, 85] indicating that the interpretation of fragmentation may be more complex than simply its presence or absence. It is likely that fragmentation is the common end result of a heterogeneous multitude of events, which would explain why fragment or lysed blastomere removal had inconsistent results for improving clinical embryo culture outcomes [91–95].

40.8 Blastomere Symmetry and Appearance

Textbook mitosis results in an even number of cells with the cytoplasm equally split between daughter cells, resulting in even numbers of similar-sized cells, which decrease in size with each round of cell division. This ideal is reflected in many cleavage-stage embryo grading systems which extrapolate that uneven distribution of organelles, proteins, and RNA parallel asymmetric division and may be detrimental to embryo development [72, 96, 97]. Despite this concept, slight asymmetry at a random static observation is normal in human development that results in transient 3-, 5-, and 7-cell embryos to allow for cell spacing as the embryo divides [65]. Though more studies are needed to investigate the link between cell asymmetry and embryo development, studies have demonstrated that asymmetry is predictive of poor subsequent development [57, 98, 99], reduced implantation rates [61, 98], and higher rates of aneuploidy [38, 100, 101]. Day 2 cell asymmetry, regardless of morphology on days 1, 3, and 5, precluded live birth and markedly reduced the rate of a clinical pregnancy in one study, highlighting the biological importance of cell symmetry at the early cleavage stage [102]. Less consistently, blastomere cell size has been linked to the extent of fragmentation although other studies have not uniformly validated this finding [97, 99, 102].

40.9 Day 4 Assessment

Due to the rarity of transfers occurring on day 4, day 4 embryos are rarely assessed in clinical practice [103] despite the potential prognostic value of the relative timing of compaction and morulae formation [104, 105]. Compaction occurs simultaneously with the development of cell polarity. As blastomeres flatten against neighbors, cell-to-cell adhesion transitions to gap and tight junctions resulting in the loss of discernable cell borders, and cytoplasmic polarization begins to appear as a result of embryo transcription. Consequently, the blastomeres arising from the next cleavage segregate to inside apolar and outside polar cells, which may be largely determined by their pre-differentiation position within the

embryo [106]. Compaction typically occurs on day 4, while early and late compaction is regularly observed in culture. Early compaction on day 3 has been shown to positively predict implantation in embryos with minimal fragmentation, although surprisingly it negatively correlated with implantation in cleavage-stage embryos with >10% fragmentation [104]. This paradoxical result may reflect inadequate stratification in the study. Others have created more comprehensive day 4 embryo scoring systems which include fragmentation and vacuolization in addition to compaction and have reported equivalent embryo selection capabilities to blastocyst selection methods for single embryo transfers [107]. While there may be prognostic value in day 4 assessments, given the increasing utilization of trophectoderm biopsy for genetic screening and the informative variety of morphology observed in day 5/6 development, the demand for blastocyst culture and transfer will likely outweigh the utility of day 4 assessments for the foreseeable future.

40.10 Blastocyst Assessment

The blastocyst represents the ultimate stage of clinical embryo culture before transfer back into the uterus, and therefore it is the final stage at which morphological assessment is possible. Culturing to the blastocyst stage helps reveal which cleavage-stage embryos have developmental blocks and should not be transferred and offers an opportunity to make assessments at the closest point possible prior to implantation. Some studies report that blastocyst morphology assessments select different embryos for transfer than day-3 embryo morphology assessments in at least half of all cases [108–110]. Consequently, extending culture until the blastocyst stage on day 5 or 6 is likely beneficial for embryo selection, although some patients will not have any blastocysts available for assessment and transfer.

The blastocyst is defined by the onset of cavitation and the formation of the blastocoel which coincides with cell differentiation between the inner cell mass (ICM) and trophectoderm (TE) [111]. These defining aspects of the blastocyst have become the focal points of morphological assessment systems which typically focus on the degree and timing of expansion, the quality of the trophectoderm, and the inner cell mass. The Gardner and Schoolcraft grading system and the similar system outlined in the Istanbul consensus document are the two most common blastocyst grading frameworks used and focus on these aspects [112–114]. A weakness of any static morphological assessment is that the blastocyst is very dynamic, and even a short interval of minutes can change the assessment significantly. Embryos should be assessed approximately 154 hours after hCG or 112–114 hours following insemination for blastocyst development [102].

A defining aspect of the blastocyst, generation of the fluid-filled blastocoel cavity, is a result of the Na/K-ATPase membrane channels which increase the salt concentration within the embryo, driving water into the cavity through osmosis. Due to the work of the pump, the size of the blastocoel expands, and ultimately hatches through the zona pellucida, and is thought to be a proxy for the health of the embryo [111]. The Grade 1 blastocyst has a blastocoel cavity that is less than half of the volume of the embryo; Grade 2 blastocysts have a blastocoel cavity at least half of the embryo's volume; Grade 3 blastocysts have a blastocoel cavity completely filling the embryo. Grade 4 blastocysts have a thinning zona pellucida as the blastocoel is now larger than the original embryo, although there is no breach or hatching point in the zona yet; Grade 5 blastocysts are those in which the blastocoel cavity is greater than the original volume of the embryo and the trophectoderm has started herniating through a breach in the zona; Grade 6 blastocysts are fully hatched and the embryo is outside the now empty zona pellucida [114].

The degree of hatching and the day of hatching are the main focus points of hatching assessments. In non-preimplantation genetic screening cycles with a fresh embryo transfer, an earlier day of hatching (5 vs. 6) and greater degree of hatching have shown positive associations with implantation [114]. This may be explained by more embryos hatching on day 5 being euploid than those hatching on day 6 [115, 116] or those blastocysts hatching on day 5 having greater synchrony with the endometrium than those hatching on day 6. In studies analyzing frozen embryo transfer cycles without preimplantation genetic screening, no difference in implantation rates were observed when comparing day 5 vs. day 6 hatching blastocysts [117, 118] although other studies have still found an advantage of day 5 blastocysts even when transferred in a subsequent frozen embryo transfer [119]. In addition to the size and timing of blastocoel hatching having prognostic value, the presence of string-like projections across the blastocoel which do not break down over time are associated with poorer outcomes [102].

It is important to note that the use of assisted hatching, commonly performed before the cleavage stage, significantly affects the degree of blastocyst expansion and may make the assessment of expansion less useful as embryos with less cell and/or smaller blastocoel cavities may start to herniate through the artificially hatched zona.

The inner cell mass becomes clearer as the blastocoel expands. These cells which will become the fetus and extra-embryonic structures can have morphology ranging from very large tightly packed cells to loosely aggregated smaller cells. Both Gardner and the Istanbul groups postulate that the ideal ICM, denoted by a score of A or 1, is prominent and easily discernable, containing many cells that are tightly packed together. The middle ICM category, B or 2, is composed of several loosely grouped cells. The worst category, C or 3, describes an ICM that contains very few cells that are loosely bound [111, 112, 114]. In addition, an oval ICM rather than rounded or elongated shape and an ICM larger than 4500 um^2 have been associated with higher implantation rates [120].

The trophectoderm represents the cells in direct contact with the endometrium responsible for apposition, adhesion,

and invasion of the endometrium and also eventually becomes the extra-amniotic membranes and placenta [111]. Similar to the ICM, the Gardner and Istanbul systems both evaluate the TE by the number of cells and relative cohesiveness with each other. The ideal TE, category A or 1, contains many cells that form a cohesive epithelium. The middle TE category, B or 2, is composed of few cells forming a loose epithelium. The worst category, C or 3, contains few, large cells that do not form a cohesive epithelium [111, 112, 114]. Some studies without preimplantation genetic screening have found higher implantation rates among blastocysts with better TE scores [121], although this has not been observed in others [120]. It seems rational that the quality of the cells that adhere and invade the endometrium would correlate with implantation rates.

Practically, no single component of either blastocyst scoring system is used in isolation. Rather, a composite score is created, which has been demonstrated in non-preimplantation genetic screening cycles to correlate with implantation in both fresh and frozen embryo transfers [122, 123]. However, with the increasing utilization of preimplantation genetic screening and freeze-all strategies, embryos can be given additional time for expansion before biopsy and then transferred in a subsequent frozen embryo transfer cycle with better synchrony with the endometrium. The investigation of clinically useful morphological assessments will need to be revisited in this context, which also often employs artificial hatching, to determine which morphological assessments are still clinically useful in this clinical scenario.

40.11 Conclusion

Morphological assessment of embryos for culture decision making and embryo selection is one of the most challenging aspects of IVF. To create a system that uses a series of static assessments of an extremely variable and dynamic process to create an accurate, noninvasive, reproducible, and quick grading system is a tall order. The advent of time-lapse imaging to incorporate morphokinetic analyses and capture important morphological changes and the pathways to particular checkpoints is a step in the right direction to capture key attributes of embryo development. Initial studies investigating the predictive value of morphokinetic assessments have been mixed [42, 124–127]; however, the optimal way of utilizing time-lapse imaging in conjunction with morphological [128] and molecular assessments may be ahead of us and need further elucidation with ongoing research. Various scoring systems that include different combinations of multiday evaluations have been proposed, and many have been found to be associated with improved developmental competency of the embryo [129]. However, consensus on most aspects of sequential analysis remains elusive, including the parameters used in the different scoring systems, optimal times for evaluation, predictive accuracy of the various scores, and interobserver consistency of evaluation.

Many of the timing parameters observed to favorably or unfavorably correlate with implantation will need to be revisited again in frozen embryo transfer studies to adequately address the potential confounder of embryo-endometrium dyssynchrony, which may have been encountered in studies utilizing all fresh embryo transfers. Many of the checkpoint parameters with prognostic value were identified before cryopreservation was performed as reliably as today. In these studies, many embryos reaching developmental checkpoints relatively slower were deemed less viable; however, they may be just as viable as embryos who reach certain milestones on time when placed back in sync with the endometrial environment via a frozen embryo transfer.

Just as many aspects of embryo culture must be tailored toward any specific clinic's lab, the morphological assessments employed must also be personalized to particular IVF lab's workflow, staffing, patient population, and procedures performed, as well as its culture system. Morphological assessments can improve patients and providers' expectations, increase the number of patients reaching embryo transfer, and help choose the embryo most likely to become a successful pregnancy. When done effectively, this can strengthen the argument for single embryo transfer without compromising pregnancy rates, reduce patients' time to pregnancy, and possibly also reduce treatment expenses. While new technologies with applications in gamete and embryo assessment are being developed at a rapid pace, the use of static morphological assessments will continue to be the gold standard comparator for embryo selection to which any new technique's superior utility in clinical practice will need to be demonstrated before adoption.

Review Questions

1. How many hours after conventional insemination or intracytoplasmic sperm injection should the fertilization check be performed?
   10–12
   14–16
   16–18
   18–20

2. Which are the attributes of pronuclei assessed in most pronuclear scoring systems?
   (A) Size
   (B) Symmetry
   (C) Location
   (D) Position
   (E) B, C, and D

3. True or **False**: Embryos undergoing cleavage from 1 to ≥3 cells have significantly higher implantation rates than other embryos.

4. What number of cells on day 3 of development correlates with higher rates of implantation?
   (A) 4
   (B) 4–6
   (C) 7–9
   (D) 10–12

5. Which micromanipulation technique may confound blastocyst grading?
   (A) Intracytoplasmic sperm injection
   (B) Laser-assisted hatching
   (C) Trophectoderm biopsy
   (D) Delayed stripping of cumulus cells

Predicting Embryo Implantation Potential Using Video Monitoring by the EmbryoScope™ Time-Lapse System

Lucía Alegre Ferri, Carmela Albert Rodríguez, Sonia Pérez Albalá, and Marcos Meseguer Escrivá

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_41

Learning Objectives

- Evolution of time-lapse due to EmbryoScope™ technology.
- Integrating EmbryoScope™ device in IVF Laboratory routine.
- The most principal time-lapse algorithms.
- EmbryoScope™ Plus. Advantages and differences.
- The contribution of EmbryoScope™ to improve the implantation rate.

41.1 Introduction

Standard methods of embryo assessment in an IVF laboratory are based on subjective morphology evaluations. These evaluations are done at discrete time points because of the negative effects that manipulation and interrupted incubation have on embryo development, but information for selecting the best embryos is limited. The efforts aimed at improving pregnancy rates have focused on the search for additional markers of viability and new methods of retrieving more information for embryo evaluation to supplement current criteria for embryo selection.

Time-lapse technology represents a powerful tool in assisted reproduction techniques. It is based on specially designed instruments which take images of the embryos at set time intervals during incubation for minimized manipulation. This technique provides additional information to the embryologist by enabling evaluation of embryos from a dynamic point of view to study exact timings of important events during embryo development.

The aim of time-lapse technology is to improve IVF success rates by having extra information to describe embryos with higher developmental potential. The embryologist therefore has a wider range of variables to rely on for the selection of viable embryos, which – all other things being equal – should result in a better embryo selection.

41.2 EmbryoScope™ Time-Lapse Technology

The EmbryoScope™ (ES) time-lapse system (Unisense FertiliTech A/S, Aarhus, Denmark) is a tri-gas oocyte/embryo incubator with a built-in microscope and camera to automatically acquire images of up to 72 individual embryos from 6 patients during development (Fig. 41.1).

Culture conditions can be set as for conventional incubators. Temperature and gas concentrations are registered and logged by an embedded PC, which automatically generates a graph for easy monitoring of the incubator conditions over time.

EmbryoScope® time-lapse instruments are designed to optimize culture environment. The system has a non-humidified incubation chamber with a very short recovery time of O_2 and CO_2 concentrations, a direct heat transfer system for stable culture temperature even at door openings, and active carbon and HEPA filters to remove VOCs and other particles. Furthermore, all system components potentially in contact with embryos or embryo environment are toxicity tested prior to release from the manufacturer.

Fig. 41.1 The EmbryoScope™ time-lapse system

41.2.1 The Microscope Imaging System

The imaging system in the ES uses low-intensity red light (635 nm) from a single LED with short illumination times for image acquisition to minimize embryo exposure to light and to avoid damaging short-wavelength light [1, 2].

Optics employed to perform the imaging of oocytes/embryos closely resemble those of an inverted microscope with Hoffman modulation contrast. However, the microscope unit is fully automated and the images are recorded as in a digital microscope. The design is much more compact than in a conventional laboratory microscope. The 20× objective lens is custom-built (Leica) and optimized at relevant wavelengths.

Digital images are recorded by a highly sensitive CCD camera (1280 × 1024 pixels) with a resolution of 3 pixels per µm, and image stacks are acquired at equidistant focal planes during embryo culture. The number of planes acquired can be selected by the embryologist (up to 17 planes).

Although recording several thousand images during embryo culture, the total exposure time in the EmbryoScope® time-lapse system during culture and acquisition of images is significantly lower than the microscope light exposure time reported for a standard IVF treatment [1].

41.2.2 Description of EmbryoSlide® Culture Dishes

The EmbryoSlide® (EmbryoSlide(R), Unisense FertiliTech, Aarhus, Denmark) holds up to 12 embryos, each in individual wells with a design patented one-to-one identification system for easy identification under the microscope

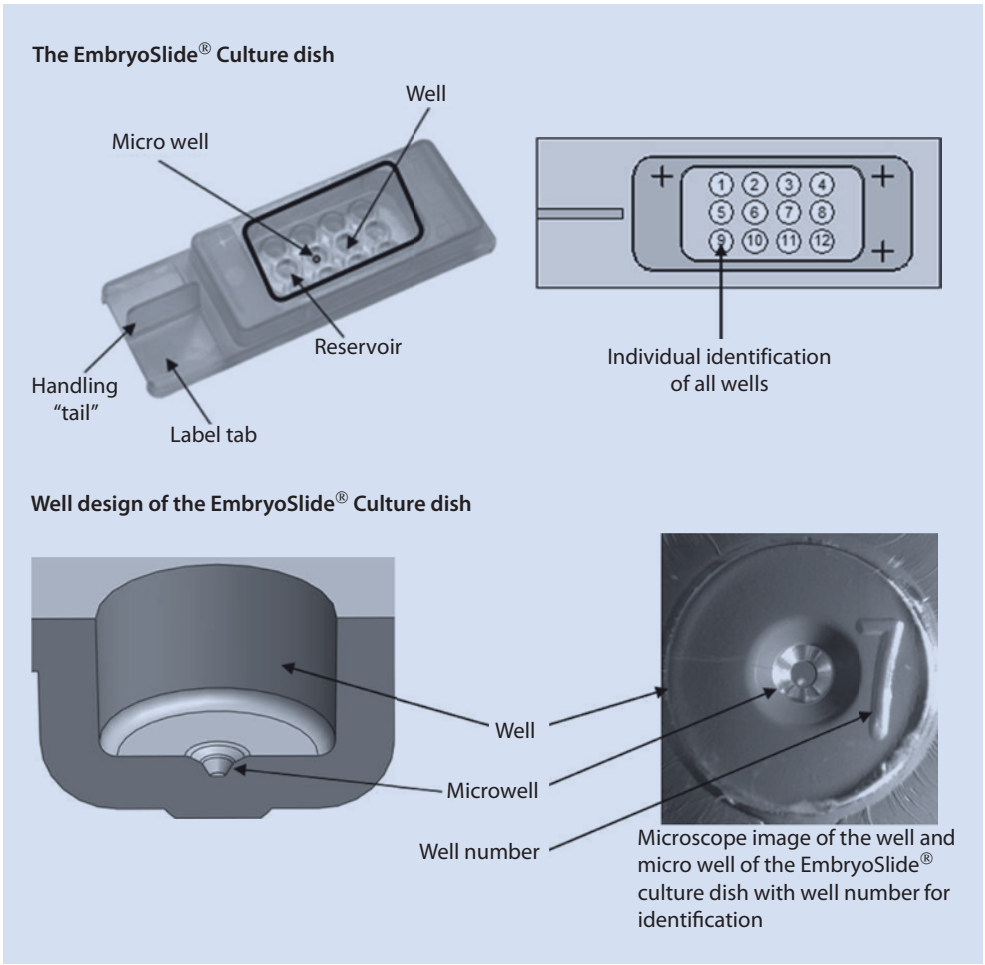

Fig. 41.2 The EmbryoSlide® design

(Fig. 41.2). The well numbers are equivalent to the embryo identifier associated to time-lapse recordings in the system. Embryos settle in a central depression at the bottom of each well (microwell) and are normally cultured in 25 µL droplets, each under a common oil overlay.

EmbryoSlide® culture dishes are packed in sterile pouches and are recommended to be prepared in a sterile, non-heated environment.

Upon media and oil loading and appropriate temperature and gas equilibration, EmbryoSlide® culture dishes can be loaded with embryos before transfer to the EmbryoScope® time-lapse system for culture and monitoring.

41.2.3 Working Procedure/Methodology

The text below describes the working procedures as performed at IVI clinics:

Oocytes are placed in the microwell just after microinjection (day 0). Therefore, the exact timing for each embryo division is calculated in hours after microinjection.

For placing embryos safely in the microwell, we use Stripper® pipettes (MXL3-275 de MidAtlantic Diagnostics, Inc.) and ensure embryo settlement at well bottom by microscope inspection.

When culturing embryos in the EmbryoScope® time-lapse system, EmbryoSlide® culture dishes containing the individually cultured embryos must be loaded in the EmbryoScope® time-lapse system both physically and electronically. Physical load is easily done by inserting into the specially designed dish holder of the embryo chamber. Electronic load is equally easily achieved at the touch of a single button on the EmbryoScope® Home screen ("Add Slide," Fig. 41.3).

Introduction of an EmbryoSlide® in the EmbryoScope® time-lapse system prompts information to be added about the patient (patient identification, date and time of fertilization) and a check for association with time-lapse images (Fig. 41.4).

It is very important to introduce the correct time at which the microinjection has been performed, as all recorded events will be defined taking that time as starting point.

In the table that appears in the right-hand side (Fig. 41.4), we add any information related to each particular embryo.

Once the EmbryoSlide® culture dish has been placed inside the embryo chamber, the software automatically

locates the wells of the dish and most informative focal plane (Fig. 41.5). After autofocusing, the system starts time-lapse image acquisition from each well in multiple focal planes as defined by the user. We sometimes use the refocus option ("New Focus") provided by the system to manually settle the focus plane (Fig. 41.6).

While the instrument is running, an overview of the cultured dishes is presented on the Home screen with the option to access details about culture conditions and each EmbryoSlide® culture dish (Fig. 41.7).

By pressing a Slide tab, we can view the full slide with the last image recorded in each well. Such an overview of the embryo development of a particular patient is very informative and useful for a quick overview of instrument content. It is also possible to focus on an individual embryo by a single touch on the screen which retrieves last image and more detailed information of that particular embryo. This feature includes several options including a live view, a video playback function which will play the entire time-lapse video of the particular embryo, and navigation within the current EmbryoSlide® culture dish (Fig. 41.8).

All data related to each EmbryoSlide® culture dish, including time-lapse images and incubation summaries, are saved in an integrated PC and on the appertaining EmbryoViewer™ workstation (EV).

41.2.4 Image Analysis Using the EmbryoViewer™ Software

The EmbryoViewer™ software (Unisense FertiliTech A/S, Aarhus, Denmark) is an advanced software specially designed for the EmbryoScope® time-lapse system for image analysis of the time-lapse acquisitions recorded by the system. Using this software, all embryo developmental events throughout the entire culture time (up to blastocyst stage) are annotated together with the corresponding timing of the events in hours after microinjection (Fig. 41.9). Blastomere divisions are routinely marked by the embryologist as well as events characteristic of fertilization, compaction and blastulation, multinucleation, unevenness in blastomere size, and degree of fragmentation.

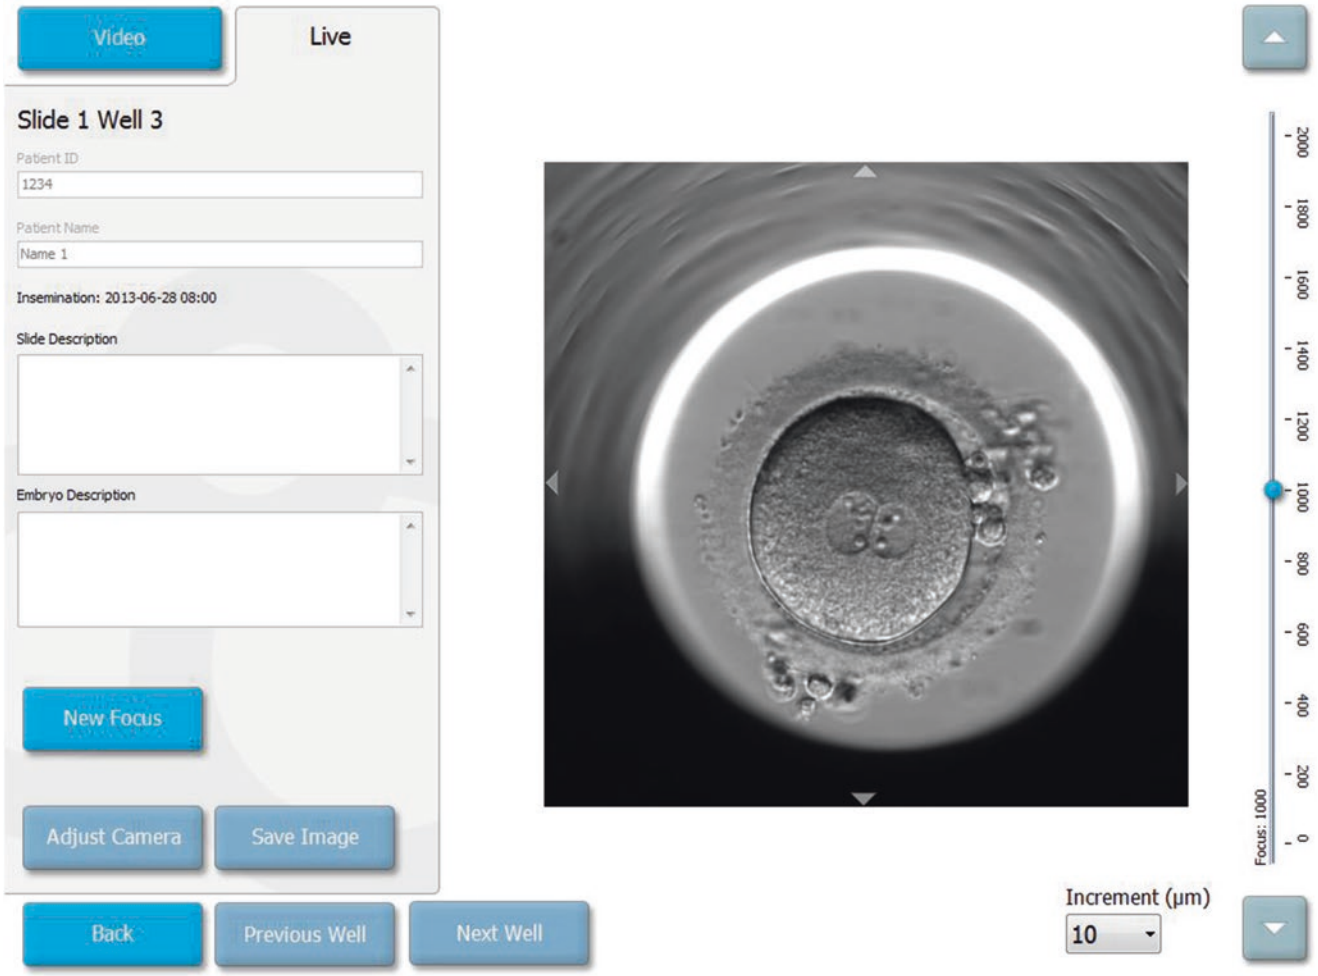

Fig. 41.6 Manual system for new embryo focus

At all our centers, we apply the embryo evaluation algorithm designed by Meseguer et al. [3]. Using the Compare & Select feature of the EmbryoViewer™ software, which ranks embryos according to user-defined criteria, this automatically provides the quality grade or category for each embryo according to the algorithm (Fig. 41.10).

The EmbryoViewer™ workstation provides the user with decision tools to mark embryo images once the selection of which embryos to be used for transfer and freezing or kept in the laboratory for further observation is performed (green for transfer, blue for freezing, red for not viable, and yellow for observation) (Fig. 41.11).

The system also provides the option to generate report formats of the embryos selected for transfer and freezing which can be tailored to clinic design and printed. We use the "Patient Report" for presenting the patient to images of the development of the embryos chosen for transfer and the final image acquired of embryos that are going to be cryopreserved. Moreover, a video of the complete development can be generated from the recorded stack of images and provided to the patients.

41.3 EmbryoScope™ Plus: New Version

EmbryoScope™ is the world's most used time-lapse system for IVF since 2009.

This year Vitrolife® has launched their new time-lapse system incubator: EmbryoScope™ Plus (Fig. 41.12). This new device has been validated and used clinically in five Scandinavian clinics, after having been involved in more than 500 treatments.

The main advantages of EmbryoScope™ Plus:

- Large capacity.
- Small footprint.
- Efficient workflow.
- Resource optimization.

EmbryoScope™ Plus has a capacity for 15 patient culture dishes and each of them can get up to 16 embryos. This would represent more than double the patient capacity, compared to other bench-top time-lapse systems and three more than previous EmbryoScope™ version. EmbryoScope™ Plus is

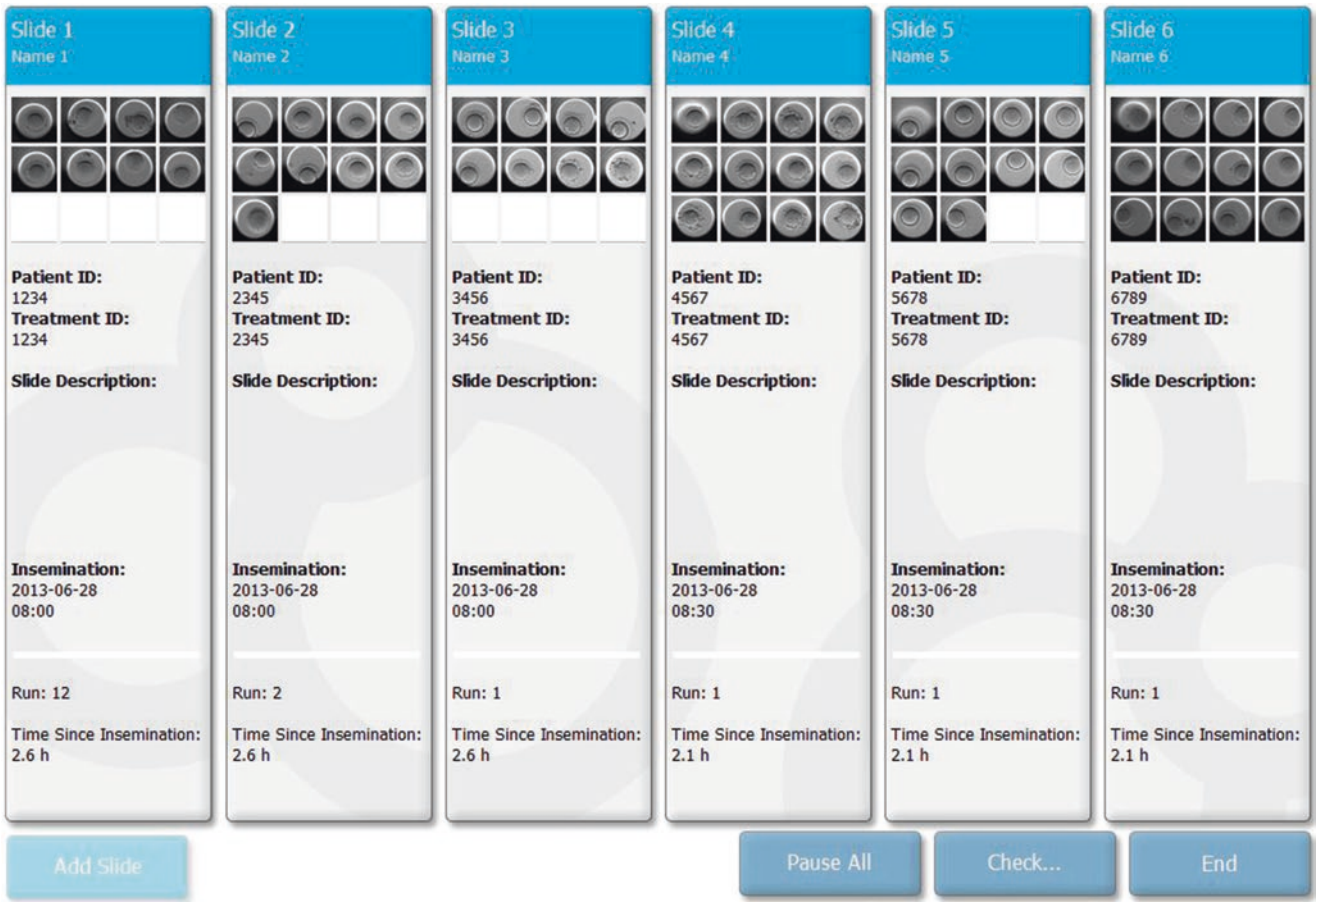

Fig. 41.7 Home screen with details about culture conditions of each EmbryoSlide® culture dish

used with an EmbryoViewer™ Software version allowing you to see all 16 embryos at a time.

To improve workflow, the EmbryoSlide® Plus culture dishes are automatically registered using a special patient barcode labeling system (Fig. 41.13). A patient identification barcode system offers a flexible and efficient workflow. The device automatically reads and registers entry of a new patient and reentry of an existing patient slide.

41.4 Overview of Studies Undertaken to Date Using EmbryoScope™

The study presented by Cruz et al. was the first step to evaluate whether the EmbryoScope™ time-lapse system provides a safe and controlled environment compared with conventional incubators [4]. In this study, embryo selection for transfer was based on morphological evaluation at the same time points for both the time-lapse system and the conventional incubator groups, the additional information provided by the time-lapse system not being taken into account.

Results obtained showed no significant variation between the two incubator groups when comparing embryo quality, development, and ongoing pregnancy rates, which confirmed the safety of the system for clinical use.

Kirkegaard et al. [5] also developed a randomized clinical trial to evaluate the safety of the EmbryoScope™ time-lapse system before introducing the instrument in a clinical setting. Results obtained in this study confirm no differences on development, clinical pregnancy, or implantation rates between incubation in the EmbryoScope™ system and a conventional incubator. With these results, they concluded that EmbryoScope™ time-lapse system supports embryonic development equally and can therefore be introduced clinically providing a potential tool for embryo evaluation [5].

Upon demonstration of the safety as an incubator with controlled incubation conditions, the next purpose of Meseguer's group was to generate and evaluate a tool for the selection of viable embryos based on the exact timing of embryo development events together with morphological patterns by using EmbryoScope™ time-lapse system to monitor embryo development. They presented the largest data set on transferred ICSI-generated embryos analyzed by time-lapse, to correlate morphokinetic parameters with implantation and pregnancy rates [3]. The precise timings of numerous morphokinetic parameters were identified where

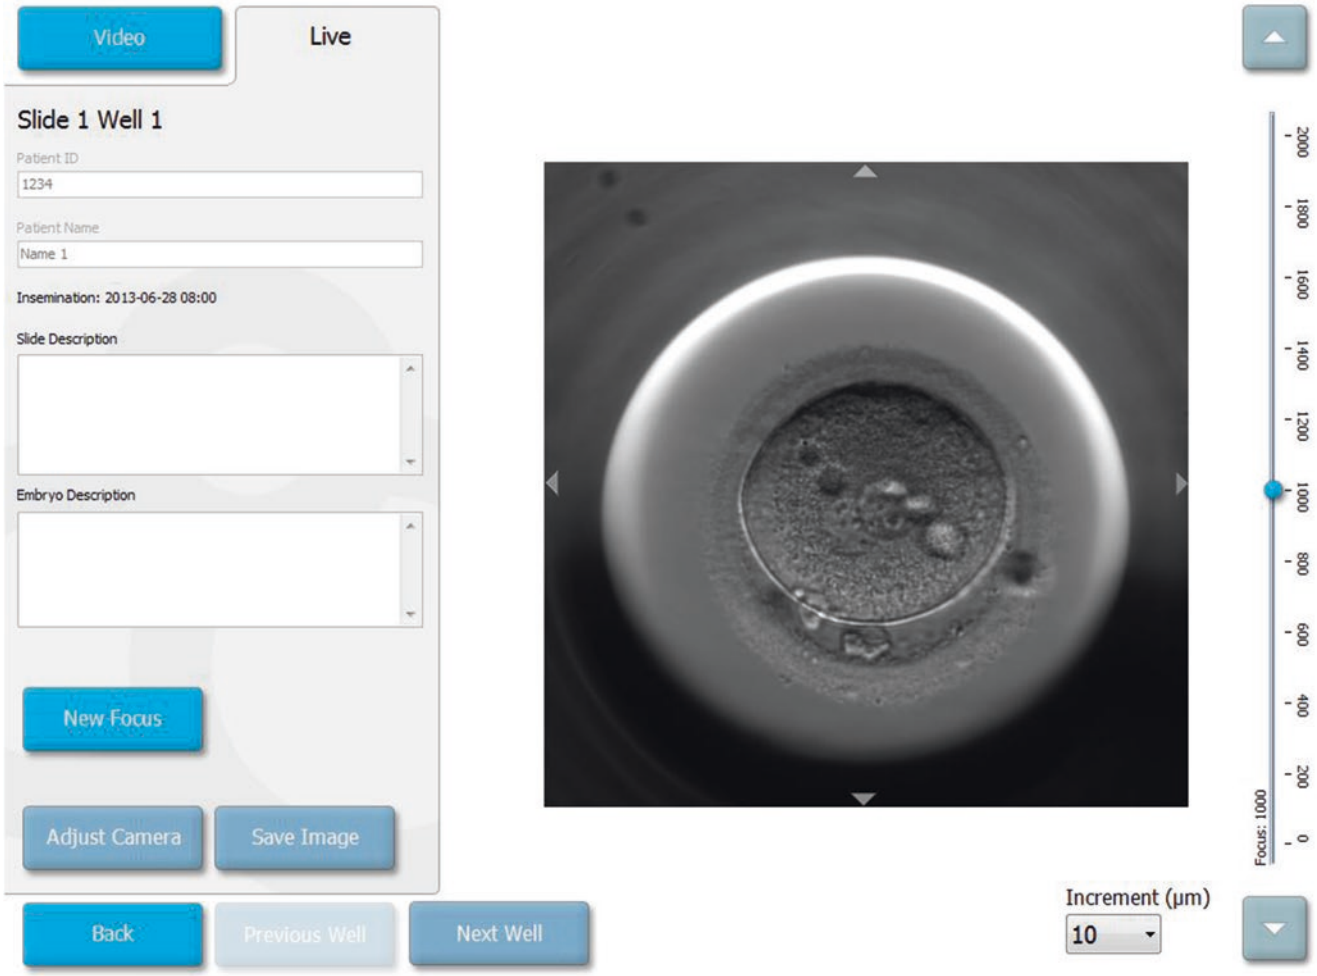

Fig. 41.8 Time-lapse video and navigation within the current EmbryoSlide® culture dish

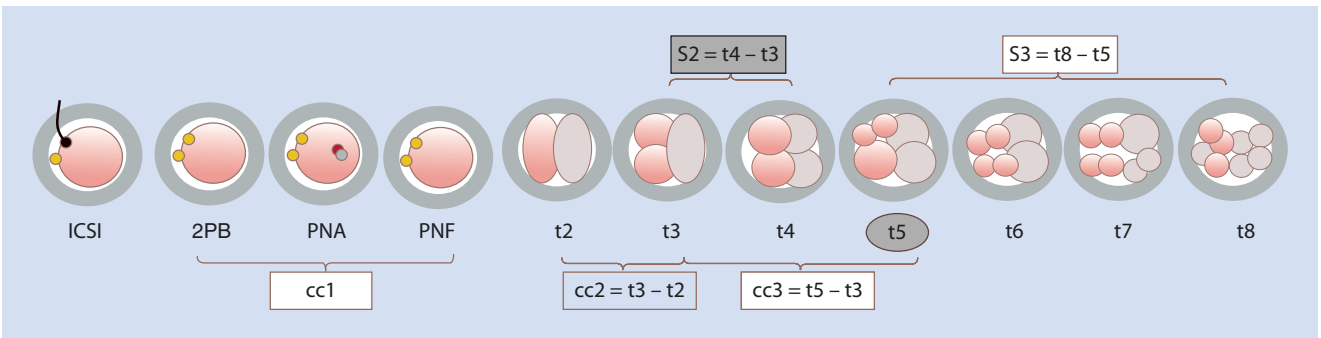

Fig. 41.9 Morphokinetic parameters of embryo development

time zero was the time of microinjection. Division into two cells was defined as t2, into three cells t3, into four cells t4, and into five cells t5, defining time of cleavage as the first observed time point when the newly formed blastomeres were completely separated by clearly defined membrane. Cell cycle duration was also evaluated, the second cell cycle (cc2) being the duration of the period as a two-blastomere embryo (i.e., t3 − t2) and the second synchrony (s2), synchrony in division from two-blastomere embryo to four-blastomere embryo (i.e., t4 − t3). The four quartiles for the timing of each of these parameters were compared with the percentage of successfully implanting embryos in each of the quartiles. Optimal ranges were established considering the two consecutive quartiles with the highest implantation probabilities in each category. Statistical analysis defined the most relevant parameters for embryo evaluation. The results obtained were

Fig. 41.10 Quality grade or category for each embryo according to the algorithm defined

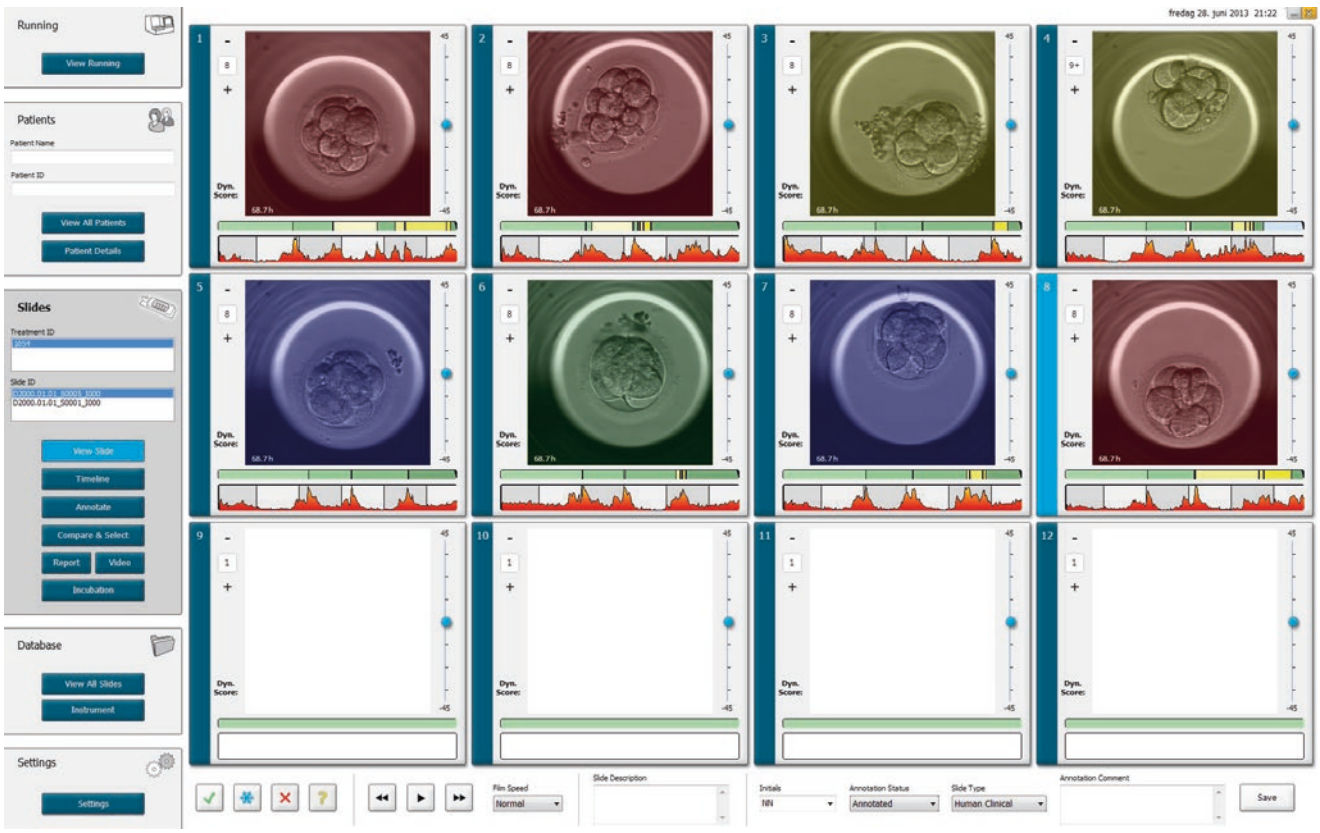

Fig. 41.11 Decision tools to mark embryo images: green for transfer, blue for freezing, red for not viable, and yellow for observation

Fig. 41.13 Special patient barcode labeling system: EmbryoScope™ Plus

then used to design a hierarchical classification algorithm for the selection of embryos with the highest implantation potential. The timing of the cleavage to five cells turned out to have the best correlation with implantation success and was superior to the timing of the first cell division used in earlier studies of early cleavage [3].

The algorithm starts with a morphological screening of the embryos to discard the embryos that are clearly not viable and which are consequently classified as category F. Another point to be considered in implementing this algorithm is to exclude embryos fulfilling at least one of the following exclusion criteria: (i) uneven blastomere size after the first cleavage (when the embryo has two cells) (blastomeres were considered uneven if the average diameter of the large blastomere was 25% larger than the average diameter of the small blastomere), (ii) abrupt division from one to three cells, or (iii) multinucleation at the four-cell stage (category E). After evaluation for these criteria, the remaining levels of the hierarchy are defined according to the defined ranges of some of the variables (t5, s2). Once the embryo is classified with a specific grade, the timing of cc2 is taken into account, adding a plus (+) if it is inside the range established as optimal or minus (−) if it is outside this optimal range. In this way, embryos are graded $A^+ - D^-$, E, or F using the algorithm (Fig. 41.14).

One of the exclusion criteria defined in Meseguer's algorithm was studied in detail by Rubio et al. [6]. By using the EmbryoScope™ time-lapse system, they precisely identified each cell cycle and observed abnormal lengths of the cell cycle, such as the abrupt cleavage of human embryos from two to three cells in less than 5 h, defined as a direct cleavage (DC 2–3) (Fig. 41.15). Clinical pregnancy and implantation rates of embryos undergoing abrupt cell division from two to three cells were studied to evaluate the clinical applicability of this morphokinetic parameter. The known implantation rate of DC 2–3 embryos was statistically significantly lower than for embryos with a normal cleavage pattern. The incidence of direct cleavage was about 14% in the total embryonic cohort which, combined with the markedly decreased implantation rate of direct cleavage, suggests this to be a strong morphokinetic parameter for clinical use.

Using this algorithm and the EmbryoScope™ time-lapse system, Basile et al. compared different culture media, demonstrating identical timings and proportion of optimal embryos for the two media analyzed [7]. These results validate the algorithm for embryo selection developed by Meseguer et al. [3] in diverse culture conditions.

The further use of the described algorithm by Meseguer et al. [3] is in the largest retrospective study to date on pregnancy outcomes comparing conventional incubation with time-lapse technology [8]. Even though prospective studies are obviously preferable, this was a first approximation where all the available data from ten different IVI clinics was analyzed, adding up to a large quantity of heterogeneous

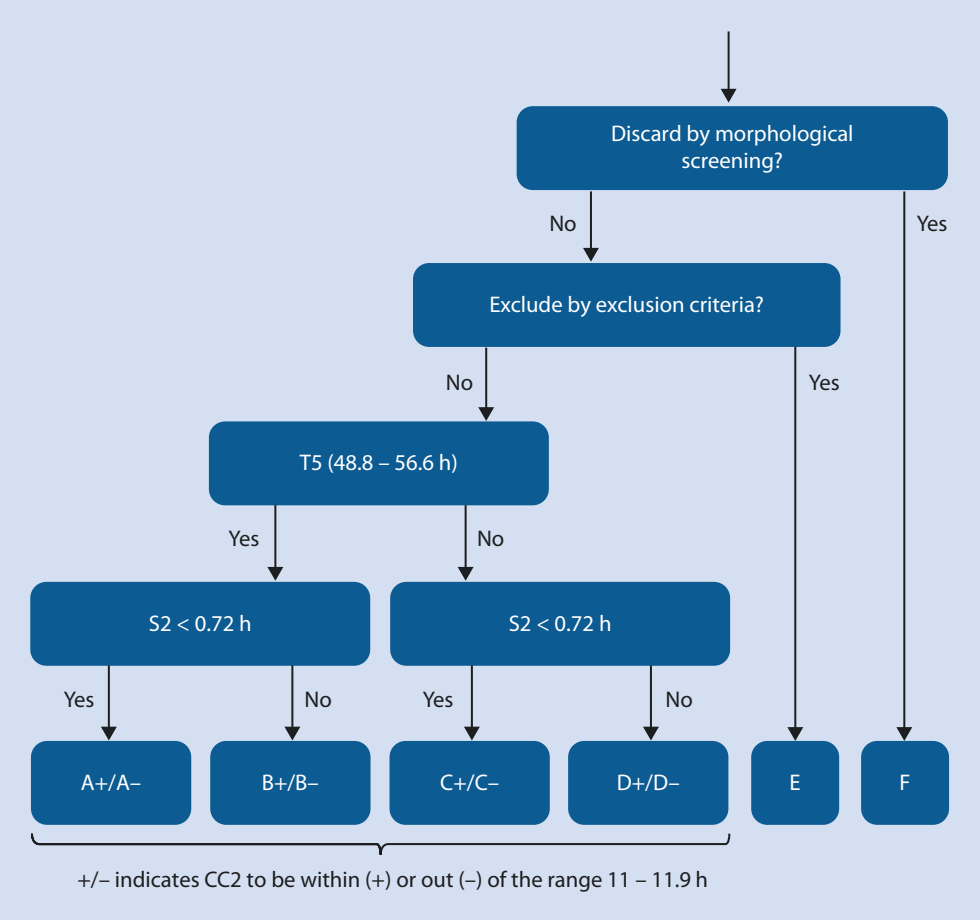

Fig. 41.14 Hierarchical classification algorithm for the selection of embryos with the highest implantation potential. Meseguer M.

In this figure are represented the levels for algorithm implementation. The morphological assessment and the exclusion criteria can classify embryos as E or F. The embryos which pass this initial screening and are not discarded will be included in eight categories +/– (A+/–, B+/–, C+/–, D+/–), according to the most relevant morphokinetic parameters in order of relevance: T5 (48.8–56.6 h), S2 (< 0.72 h) and CC2 (11–11.9 h)

information. A key limitation of this study, because of its retrospective design, was that patients were not evenly or randomly distributed between the two different incubators, which can affect and distort final conclusions. Because of this, it was essential to analyze for any confounding factors that may significantly influence pregnancy rates and their uneven distribution between incubators. Oocyte source, maternal age, day of transfer, and number of retrieved oocytes were identified as significant confounding factors and included in a logistic regression model. The results obtained suggested a relative 20% improvement in pregnancy rates in the time-lapse incubator system compared with the conventional incubator, which implies a larger impact than the improvement associated with blastocyst culture [8]. For treatments with conventional incubators, the average clinical pregnancy rate per initiated cycle with oocyte retrieval was 44.9%. If they had been incubated using time-lapse, a relative improvement of 20% would imply an expected clinical pregnancy rate for the same cycles of 53.9%, an absolute improvement of 9%.

Those results needed to be confirmed with prospective studies which have already been started. In 2014 Rubio et al. [9] presented a prospective study to determine if the combination of EmbryoScope™ time-lapse monitoring system (TMS) and morphokinetic multivariable models implies an outcome clinics improvement versus conventional incubator culture and an exclusive classic morphological analysis. Significant differences were found according to ongoing pregnancy rate 51.4% (95% CI, 46.7–56.0) vs. 41.7% (95% CI, 36.9–46.5), early pregnancy loss 16.6% (95% CI, 12.6–21.4) vs. 25.8% (95% CI, 20.6–31.9), and implantation rate 44.9% (95% CI, 41.4–48.4) vs. 37.1% (95% CI, 33.6–40.7), TMS and CI, respectively. This publication placed the EmbryoScope™ at the top of incubation systems.

Basile et al. [10] in line with the results obtained by Meseguer et al. conducted a multicenter study in which a total of 1664 oocyte donation cycles were included. Cleavage timing and cellular cycles were analyzed in all embryos. A significant correlation was established between t3, cc2, and t5 parameters and implantation rate. They also identified three events that affected the embryo quality: direct cleavage from one to three cells, uneven blastomere size in cc2, and multinucleation in cc3. According to these results, an improved algorithm version classified the embryos into five categories related to implantation potential (A, 32%; B, 28%; C, 26%; D, 20%; and E, 17%, $p < 0.001$).

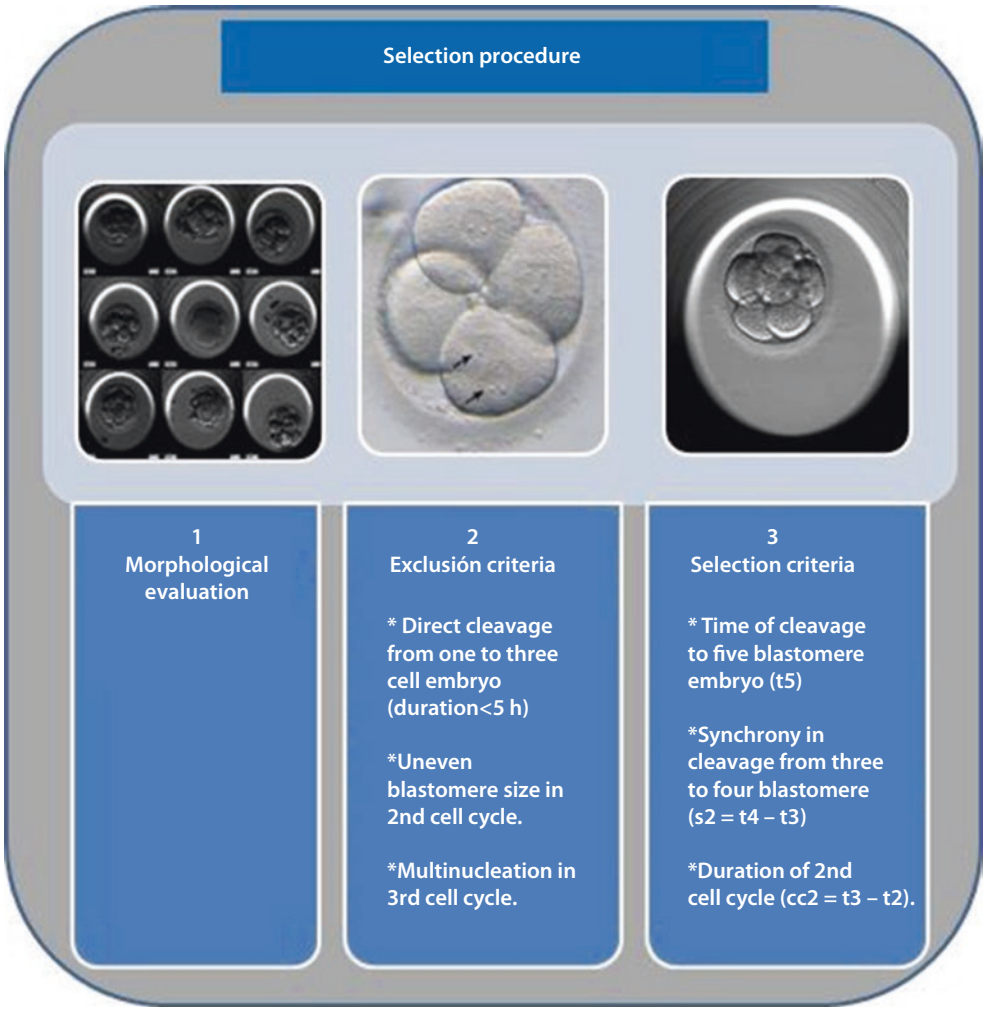

Fig. 41.15 Exclusion and selection criteria based on time-lapse markers

In order to demonstrate associations between various cleavage-stage kinetic parameters and the ability of the embryos to reach the blastocyst stage, Cruz et al. [11] compared the blastocyst rate and morphological features for cleavage-stage embryos, which were graded according to their morphokinetic development. The blastocyst rate and morphology were highest for embryos from the best morphokinetic grade A and gradually decreased to the lowest rates and qualities for the lowest grade D. From their results, Cruz et al. concluded that time-lapse-based evaluation of the exact timing of early events in embryo development is a promising tool for the prediction of blastocyst formation and quality.

Based on a thorough study of the EmbryoScope®-acquired time-lapse images, Dal Canto et al. [12] found human embryo cleavage rates to be suggestive of their ability to develop to the blastocyst stage and to implant. They showed similar cleavage patterns up to the six-cell stage of embryos that later developed into blastocyst and those that did not, but highlighted the importance of timings of cleavage to the seven- and eight-cell stages for predicting blastocyst potential. In this study implanting embryos developed to the eight-cell stage in a significantly shorter period than those unable to implant. With these results, they concluded that cleavage from the two- to the eight-cell stage occurs progressively earlier in embryos with the ability to develop to expanding blastocysts and to implant [12].

After the study of 17 parameters of embryo development in blastocysts incubated in EmbryoScope™ time-lapse, Motato et al. [13] created the largest database of human blastocysts (a total of 7.843 embryos) and two independent models. In a first study phase, they observed that if tMC and t8 − t5 took place between 81.28 and 96.0 and ≤8.78 h after ICSI, respectively, the probability of blastocyst formation was higher. Furthermore, a second model of implantation potential was published considering t8 − t5 and tEB as key morphokinetic parameters. The implantation rate was significantly higher when tEB happened between 107.9 and 112.9 h and t8 − t5 had a length ≤5.67 h after ICSI. The concept that blastocyst formation and implantation should not be ruled by the same parameters was already established in 2014 by Desai et al. [14]. The morphokinetic mechanisms registered in each event were different. Other models emerged from embryo morphokinetic study; this was the case of Milewiski et al. [15], those who identified t2, t5, and t3 − t2 as relevant markers of blastocyst formation likelihood. Thanks to EmbryoScope™,

Mizobe et al. [16] observed that when two-cell and three-cell stage took place in 25.90 and 37.88 h, the quality of blastocyst was higher and had more likely to show "B" or "A" categories in their inner mass and trophectoderm.

The multinucleation in blastomeres of embryos from two to eight cells during embryo development is the subject of interest, and it has long been studied. Aguilar et al. [17] in accordance with that established by Basile et al. identified the multinucleation as an event which can influence embryo quality. For that reason, Aguilar et al. presented a retrospective EmbryoScope™ survey with the aim of finding a possible relation among multinucleation and implantation rate. They observed that S-phase length average in cc1 of KID+ embryos was longer than in KID- cases (15.50 h vs. 14.38 h) and a little shorter in cc2 (8.35 h vs. 8.60 h), respectively. Furthermore, multinucleated embryos at four-cell stage showed a lower implantation rate; however it was not significant. So they concluded that the reason that multinucleation and implantation rate was not correlated as due to self-correction event is much more common than we might think. This theory is backed up by other research groups.

The study published by Balakier et al. [18] defined recently published a study where it was observed that multinucleation process had the same incidence in both euploid and aneuploid embryos. They analyzed a total of 1,500 embryos, which were biopsied in D5 and incubated in EmbryoScope™ incubator. After conducting an exhaustive analysis, it was established that, despite the embryos with multinucleated blastomeres experimented later division in early stages than mononucleated embryos, no differences in aneuploidy percentage was found in blastocyst stage. Only women's age showed a significant correlation with multinucleation events.

The EmbryoScope® time-lapse system has been demonstrated of great value in assisting more resource-consuming laboratory procedures due to the precise and continuous recordings of embryonic development.

Preimplantation genetic diagnosis encourages further investigations using time-lapse systems such as the impact of blastomere removal and correlation of morphokinetic parameters with aneuploidy risk.

Kirkegaard et al. presented the first study to evaluate the effect of blastomere biopsy on early human embryonic development using time-lapse analysis. Using the EmbryoScope™ time-lapse, they demonstrated that although cleavage-stage embryo biopsy prolongs the cell stage at which the biopsy is performed, the cleavage rate after this initial delay seems unaffected [19]. Biopsied and non-biopsied embryos started hatching at the same time, which caused duration of the blastocyst stage to be shorter in the biopsied group, due to a shorter time from reaching the full blastocyst stage until hatching. Moreover, the study confirms previous findings from studies on assisted hatching, showing the embryo to hatch through the artificial breach in the zona pellucida. The study hereby contributes to the understanding of the effect of blastomere biopsy and the early development of the human embryo.

Table 41.1 Classification of ploidy with associated incidence rates and probability of aneuploidy

Risk class	No of embryos	Incidence of aneuploid embryos	Probability of an embryo being aneuploid
Low $t_B < 122.9$ h and $t_{SB} < 96.2$ h	36	0.36	0.37
Medium $t_B < 122.9$ h and $t_{SB} \geq 96.2$ h	49	0.69	0.69
High $t_B \geq 122.9$ h	12	1.00	0.97

To evaluate the difference in morphokinetics between aneuploid and euploid embryos [20], Campbell et al. (2013) compared morphokinetic variables of these two groups of embryos using EmbryoScope® time-lapse images. Their results showed that multiple aneuploid embryos were delayed at the initiation of compaction (t_{sc}) and the time to reach full blastocyst stage (t_B). Embryos having single or multiple aneuploidy also presented a delay in initiation of blastulation (t_{SB}) compared with euploid embryos [20].

Morphokinetic variables found to differ between euploid and aneuploid embryos were used to build a risk classification model by classifying the embryos into groups depending on the value of the variables t_{SB} and t_B and finally developed the following algorithm: low risk, $t_B < 122.9$ h and $t_{SB} < 96.2$ h; medium risk, $t_B < 122.9$ h and $t_{SB} \geq 96.2$ h; and high risk, $t_B \geq 122.9$ h (Table 41.1).

This same group also developed a retrospective analysis to evaluate the effectiveness and potential impact of this classification model for unselected IVF patients without biopsy and preimplantation genetic screening (PGS) [21].

When the aneuploidy risk classification model was applied, the medium- and low-risk classes for aneuploidy were significantly different from each other with respect to known implantation rates (Table 41.2). Of the few embryos classified as high risk subsequent to transfer, none implanted. The aneuploidy risk classification model, therefore, indicated the predictive power of this algorithm to identify and avoid selecting embryos at high risk of implantation failure using noninvasive objective criteria.

Soon after, other researchers used time-lapse technology to identify morphokinetic parameters that could be markers of chromosomal aneuploidies. The morphokinetic differences between euploid and aneuploid embryos were also described by Chawla et al. [22] in a retrospective study. Basile et al. [23] already in 2013 created a logistic prediction model through a prospective study in PGS embryos that were incubated in EmbryoScope. On that model, t5 − t2 (>20 h), cc3 (11–18 h), and t5 (47–58 h) were proposed as health genetic

Table 41.2 Known implantation data rate for fetal heart beat and live birth for each aneuploidy risk class

Risk class	Fetal heart beat in known implantation data	Live birth in known implantation data
Low $t_B < 122.9$ h and $t_{SB} < 96.2$ h	72.7[a] ($n = 33$)	61.1[b] ($n = 18$)
Medium $t_B < 122.9$ h and $t_{SB} \geq 96.2$ h	25.5[a] ($n = 51$)	19.2[b] ($n = 26$)
High $t_B \geq 122.9$ h	0 ($n = 4$)	0 ($n = 2$)

[a] $p < 0.0001$
[b] $p < 0.01$

embryos indicators. With the same objective in mind, in 2014 the same research group analyzed 504 embryos from 77 patients that were subjected to array comparative genome hybridization (CGH) in day 3 of development. In this case, the same correlation was found between morphokinetic timing events and genetic endowment of the embryos: t5 − t2 OR = 2.853 (95% CI 1.763–4.616), followed by cc3 OR = 2.095 (95% CI 1.356–3.238). According to these findings, they created an algorithm which classified the embryos into four categories (A to D) by t5 − t2 and cc3 development parameters. Each category exhibited significant differences in the percentage of euploidy embryos (A, 35.9%; B, 26.4%; C, 12.1%; D, 9.8%).

Recently, other researches as Patel et al. [24], according to Basile algorithm, found differences between morphokinetic parameters of euploid and aneuploid embryos (t5, 28.6% vs. 17.5%; cc3, 25.9% vs. 20.8%; and t5 − t2, 26.7% vs. 14.3%). Excellent results were also registered by Yang et al. [25] in trophectoderm biopsied of day 5 blastocysts. They formed two groups: time-lapse and conventional incubator group. Time-lapse parameters were used as powerful tool in embryo transfer selection, since implantation rate, clinical pregnancy rate, and ongoing pregnancy in these patients were significantly higher (66.2% vs. 42.4%, $p = 0.011$; 71.1% vs. 45.9%, $p = 0.037$; and 68.9% vs. 40.5%, $p = 0.019$) in time-lapse and conventional incubator group, respectively. The time-lapse technology and PGS combination is a great strategy to improve clinical results.

Other field, where time-lapse opened newest investigation lines, is collapse events taking place in blastocyst stage. Monitoring images allow us to detect and quantify collapse events during embryo development.

Brodi et al. [26] performed a study to clarify if blastocyst collapse episodes are in some ways correlated with live birth rate (LBR). Three collapse blastocyst groups were defined: no, single, or multiple. They observed that LBR was lower as collapse events were more frequent: 36% (no collapse group), 31% (single), and 14% (multiple). However, that collapse events are not predictive markers was determined.

Most recently, at the 32nd Annual ESHRE congress, Galán et al. [27] presented a re-expansion blastocysts survey. A total of 435 thawed-warmed KID blastocysts were analyzed. Embryoscope incubator was used to study re-expansion blastocyst after warming until transfer. The variables included were ZP thickness (μm), blastocyst area (μm^2), inner cell mass (μm^2), and collapse events. Significant differences in implantation rate were observed depending on ZP thickness and blastocyst area. These results showed that time-lapse analysis offers new implantation markers for warmed embryos.

One of the great advantages by time-lapse technology is the option to study all embryo development retrospectively. Domínguez et al. [28] wanted to check if it was a relationship between interleukin (IL) 6 and the duration of cellular cycles. To that end, they compared morphokinetic parameters with presence/absence of IL-6. A correlation was found between the duration of cc2 and IL-6 presence. These two parameters were combined to generate a hierarchic model including four categories: A, B, C, and D. They observed that embryos with the presence of IL-6 and 5–12 h cc2 duration showed a significant higher implantation rate.

In summary, time-lapse systems improve our knowledge of the real time distribution of the main events of embryo development making it possible to establish, with accuracy and objectivity, the basis of the embryo development timing. The EmbryoScope® technology provides flexibility in working routines and evaluation protocols due to the platform design. This technology might also improve effectiveness of IVF cycles increasing the ability to identify embryos with higher implantation potential, in order to perform elective single embryo transfer reducing multiple pregnancy rates.

Review Questions

1. Which is the main reason that you should consider if you have (or plan to have) an EmbryoScope™ incubator in your IVF laboratory?
   (a) To improve the embryo selection provided by morphology.
   (b) To automate the procedure of embryo selection.
   (c) To provide better culture conditions to the embryos by not disturbing them.
   (d) To simplify the daily workflow and reduce costs.

2. What were the most significant parameters of Meseguer's algorithm?

3. What are the main advantages of EmbryoScope™ Plus?

Learning Objectives

- Limitations of traditional embryo assessment methods based on embryo morphology
- Emerging noninvasive technologies for embryo assessment
- Validation steps needed to introduce new tools and technologies into the IVF laboratories
- Automated time-lapse analysis in the Eeva Test
- Clinical outcome studies using the Eeva Test

42.1 Introduction

In in vitro fertilization (IVF) practice, technologies or tests that can help assess the viability and developmental competence of embryos may not only improve IVF success rates; they may also enable broader adoption of single embryo transfer (SET), which would in turn reduce multiple gestation pregnancies and lower associated maternal/fetal risks [1]. Currently, standard embryo assessment methods depend on morphological evaluation by microscope at a few static points in time (e.g., Day 1, Day 2, Day 3, and Day 5 post-insemination) [2, 3]. Morphological evaluation and selection, however, have lacked underlying biological understanding and sufficient predictability for implantation due to the inherent subjectivity of morphological grading [4–6] and the weak correlation between morphology and embryonic health [7–9]. Without predictive and objective tools that can supplement morphology, clinical embryologists are routinely forced to make their best guess of which embryo(s) to transfer among morphologically similar embryos.

New research in embryo assessment promises to provide additional information to help discriminate among morphologically similar embryos and improve the likelihood of selecting the single embryo that will successfully develop, implant, and result in a live birth. However, before new tools and technologies can be introduced into the IVF laboratory, several validation steps should be taken to ensure their safety, accuracy, and efficacy. These steps, which follow the initial discovery and development phases, may include biological validation, clinical validation, performance characterization, and comparison to standard of care [10]. Increasingly, clinical practitioners and patients also expect successful validation to result in approval from a regulatory body [11]. In this case, the regulatory body would require the intended use of the new tool or technology to be clearly stated and validated.

The objective of this chapter is to describe the development, validation, and practical application of the first noninvasive embryo viability assessment tool that has been designed to meet clinical test criteria and proven to add critical information to the decision-making practices of clinical embryologists. In describing this novel test, we review the criteria for development and validation of a clinical test, assess the scientific underpinning of prediction using time-lapse imaging, and introduce new advances in automation enabled by state-of-the-art computer vision software.

42.2 Clinical Testing

The goal of clinical testing is to help clinicians improve assessment or treatment decisions by determining a disease risk probability (in the case of a screening test) or diagnosing a disease (in the case of a diagnostic test) [12]. Typically, a clinical test is developed against a reference standard test that is more invasive, more risky, or prohibitively expensive. A clinical test may also be developed as a first-pass surrogate for a more invasive procedure (e.g., venous ultrasonography serves as a surrogate marker of vein thrombosis and reduces the need for a highly invasive venography procedure [13]; cell-free fetal DNA analysis of maternal blood can detect fetal genetic anomalies without requiring invasive amniocentesis or chorionic villus sampling procedures [14]).

In clinical embryology, several noninvasive candidate technologies have been proposed as surrogates for invasive embryo assessment and predictors of embryo developmental potential, including culture media assessment [15–17], cumulus cell assessment [18, 19], and time-lapse imaging [20–22]. Parallel advances in assay and embryo biopsy techniques have resulted in increased use of preimplantation genetic testing (PGT) together with blastocyst culture for assessing not only the genetic and chromosomal status of an embryo but also its overall implantation potential [23, 24]. While embryo biopsy is invasive to the embryo and typically relevant for IVF patients indicating a need for PGT, noninvasive technologies have the potential to be more economical and more broadly applicable. However, most noninvasive technologies are in early development stages; as such, they have not been prospectively validated in independent clinical trials and lack the basic prerequisites for successful clinical translation.

Three major requirements are needed in order to successfully implement a novel embryo assessment technology or test into the IVF laboratory. First, a predictive biomarker based on scientific evidence and validated in clinical studies must be associated with a confirmable and desirable outcome. Second, the detection of the predictive biomarker must be accurate, reliable, and practical to use by clinicians. Finally, the combined test (predictive biomarker + detection method) must be characterized for performance and shown to provide actionable information that improves the standard of care. In addition to these major requirements, scientists have increasingly demanded that new technologies be brought to patients via an evidence-based approach that includes basic research, which provides scientific understanding and clinical confidence in the test [10, 11, 22]. In a recent review, Palmer et al. noted that in reproductive medicine, it is common for only the first milestone—report of a novel biomarker correlation—to be achieved; whereas, successful culmination of all milestones ideally results in content for regulatory submission documents and eventual regulatory approval [11]. In support of this approach, new standards for reporting diagnostic accuracy (STARD) are being required of authors seeking to publish new test results [25].

42.3 The Eeva Test

The *Eeva™* Test was designed with clinical test criteria in mind and combines both a highly robust predictive marker of embryo development *and* a novel detection assay to rapidly obtain quantitative measurements of the biomarker in a clinical setting. Below we detail the use of Eeva in the IVF laboratory workflow and its underlying science and technology. We further describe clinical results from multiple prospective, multicenter studies that compare the use of Eeva results combined with morphology (adjunctive grading method) against morphology alone (traditional morphology grading method).

42.4 The Eeva Test Deployed in Standard Incubators or Benchtop Incubators

The original Eeva Test consisted of (1) a multi-well dish that provides individual culture for embryos with the same media drop, (2) an imaging system that collects data inside a standard incubator, and (3) intelligent software that automatically analyzes and measures cell division timings (Fig. 42.1).

Recently, other incubator formats have been developed and adapted for use with the *Eeva™* Test. Benchtop incubators are now being fitted with cameras, lighting sources, and time-lapse imaging software so that benchtop incubator users may also leverage Eeva's unique automation capabilities. Importantly, these new time-lapse benchtop incubators utilize both brightfield and darkfield imaging. Utilizing both brightfield and darkfield modalities together provides more information about embryos than brightfield alone and may lead to further discovery of novel features correlated to embryos' development potential.

42.5 Predictive Information Enabled by Time-Lapse

The first major requirement of a clinical test is identifying a predictive biomarker with correlation to a measureable, clinical outcome. Recently, increasing availability and usage of time-lapse imaging systems—both homemade and commercial variations—have enabled researchers to identify potential image biomarkers during human embryo culture in a safe and noninvasive manner. Time-lapse systems currently vary in a number of ways, harboring variations in format/footprint (e.g., some are enclosed in stand-alone box formats [26, 27], while others integrate seamlessly with conventional incubators [28–31]), embryo culture environment (e.g., some require individual culture of embryos [27], while others enable group culture [28–31]), and mode of illumination (e.g., most offer brightfield imaging, while others offer

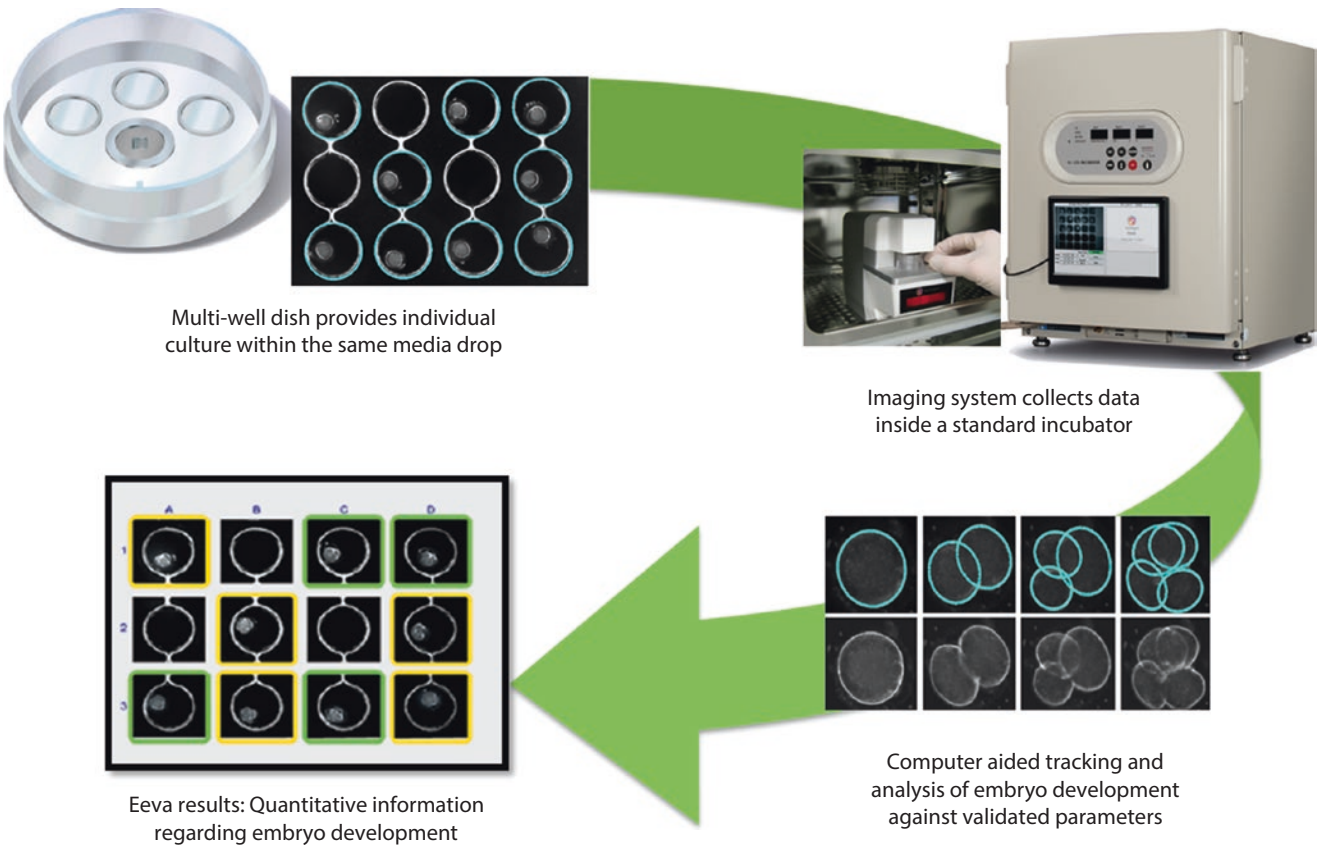

Fig. 42.1 The Eeva™ Test in the IVF laboratory workflow

darkfield or multimodal imaging). Importantly, all systems inherently have optical alignment, focusing, image capture, and image storage capabilities and utilize low-power illumination that exposes embryos to overall less light than conventional microscopy [27, 29, 31]. As a result of these advances, the clinical embryology field has been able to study the function and consequences of dynamics occurring during human embryo development and explore application to clinical practice.

Time-lapse imaging in clinical embryology has a relatively long history that can be broken down into two phases: an observational phase and a predictive phase. Beginning in 1997, time-lapse imaging was focused on observing new aspects of embryo development, such as polar body extrusion, fertilization, pronuclear formation and abuttal, cytoplasmic flares, and embryo hatching [26, 32–34]. Since 2010, time-lapse imaging has shifted focus to identifying predictive parameters that can help assess developmental outcomes of the embryo, such as blastocyst development, implantation, and most recently ploidy [27, 29, 30]. Numerous publications since 2010 have reported statistically significant correlations between time durations of cell stages and embryo outcomes. These studies, together with studies that have demonstrated safety of time-lapse and continuous monitoring of human embryos, are reviewed in detail elsewhere [20–22]. Overall, the increasing intensity of interest in time-lapse imaging suggests that noninvasive biomarker discovery is feasible, ongoing, and promising for use in the clinic.

Time-lapse biomarkers have great potential as predictive clinical tests, but the reproducibility of their predictive ability is critical to validating clinical utility. An analysis of the studies that defined a precise time window for embryo development prediction showed that the major predictors are biomarkers observed in early embryo development, before the 5-cell stage. In particular, the time from 2- to 3-cell (P2) and the time from 3- to 4-cell (P3) stage were reported in six out of seven of the studies that investigated which embryos are most likely to become a blastocyst or implant or be euploid [27, 29, 35–37] (Fig. 42.2) and several following reports [35, 38]. These P2 and P3 timings were consistent embryo viability predictors even when stimulation protocols [39], fertilization methods [40], culture media [41, 42], and culture environments [43] were varied. In addition to clinical reproducibility, mechanistic studies have also demonstrated that embryos with abnormal P2 and P3 timings exhibit distinct gene expression profiles [29], aneuploidy probabilities at

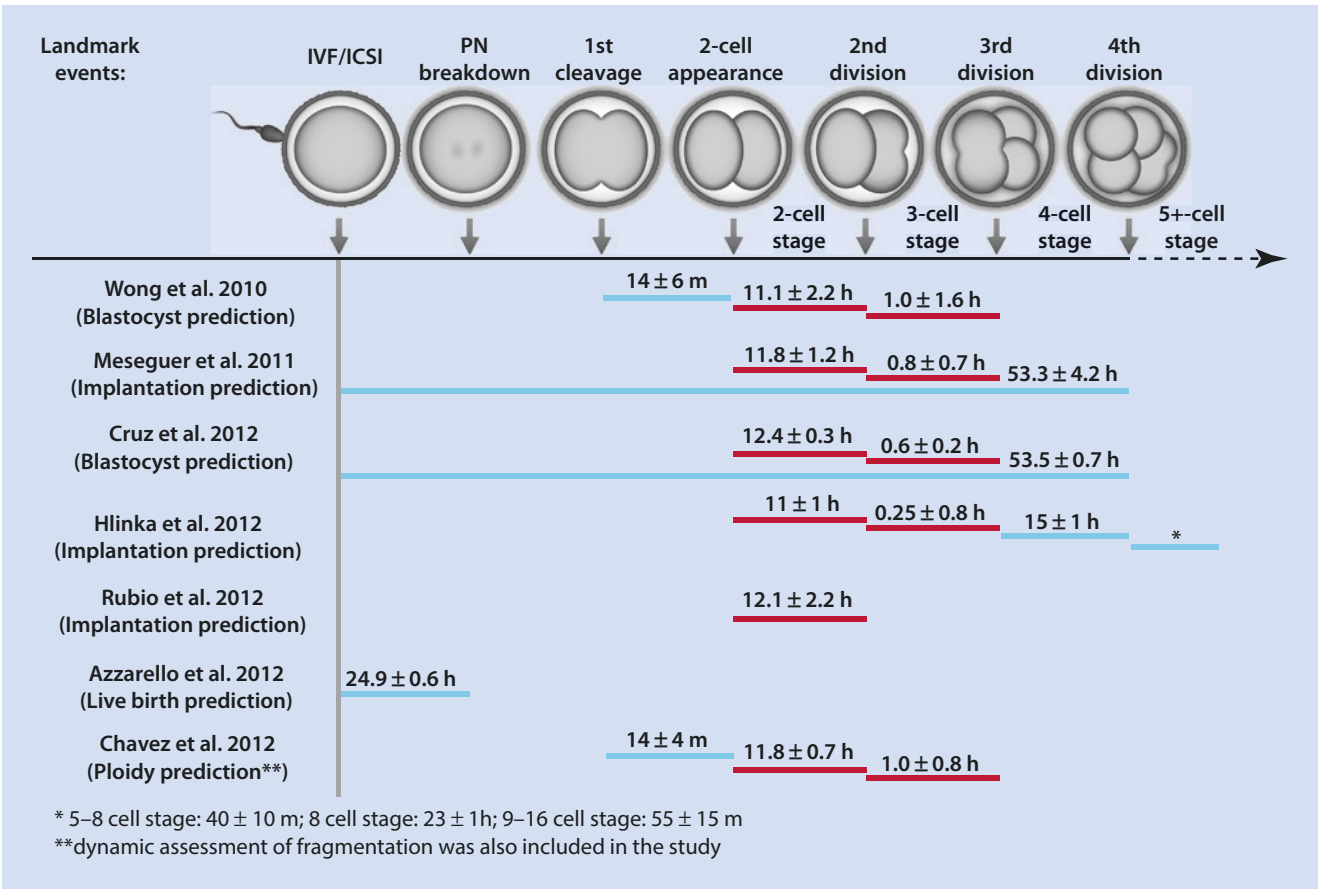

Fig. 42.2 Overview of published time-lapse biomarkers that are predictive of clinical outcomes. Landmark events captured by time-lapse imaging are mapped to the progression of preimplantation embryo development. Time-lapse biomarkers that have been used for prediction in at least three publications—and are implemented in the Eeva Test—are colored dark red, while others are *colored light blue*. Average values for embryo outcomes within the optimally predictive windows are labeled above *colored bars*. (Adapted with permission from Chen et al. [22])

the embryo level [30], aneuploidy at the single blastomere level [44], and micronuclei patterns [30], compared to embryos with normal P2 and P3 timings. This collection of evidence supports the conclusion that P2 and P3 are reliable across independent datasets, and, moreover, are grounded in basic scientific understanding. Development of the Eeva Test, therefore, was based on (1) incorporation of P2 and P3 into a simple classification tree and prediction algorithm and (2) development of intelligent image analysis software that could reliably measure P2 and P3 in a busy clinical laboratory.

42.6 Automation Enabled by Intelligent Software

The second major requirement of a clinical test is that it is technically reliable, accurate, and practical for daily laboratory use. Although time-lapse biomarkers may provide great clinical value, extraction of these markers requires manual assessment of hundreds of images per embryo, which would be prohibitively time-consuming and laborious for routine use. In order for predictive time-lapse biomarkers to be clinically realized, novel detection methods are required to automatically extract and quantify image data in a high-throughput fashion.

Computer vision software that can analyze embryo videos in real time is now transforming the time-lapse imaging field and allowing predictive biomarkers to be rapidly quantified in the clinical laboratory. Image analysis software is widespread in many areas of clinical laboratory medicine, such as oncology and pathology. In reproductive medicine, software tools for quantitative and rapid image analysis of sperm quality [45] and for screening cervical cytology samples [46, 47] are also available. Applied to clinical embryology, image analysis software is particularly challenging due to several unique features of the developing human embryo. Blastomeres of the human embryo may divide in multiple dimensions (e.g., in and out of plane) and may include confounding events (e.g., fragmentation, reverse cleavage, abnormal cleavage). In addition, for each patient, multiple embryos developing at variable rates must be surveyed.

In their 2010 report demonstrating the first use of three cell cycle parameters to predict embryo development, Wong et al. also established the first proof of concept of cell tracking software used to measure the cell cycle parameters in human embryos [29]. The Wong et al. approach utilized computer vision techniques to simulate images and compare the simulations to observed image data for 14 cryopreserved embryos. In their study, darkfield imaging was employed as it provided strong contrast of blastomere membranes for model estimations. The development of the Eeva Test introduced a data-driven probabilistic framework that uses approximate inference to quantify P2 and P3 and validated the Eeva Test's predictive performance for approximately 1000 fresh human embryos [31]. Eeva software predictions were shown to have good (>90%) agreement with manual predictions made by human observers [31]. Separate from this technological advance, other groups have performed research to help automate the morphological analysis of static embryo images to the blastocyst stage [48, 49] and the detection of cytoplasmic waves generated post-fertilization [50]. Since the objective in designing the Eeva Test was to provide embryologists with quantitative information about embryo development, the test focused on the clinically and scientifically validated predictive markers P2 and P3 and integrated automated software to quantify these validated parameters.

42.7 Clinical Outcomes for Using the Eeva Test

The final and often most elusive requirement for a novel clinical embryology test is that it is characterized for performance and shown to improve the standard of care. When performing a retrospective study, it is relatively straightforward to extract one or more promising biomarkers from a sampling of time-lapse videos. However, it is challenging and significantly less common to demonstrate comparable performance of the biomarker on an independent set of prospectively collected test data from multiple centers. It is rarer still that new potential selection methods are compared to traditional embryo selection methods based on morphology. Here, we describe how the Eeva Test provides validated and actionable information that may improve current embryo selection based on morphology.

42.7.1 The Eeva Test Is Independently Validated in Diverse Clinical Embryology Laboratories

Following the development of the integrated Eeva Test, we conducted a prospective, five-center clinical study that was designed to assess its performance on a diverse and independent clinical dataset and to evaluate the effectiveness and utility of using the test as an adjunct to traditional morphological assessment (► ClinicalTrials.gov #NCT01369446) [31]. Specifically, we sought to test the Eeva Test's ability to assist embryologists in selecting embryos that have the greatest potential to develop into usable blastocysts (i.e., blastocysts suitable for transfer or freezing) as well as the Eeva Test's impact on embryologists' embryo selection decisions. The ability to predict blastocyst formation by Day 3 has clinical value as it could potentially improve IVF success rates while avoiding the potential risks associated with extended culture for blastocyst transfer [51–56].

Our initial results demonstrating the predictive power of time-lapse biomarkers P2 and P3 for identifying embryos with high developmental competence were consistent with Wong et al. and other successive studies [29]. Using refined cutoffs of P2 9.33–11.45 h and P3 0–1.73 h, the Eeva Test automatically differentiated a usable blastocyst from an

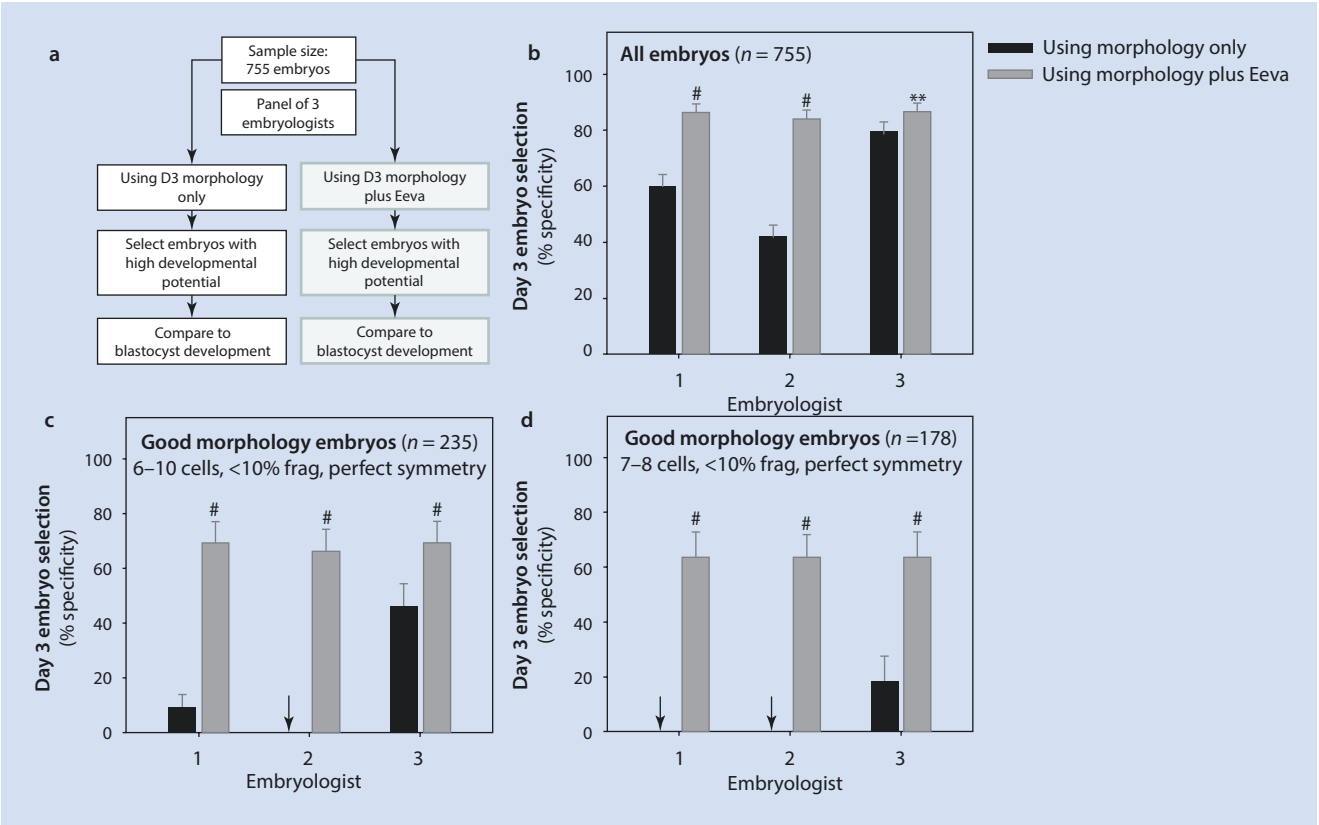

Fig. 42.3 Adjunctive use of D3 morphology plus Eeva Test results significantly improves the specificity of D3 embryo selection. **a** Design for an embryo selection cohort study comparing the use of D3 morphology vs. D3 morphology plus Eeva Test results. **b**–**d** D3 embryo selection by individual embryologists (1, 2, and 3) using morphology only versus morphology plus Eeva Test for **b** all embryos ($n = 755$); **c** "good morphology" embryos ($n = 235$), defined using criteria of 6–10 cells, <10% fragmentation, and perfect symmetry; and **d** "good morphology" embryos ($n = 178$), defined using more stringent criteria of 7–8 cells, <10% fragmentation, and perfect symmetry. Note that embryologists 1 and 2 were very conservative in their morphological assessments and expected that almost all D3 "good morphology" embryos would become usable blastocysts. Error bars represent upper 95% confidence interval. $^{**}p < 0.01$, $\#p < 0.0001$. (Adapted with permission from Conaghan et al. [31])

arrested embryo with significantly improved diagnostic specificity (85%) compared to traditional morphology (57%, $p < 0.0001$) [31]. Specificity, or the ability to correctly predict which embryos will arrest, is highly relevant to embryo selection since traditional morphology is most limited in selecting among "good morphology" embryos. Furthermore, development and validation of the Eeva Test were performed on clinical data collected from five IVF clinics undergoing their own standard procedures for stimulation, egg retrieval, embryo culture, and insemination, suggesting broad applicability of the Eeva Test in diverse clinical embryology laboratories.

42.7.2 The Eeva Test Improves Embryo Selection and Reduces Embryologist Variability

Since clinical embryologists are faced daily with the challenge of selecting from among several comparable embryos those which are the top candidates for transfer, it was important to assess the impact of the Eeva Test on embryologists' embryo assessment decisions. Our prospective study design evaluated the embryo assessment of three experienced clinical embryologists for 755 embryos. Two methods of embryo assessment were compared: in the first arm, embryologists made predictions about embryo development using Day 3 morphology only (traditional grading method); in the second arm, the same embryologists made predictions about embryo development using Day 3 morphology plus Eeva Test results (adjunctive grading method) (Fig. 42.3a).

When Eeva Test was used adjunctively with Day 3 morphology, each embryologist's likelihood of selecting embryos that would develop to blastocysts was significantly improved compared to traditional morphological methods alone (Fig. 42.3b). This improvement was even more pronounced among a subset of $n = 235$ embryos that were preselected as having "good" morphology (6–10 cells, <10% fragmentation, perfect symmetry) (Fig. 42.3c) and a subset of $n = 178$ embryos where "good" morphology was more stringently defined (7–8 cells, <10% fragmenta-

tion, perfect symmetry) (Fig. 42.3d). As expected, each case demonstrated remarkably high inter-individual variability when morphology alone was used for embryo assessment. When the Eeva Test was used together with morphology, the embryologists' performances were more consistent, as the standard deviation among embryologists was reduced [31].

In a separate study, we used the Eeva Test to assess differences in embryo scoring among a diverse set of embryologists, postulating that better, more consistent embryo scoring would positively impact any embryologist's ability to choose the embryo with the highest developmental potential [57]. This study was performed by looking at five different embryologists from unique practices around the United States, including three senior embryologists with at least 10 years of clinical experience and two junior embryologists with less than 3 years of experience from practices that performed between 300 and 1000 fresh IVF cycles per annum. To assess embryologists' performance, odds ratio (OR) and other diagnostic measures were calculated by comparing prediction results to true blastocyst outcomes.

When Eeva Test results were used adjunctively with morphology, the odds of an embryo forming a blastocyst was 3.51-fold (95% CI = 2.62–4.69) higher in the group predicted to develop into blastocysts than in other embryos. In contrast, the OR using morphology alone was 2.69 (95% CI = 2.06–3.50). This improvement in OR was also assessed in the subset of morphologically good and fair embryos. By morphology alone, the OR for this subset dropped to 1.68, slightly better than random prediction ($p < 0.0001$). Adding Eeva Test results improved OR to 2.57, a 53% increase over traditional morphology and significantly better than random prediction ($p < 0.0001$, Fig.42.4a). In addition to OR, Eeva Test results also helped improve the positive predictive value (PPV) over morphology alone (54% vs. 43%, $p = 0.02$) while maintaining the same level of negative predictive value (NPV, 68% vs. 68%, Fig. 42.4b).

These results indicate that the Eeva Test aids embryologists of diverse backgrounds by distinguishing among similar-looking embryos that are evaluated first by morphological criteria. Using Eeva Test results as an adjunct to morphology, every individual embryologist's prediction performance was improved (Fig. 42.4c). Using the Eeva Test adjunctively to morphology, the variability in performance across all five embryologists was reduced from a range of 1.06 (OR = 1.14–2.20) to a range of 0.45 (OR = 2.33–2.78, Fig. 42.4c). Notably, the embryologist with the greatest improvement in OR was one of the senior embryologists with more than 10 years of training in morphology grading. Since intra- and inter-operator variability in morphological grading has been shown to negatively impact IVF success rates [4, 6], adjunctive use of the Eeva Test may improve the standardization, reproducibility, and ultimate success of Day 3 embryo selection.

42.7.3 Eeva Test Results Correlate to Implantation and Pregnancy

While the first critical steps in developing the Eeva Test as a predictive and automated clinical assay have been achieved, further work is needed to confirm the impact of Eeva Test results on implantation and pregnancy outcomes. Toward this goal, we performed the first analysis examining whether the time-lapse markers used by the Eeva Test correlate with implantation and pregnancy outcomes. We focused our analysis on embryos that were transferred at the blastocyst stage using standard morphological selection criteria (without Eeva Test results). Of 141 embryos transferred at the blastocyst stage, those embryos denoted by the Eeva Test as having a high probability to develop (Eeva High indicating P2, 9.33–11.45 h, and P3, 0–1.73 h) had a statistically higher chance of implantation than those embryos denoted by the Eeva Test as having a low probability to develop (Eeva Low indicated by P2 or P3 out of specific timing windows) (49% vs. 21%, $p < 0.001$) (Fig. 42.5). Similarly, for these 77 blastocyst transfer patients, those with at least one Eeva High embryo transferred were more likely to achieve clinical pregnancy (60% vs. 40%, $p = 0.09$) and ongoing pregnancy (56% vs. 37%, $p = 0.11$) than those with only Eeva Low embryos transferred. These results add further evidence to recent retrospective reports showing correlation between P2, P3, and implantation [27] and pregnancy outcomes [58].

The Eeva Test's fully automated algorithm was further examined in a blinded, multicenter study published in 2014 [59]. This study took place in six different IVF centers, each recruiting and treating patients using their own protocols, laboratory equipment, and consumables. A total of 331 transferred embryos with known implantation from 205 patients enrolled at 6 IVF clinics were analyzed. We found that Eeva High embryos had a significantly higher probability of successful implantation (37%, 41/111) than Eeva Low embryos (23%, 50/220, $p = 0.003$, Fig. 42.6a). Eeva Test results were also correlated with clinical pregnancy rates. Patients were divided into two groups: patients with at least one Eeva High embryo transferred and those with no Eeva High embryo transferred. Patients' clinical characteristics for the two groups were compared, including egg age, number of eggs retrieved, number of 2PNs on Day 1 and number of embryos transferred. There was no statistically significant difference found for any of the clinical characteristics assessed. However, patients with at least one Eeva High embryo transferred had significantly higher clinical pregnancy rates than those with no Eeva High embryos transferred (51% vs. 39%, $p = 0.04$). Additional analysis of embryo implantation revealed a statistically significant difference between the two groups of patients (34% vs. 25%, $p = 0.03$). In a three-category version of the Eeva Test results (High/Medium/Low), Eeva High embryos had the highest likelihood of implantation (37%), followed by Eeva Medium

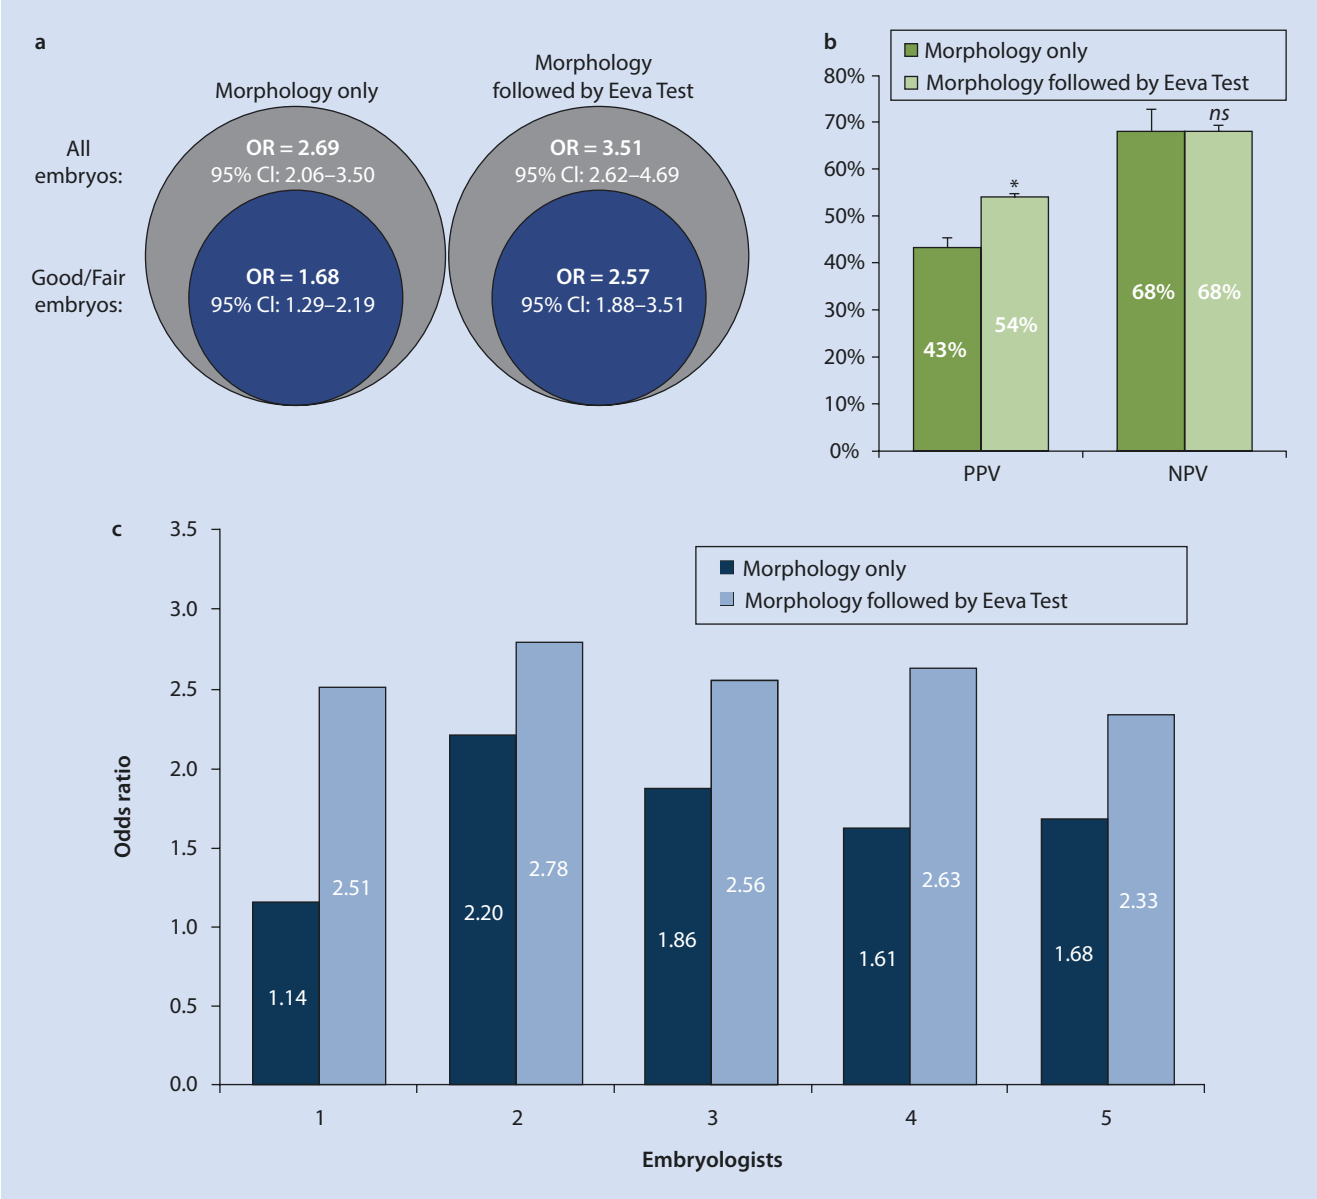

Fig. 42.4 Adjunctive use of Day 3 morphology plus Eeva Test results significantly improves Day 3 embryo selection and consistency among embryologists. **a** OR for predicting blastocyst formation using Morphology Only (left) and Morphology followed by Eeva Test (right). ORs and 95% confidence intervals were calculated for all embryos (represented in gray) and for the subset of embryos graded as good/fair (represented in blue). **b** Mean PPV and mean NPV across all embryologists predicting blastocyst formation using Morphology Only and Morphology followed by Eeva Test, among good/fair embryos. *$p = 0.02$, ns (not significant; error bars represent upper 95% confidence intervals). **c** Consistent improvement in ORs for individual embryologists who predicted blastocyst formation using Morphology Only and Morphology followed by Eeva Test, among good/fair embryos. (Reproduced with permission from Diamond et al. [57])

(35%) and Eeva Low (15%); and the difference in implantation rates between Eeva High vs. Eeva Low embryos and Eeva Medium vs. Eeva Low embryos was statistically significant ($p < 0.0001$, $p = 0.0004$, respectively, Fig. 42.6b). Furthermore, although the IVF centers each followed their own standard procedures for embryo culture and selection, Eeva Test results correlated to embryo implantation consistently across the different IVF centers (Fig. 42.6c).

Consistent with our study results, a growing body of published, independent studies have reported that Eeva Test results correlate to implantation and/or pregnancy regardless of patient population or IVF practice patterns. Kirkegaard and colleagues performed a retrospective multicenter analysis of 1519 transferred embryos from 7 clinics located in 3 countries and found that embryos manually analyzed and classified as High had a statistically significantly higher implantation rate (30% relative increase) than embryos that were manually classified as Low [60]. Kieslinger and colleagues showed that in good prognosis patients (<41 years old, <3 previous attempts, and ≥ 5 2PNs) with mostly SET,

Patient population	# Pts	# Embs	Avg age (years)	Implantation rate	Clinical pregnancy rate	Ongoing pregnancy rate
At least 1 Eeva High transferred	47	89	32.1 ± 5.2	**49%** (44/89) 	**60%** (28/47) 	**55%** (26/47) 
Only Eeva Lows transferred	30	52	32.2 ± 5.1	**21%** (11/52) 	**40%** (12/30) 	**37%** (11/30) 
p-value			*p = 0.9*	*p<0.001*	*p = 0.09*	*p = 0.11*

Fig. 42.5 Time-lapse markers used by the Eeva Test are correlated with positive implantation and pregnancy outcomes. A retrospective analysis of implantation and pregnancy rates was performed for two populations of patients with Eeva imaging and blastocyst transfer based on morphology only. The two patient populations included those with at least one Eeva High transferred (i.e., one Eeva High embryo could be transferred with another Eeva High or Eeva Low embryo) and those with only Eeva Low transferred (i.e., one or more Eeva Low embryos were transferred). The Eeva High vs. Low denominations are based on whether time-lapse markers P2 and P3 are within defined time windows (P2, 9.33–11.45 h, and P3, 0–1.73 h). (Adapted with permission from Chen et al. [22])

transferring Eeva High and Medium embryos resulted in a significantly higher ongoing pregnancy rate of 36.8% (89/242) compared to 18.4% (7/ 38) for Eeva Low embryos (p = 0.02) [61]. Aparicio-Ruiz and colleagues conducted a multicenter retrospective study of 626 IVF cycles using donor oocytes with the following findings: (1) Eeva Test results were correlated with embryo implantation in not only cleavage-stage embryo transfer but also blastocyst transfer (implantation rates for cleavage stage transfer: Eeva High 38.2%, Medium 31.7%, and Low 26.1%; implantation rates for blastocyst transfer: Eeva High 66.7%, Medium 50%, Low 31%); (2) Patients where no Eeva High embryos were transferred had an ongoing pregnancy rate of 46.7%, while patients where at least one Eeva High embryo was transferred experienced a significantly increased ongoing pregnancy rate of 67% [62]. In comparison, no significant difference was observed for ongoing pregnancy rates in patients with or without morphology grade A embryos transferred (60.2% vs. 59.3%). This broad collection of publications by independent investigators provides strong evidence that the Eeva Test differentiates embryos with higher implantation potential, and may therefore complement traditional morphology to aid in embryo assessment.

42.7.4 The Eeva Test Improves Clinical Outcomes

The gold standard for evaluating the effectiveness of time-lapse-based embryo assessment is a well-designed randomized controlled trial (RCT). To ensure that an RCT is adequately powered, pilot studies are needed to estimate the sample size for RCT. Adamson and colleagues assessed the impact of using the Eeva Test in adjunct with traditional morphology by conducting a prospective concurrent cohort-controlled pilot study [63]. A total of 319 patients were assessed, 98 in the test group (the Eeva Test was used in embryo selection) and 221 in the control group (traditional morphology alone was used for embryo selection). All patients met the same inclusion/exclusion criteria including <41 years of age at the start of the IVF cycle, planned day 3 transfer, fewer than three failed IVF cycles, at least four zygotes (2PN on Day 1), and no PGT. Implantation rate and clinical pregnancy rate were significantly higher in the test group in which the Eeva Test was used compared to the control group (implantation rate, 30% vs. 19%, p = 0.003; clinical pregnancy rate 46% vs. 32%, p = 0.02, Fig. 42.7a, b). In a sub-analysis of the test group, the authors found that patients receiving at

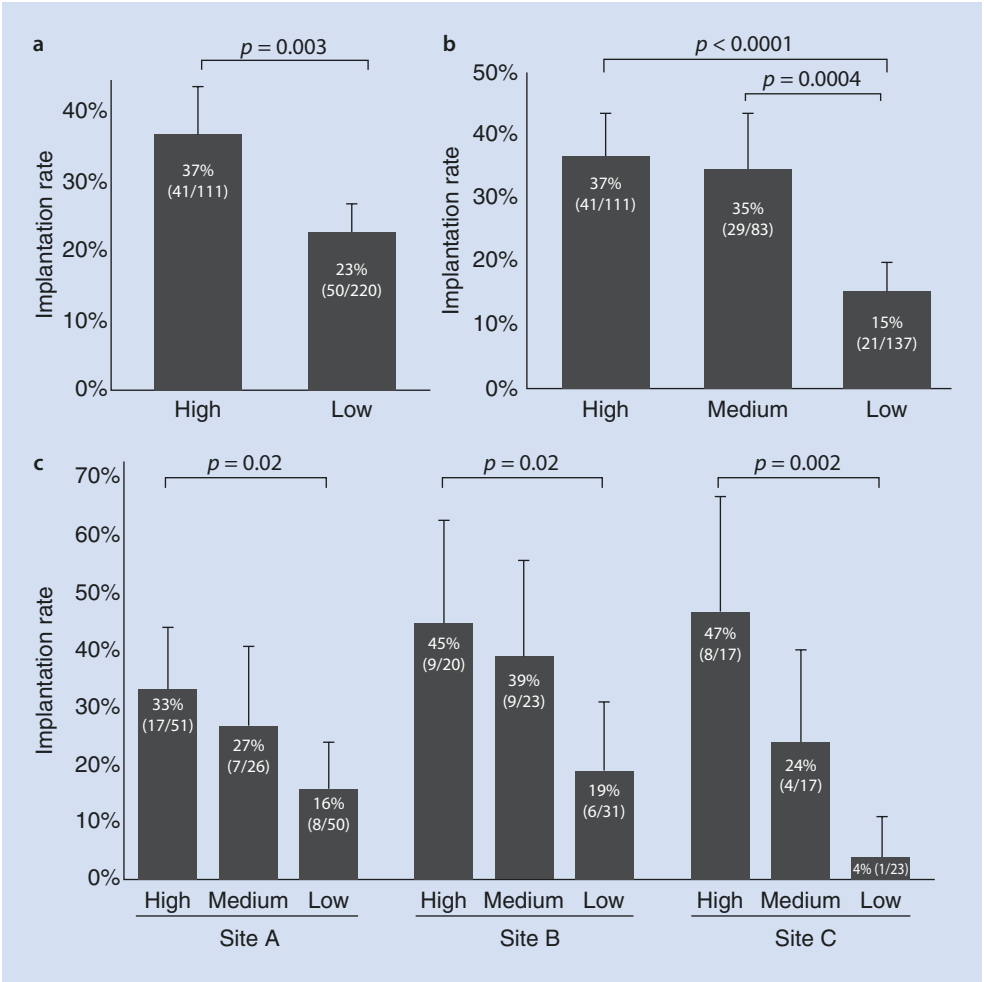

Fig. 42.6 The Eeva Test results are correlated with implantation. **a** Implantation rates for Eeva two-category High versus Low scored embryos. The difference in implantation rates between Eeva High and Eeva Low embryos is statistically significant: $P = 0.003$. **b** Implantation rates for Eeva three-category High, Medium, and Low scored embryos. Implantation rates between High versus Low and Medium versus Low were significantly different ($P < 0.0001$ and $P = 0.0004$, respectively). **c** Implantation rates for embryos with Eeva High, Medium, and Low scores from three clinical sites with at least 50 embryos of known implantation data per site. For all three sites, the difference in implantation rates between Eeva High and Low embryos is statistically significant (chi-squared test): $P = 0.02$ (site A); $P = 0.02$ (site B); $P = 0.002$ (site C). Error bars represent 95% upper confidence limit. (Reproduced with permission from VerMilyea et al. [59])

least one Eeva High embryo had significantly higher implantation rates than patients receiving only Eeva Low embryos (36.8% vs. 20.6%, Fig. 42.7c). Eeva High embryos compared with Low embryos also had significantly higher implantation rates (44.7% vs. 20.5%, Fig. 42.7d). Among morphologically good or top embryos, Eeva High embryos were also more likely to implant than Eeva Low embryos (Fig. 42.7e–f). These results demonstrated the clinical impact of the Eeva Test in patients receiving Day 3 embryo transfers, adding further evidence that the Eeva Test results add valuable information beyond traditional morphology.

42.8 Conclusion and Future Work

The Eeva Test is the first time-lapse-based clinical test for embryologists that has been cleared by the US Food and Drug Administration to aid in embryo selection. The Eeva Test has been validated in a series of prospective, multicenter studies and shown to add value to embryologists' morphological evaluations by improving embryo assessment and reducing variability among embryologists. It combines both robust, predictive markers of embryo development along with a novel automated detection assay to rapidly obtain quantitative measurements of early embryo development markers that have been proven to be of value in determining the best embryo in a cohort of multiple embryos. The Eeva Test meets several important prerequisites for implementation in clinical practice: it is scientifically and clinically validated, it considers a practical intended use model, and it has demonstrated clinical utility compared to the standard of care.

As the Eeva Test continues to be developed in the lab, new markers of embryo viability and/or implantation potential can be unearthed. Additionally, as more labs routinely grow embryos to the blastocyst stage, significantly more frames of videos may be assessed to learn more about embryo develop-

ment. Invasive tests of embryo chromosomal abnormality, for instance, PGT, continue to be applied to more embryos around the world, which supplies further outcome data to aid in ongoing time-lapse research. Ongoing time-lapse research will assess how noninvasive time-lapse imaging may be used in conjunction with invasive tests such as PGT to further improve embryo assessment. We envision that future versions of the Eeva Test will incorporate complementary morphological features and timings, blastocyst stage milestones, and other prospectively validated parameters. We further expect that automated analysis of these more complex morphological and timing features will require increasingly sophisticated approaches and likely a combination of illumination techniques. The introduction of any automated algorithm will be accompanied with the full spectrum of clinical validation steps described here to ensure safety and efficacy for clinical use.

Acknowledgments We gratefully acknowledge the physicians, embryologists, and patients who participated in the development and validation studies of the Eeva Test. We also thank the clinical trial experts, biology scientists, and computer vision engineers, for their technical contributions and insightful discussions.

Review Questions

1. What are the limitations of traditional embryo assessment methods based on embryo morphology?
2. What are the emerging noninvasive technologies for embryo assessment?
3. What is the information provided by time-lapse imaging?
4. What are the validation steps needed before new technologies are introduced?
5. What types of evidence support the use of the Eeva Test?
6. What are some of the future directions for time-lapse-based embryo assessment tool?

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_43

Learning Objectives

- Different proteomic and metabolomic techniques currently applied in practice
- Proteomic and metabolomic biomarkers for assessing embryo quality
- Predictive model developed based on metabolomic technique for embryo viability
- Secretome/spent culture media as a source for embryo quality assessment
- Oocyte and embryo selection using the omics platform

43.1 Introduction

Embryo grading and selection are the most essential steps involved in assisted reproductive technology (ART) prior to embryo transfer (ET). Unfortunately, not all ETs will result in successful implantation or establish a pregnancy as ~70% of embryos transferred will fail to implant and the pregnancy rate for each ET cycle is only 35.5% [1, 2]. The development of advanced embryo hatching techniques such as laser-assisted hatching (LAH) has been able to increase clinical pregnancy and embryo implantation rates, but has failed to decrease miscarriage and stillbirth rates [3]. Therefore, successful ET and implantation depend not only on factors such as ET technique and endometrial receptivity but also on the quality of embryo used in the ET procedure. In IVF practice, multiple ETs are performed in a single cycle to increase pregnancy rates. However, multiple pregnancy due to ART is considered as a significant health issue for pregnant women that could result in preeclampsia, heart failure, and pulmonary edema [4], while in infants it is associated with the risk of premature birth and physical disability [5]. Therefore, single embryo transfer (SET) is advised to minimize the risk of multiple pregnancies to avoid the associated health complications and is achieved by selection of high-quality embryos with high implantation potential [6].

In general, the conventional technique for grading and selection of viable embryos relies on microscopic evaluation and real-time morphological assessment of embryos [7]. This simple approach mainly determines cleavage and blastocyst formation in a subjective manner, which is inadequate for the prediction of embryo quality. Poor understanding of the molecular biology and processes involved in embryo development is among the limitations in distinguishing viable embryos [8]. Even though the traditional means of morphological assessment of embryo quality is inexpensive and used extensively in clinical practice, its prediction power is moderate for embryo implantation with low inter- and intra-observer variations [9]. The prolonged or extended in vitro culture of embryos also has increased risk of epigenetic alterations [10, 11]. Hence, non-morphological parameters have to be accounted for as well during the selection of embryos that are of superior quality. Techniques such as fluorescent in situ hybridization (FISH) [12, 13], comparative genetic hybridization (CGH), and single nucleotide polymorphism (SNP) arrays [14, 15] have been used successfully for preimplantation genetic diagnosis (PGD) and preimplantation genetic screening (PGS) to assess the nuclear quality of the embryo. However, analysis of genetic material using these techniques would mean that the embryos are subjected to invasive biopsy methods. As such, the use of noninvasive techniques for identification of biomarkers in assessing embryo quality could potentially overcome the abovementioned hurdles to improve ART outcomes.

The high-throughput platforms proteomics and metabolomics are two promising noninvasive techniques for studying biomarkers at a molecular level for selection of high-quality embryos. In-depth analysis of proteins and their post-translational modifications (PTMs), as well as metabolites secreted by embryo into the culture media, provides valuable information about key biomolecules that could help differentiate normal embryos from abnormal ones (Fig. 43.1).

43.2 Proteomics and Embryo

Proteomics is the quantitative and qualitative study of the cell or tissue proteome. New-generation technologies have enabled the identification of thousands of proteins in a short period of time using shotgun or bottom-up proteomic approaches. In the field of ART, proteomic tools can be used efficiently either for prognosis or diagnosis, using potential protein biomarkers to improve pregnancy rates. Proteomics is heavily dependent on bioinformatics tools to simplify the complicated raw data. Innovative global proteomic approaches are able to identify the complete protein profiles of the embryonic secretome at different developmental stages of the embryo. Apart from this, additional information about PTMs and interactions between proteins could explain the complex biological and molecular pathways regulating embryo development [16].

Numerous studies have reported the involvement of proteins during different stages of oogenesis, embryo implantation, and pregnancy maintenance using modern proteomic techniques such as MALDI-TOF (matrix-assisted laser desorption/ionization time-of-flight) and SELDI-TOF (surface-enhanced laser desorption/ionization time-of-flight) that combine the precision of mass spectrometry (MS) with high-throughput protein microarrays [17, 18]. As the expression of these proteins differs from normal to abnormal cells and even between the same cells at different time periods based on their function, protein profiling would help in detecting malfunctioning embryonic proteins. Also, the expressions of specific protein are altered in endometriosis, polycystic ovary syndrome (PCOS), and preeclampsia, which can affect oocyte maturation and embryo implantation [19–22].

Therefore, proteomic approaches are widely recommended for the identification of embryonic protein biomarkers, which can be used as noninvasive techniques to access embryo quality. This will aid in single embryo selection during assisted reproductive techniques to decrease unwanted multiple gestation as well as failed ART procedures.

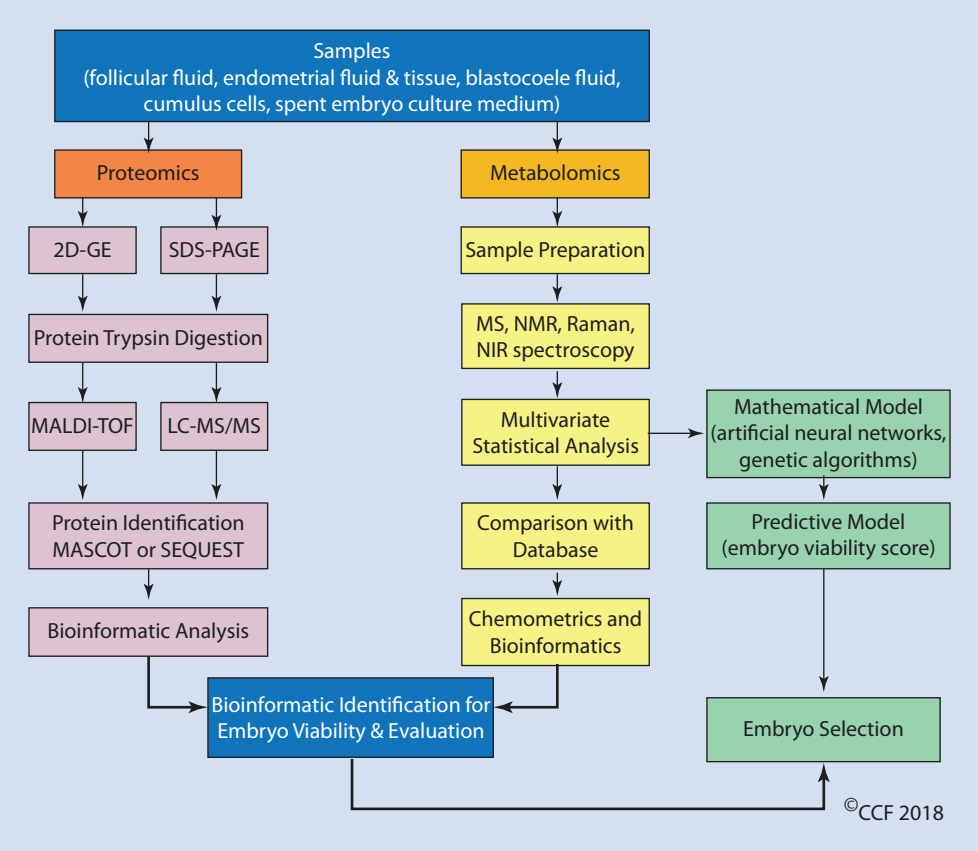

Fig. 43.1 Proteomic and metabolomic pipeline for embryo evaluation and selection

43.3 Different Proteomic Techniques

Basically, proteomic techniques are categorized into separation and identification techniques. Their usage differs between laboratories based on experimental requirements. Current proteomic approaches are aimed at protein profiling, differential expression of proteins, localization and identification of PTMs, analysis of protein-protein interactions, and protein involvement in regulating biological and molecular pathways. The extracted proteins are initially either subjected to 1D or 2D electrophoresis followed by MS to analyze the proteome. Furthermore, these identified proteins are validated or conformed by western blotting (Fig. 43.1).

43.3.1 Two-Dimensional (2D) Gel Electrophoresis

2D-elecrophoresis is the most widely used technique in proteomic research for resolving proteins. Proteins are separated according to their isoelectric focusing (IEF) property and molecular weight (MW) on SDS-PAGE. Proteins resolved on the gel are visualized by staining the proteins and then quantified based on the intensity of the spots on the gel. A modified version of the 2D-gel electrophoresis known as difference gel electrophoresis (DIGE) is used to identify differentially expressed proteins (DEPs). Two samples (control and test) are labeled separately with fluorescent cyanine (Cy) dyes (Cy3 and Cy5) and electrophoresed together on the same 2D-gel. The fluorescent signals generated by the same protein (with identical IEF and MW) present in two different samples are analyzed using the image analysis software program for relative quantification of the DEPs. DIGE is a high-sensitive technique and can even detect proteins with a 10% difference in their expression [23].

43.3.2 Mass Spectrometry

Mass spectrometry (MS) is an important and highly reliable high-throughput technology in the field of proteomic research that is utilized to identify the proteins and polypeptides based on their ion mass/charge ratio (m/z). Mass spectrometry can analyze thousands of peptides and proteins in an unbiased, systematic manner [24]. Tandem MS (MS/MS) further provides information about the specific ions. MS-based proteomics is used for protein identification, protein sequencing, identification of PTMs, and characterization of multi-protein complexes. Prior to injecting the sample into the MS instrument, they are subject to either gel-based or gel-free proteomic approaches to separate the proteins. Gel-based techniques include separation of proteins using 1D electrophoresis, then each lane of gel is excised into small parts. The proteins present in the gel are subjected to "in-gel" proteolytic digestion with trypsin. Furthermore, these proteins are eluted from the gel and analyzed using MS [23].

In the gel-free approach, liquid chromatography (LC) or gas chromatography (GC) is applied for the separation of polypeptides. MS technology can measure the mass of large intact proteins (>100 kDa) and small peptides obtained after proteolytic digestion. Incorporation of such advanced analytical separation techniques (LC, GC, high-performance liquid chromatography (HPLC), and capillary electrophoresis) reduces the complexity of the protein samples analyzed in MS.

43.3.3 Bioinformatics Analysis of MS Data

The molecular masses of peptides obtained from MS is compared with previously sequenced proteins, expressed sequence tags (EST), and DNA sequences available in a global database. Protein analysis software applications such as Mascot, SEQUEST, and X! Tandem are utilized to determine the spectral counts, whereby each program works on specific algorithms to generate a list of proteins. Gene names corresponding to the identified proteins are provided for functional annotations, while gene prediction programs are used to identify the proteins unavailable in the database based on their functional group [25]. The next step for the identified list of proteins is gene ontology (GO) analysis using databases such as GO Term Finder and GO Term Mapper, which provide information about the proteins based on their function, localization, structure, and biological function in cellular pathways. The genes/proteins are basically classified into cellular components, biological processes, and molecular functions. Interaction network and pathway analysis for the group of proteins are performed using proprietary software packages such as Ingenuity Pathway Analysis (IPA) and Metacore™ to identify the pathways, interactions, and cellular distribution of the proteins. An online bioinformatics tool, Search Tool for the Retrieval of Interacting Genes/Proteins (STRING), displays the functional link in protein-protein interactions [26].

43.4 Proteome of Follicular Fluid

Proteome reflects both internal and external environmental status. Follicular fluid (FF) provides the microenvironment for the development of oocytes. It determines the quality of the oocyte and also the fertilization potential with spermatozoa and embryo development [27]. FF is an easily available, noninvasive biological material that is highly suitable for proteomic studies. In general, during ovum pick up or retrieval, FF is also aspirated together with the oocytes. As it is enriched with proteins, FF serves as good medium for identification of potential biomarkers to assess oocyte quality and ART outcome.

Proteomic profiling of FF began 20 years ago, when 2D-gel electrophoresis was used to define the proteins present in the FF [28]. Preliminary FF proteomics suggested that follicular maturation is an inflammatory process that is regulated by various acute phase proteins and antioxidant proteins (such as catalase, superoxidase, and HSP27) [29]. Furthermore, Twigt et al. identified 246 proteins in FF, of which the majority were associated with coagulation and the inflammatory reaction [30]. Comprehensive data mining and bioinformatics analysis of 617 unique FF proteins revealed that metalloproteinases, thrombin, and vitamin-D receptor/retinoid-X-receptor-alpha can be used as biomarkers for assessing ovarian health and oocyte quality [2].

During oocyte maturation, many of the synthesized proteins are stored and become active after fertilization. After ovarian hyperstimulation, 43 unique proteins were identified in FF responsible for inflammation and regulation of acute-phase, complement and coagulation, response to wounding, protein-lipid complex/lipid metabolism and transport, and cytoskeleton organization. Core protein alpha-1-antitrypsin was differentially expressed in the FF and sera of younger and older women [31]. Similarly, the differential expression of transferrin, complement component C3, haptoglobin, and alpha-1-antitrypsin were able to differentiate the women subjected to controlled ovarian hyperstimulation from natural cycles [32]. A panel of 11 potential FF protein biomarkers (haptoglobin alpha, mitochondrial integrity genome (ATPase), apolipoprotein H, dihydrolipoyl dehydrogenase, lysozyme C, fibrinogen alpha-chain, immunoglobulin heavy chain V-III (increased), antithrombin, vitamin D-binding protein, and complement 3) were used to differentiate the successful and unsuccessful IVF outcomes [33].

43.5 Protein Biomarkers and Embryo Quality

Embryonic regulatory proteins play a vital role beginning from fertilization to embryo implantation. Differential protein expression was observed between the different stages of blastocyst development. Proteins involved in the apoptotic and signal inhibition mechanism were prominent in blastocysts. Ubiquitin is considered as a potential biomarker for monitoring blastocyst development [34, 35]. Similarly, Tedeschi et al. reported that DEPs involved in the ubiquitin system (LAMC1, EEF1A2, RANGAP1, UCHL1, BEND4, PCGF1, UBQLN2, UBC, and PSMD4) that are present in the blastocoel fluid determines the quality of the developing blastocyst [36]. Other proteins such as GAPDH and H2A present in the blastocelic fluid were also associated with embryo implantation [37].

43.6 Secretome Proteomics and Embryo Quality

Embryo-secreted proteins in in vitro culture medium are a good source for noninvasive assessment of their quality. Cortezzi et al. analyzed proteins in the spent culture media and proposed the Jumonji (JARID2) protein as a positive

biomarker for embryo implantation, whereas TSGA10 could serve as a negative biomarker of embryo implantation [38]. During adverse conditions, overexpression of lipocalin-1, a stress protein, leads to the failure of embryo implantation [39]. APOA1 in the spent culture media is associated with better morphology of the blastocysts and embryo implantation [40, 41]. Presence of the human chorionic gonadotrophin (HCGh) isoform in the spent culture media serves as a negative biomarker for embryo development [42].

43.7 Endometrium Proteomics

Besides the selection of high-quality embryo, a well-thickened endometrium is another factor that determines implantation and subsequently the establishment of pregnancy. Protein-protein interactions between the embryo and endometrium also have an impact on embryo development and implantation. In-depth proteomic knowledge about the endometrium and its secretions will help decipher the role of the vital proteins involved in endometrial receptivity toward embryo implantation [43]. Inflammation of the endometrium is associated with fertility-related problems. Reception of embryo by the endometrium is essential for implantation and development of the embryo. In ART, unsuccessful pregnancy is mainly due to poor endometrial receptivity even though the superior-quality embryo is involved in ETs. In general, most of the endometrial proteins are differentially expressed during the proliferative and secretory phases [44–46]. Glutamate NMDA receptor subunit zeta 1 precursor and FRAT1 are two examples of such DEPs [44].

Differential expression of proteins in the endometrial secretome affects the endometrial receptivity of fertile and infertile women [47]. High-throughput screening of proteins in receptive versus non-receptive endometrium identified annexin A2 and stathmin as potential biomarkers of endometrial receptivity [19]. In patients undergoing IVF cycles with administration of progesterone, the progesterone receptor membrane component 1 (PGRMC1) and annexin A6 (ANXA6) proteins are involved in acquiring endometrial receptivity [20], whereas the ACO2, CDC5L, GNAS, ARF1, ANPEP, SERPIND1, and SEC23B proteins were found to be differentially expressed in GnRH antagonist-based ovarian stimulation protocols [48].

43.8 Cumulus Cell Proteomics

The oocyte is surrounded by layers of cumulus cells (CCs) and its maturation is dependent on communication with the CCs. Oocyte grading and its fertilization capacity is assessed by the CCs morphology [49]. Human CCs serve as biomarkers for embryo and pregnancy outcomes [50]. However, studies on the proteomic profiling of CCs are very limited. Hamamah et al. demonstrated the difference in the protein expression profiles of human CCs with different ovarian stimulation protocols. A correlation between the protein profile of CCs and the maturation and fecundity of the oocytes was established [51]. In patients undergoing ICSI, 72 CC proteins were differentially expressed in pregnant and non-pregnant women. Most of these proteins were binding proteins and enzymes. CCs proteomic profiling was able to identify potential biomarkers for blastocyst formation and successful pregnancy [52].

43.9 Metabolomics and Embryo

The profiling or fingerprinting of the end products (metabolite) of metabolism using a nontargeted approach [53] is known as metabolomics. The metabolome refers to the complete set of small molecules (<1 kDa) such as hormones, signaling molecules (amino acids, lipids, and nucleotides), and secondary metabolites. The concentration and composition of the metabolome reflect the output (end product) of gene expression at a metabolomics level, i.e., they act as an interface between the cellular genotype and phenotype. In general, the metabolites produced are lesser than the mRNA transcripts and proteins synthesized by the cells. Therefore, metabolomic analysis is comparatively faster than other omics (genomic or proteomic) analysis. Not only does alteration in protein expression affect cellular processes, it also disturbs the dynamic balance of the metabolites leading to a pathophysiological state [18]. Metabolomics deals with a different diverse class of molecules such as amino acids, carbohydrates, fatty acids, and carboxylic acids. Biofluids that perfuse the cells are considered as the ideal suitable material for the analysis of the metabolites [54].

Metabolomics could potentially be more informative than genomics, transcriptomics, or proteomics because the metabolites represent the final products of cellular regulatory processes and may signify the final response of a biological system to genetic factors and/or changes in its environment [55] (Fig. 43.2). Targeted and nontargeted approaches have been used to study the metabolomics. Targeted metabolomics have been practiced for the past 30 years and known metabolites are quantified noninvasively, which mainly include glucose and amino acids. However, the introduction of high-throughput platforms such as Raman spectroscopy and ^{1}H nuclear magnetic resonance (NMR) spectroscopy, near infrared (NIR) spectroscopy, electrospray ionization mass spectrometry (ESI-MS) [56], and direct injection mass spectrometry (DI-MS) [57] provided complete profiles of the metabolites with minimal amount of sample.

Metabolomics has been previously used to demonstrate metabolites in a cellular system under a given set of physiological conditions and deal with a diverse class of molecules with different properties. Nowadays, it is used to determine the growth of embryo and a favorable environment under in vitro conditions. It also assesses the connections between substrates and pathways, as well as interactions between metabolic reactions within the embryo. The main objective of metabolomic profiling is to identify and quantify all the metabolites in a biological fluid (FF, endometrial secretion,

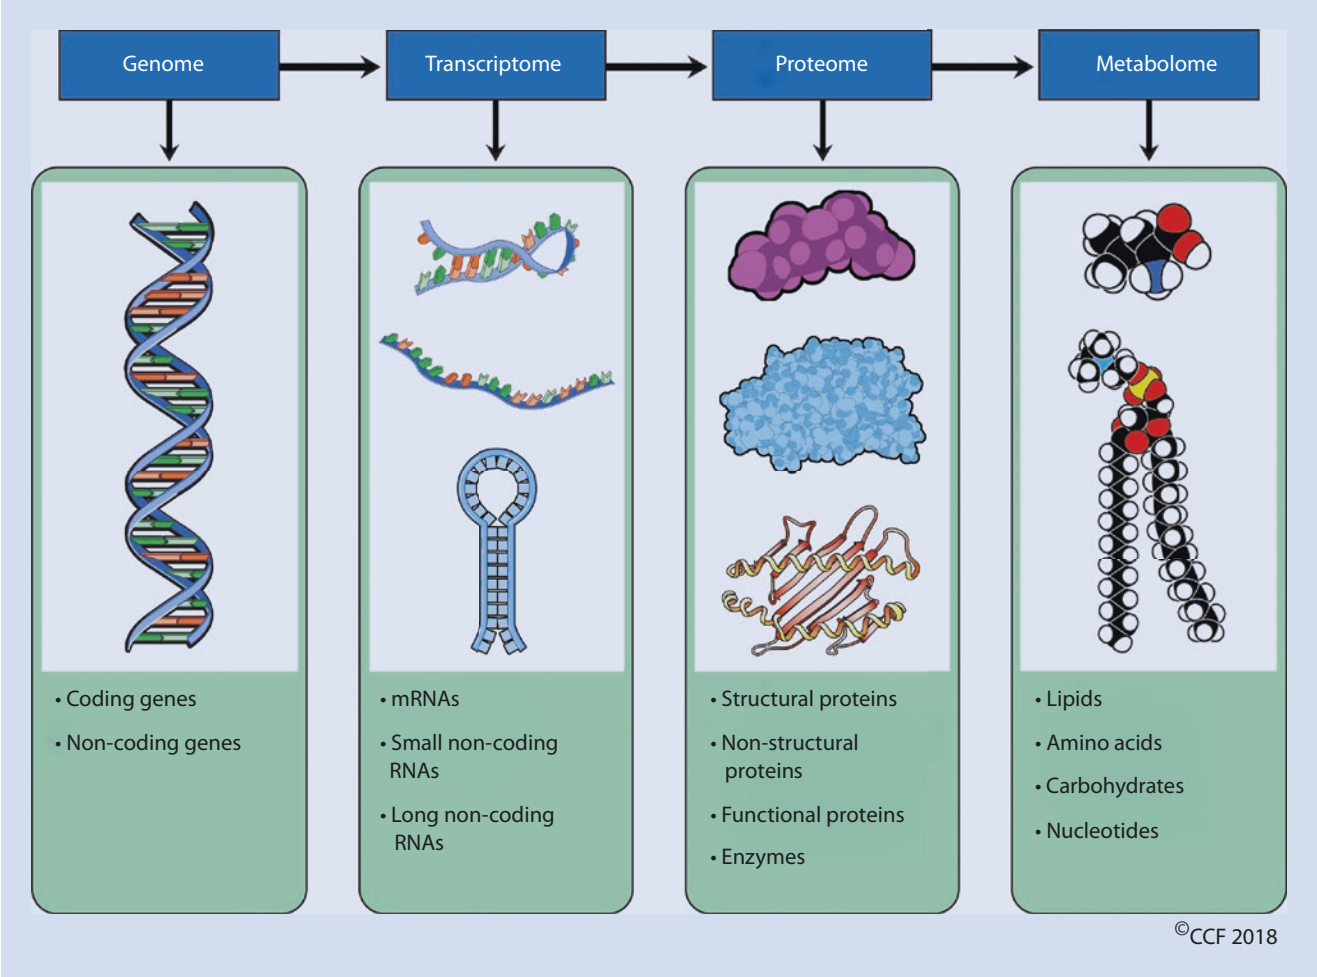

Fig. 43.2 Interaction of the genome, transcriptome, proteome, and metabolome with the environment manifests as a biological phenotype. Metabolites are thus the final product of interactions between the gene and the environment

and spent embryo culture medium). Metabolites are measured in embryo culture medium via noninvasive methods to avoid damage to the developing embryo. Even though metabolomic profiling does not correlate with the fertility outcome, it provides complete information and metabolite composition in the developing oocytes and embryos [58]. This has potential implications in assessing the quality of the embryo.

43

43.9.1 Commonly Used Metabolomics Techniques

New techniques were applied to study the complete array of small molecules in embryo metabolism [59, 60]. Several platforms such as MALDI, MS-coupled with gas or liquid chromatography (GC or LC), NMR, NIR, or Raman spectroscopy have been used to assess the metabolomic activity of embryos [17, 18, 61]. Prior to the processing of samples for metabolomic studies, metabolic activity in biofluids is halted by storing the samples at −80 °C or by snap freezing in liquid nitrogen. The information generated through these high-throughput techniques are complex and require powerful statistical and bioinformatics tools for analysis and interpretation.

43.9.2 GC-MS and HPLC Coupled with MS

MS is a powerful analytical technique for rapid and quick quantification of metabolites with high sensitivity in samples. MS-based metabolomic analysis is well-suited for samples with a complex mixture of compounds and even to detect low-abundance metabolites [62]. MS alone cannot resolve all the compounds; it requires comprehensive sample preparation steps. When combined with advanced GC or HPLC separation techniques, the analytes are detected more efficiently by the instruments used [63]. The abundance and expression of the metabolites are quantified by spectral deconvolution. Capillary electrophoresis MS is applicable to samples with very low volumes to analyze both polar and thermolabile compounds. However, GC-MS platform is preferred due to the poor reproducibility of capillary electrophoresis MS [64].

43.9.3 NMR Spectroscopy

Nicholson et al. used the NMR technique for the very first time to profile the metabolome in biofluids [53, 65]. Later, the technique was widely used to profile the metabolome of different biological samples. The NMR technique can analyze the metabolites in both solid and fluid samples directly without sample processing. However, this technique requires larger volumes of samples for analysis and is less sensitive than MS particularly to low-abundance metabolites. In the field of ART, high-resolution nuclear magnetic resonance (^{1}H-NMR) spectroscopy has been successfully employed to identify specific metabolic changes in follicular fluid and spent embryo culture medium [66–68]. Apart from the complete profiling, NMR is able to detect isotopes such as ^{13}C, ^{31}P, and ^{15}N [69]. Therefore, metabolomics can be used in the future to decipher the molecular pathways regulating embryo development.

43.9.4 Raman and Near Infrared Spectroscopy (NIR)

There are noninvasive techniques with a rapid turnaround time (<1 min/sample) that do not require any preparatory step or reagents for sample analysis. They are based on the principle that chemical bonds absorb light energy when samples are subjected to light or electromagnetic radiation. This results in the stretching of the bonds, which is compared with the functional groups or single bonds of the molecules to identify the unknown metabolites. Raman spectroscopy measures the vibration of bonds within the functional groups present within the sample [70], whereas NIR spectroscopy measures the intensity of overtones and combination vibrations of the bonds [61]. These two spectroscopy techniques are frequently used in several metabolomic studies, including assessing the metabolomic profile of human embryo spent culture media [60, 71–73]. Viability index for the embryos has been developed using a mathematical model-based algorithm in association with the metabolomic profile [60].

43.9.5 The ViaMetrics-E™ Procedure

ViaMetrics-E™ is a highly sensitive and rapid method performed on-site to assess embryo quality based on the metabolomic profile of the spent culture medium. Initially, morphologically selected embryos from the same patient are cultured individually. A small volume of spent culture medium is collected and loaded into sample cells using a gel loading pipette. The sample cell is then inserted into the ViaMetrics™ instrument, which scans the same sample thrice. It then measures the metabolites present in the culture medium using NIR spectroscopy. Depending on the composition of the metabolites in the spent culture medium, the viability score of the embryo is assessed. Embryos with higher viability scores have higher reproductive potential [74]. Further, the embryos are ranked based on the viability score obtained from a single patient and are selected for the single embryo transfer (SET) technique [58].

This procedure can provide the features of the embryo, but cannot improve the quality of poorly graded embryos. It is a personalized test and the quality of embryos can only be compared among the patients. Due to the inconsistency and inaccuracy in the measurement, this technique is not used in the clinical laboratory.

43.9.6 Bioinformatics Analysis of Metabolomic Data

Complexity in the bioinformatics analysis of metabolomic data depends on the metabolomics approach used to identify metabolites. Analysis of targeted metabolic profiling data is simpler than the data generated from the nontargeted metabolomics approach, because of targeting the specific compounds in the sample. Data normalization is done prior to the bioinformatics analysis of the metabolomic data to overcome the variation in the expression of the metabolites already present in the culture media or spent media. In silico analysis provides the functional role of all the metabolites and their involvement in different molecular pathways [75].

Efficacy of the metabolomics technique to assess embryo viability is verified based on predictive models. Predictive models are developed by applying the mathematical background (decision trees, artificial neural networks, genetic algorithms, etc.) to the metabolomics data. The power of the model is determined by receiver operating characteristics (ROC) curves analysis, to evaluate the sensitivity and specificity of the predictive model [76] (Fig. 43.1).

43.10 Metabolome of Follicular Fluid

FF is considered as a potential source of metabolic biomarkers in determining oocyte quality, as they reflect the physiological status of the oocyte. Metabolomics profiling of FF provides a snapshot of all the metabolites based on the sensitivity of the technique. Piñero-Sagredo et al. (2010) reported 42 different metabolites in the FF. Metabolites such as glucose, lactate, acetate, acetoacetate, pyruvate, and beta-hydroxybutyrate present in the FF were associated with anaerobic glycolytic metabolism in follicles and fatty acids synthesis having influence on the fertilization process [77]. The composition of palmitic acid, arachidonic acid, and stearic acid was significantly different between the cleaved and non-cleaved embryos among the 21 identified fatty acids in FF [68]. Similarly, other metabolites such as lactate, phosphocholine, glucose, and high-density lipoproteins (HDL) have been demonstrated as potential biomarkers to determine oocyte quality for development into a two-cell embryo [71].

In repeated IVF failure patients (RIF), increased levels of amino acids and decreased levels of dicarboxylic acids, cholesterol, and organic acids can serve as biomarkers for predicting the fertilization outcome in RIF conditions [78].

43.11 Metabolic Biomarkers of Embryo Culture Media

Metabolic turnover is crucial for a preimplanting embryo to grow and achieve successful pregnancy. Accordingly, the nutrients and metabolites secreted by the embryos in the culture media have been studied as potential predictors of embryo quality using noninvasive tests. Raman spectroscopy has detected an increased amount of –SH group metabolites and decreased amount of –CH and –NH metabolites in the culture of embryos with high implantation potential [60]. High levels of glutamate were present in the secretome of the embryos resulting in positive pregnancy [79]. Similarly, in another study, NMR-based metabolic profile of spent embryo culture medium showed formate:glycine and citrate:alanine as biochemical markers for the selection of viable embryos [72]. In addition, alanine and leucine levels can be used as noninvasive markers of embryo quality in SET technique [80].

Bellver et al. (2015) reported different metabolic profiles in obese women and 551 metabolites differentially regulated in the culture medium of day 3 embryos. Saturated fatty acid composition was low in the secretome, affecting embryo quality [81]. A metabolic profiling approach was also used to detect aneuploidy in IVF embryos. Differentially expressed metabolites androsterone sulfate and caproate and the isoleucine spectral signals can serve as potential noninvasive biomarkers to detect Down's syndrome prior to embryo transfer [82].

43.12 Metabolomics of Endometrial/ Blastocoele Fluids

It is very important to understand the dynamic cellular processes and metabolism of the embryo and endometrial receptivity, as they are directly associated with embryo implantation or pregnancy failure. Metabolites such as ATP, glucose-6-phosphate, lactate, 6-phosphogluconic acid, glutamic acid, and α-ketoglutarate present in the blastocoele fluid are vital for embryo development [83]. MS-based analysis can also detect most of the metabolites of potential interest responsible for assessing embryo quality in the blastocyst [84].

Metabolites, especially the lipid composition of endometrium, decide endometrial receptivity toward embryo implantation. Lipidome analysis describes prostaglandins E_2 and $F_{2\alpha}$, responsible for blastocyst development during implantation, as potential biomarkers to predict endometrial receptivity [85].

43.13 Metabolic Assessment of Oocyte and Embryo Quality

Oocyte and embryo quality assessment is one of the major objectives of embryologists to increase pregnancy rates during human IVF. The assessment must be rapid and reliable and evaluated based on the embryo viability score. In general, embryos with high viability score are preferred in the ET technique. Metabolic profiles predict embryo quality and viability at the early stages of development (day 3 and day 5 embryos) [86]. Advanced spectroscopy techniques such as Raman determine embryo viability with a sensitivity of 86% and a specificity of 76.5%, whereas NIR has a sensitivity of 75% and a specificity of 83.3% [60]. Nonetheless, these techniques are unable to prove their advantage over conventional morphology grading of embryo in terms of pregnancy and live birth rates [87, 88]. It was the same with embryos selected using NMR-derived metabolomics, as these did not exert significant differences on pregnancy outcomes compared to embryo morphology assessment [67, 89]. Currently, there is no evidence that metabolite profiling can improve fertility outcomes. However, it provides the nutritional and developmental status of the oocyte and embryo. In the future, it has a pronounced potential diagnostic value to identify the etiology for pregnancy failure.

43.14 Embryo Selection

Appropriate selection of good-quality embryos is compulsory to achieve successful IVF results. In routine IVF practice, to improve the success rates, multiple ETs were done following the superovulation protocol. This may result in multiple gestations complicating the pregnancy, including preterm delivery, low birth weight, and dramatic increase in the relative risk for cerebral palsy [4, 5]. Therefore, the SET technique has been recommended to minimize the risk of multiple gestations [58, 74].

Since a decade ago, morphological assessment of embryos was practiced to select the superior quality embryo. However, it is highly subjective and fails to identify genetic or epigenetic defects [61]. However, metabolomics has a great potential as a noninvasive method to replace the existing techniques for embryo selection for SET. To be more effective, the technique has to measure embryo viability with high accuracy but without causing any damage to the embryo.

43.15 Proteomic and Metabolomic Biomarkers

In the past 20 years, various molecular biomarkers have been proposed for embryo evaluation in the field of ART. Sophisticated metabolomic and proteomic techniques proved to be promising platforms for discovering these biomarkers to assess embryo quality. Bioinformatics analysis of

Table 43.1 Recent proteomic studies related to embryo viability assessment

Study	Technique used	Sample	Key findings
Oh et al. [90]	TMT isobaric labeling and LC-MS	FF from POR patients	Inflammatory regulating proteins are differently expressed. PZP, RENI, SRPX, and SHBG are validated as biomarkers of POR
Bianchi et al. [2]	Computational and manual data mining	FF	Metalloproteinases, thrombin, and vitamin-D receptor/retinoid-X-receptor-alpha are suggested biomarkers of oocyte quality
Tedeschi et al. [36]	nLC-ESI- MS/MS	Blastocoel fluid from women aged <37 years and ≥37 years	DEP related to ubiquitin system affects blastocyst survival and implantation
Dominguez et al. [91]	Affymetrix Procarta immunoassay	Spent media of implanted and non-implanted embryos	IL-6 was overexpressed in the culture medium of implanted embryo
Wu et al. [32]	MALDI-TOF-MS	FF from infertile women undergoing COH and natural ovulatory cycles	DEPs were involved in the regulation of immune and inflammatory responses. Transferrin, complement component C3 (C3), haptoglobin, and alpha-1-antitrypsin (AAT) are validated biomarkers
Regiani et al. [92]	Tandem MS	FF from endometriosis and endometrioma patients	Coagulation process and sterol metabolism pathway were enriched in endometriosis, whereas response to reactive oxygen species, oxygen transport, and hemoglobin complex were enriched in endometrioma
Garrido-Gomez et al. [20]	DIGE, MALDI-MS	Endometrial tissue from receptive and non-receptive patients	Significant difference was observed in carbohydrate biosynthetic process and "nuclear mRNA splicing" pathways. ANXA6 and PGRMC1 are predictive biomarkers
Bianchi et al. [31]	2D-gel electrophoresis and MALDI-TOF/TOF	FF from COH women	Reported alpha-1-antitrypsin as biomarker for COH under IVF procedure
Nyalwidhe et al. [41]	LC-ESI-MS-MS	Culture medium of 2–3-day-old embryos	Apolipoprotein A-1 predicts the embryos with high and low implantation rates

2D two-dimensional, *COH* controlled ovarian hyperstimulation, *DEP* differentially expressed protein, *DIGE* difference gel electrophoresis, *ESI* electron spray ionization, *FF* follicular fluid, *LC* liquid chromatography, *MALDI* matrix-assisted laser desorption/ionization, *MS* mass spectrometry, *POR* poor ovarian response, *TMT* tandem mass tag, *TOF* time-of-flight

the massive proteomic and metabolomic data using advanced software tools provides first-hand functional information about the proteins and metabolites regulating biological pathways related to oocyte and embryo development. Some of the potential biomarkers used for the prediction of embryo quality are listed in Tables 43.1 and 43.2.

43.16 Future Directions

ART specialists are in great need of an accurate and precise technique to select the highest-quality embryo for ET to increase the success rate of pregnancy. In addition to recent advances in the proteomic (LC-MS/MS, MALDI-TOF) and metabolomic (Raman, ^{1}H NMR, NIR, ESI-MS) techniques, extensive research is required to validate biomolecules in a large population. The clinical acceptability of these techniques depends on increasing the number of available studies and powerful meta-analysis that can recommend the suitability of biomarkers in embryo evaluation/selection.

Another forthcoming area of interest would probably be to reduce multiple ET by promoting SET procedure with the embryo that results in successful pregnancy. This mainly relies on the proteomic and metabolomic techniques for selecting the embryos. Publications on metabolomic and proteomic profiling are growing exponentially, showing a promise for its use in embryo selection techniques. Integrative analysis of data from both the omics may interlink and define the pathways involved during embryo cleavage and implantation. Further automation of these high-throughput techniques with user-friendly software as well as sample handling that allows multiple sample analysis at a single time point can increase the efficiency in embryo selection. Ultimately, it is hoped that patients will benefit from the application of advanced oocyte and embryo selection methods, with better possible ART outcomes.

Table 43.2 Recent metabolomic profiling studies that have an impact on embryo development and assessment

Study	Technology used	Sample	Key pathways and metabolites
Zhang et al. [66]	^{1}H-NMR	Follicular fluid	In PCOS: glycoprotein, acetate, and cholesterol are upregulated, but lactic acid, glutamine, pyruvate, and alanine are downregulated
Wallace et al. [72]	^{1}H-NMR	Spent embryo culture media	Increase in formate to glycine ratio and decrease in citrate to alanine ratio are indicators of positive pregnancy
Xia et al. [78]	GC-MS	Follicular fluid	Increased expression of valine, threonine, isoleucine, cysteine, serine, proline, alanine, phenylalanine, lysine, methionine, and ornithine and decreased expression levels of dicarboxylic acids, cholesterol, and some organic acids were observed in RIF patients
Vilella et al. [85]	LC-MS/MS	Endometrial fluid	Endometrial receptivity markers: PGE_2, and $PGF_{2\alpha}$
Zhao et al. [73]	Raman	Spent embryo culture medium	Sodium pyruvate and phenylalanine are important for embryo development
Wallace et al. [71]	^{1}H-NMR	Follicular fluid	In non-cleaved oocytes, glucose and HDL levels were elevated, whereas lactate, choline, phosphocholine, and glycerophosphocholine were reduced
Sánchez-Ribas et al. [82]	LC/GC-MS and NMR	Spent embryo culture media	Androsterone sulfate and caproate are potential biomarkers of Down's syndrome
Bulletti et al. [83]	HPLC-MS	Blastocoele fluid	ATP, glucose-6-phosphate, lactate, 6-phosphogluconic acid, glutamic acid, and α-ketoglutarate are vital for embryo development

GC gas chromatography, *HDL* high density lipoprotein, *^{1}H-NMR* proton nuclear magnetic resonance spectroscopy, *HPLC* high-performance liquid chromatography, *LC* liquid chromatography, *MS* mass spectrometry, *PCOS* polycystic ovary syndrome, *RIF* repeated IVF failure

43.17 Conclusion

The conventional system of morphological grading and evaluation of embryo requires highly trained and skilled personnel. Proteomics and metabolomics are two complementary omics platforms that may be used for embryo selection in the field of ART. Combining the proteomic and metabolomic profile of the embryo can provide the complete molecular status of the secretome. Moreover, a plausible explanation for altered molecular composition and validation of biomarkers in a large cohort population might further support the acceptance of these new technologies in the clinical setting. Future investigations focusing on the design of new devices by integrating both the omic platforms to assess embryo viability could potentially make a significant contribution toward the ART field. When proven as an efficient technique, the omics may possibly help increase live birth rates using the SET technique, to provide better-quality service for infertile patients.

Review Questions

1. Are the noninvasive techniques used in the assessment of embryo quality beneficial in the IVF clinic?
   - Yes, these noninvasive techniques would help avoid any damage to the embryo during the embryo assessment leading to embryo selection.
2. Why is there a need for molecular biomarkers (metabolomic and proteomic) to assess embryo quality and viability?
   - Molecular biomarkers are able to precisely point out the biological processes and the nutritional status of the embryo. This would help in the selection of a high-quality embryo.
3. Is spent embryo culture medium a good source to assess embryo viability?
   - Yes, because the spent culture medium is the secretome of the embryo. It acts a good source of diagnostic material for embryo evaluation and selection in IVF practice.
4. Could the merging of the two omics (proteomics and metabolomics) platforms lead to better embryo selection?
   - These high-throughput platforms are able to generate enormous amounts of information

which are different for each omic study (proteomic and metabolomic). Combining two data sets will provide the link and connection between both processes and subsequently help in better assessment of embryo quality.

5. What is the impact of metabolomic and proteomic tools on the single embryo transfer technique?

Proteomic and metabolomic profiling will help ensure that the superior-quality single embryo is selected to achieve pregnancy. Single embryo transfer avoids multiple pregnancies, which is considered as a significant health issue in pregnant women.

Amino Acid Turnover as a Biomarker of Embryo Viability

Christine Leary, Danielle G. Smith, Henry J. Leese, and Roger G. Sturmey

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_44

Learning Objectives

- To define the benefits of embryo selection and/or ranking during IVF treatment
- To review how traditional embryo assessment may not be sufficient for efficient embryo selection and what alternative options exist
- To describe how amino acid turnover is related to embryo development and viability
- To review the technological aspects of performing amino acid measurement from spent culture medium
- To present how amino acid profiling may be used as an additional tool for embryo selection

Most of the rise in multiple births observed since the 1980s has been attributed to the increased use of IVF and the practice of replacing more than one embryo into the uterus in order to improve the chances of success. In response to the unacceptably high risks associated with multiple births, several countries have introduced single embryo transfer policies. However, to maintain acceptable pregnancy rates, the pressure to identify the most viable embryo for transfer has intensified.

The most widely used method of embryo selection has been to assign scores on day 2 or day 3 post insemination on the basis of the embryo's cleavage rate and morphological appearance. Studies have shown that correlations exist between these observational cues of embryo quality and their capacity for continued development and subsequent implantation. However, appropriate temporal developmental patterns are critical to predicting embryo viability. For example, Cummins et al. [1] assigned scores based on the ratio between the time at which an embryo was observed at a given stage of development and the expected time taken to reach that particular stage and showed that pregnancy rates were lower for those with above or below average scores. In a powerful study based on observations from single embryo transfer, Giorgetti et al. [2] demonstrated the additional benefit of including a morphology score. Morphological markers linked to implantation include blastomere size and regularity [3] and the presence of fragmentation [2], multinucleation [4], granulation, and zona thickness. Fragmentation is the most commonly reported observation, and >20% fragmentation is regarded by many as biologically deleterious. The caveat is that morphological assessment is highly subjective, and there is evidence that the pattern of fragmentation may be more important than fragmentation per se [5].

Blastocyst formation occurs between day 5 and day 7 and is a critical developmental milestone. Approximately 50% of human zygotes have the potential to reach this stage [6]. Aneuploidy is commonly associated with developmental arrest; hence, the proportion of embryos with chromosomal abnormalities is lower in blastocysts compared to cleavage-stage embryos. The method of grading blastocysts is similar to that of grading cleavage-stage embryos; blastocysts are scored on how similar they are to the *morphological ideal*. This involves grading according to the presence of a cavity, a visible inner cell mass (ICM), regular trophoblast (TE) cells, degree of expansion, and zona thinning. The ICM and TE are graded according to how tightly cells are packed and the number of cells, particularly in the ICM.

Selection of the most viable embryo to transfer and at which stage of development remains one of the most challenging aspects of in vitro practices. There is little consensus regarding the observations to make and how frequently to record them. Many schemes use a combination of criteria, including the addition of pronuclear morphological scores, early cleavage, and more controversially aneuploidy screening, as adjuncts to those used routinely as described in this section.

Attempts to draw conclusions on the effectiveness of current observational embryo grading and selection tools have been hampered by a lack of generic terminology and methodology. There is a clear need for a standard embryo scoring/selection system, and attempts to introduce external quality assessment schemes are currently being piloted in the UK. It is hoped that with the introduction of consistent terminology and reduced operator scoring variability, this will permit large-center studies and allow more definitive correlations to be drawn, leading us closer to defining what indicates a viable embryo.

44.1 Why the Need for Objective Markers of Viability?

Embryo selection is currently based on operator observations of embryo developmental and morphological score on the assumption that these two features are affected by intrinsic factors and as such are a reflection of genetic viability of an embryo. They may also be influenced by extrinsic factors such as the culture environment. For example, Lane et al. [7] showed that media composition can affect cleavage rates, and improvements to embryo culture systems have supported the increased development rate of embryos to the blastocyst stage such that extended culture and blastocyst formation is now frequently used to select competent embryos for transfer.

Blastocyst transfer is not a suitable strategy for all patients as it may result in fewer embryos being available for freezing and an increased risk of canceled cycles. Furthermore, embryos are able to adapt to their environment, and if the in vitro environment is suboptimal, prolonged culture may reduce embryo viability or have other more subtle effects such as an undesired modification of epigenetic changes or metabolic dysregulation, although further rigorous evaluation is required. In other words, there is a need to find the safest and most effective method to help patients achieve a single healthy pregnancy. An accurate system for assessment of embryo viability will enable practitioners to counsel patients on their chances of conception and reduce the numbers of embryos transferred.

44.2 Amino Acid Profiling

The search for biomarkers of embryo viability in spent embryo culture medium has a long history. Potential markers have included the consumption of glucose, lactate, pyruvate, oxygen, and glutamine and the appearance of proteins such as sHLAG and PIF. However, there is increasing evidence to support the proposition that *amino acid profiling* reflects the developmental capacity of early embryos. By measuring a group of 18 compounds, amino acid profiling provides a snapshot of embryo phenotype by virtue of the many roles played by amino acids during embryo development, some of which are considered below. Thus, amino acid profiling differs from conventional metabolic assays, where typically, only one or two metabolites are measured.

Since the first application of amino acid profiling of mouse embryos was published in 1994 by Lamb et al. [8], the technique has been applied to bovine [9–12], porcine [13], and, critically, human embryos [14–16]. Without exception, in those studies in which it was addressed, the research has demonstrated that the amino acid composition of spent culture medium, i.e., amino acid profile (AAP) of *viable* embryos differs from that given by subviable embryos. These studies have used different indicators of embryo quality, from blastocyst formation [14], through molecular scale observations of DNA damage [15], to correlation with clinical pregnancy [16]. Crucially, the link between AAP and viability is independent of embryo morphological grade and is apparent from day 1 to 2 or day 2 to 3 post insemination.

44.3 The Biology of Amino Acids

It is well recognized that amino acids have a variety of roles in the cell in addition to their traditional function as constituents of proteins. Some such roles are listed below with a brief consideration of their contribution in the early embryo.

44.3.1 Protein Synthesis

Protein synthesis is relatively low during the cleavage stages of preimplantation development but increases sharply with blastocyst formation [17, 18]. This is consistent with the observation that the protein content of preimplantation embryos is relatively stable during cleavage before increasing in the blastocyst, with the onset of true growth [19]. This is reflected in the uptake of certain amino acids from within a mixture when provided in culture, as seen in bovine [9], porcine [20], and human [14] embryos.

44.3.2 Energy Sources

Approximately 14% of human energy needs are provided by the oxidation of protein, ultimately provided by the diet, and it is likely that early embryos cultured with a physiological mixture of amino acids will exhibit a similar figure. When cells are provided with an excess of protein or amino acids, then once the requirement for the synthesis of protein and other amino acid-derived products has been met, they will first tend to be oxidized, in preference to carbohydrate and fat, since mammalian cells have no capacity to store amino acids or protein. In most mammalian cells, protein synthesis is one of the two major consumers of energy, the other being the Na+, K+, and ATPase; their contributions to the energy budget is ~25% each, though with considerable variation depending on the cell type and physiological state [21–23].

This issue was addressed for mouse blastocysts by Leese et al. [24], who reported considerable variation in the energy cost of protein synthesis depending on the methodology and assumptions. Despite these caveats, it is most likely that protein synthesis will be a major component of energy homeostasis and, in the context of the present discussion, provide a good marker for the overall nutritional requirements of the early embryo.

44.3.3 Nucleotide Synthesis

Glutamine, aspartic acid, and glycine provide carbon and nitrogen atoms for purine and pyrimidine de novo synthesis—metabolic pathways which are essential to mouse preimplantation development [25]. A key amino acid is thought to be glutamine, which is readily consumed by rapidly dividing cells, and in early embryos [19], in addition to providing purine and pyrimidine nucleotide precursors, it acts as an energy source.

44.3.4 Osmolytes

Notable among amino acids which act as osmolytes during mouse preimplantation development are glycine, betaine, glutamine, and proline [26].

44.3.5 Provision of 1-Carbon Units

Methylation reactions, which are integral to appropriate gene silencing by methylation pathways, require functioning methyl group cycling, in which the amino acid methionine is a key component together with derivatives of the vitamin folic acid.

44.3.6 Signaling Molecule Precursors

In the context of the early embryo, perhaps, the best-characterized example of the function of amino acids as precursors of signal transducers is the formation of nitric oxide from arginine. The role of NO has been the subject of a number of studies in the early embryo. For example, Manser et al. [27] reported data consistent with NO having an obligatory

role in mouse preimplantation development, in terms of Ca^{2+} signaling in mitochondria [28], and Lipari et al. [29] reported an association between human embryo-mediated NO production and subsequent blastocyst formation.

Thus, the biological rationale for the ability of amino acids to act as biomarkers of early embryo viability is compelling. The practicalities of assaying amino acid metabolism by early embryos are now considered.

44.4 How to Measure Amino Acids

44.4.1 Principle of Chromatography/High-Performance Liquid Chromatography

High-performance liquid chromatography (HPLC) is a form of column chromatography, in which compounds of interest are separated according to their chemical and physical properties. A sample containing a mixture of compounds of interest, in the present context, amino acids, is diluted into a liquid carrier, the *mobile phase*, and pumped under high pressure onto a *solid-phase* column. The column impedes the passage of the amino acids as they interact with the packing substrate within the column. By modifying the conditions of the mobile phase, the amino acids are washed off, or *eluted*, from the column and detected by an appropriate system. Each amino acid differs in terms of structure and chemistry and on this basis interacts with the column in a different way such that it is *retained* on the column for a different length of time. Using this concept of *retention time*, each amino acid may be identified as it is eluted sequentially from the column. Each amino acid generates a quantifiable signal, which is directly proportional to the signal given by a standard mixture of amino acids at a known concentration. Using this simple approach, it has been possible to measure changes in the amino acid content of spent embryo culture droplets to a very high degree of sensitivity.

44.4.2 Chemical Properties of Amino Acids

When most of us think of amino acids, we are generally referring to a subset known as the protein amino acids, of which there are 20 naturally occurring L-isomers that are the constituents of proteins. This section will refer to only these naturally occurring amino acids as these are the only relevant subset in the current context. All amino acids share a common structural scaffold, consisting of an amino group, a carboxyl group, and a distinctive side chain denoted as R with each side chain unique to each amino acid. An exception to this general scaffold rule however is proline where the side chain forms a five-membered ring with backbone. Amino acids can be categorized into four main subgroups based on their general chemical nature: weakly acidic, weakly basic, hydrophobic, and polar hydrophilic. These chemical features can be exploited to isolate individual amino acids.

The pI value of most amino acids is approximately six, meaning that at neutral pH, amino acids ionize and are typically zwitterionic. That is, they exhibit both a positive charge on the amine and a negative charge on the carboxylate; however, the pI of the side chains of the amino acids varies, which affects the overall charge of the particle. It is the chemical and structural properties of the side chain that dictate which subgroup an amino acid falls into, affecting charge, reactivity, and hydrogen-bonding capacity of the amino acid. Therefore, changing the pH and ionic strength of the mobile phase can be used to separate amino acids during chromatography, allowing individual amino acids to be isolated. To give one example, under chromatographic conditions of pH 5.9, the solvent, or mobile phase, is positively charged; thus, the first amino acids to elute are *acidic* amino acids: aspartate and glutamate (conjugate bases for aspartic acid and glutamic acid). At this pH, the acidic side chains are deprotonated, meaning they are carrying a negative charge and therefore interact with the positively charged mobile phase rather than the uncharged column substrate and so elute very rapidly. Aspartate has a shorter retention time than glutamate because it has shorter hydrocarbon chain and is therefore slightly less hydrophobic and thus can pass through the column substrate more rapidly than glutamate.

This one example illustrates how on the basis of their chemical and physical properties amino acids may be separated from the mixture present in embryo culture media. It is also important to emphasize that this is an example of *reverse phase* HPLC, distinguished from conventional HPLC because the mobile rather than solid phase in the column is charged (Fig. 44.1). This small distinction is vital as RP-HPLC offers an extra dimension of flexibility with regard to separation parameters since combinations of mobile phases can be run according to the *gradient* method chromatography. Thus, aspartate and glutamate mentioned above can be eluted in a positively charged mobile phase. Conversely, hydrophobic amino acids such as leucine will not elute from a column when the mobile phase is predominantly aqueous and must therefore be eluted in a nonaqueous mobile phase, for example, consisting predominantly of methanol. Gradient HPLC allows the composition of the mobile phase to be changed gradually from a positively charged aqueous buffer, allowing the rapid elution of small acidic amino acids, to a nonaqueous mobile phase, which will enable the elution of hydrophobic amino acids, such as leucine.

44.4.3 Chemical Principles of Amino Acid Derivatization

Amino acids can be detected fluorometrically by derivatizing them with *o*-phthaldialdehyde (OPA). Amino acids need to be derivatized as only a subset is able to detect ultraviolet absorbance (tyrosine, tryptophan at 280 nm). OPA is fluorescent due to the aromatic ring but forms an isoindole upon reaction with amino acids, peptides, and proteins, which can

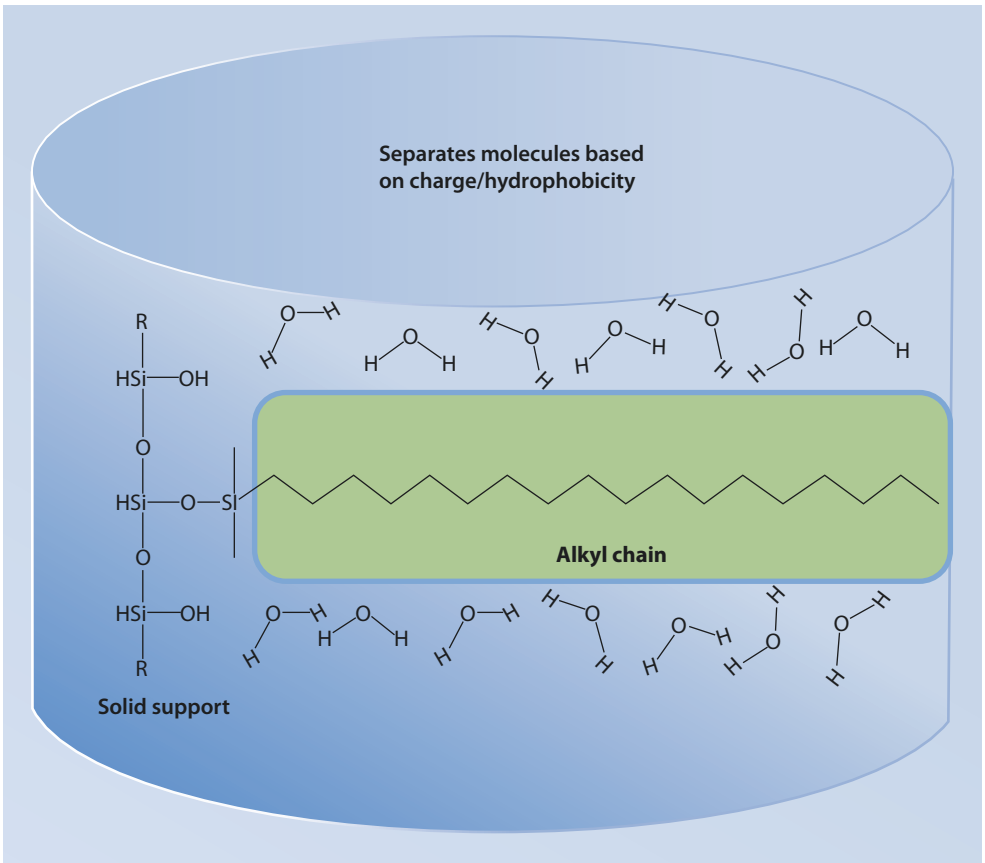

Fig. 44.1 Reverse phase column. The solid support of the column is usually made of chemically inert material of a large pH range, for example, silica. Attached to the inert core are hydrophobic fingers (*green*) made up of alkyl chains. Hydrophilic pockets are formed between the alkyl chains as the column is hydrated with aqueous phase (H_2O) (*blue*). The degree of hydrophilicity of the mobile phase dictates the size of the hydrophilic pockets which in turn affects the ability of the molecules passing through the column to interact with the alkyl chains. These hydrophilic pockets allow charged particles to be retained in the column and separated by manipulating the amount of hydrophilic component in the mobile phase

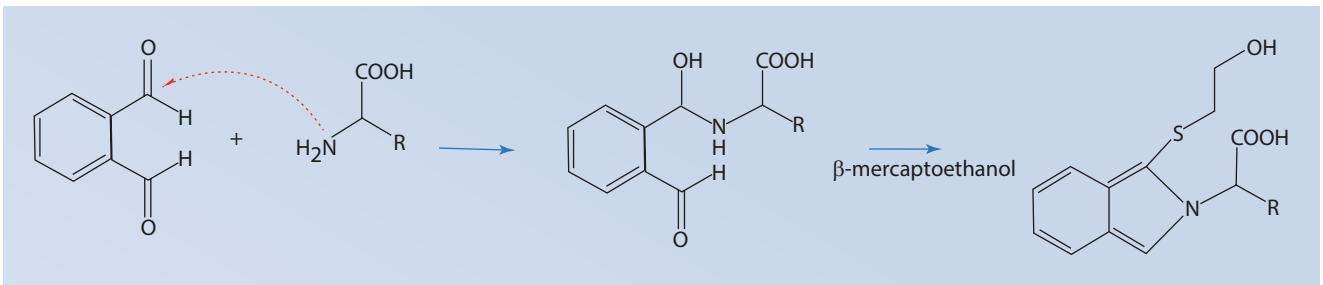

Fig. 44.2 Amino acid derivatization with OPA. The carbonyl of the OPA undergoes nucleophilic attack by the nitrogen of the amine of an amino acid generating intermediate B. In the presence of mercaptoethanol, intermediate B will rapidly convert to the fluorescently detectable isoindole product C

be detected at different wavelengths by exciting at 350 nm and collecting the emission at 430 nm. Derivatization of these moieties with OPA is pH dependent. In order to derivatize amino acids, the pH must be above 9. Under these conditions, OPA reacts with the nitrogen of the backbone amine and in the presence of b-mercaptoethanol forms the isoindole, as shown in Fig. 44.2.

44.4.4 Equipment and Consumables Required

In order to perform HPLC analysis of spent culture medium, an appropriate HPLC system is required. Numerous instrumentation suppliers produce HPLC systems with different options, and most systems are modular. However, regardless of the system used, there are certain features that are important for analysis of amino acids in spent culture medium. The system employed to perform the analysis should have a binary pump system, capable of delivering a changing gradient of elution buffers, and able to pump at a flow rate of up to 2.5 mL min^{-1}. Due to the vast number of samples and controls analyzed, an autosampler, with the capacity to carry out automatic derivatization, is also essential. The autosampler also needs to be temperature controlled and able to maintain the samples at 4 °C to minimize sample degradation during analysis. A column oven is required to ensure that the chemistry on the column is performed at a standard temperature, usually 25 °C. The final component required is the detection system. Since derivatization with OPA yields a fluorescently

labeled amino acid, a fluorescent detector is capable of exciting the eluted samples at around 300 nm and detecting emission at approximately 450 nm.

In addition to the system, selecting an appropriate column is fundamental to efficient separation of amino acids with a mixture. Columns commonly used for this type of separation are silica-based; that is, they are packed with inert silica beads. The mean diameter of the particles used to pack the column is given in the column information. Particle size is important since it affects column separation efficiency; a smaller particle size gives superior separation and smaller interparticle space; that is, the column is *more tightly packed*. However, this will lead to a corresponding increase in the pressure applied to the column, termed the *back pressure*. Prolonged exposure to elevated back pressure (in excess of 250 bar) will significantly impact on the column lifetime; thus, it is necessary to maintain back pressure below 250 bar, preferably below 200 bar. In other words, the choice of particle size is a compromise between separation efficiency and acceptable back pressure. In addition to particle size, the size and volume of the pores on the packing particles must be considered. Pore size is relevant with respect to the size of analytes; separation of small analytes is optimum with smaller pore sizes; a small analyte in a large pore will have more space to fill as it traverses the column; thus, retention times will increase. The pore volume gives an indication of the surface area of the particle; the smaller the pore size and the higher the volume of pores, the higher the overall surface area of the column packing material, which has the effect of increasing column volume and compound retention times.

Next, one needs to consider the physical dimensions of the column; the internal diameter and the length which combined can be used to calculate the overall column volume, known as the bed volume. As a general rule, a smaller column diameter will lead to improved sensitivity and will enable chromatography to be performed at a lower mobile phase flow rate without any effect on linear flow rate of the mobile phase through the column. However, this will lead to a reduction in analyte loading capacity. Similarly, a longer column will improve peak resolution, but at the cost of increased analysis time.

The final key consideration when choosing the column is the carbon load. Typically, for amino acid analysis of spent culture medium, octadecyl silane or *ODS* columns are most commonly used, which are chemically bonded to the silica particles within the column, producing $C_{18}H_{37}$ chains. The length of the carbon chain is an important consideration; as a general rule, the longer the carbon chains, the higher the retention of the analytes. C18 is commonly used in RP-HPLC and is suitable for the separation and detection of amino acids in spent culture medium. This is above the *critical chain length* of ten C molecules [28] and is preferable over an alternative C8 column available from many column manufacturers. The carbon chain length, along with the particle size, number of particles, and pore size (i.e., surface area), influences the efficiency of the column.

It is wise to include a precolumn filter. This is a device through which the samples are passed prior to being loaded onto the column and which retains large contaminants. Precolumn filters are an inexpensive option ensuring column protection from blockages and improving column life-span. Normally, these consist of the same material used in the separating column with a lower packing density.

For the separation of amino acids from spent embryo culture medium, there are a number of key considerations; peak resolution must be maintained, as must repeatability and confidence in repeated assays. A series of five identical standards should be run prior to the loading of any samples to account for interrun variability. The variation between areas given on each of these runs should be less than 5%. However, analysis time needs to be kept to a minimum to ensure sufficient sample throughput. It is therefore necessary to make a suitable compromise, based on the factors described above, to ensure that column properties are suitable for a given application.

It is also necessary to consider the components of the mobile phase. Solvents, such as methanol and tetrahydrofuran (THF), should be *HPLC grade*. These are confirmed as high-purity solvents that have been tested to ensure adherence to strict specifications relating to spectral properties and ionic interactions. Solvents must be stored appropriately but not for prolonged periods as the quality can diminish as the solvents react with the containers in which they are stored. It is therefore preferable to store mobile phases in glass bottles rather than those made of plastic. HPLC-grade water is commercially available; however, it is sufficient to use ultrapure water collected from a suitable water purification system that is capable of producing water with a resistance of 18 Ω. This is preferential to using HPLC water stored for prolonged periods as the impurities arising from the storage container are minimized.

The mobile phase of the HPLC system will contain dissolved gases, and it is important to degas the solvents. This is commonly achieved by the inclusion of an in-line degasser in the HPLC system. The removal of dissolved gases is important to ensure consistent chromatographic performance.

44.5 How to Prepare Samples and Perform High-Performance Liquid Chromatography

Embryos should be placed into small droplets of culture medium containing amino acids; typically, these droplets are 4 μL in volume, placed under oil to minimize evaporation. This is the optimum volume, since it contains amino acids at a concentration low enough to enable detection of small changes but is sufficiently high to ensure that no single nutrient becomes limiting. At the end of the incubation, typically 24 h, the embryo is removed from the droplet, and the droplet is diluted at a ratio of 1:12.5 in HPLC-appropriate water. In practice, 2 μL of sample is added to 23 μL of water in an

HPLC vial. This gives a convenient 25 μL sample volume that is loaded onto the autosampler. At this stage, the samples are derivatized with OPA (see above), using the autosampler device to inject 25 μL of OPA in solution from a reservoir into the sample. After a suitable reaction time, typically 2 min, the sample is injected onto the column commencing separation of the analytes. The eluted peaks are then quantified.

44.5.1 Data Interpretation

The method of amino acid profiling offers significant promise in predicting embryo viability. At present, with conventional scoring methods, even when strict criteria are applied, approximately 25% of embryos graded as top quality will be aneuploid [8], and there is a clear need for improvement. The assignment of embryo *viability scores* based on their amino acid metabolism may provide a superior, more objective, quantitative selection method. Patients may have a cohort of embryos of differing morphology grades and cleavage rates, as well as embryos that exhibit different amino acid profiles indicative of differing embryo viability. The challenge is to discover the biological basis of these differences.

44.5.2 Statistics and Power

The amino acid profile data generated from animal and human models has been related retrospectively to various outcome measures, including blastocyst development and clinical pregnancy. Data from the analysis of 18 amino acids must be interpreted with care. The utilization of individual amino acids is unlikely to be independent of one another; each must be considered as a latent variable where each amino acid will have a unique contribution to the outcome. One must therefore consider how the specific contribution of any given amino acid differs from the remaining amino acids. For this purpose, the technique of principal components analysis is often used to combine the data into a single index that can serve as a measure of embryo viability [16].

Within any dataset, there will be sample variability and measuring errors. The question that needs to be addressed is whether ordinary sampling variance can account for the differences in viability indices between the pregnant and nonpregnant groups. If the possibility of measuring errors is reduced, only then will we be able to ascertain how much of the variability in the outcome can be apportioned to variance in the amino acid data. For instance, if leucine utilization is compared in a pregnant and nonpregnant group, and the variability between the two groups is higher than the within-group variance, we can then say with some confidence that any differences are due to more than sampling variability, and the null hypothesis can be rejected. However, a strength of the system used to quantify amino acid metabolism is the inclusion of an internal reference standard, for example, D-α-amino-butyric acid (DABA), a nontoxic, chemically inert compound incapable of being metabolized by mammalian cell, enabling sampling variance to be corrected.

In significance testing, there are two opposite risks; a type I error is the acceptance of a difference as significant when it is not, i.e., rejecting the null hypothesis when it is true. The converse is a type II error, i.e., accepting the null hypothesis when it is false. The emphasis is generally placed on avoiding type I errors—i.e., false claims. In order to reduce the likelihood of this occurring, emphasis is often placed on significance at 1% level. However, a balance needs to be struck between statistical significance and clinical relevance, and clinically relevant end points need to be defined. The test may aid embryo selection but may not translate to an immediate difference in clinical pregnancy rates. It could, however, improve cumulative pregnancy rates by enhanced selection criteria for cryopreservation. Rigorous follow-up is therefore required to test the merits of amino acid testing.

44.5.3 Relating to Outcome

The question of *cause or effect* poses a challenge, and confounding variables may bias the results. Statistical modeling has been applied to investigate the relationship with known predictors of pregnancy, such as female age and embryo quality, and in the human, amino acid turnover is a powerful, independent predictor of the outcome [16]. However, in order to draw further conclusions from these types of approaches, full randomized prospective clinical trials are now required.

Review Questions

1. Please describe the importance of embryo assessment.
2. Please explain why traditional, morphology-based embryo evaluation is not very efficient.
3. Please describe how amino acid turnover relates to developmental capacity of embryos.
4. Please define how amino acid profiling is different from other assays and how it may be used as a predictive marker for embryo selection.

Learning Objectives

- Limitations of conventional methods of embryo assessment
- Embryo viability is far more than how it looks
- Metabolism is linked to embryo viability
- Hyperspectral and FLIM microscopies can be used to quantitate autofluorescence, a measure of cellular metabolic activity
- Microfluidic devices, such as laboratory-on-a-chip, can be used to handle and quantitate submicrolitre volumes of culture media
- Laboratory-on-a-chip devices can be automated
- Future of IVF could incorporate both laboratory-on-a-chip and hyperspectral or FLIM microscopies, together with time-lapse image analysis

45.1 Introduction

Over the past decade, we have witnessed a worldwide movement towards single embryo transfer in human IVF. This has been driven by the adverse maternal and fetal consequences associated with multiple embryo transfer [1], and which has been facilitated by improvements in human embryo culture conditions, resulting in a significant increase in embryo implantation rates [2]. Together with improvements in embryo cryopreservation through vitrification, the cumulative success rates of cycles have improved overall. However, in order to reduce the time to pregnancy in each cycle, we need to be able to select the most viable euploid embryo for transfer. Identification of euploid embryos has been greatly facilitated by recent developments in comprehensive chromosome screening technologies, combined with trophectoderm biopsy from the blastocyst [3]. However, not all euploid embryos are viable, and hence there remains a need to quantitate embryo viability prior to transfer.

Since the birth of Louise Brown in 1978, we have relied almost exclusively upon morphology to assess the health of the preimplantation embryo. Over the past four decades, we have witnessed the development of elegant grading systems for all the preimplantation stages, and this approach has certainly aided in the deselection of embryos with abnormal phenotypic traits [4]. More recently, we have witnessed the introduction of time-lapse incubation systems, which have created the possibility to image embryos every few minutes, thereby increasing the amount of information we have regarding the times of key developmental events [5, 6]. This approach in turn is leading to the development of algorithms, further capable of improving embryo deselection [7, 8]. However, one can only glean so much information by looking at cells using basic light microscopy. Hence, it is important to consider novel technological means of assessing embryo physiology. We propose that by assessing physiological traits, such as nutrient utilisation and metabolic activity, or the production of embryo-specific factors, we will be able to identify the healthiest embryos within a cohort with increased accuracy for transfer.

45.2 Significance of Analysing Embryo Physiology

The preimplantation period is characterised by changes in embryo morphology and gene expression as the fertilised oocyte develops and differentiates into the blastocyst. Furthermore, during this period, the physiology of the embryo undergoes remarkable transformations, so much so that the pronucleate oocyte and the resultant blastocyst are as distinct in their metabolism as any two cell types in the body [9]. This in itself is a remarkable observation. Additionally, we are still unravelling the complexities associated with the metabolism of the preimplantation mammalian embryo [10–12]. What we have ascertained to date is that the pronucleate oocyte and cleavage-stage embryos are heavily dependent upon pyruvate, lactate and specific amino acids such as aspartate to support their unique metabolic functions, whereas the blastocysts have a high demand for glucose, as well as amino acids and vitamins [9, 13]. From a practical perspective, this means that the metabolic biomarkers of the preimplantation embryo will be different for each successive stage of development. Therefore, should a clinic decide to transfer embryos at the cleavage stages, then the measured metabolism will heavily reflect the quality of the oocyte. Should a clinic undertake blastocyst transfer, then the metabolic analysis will indicate that of the embryo proper. As the embryo develops and differentiates, the overall metabolic activity of the embryo increases. Therefore, there will be greater differences in the metabolic activity in the later stages of development, thereby making embryo selection using a quantitative measure of nutrient utilisation more realistic (Fig. 45.1).

To date, there have been few studies on the relationship between nutrient uptake and metabolism of the human embryo and the relationship with transfer outcome. Both animal and human studies show that a positive relationship between metabolic activity and embryo viability on days 4 and 5 of development exists [14–17]. Figure 45.2 shows clinical data obtained from the analysis of glucose uptake by individual human blastocysts prior to transfer. On both days 4 and 5 of development, there is very little overlap between the two populations of embryos (viable vs. nonviable), indicating that glucose uptake is a useful marker of viability in the post-compacted human embryo.

Such targeted and accurate measurements of specific nutrients and metabolites is made possible by enzyme-based assays and quantitative ultramicrofluorescence [18] and should not be confused with the attempts to assess human embryo viability utilising metabolomic platforms [19]. Technologies such as nuclear magnetic resonance (NMR)

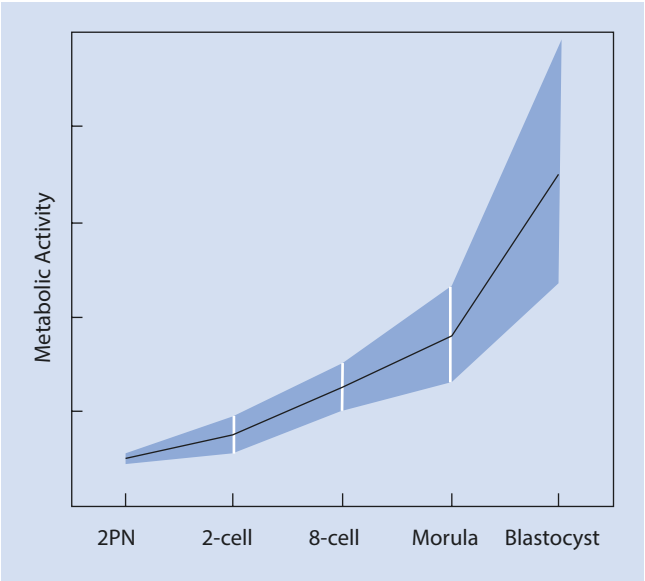

Fig. 45.1 Range of metabolic activities as the embryo develops through the preimplantation period. During the cleavage stages, the embryo has low metabolic activity; hence, there will be a small range of activities around the mean. In contrast, at the blastocyst stage, the embryo is metabolically at its most active, and further there exists more variation in embryonic cell number. Hence, at the blastocyst stage, there is a greater spread of metabolic activities, thereby making it more feasible to use metabolic activity as a selection criterion of embryos for transfer

imaging do not possess the sensitivity or resolution to work at the single embryo level. Raman and near-infrared (NIR) spectroscopies have been used to analyse human embryo culture media [20]; however, NIR spectroscopy is unable to quantitate the levels of specific nutrients but rather create spectra reflecting the relative abundance of metabolites in a sample. Although the latter approach was utilised to create a viability index of human embryos [21], this approach was not able to identify viable embryos in a prospective manner [22]. Nevertheless, research continues in these and other spectroscopy fields as such technologies rapidly advance [23].

45.3 Novel Microanalysis Techniques

All IVF labs are equipped with basic microscopes, such as dissecting microscopes used for visualisation and grading of oocytes and embryos, to advanced microscopes that provide enhanced contrast, such as phase contrast (especially useful for visualising spermatozoa), differential interference contrast, polarisation or Hoffman contrast optics. These latter optical systems are invaluable for visualising morphological features of cells, and are therefore highly effective tools to identify distinctive differences between gametes and embryos.

Fluorescence microscopy is found in many clinics because several fluorescent stains are particularly useful in the andrology laboratory for distinguishing live and dead sperm and morphological anomalies. Fluorescence microscopy is widely

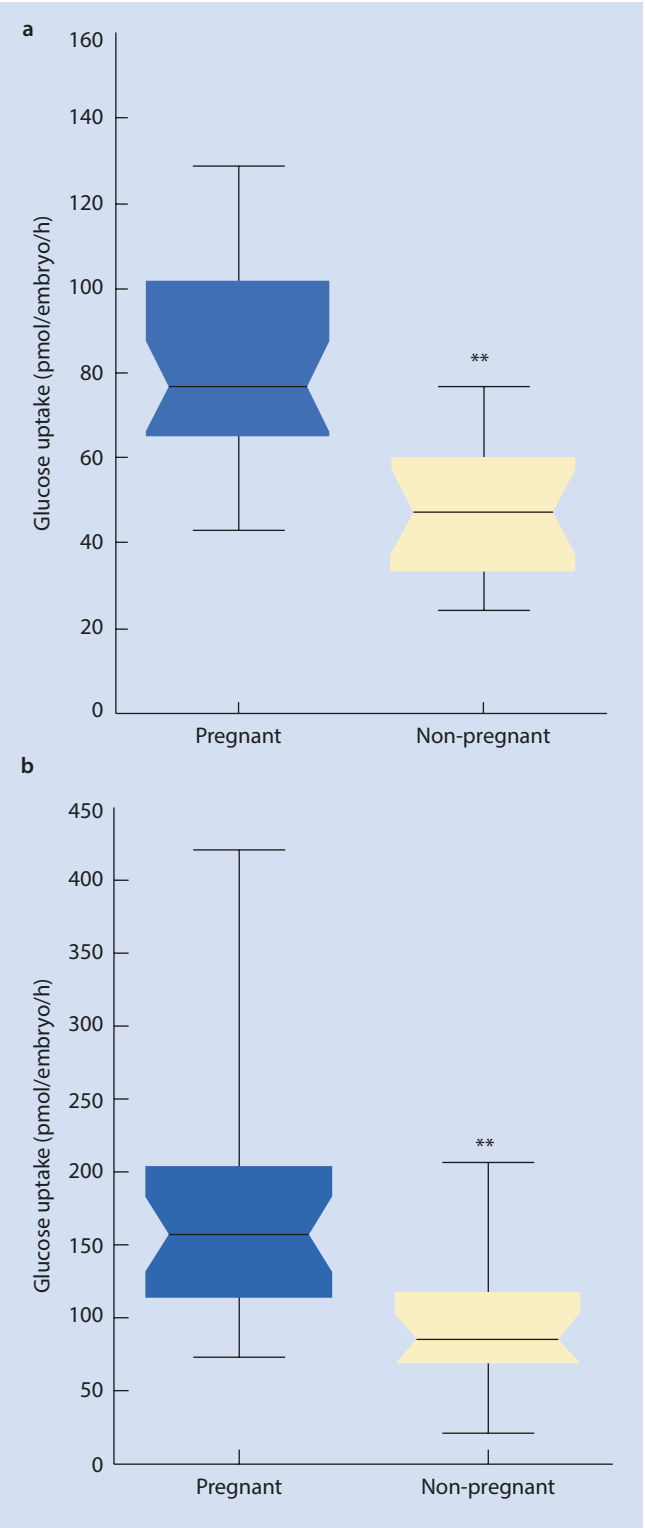

Fig. 45.2 Relationship between glucose consumption on days 4 and 5 of development and human embryo viability. **a** Glucose uptake on day 4 of embryonic development and pregnancy outcome (positive fetal heart beat). **b** Glucose uptake on day 5 of embryonic development and pregnancy outcome (positive fetal heart beat). Notches represent the confidence interval of the median, and the depth of the box represents the interquartile range (50% of the data), whiskers represent the 5 and 95% quartiles. The line across the box is the median glucose consumption. **, significantly different from pregnant ($P < 0.01$). Adapted from Ref [17]

used as a research and diagnostic tool. Its main advantage over many other microscopy techniques is that specific parts of a cell, such as a particular protein or organelle, can be identified and located in a fluorescence microscopy image with subcellular resolution. This is achieved by labelling a specific part of a cell with a fluorophore, which also enables very high image contrast. To image the sample, the fluorophore is 'excited' with the light of a specific wavelength (e.g. green), and only the light of longer wavelengths (e.g. red) emitted by the fluorophore is collected to create an image on an otherwise black background. Confocal fluorescence microscopy even allows the acquisition of these images in 3D with subcellular optical resolution. All fluorescence microscopy techniques are generally suited for live-cell as well as fixed-cell imaging. However, the relative high intensity of the excitation light, especially blue and UV light, can have adverse effects on live cells and embryos in particular [24]. The intensity and wavelength of light used for imaging embryos during their manipulation are important factors for maintaining the viability of preimplantation embryos in vitro.

Two-photon fluorescence microscopy allows 3D imaging of biological samples up to a depth of almost 1 μm at subcellular resolution and can be used to image live mammalian embryos [25]. It generally uses near-infrared light, which enables higher tissue penetration compared with visible light and minimises light-induced tissue damage.

Autofluorescence refers to the natural fluorescence emission of light from endogenous biological structures and molecules upon light excitation. Autofluorescence is usually highly undesirable, since it creates a fluorescent 'background' in most biological samples, which reduces the image contrast created by the exogenous fluorescent label in an image. However, it may also create new opportunities to identify and image biologically important molecules based on their autofluorescence, many of which are involved in metabolism (see Table 45.1). Several studies have shown that metabolic activity can be investigated in oocytes and embryos through autofluorescence imaging and spectroscopy [26, 27]. The best-characterised autofluorescent metabolic molecules are NAD(P)H, which both fluoresce in blue upon UV-excitation, and FAD, which fluoresces in green upon blue light excitation. Both NADH and FAD participate in electron transport for oxidative phosphorylation, and the fluorescence ratio between the two is a measure of the cellular reduction-oxidation ratio.

Further advances in both fluorophore-mediated and autofluorescence microscopy have focussed on being able to distinguish very subtle differences in the fluorescence properties of closely related molecules. For example, small differences in fluorescence of bound- and free-NADH can be measured using fluorescence lifetime imaging microscopy (FLIM). The ratio between bound- and free-NADH is indicative of glycolytic or oxidative phosphorylation activity. FLIM was used to demonstrate the differences between mural granulosa and cumulus cell metabolism compared with oocyte metabolism within ovarian follicles in situ [28]. Another emerging fluorescence-based technique is hyperspectral autofluorescence microscopy. Most fluorescence microscopes utilise not more than four different excitation light wavelengths (colours), generated by different lasers or LEDs. However, with the development of lasers that generate continuously tunable excitation light from the UV to the near-infrared spectral range, or the use

Table 45.1 Excitation and emission maxima of endogenous cellular autofluorescence fluorophores

Endogenous fluorophore	Excitation maxima (nm)	Emission maxima (nm)
Amino acids		
Tryptophan	280	350
Tyrosine	275	300
Phenylalanine	260	280

of multiple LEDs, a broad range of autofluorescence signals can be investigated. This approach has enabled new insights into the heterogeneity of cellular metabolism between individual cells (including oocytes and embryos) within a defined environment. Its application to oocyte and embryo metabolomics remains a research tool at this stage, requiring answers to questions such as light toxicity and the clear identification of autofluorescent molecules. However, there is now good evidence that, in conjunction with image-analysis, hyperspectral autofluorescence can distinguish between embryos cultured in different environments [29, 30].

45.4 Why Has Metabolic Analysis of Embryos Not Been Applied Clinically?

Two principal reasons why analysis of individual human embryos has not been widely applied clinically are (1) there are no completely noninvasive intracellular metabolic assays available, and (2) the technologies to quantitate single embryo physiology accurately, such as ultramicrofluorescence assays and mass spectrometry of the media surrounding the embryo, used to analyse carbohydrates and amino acids, respectively, are both time-constrained and require equipment and skills not normally found in the IVF laboratory. Indeed, ultramicrofluorescence for single-cell analysis is restricted to a handful of laboratories worldwide. Hence, its implementation has been restricted to research and pilot studies to date. It was envisaged several years ago that this problem would be overcome through the development of microfluidic devices, capable of manipulating and analysing sub-microlitre samples of human embryo culture medium (Fig. 45.3) [31]. In the intervening decades, such laboratory-on-a-chip technologies have developed rapidly, and two proof-of-principle devices have been developed, each capable of performing metabolic analysis of single embryos [32, 33]. So, what are laboratory-on-a-chip technologies? In particular, what is the relevance of microfluidics to human embryo diagnostics?

45.5 Introduction to Microfluidic Systems: Laboratory-on-a-Chip

Microfluidic devices are capable of handling fluids in sub-microlitre volumes and take advantage of the physical differences of fluids between macro- and microscales. In the sub-microlitre scale, fluid flow is linear, i.e. nonturbulent, and through the use of appropriate on-chip valving, fluids can be moved and measured with remarkable accuracy [32]. Given the small volume of the human embryo, ~5 nl, this ability to quantitate small volumes of fluid makes microfluidic devices ideally suited for single embryo analysis. Further, the ability to deliver volumes accurately in this range ensures the accuracy of analysis. An exciting prospect for microfluidic devices for embryo analysis is that analytical technologies are already available that can be incorporated into chips. Micro-devices have been developed to analyse nucleic acids, proteins and peptides, amino acids and small metabolites [34–36]. A variety of technologies are applicable for integrated noninvasive analysis of the metabolism of embryos [37]. Furthermore, on-chip imaging can already produce images with resolution below 1 μm [38].

An attractive attribute of microfluidic devices is that their operation can be automated. Automation has the advantages of removing human error and facilitates assessment and manipulation of gametes and embryos based on optimal developmental stage of the embryo, rather the work schedule of a busy IVF laboratory. It is known that embryos

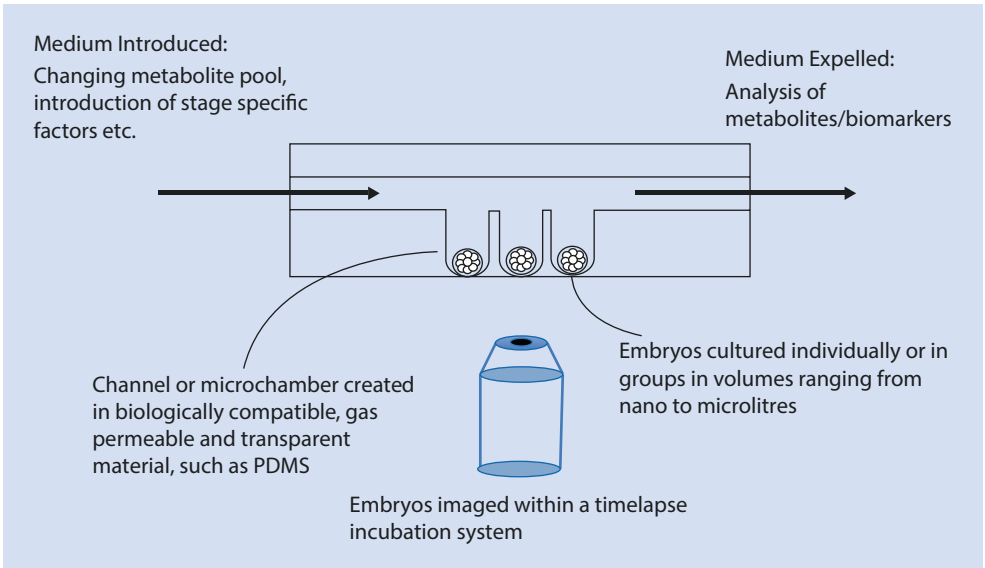

Fig. 45.3 Schematic of an embryo culture system for perfusion culture and analysis of biomarkers. Culture media are continuously passed over the embryo(s). The composition of the culture media can be changed according to the specific requirements of each stage of the embryonic development. Toxins, such as ammonium, are not able to build up and impair embryo development, while more labile components of the culture system are not denatured. Samples of the culture media can be removed for biomarker analysis. (Adapted from Ref. [31])

within a cohort show differences in developmental rates, even when they are fertilised at the same time. It is feasible that some of the biological variability in analyses can be removed if embryos are analysed according to precise developmental staging rather than based on the time post-fertilisation.

Microfluidic fabrication uses highly specialised and complex engineering methodology, and devices can be made using a number of different materials. Methods available include photolithography, soft lithography, laser machining, micromilling, bead blasting, chemical etching, wax printing and hot embossing. All of these are essentially surface modification techniques capable of creating high-resolution features, with micro- and nano-scale width and depth precision and with high reproducibility. Devices for biological uses have been fabricated from materials including borosilicate glass, light-sensitive films (photoresists), polymers (e.g. poly(dimethyl)siloxane (PDMS), polycarbonate (PC), poly(methyl-methacrylate) (PMMA)), teflons, waxes, shrink-wrap films and even paper-based materials. Most microfluidic devices for biotechnology applications have been made from glass [39] or from a polymer, typically PDMS [40].

Poly(dimethyl)siloxane is a silicon-based elastomer and optically clear, and devices are typically designed using photolithography and soft lithography, in which liquid polymer is typically poured over a rigid mould (master) produced as the inverse of the channel layout. The polymer is then cured by baking, and mounted on glass or other planar surfaces. This process is considerably cheaper than that for glass. Once the master has been prepared, the same master can be reused to make multiple single-use or minimally reused device copies. Drawbacks of PDMS for biological device applications include its reactivity to organic solvents, heat sensitivity and porosity. This latter property can promote reactions with aqueous samples contained within the device, such as small molecule absorption into the bulk material [41] or release of trace amounts of PDMS monomers and oligomers [42] which may confound mass spectrometry studies. However, in its favour, the elastomeric properties of PDMS make it highly suited for pneumatic valving, and it has been this which has been used to create analysis chips for individual preimplantation embryos [32].

45.6 Lab-on-a-Chip Analysis of Individual Preimplantation Embryo

In order to quantitate the utilisation of nutrients by single mouse embryos, a microfluidic device was created capable of measuring metabolites in spent culture medium (Fig. 45.4) [32]. This automated device can determine the concentration of glucose, lactate or pyruvate in just a few nanolitres of culture medium in 20 s. Particularly attractive devices for in-line monitoring of metabolites are biosensors that convert binding or a chemical reaction of a substrate on the surface of a sensor to an electrical signal [43]. These sensors can be fabricated very inexpensively using thick-film printing and can be developed to detect a wide variety of analytes. With the tremendous amount of ongoing research in microanalytics, we expect that even better technologies will emerge in the near future (see the following section).

45.7 Integration of Future Technologies into the Clinic

In research laboratories around the globe, new biomedical imaging and sensing technologies are advancing rapidly, driven by the clinical and scientific need for ever more sensitive measurements in living organisms at higher resolution. Image analysis approaches, such as grey-level co-occurrence matrix analysis, have been combined with artificial intelligence systems for embryo diagnostics [44, 45]. Conventional time-lapse images can be analysed using neural network algorithms to aid and improve the embryo selection process [46]. Fluorescence imaging and sensing, especially with near-infrared light, holds great potential for the development of novel and completely noninvasive embryo screening platforms. A prerequisite for this and all other light-based technologies is a better fundamental understanding of the effect of light itself on the physiology and viability of embryos.

Another frontier is the use of novel nanoscale materials for imaging and sensing in biology and medicine in general and embryology in particular. These so-called nanomaterials include FDA-approved molecules like fluorescein that are used today in the clinic as well as many different types of nanoparticles that are about 10,000 times smaller than an oocyte. Some of these new materials may enable next-generation imaging and sensing technologies through their unique physical and chemical properties. Nanomaterials that show stable fluorescence in the near-infrared spectral region [47] or that have the ability to detect vital ions or metabolites with high precision and sensitivity [48] are two examples. However, the effect of nanomaterials on biological systems in general and embryos in particular remains a major hurdle. Even biocompatible materials can affect cell stress, signalling processes or gene expression [49], which necessitates a better understanding of the underlying mechanisms. To date, several nanoparticles have been approved by the FDA or the EMA for clinical use [50]. On the other hand, no nanoparticles are approved for use in stem-cell therapies by the FDA. Preliminary evidence suggests that nanoparticles may be a useful tool for an improved assessment of embryos, such as the self-illuminating quantum dots for noninvasive bioluminescence imaging of mammalian gametes [51]. But this approach has not yet been established as safe. However, it has been demonstrated that the injection of ligand-free gold and silver nanoparticles into murine embryos has no impact on preimplantation

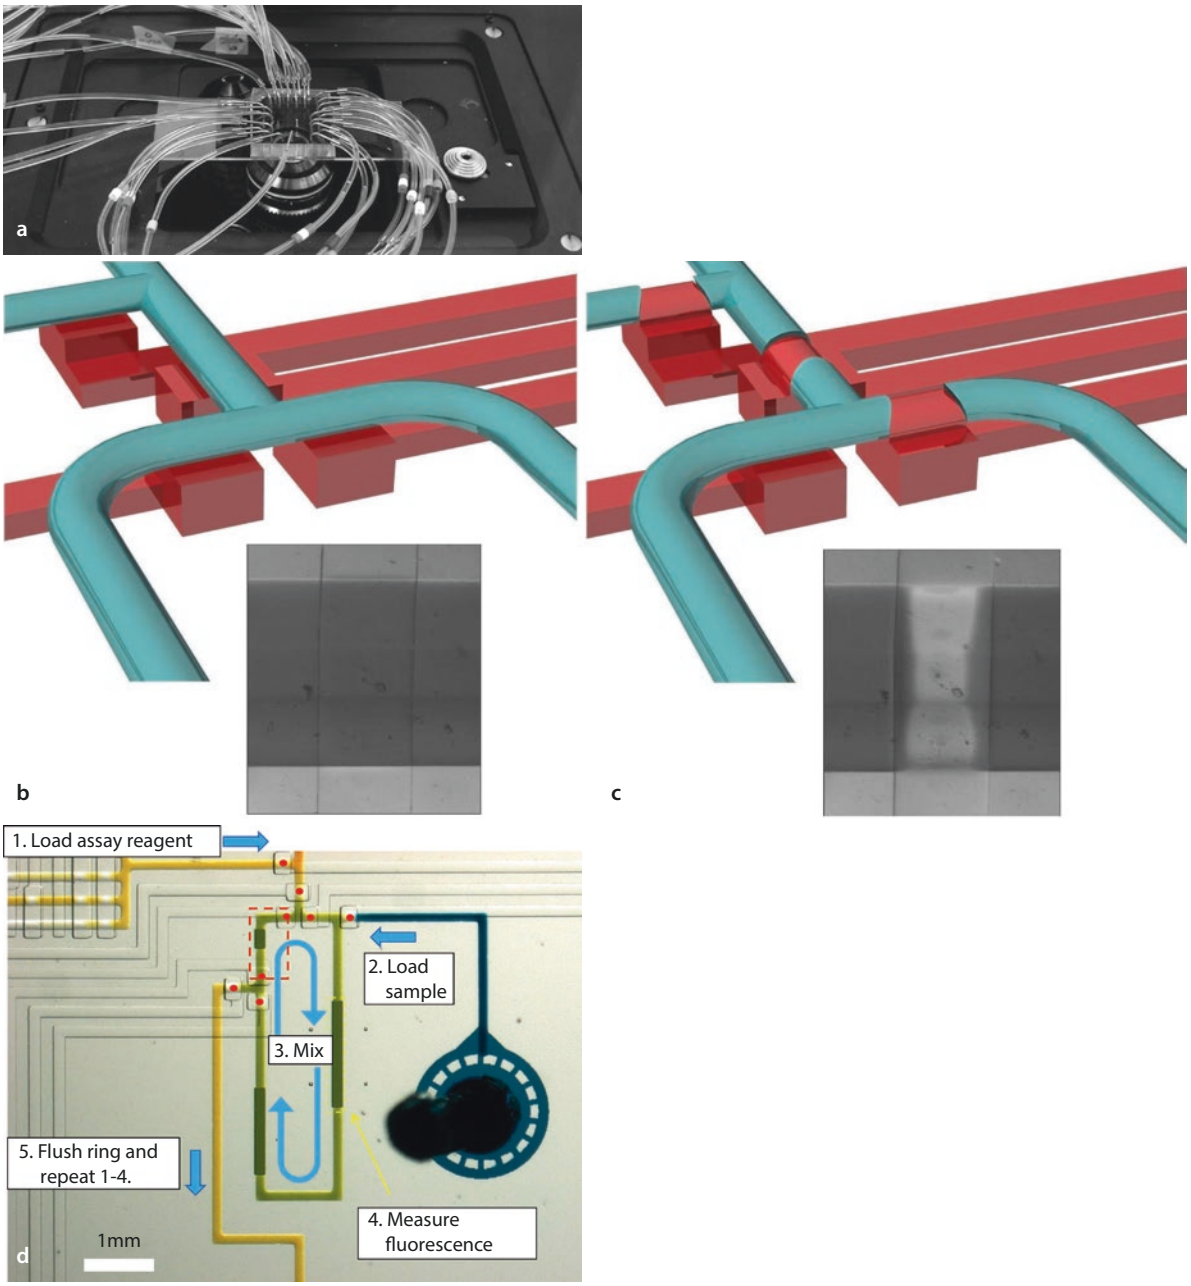

Fig. 45.4 Microfluidic device for determining the concentrations of metabolites in the culture media. **a** Image of a microfluidic device/chip, prepared for the analysis of embryo culture media [32]. The microfluidic circuits are prepared out of poly(dimethyl)siloxane, an elastomer, that facilitates the creation of pneumatic valving in order to move accurately volumes in the nanolitre range. **b**, **c** Computer-generated rendering of the microfluidic device, illustrating in 3D how the microchannel flow is controlled. The overall device format **b** shows individual fluid flow channels (blue) lying above a layer of control channels (red), which are driven pneumatically. Flow channels are a combination of rectilinear and rounded cross sections, with channel width uniformly around 100 microns. Red boxes represent valves that make contact with the blue flow channels from beneath, which appear in high density in the grid regions, representing the main control interface. A blow-up of a channel T-intersection **b**, **c** shows how each channel branch is positioned over three individual valves, the blind ending of a control line. When valves are open **b**, no hydraulic pressure is in the line, and fluid can move freely in the flow channel (inset micrograph of a valve from a PDMS device, viewed from above). To close a valve, the hydraulic pressure in the control line is increased, pushing the channel floor upwards and preventing fluid flow in that region (inset photo with lighter region is where flow is blocked) **c**. **d** A multiplexor with 10 input channels for automated loading of assay cocktail and standards. To the right is a sample-loading port where approximately 100 nl of culture medium is loaded manually. By automatically activating pneumatic valves (marked with red dots) in defined sequences, 9/10 of the mixing circuit with assay cocktail and 1/10 of the ring with sample (section of the mixing ring outlined with the red dashed line) is filled. Sequential firing of the valving within the mixing circuit then mixes the samples. The NAD(P)H fluorescence of the fluid within the measurement chamber (highlighted by dashed yellow lines) is then determined using an automated fluorescence scope equipped with a photomultiplier tube. The sample port and mixing circuit are then flushed clean, another culture medium sample loaded and the sequence repeated. To see this procedure in real time, go to the supplementary video file included with reference number [32]

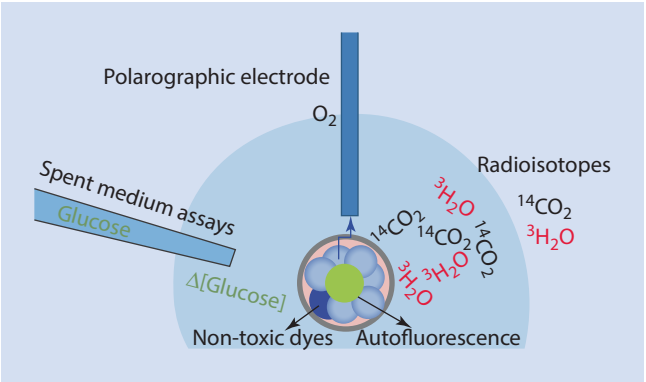
development [52]. The field of nanotoxicology is a rapidly growing field of fundamental and applied research. Its findings will be decisive for the future development of nanomaterial-based technologies that are safe for clinical use. Many of the nanomaterials that are used in the clinic today are administered systemically. An alternative and in some cases more realistic approach is the integration of nanomaterials into new microscopic imaging and sensing devices such as optical fibres. These may allow for high-precision chemical sensing, optical imaging and real-time monitoring of the embryo metabolism during development without the need for a global exposure of the biological system to the nanomaterial (■ Fig. 45.5 and ■ Table 45.2).

In conclusion, real-time monitoring of embryonic physiology is soon to come and will revolutionise how embryos are cultured. Culture conditions will no longer be static or invariably dynamic but instead will be constantly adjusted in response to the embryo's changing needs [31, 53]. Real-time read out of embryonic physiology will be tremendously valuable both for optimising and monitoring culture conditions and for assessing the health and developmental potential of the embryo [56].



■ **Fig. 45.5** Different methodologies that are currently used to measure the metabolism of early embryos. Radioactive isotopic energy substrates, such as [U-14C]- or [5-3H]-glucose, were invaluable research tools, but not suitable as noninvasive markers for subsequent embryo transfer. The same applies to dyes and stains, even if they are relatively nontoxic. Sampling the media surrounding embryos for subsequent analysis, usually in nanolitre volumes, or direct measurement of O_2 consumption using electrodes, is currently the safest and most clinically applied. Autofluorescence is a direct yet virtually noninvasive measure of cellular metabolism. Clinical application requires further assessment about its safety and reliability. (From Ref. [54] with permission)

Review Questions

1. What are the limitations of morphological assessment?
2. Which nutrients are related to embryo viability?
3. What is laboratory-on-a-chip?
4. What types of novel microscopies offer potential means of assessing embryo physiology?
5. Are the technologies now ready for automated embryo culture and analysis?

■ **Table 45.2** Near-infrared fluorescent nanomaterials. The table summarises some of the basic optical properties of important nanoparticle types

	Excitation range (nm)	Emission range (nm)	Fluorescence lifetime	Photostability
Quantum dots	700–1300	700–1500	20 ns–5 μs	High
Polymer dots	500–800	650–1200	≤1 ns	Medium
Nanodiamonds (NV)	520–580	650–750	10–30 ns	Very high
Organic dyes	600–800	650–1100	<1–6 ns	Low
Carbon dots	500–650	650–650	≤10 ns	Medium
Gold clusters	500–650	650–850	3–800 ns	Medium
Carbon nanotubes	700–1300	1000–1500	≤1 ns	High
Graphene oxide	400–650	650–700	≤1 ns	Medium
UCNPs	980	650–800	>100 μs	High

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_46

Learning Objectives

- Structure and function of the *zona pellucida* during fertilization, embryo development, and hatching
- Assisted hatching: concept and techniques
- Clinical cases that benefit from assisted hatching
- Optimization of noninvasive and effective assisted hatching procedures

46.1 The Zona Pellucida Mediates Gamete Recognition and Protects the Embryo Until Implantation

Successful monospermic fertilization defines the onset of proper embryo development and requires gamete recognition and a block to polyspermy. Both necessary biological processes are mediated by the *zona pellucida* (ZP), an extracellular glycoprotein matrix that surrounds mammalian ovulated eggs. Mouse and human ZP appear different in thickness (mouse ZP ~7 μm thick; human ~16 μm), surround oocytes of significantly different sizes (mouse oocyte ~80 μm diameter; human 120 μm), and pertain a comparable, but still different, molecular composition. Mouse and human proteins are encoded by four genetic loci. The mouse ZP is composed of three glycoproteins, defined as ZP1 (526 aa, 120 kD), ZP2 (599 aa, 120 kD), and ZP3 (329 aa, 83 kD) [1, 2], while mouse *Zp4* is a pseudogene that does not express the cognate protein [3]. Human ZP is composed of four glycoproteins, defined as ZP1 (528 aa, 100 kD), ZP2 (602 aa, 75 kD), ZP3 (328 aa, 55 kD), and ZP4 (444 aa, 65 kD) [3, 4].

The structure of the ZP has been widely studied in the mouse [5, 6] and other experimental models [6]. In mouse, the three ZP proteins form a three-dimensional *zona* matrix by non-covalent interactions. At the C-terminal region, each protein has a "ZP domain" of ~260 aa [6, 7] and a cytoplasmic tail [8] that ensure protein incorporation into the extracellular matrix of the *zona*. The ZP domain contains 8–10 conserved cysteine residues and is divided into *N*-terminal "ZP-N" and C-terminal "ZP-C" subdomains [5]. The structure of each protein is stabilized by intramolecular disulfide linkages, whereas ZP1 only provides intermolecular disulfide bonds that form homodimers within the *zona* [2, 9] and further stabilize the three-dimensional structure of the matrix [10].

Although the molecular architecture of each ZP protein has been extensively described, there has been much controversy over the characterization of the oocyte zona ligand and the identification of the cognate sperm receptor, necessary for sperm binding to the ZP. Early studies in mice had suggested that glycans on ZP3 mediate sperm-zona interaction. In particular, back in the 1980s, using soluble, SDS-PAGE-purified, and renatured *zona* proteins in an in vitro competitive sperm-binding assay with ovulated eggs, ZP3 was reported to inhibit sperm-ZP binding in vitro with the highest efficiency. Indeed, no inhibitory effect of sperm binding to ovulated eggs was observed with renatured ZP1 or ZP2; therefore, ZP3 was reported as the *zona* ligand for mouse sperm binding [11]. Further studies made this model of gamete recognition more precise, invoking *O*-glycans [12] attached to Ser^{332} and Ser^{334} of ZP3 as the zona ligands for sperm binding [13]. This model envisioned that after fertilization, these glycan ligands would have been released by a putative glycosidase exocytosed from egg cortical granules to prevent sperm binding to fertilized eggs [12]. However, phenotypes observed in genetically engineered mice were not consistent with this model. In particular, no carbohydrates were found attached to Ser^{332} and Ser^{334} in native mouse ZP [14], and even after mutating these sites to prevent glycosylation, fertilization was not compromised [15].

To define which ZP protein mediates sperm-egg binding, an alternative approach was the systematic use of mouse genetics to test the role of each individual ZP protein in gamete recognition. Using knock-out (KO) gene technology, each ZP protein has been successfully ablated in transgenic mice; females lacking ZP1 present a more loosely organized *zona* matrix and show decreased fecundity, although they are still fertile, which shows ZP1 not to be necessary for gamete recognition [10]. On the other hand, female mice lacking either ZP2 [16] or ZP3 [17, 18] present a more severe phenotype, with no ZP surrounding ovulated eggs. These female mice are infertile as their *zona*-free eggs are resorbed into the epithelial lining of the oviduct [19, 20]. Thus, ZP1 is not necessary for gamete recognition and fertility, but the absence of a ZP matrix in the $Zp2^{Null}$ and $Zp3^{Null}$ mice precludes the possibility to test the role of either ZP2 or ZP3 in gamete recognition. As these loss-of-function assays were not informative on gamete recognition, this was circumvented by taking advantage of the stringent specificity of sperm binding across taxa.

In fact, although the primary structure of secreted mouse and human ZP1 (71%), ZP2 (62%), and ZP3 (71%) is quite conserved, human sperm bind only to human and neither bind to the mouse ZP [21] nor fuse with mouse eggs [22]. Therefore, with this taxon specificity in mind, we have established transgenic mouse lines in which human ZP1, ZP2, and ZP3 replaced the endogenous mouse proteins, and we inseminated eggs from each individual line with fertile human sperm. Human sperm bound to the chimeric mouse-human ZP only in the presence of human ZP2 [23, 24], but not in the presence of human ZP1, ZP3 [23], or ZP4 [25]. To complement this gain-of-function assay, we have established loss-of-function assays to testimony that ZP2 was not only sufficient but also necessary to support sperm binding to the ZP. In mice with a ZP formed by four human proteins and lacking the three endogenous mouse proteins, human sperm bound and penetrated the zona matrix. However, in the absence of human ZP2, these mutant zona could not support human sperm binding, and female mice were infertile [24]. Moreover, mouse *zonae* in which mouse ZP2 was replaced with human ZP4 could not support mouse sperm binding, and these females were also infertile [24]. The gain- and loss-of-function assays document that ZP2 rather than ZP3 is the zona ligand for mouse and human sperm binding to the ZP, which is necessary for fertilization. Moreover, by establishing

transgenic mouse lines that express a truncated mouse ZP2 that lack the *N*-terminus of ZP2 in place of the native isoform, we found that mouse sperm must bind to the *N*-terminus of ZP2 to successfully fertilize the egg. Indeed, eggs lacking the ZP2 *N*-terminus cannot support sperm binding, and female mice are infertile [24]. Finally, by establishing chimeric human/mouse and mouse/human ZP2 in transgenic mice, we refined the gamete recognition domain for human sperm at the *N*-terminus of human ZP2.

Following fertilization, the block to polyspermy ensures monospermic fertilization, which is imperative for proper embryo development. This block includes putative or characterized molecular modifications to the ovulated egg that prevent supernumerary sperm: (1) to fuse with the egg plasma membrane; (2) to penetrate the ZP; and (3) to bind to the ZP [26, 27]. Block to fusion was found not to be associated with electrical potential changes [28, 29], and the molecular mechanisms regulating this block still remain to be defined [30]. While the block of ZP penetration has not been molecularly characterized yet, the block to ZP binding has been recently well described. Sperm can bind to the ZP surrounding unfertilized eggs, but cannot bind to the ZP of fertilized eggs or the 2-cell embryos, and this has been originally associated with an imprecisely defined "*zona* hardening" mechanism. The only documented biochemical modification of the ZP upon fertilization is the proteolytic cleavage of ZP2, after which the two fragments remain disulfide bonded [31]. This cleavage is due to the activity of a cortical granule protease defined as ovastacin [32] specifically localized in the cortical granules. After fertilization, the cortical granule exocytosis releases ovastacin, which cleaves ZP2 at the *N*-terminal region [33]. As a consequence, sperm are no longer able to bind to the ZP [33]. However, when the postfertilization cleavage of ZP2 is genetically prevented, either by mutating the ZP2 cleavage site [15] or ablating the gene encoding OVASTACIN [33, 34], sperm can bind de novo to the ZP surrounding fertilized eggs and 2-cell embryos. Of note, OVASTACIN is encoded by the *Astl* gene, which belongs to the Astacin family. In fish, *Astl* genes encode for the hatching enzymes [35] that assist the fish larvae to escape from the egg envelope upon completion of embryonic development. In mammals, this gene family seems to have acquired a different function during early embryo development, as mediator of "*zona* hardening" right upon fertilization [33], whereas other still-to-be defined mechanisms seem to assist natural embryonic hatching, which is required for appropriate embryo implantation.

For successful implantation and a healthy and safe pregnancy, the timing of hatching through the ZP is of crucial importance. While progressing toward the uterus, the forming blastocyst expands, stretching the ZP, which finally appears thinner (~3 μm) than at the time of fertilization (16 μm) [36]. This has been proposed to be due to the activity of a Na^+/K^+-ATPase plasma membrane pump of the trophoblast cells that pumps sodium into the blastocoel, which in turn recall water by osmotic pressure, leading to the enlargement of the blastocoel [37] which thereby stretches the ZP [38]. At this developmental stage, the ZP is necessary to impede the blastocyst adhering to the oviduct walls, thus blocking an ectopic (or tubal) pregnancy. However, once in the uterus, the embryo must escape from the *zona* matrix in order to implant into the uterine lining.

Studies to describe mammalian implantation have been performed in the mouse. In vitro the mouse blastocyst hatches from the *zona* by breaching through a ~3 μm hole, anywhere in the ZP [39]. It has been proposed that a proteinase expressed in the trophoblast cells, defined as strypsin/ISP1 [40, 41], controls the blastocyst's hatching [41] by digesting the entire ZP. Indeed, the inhibition of strypsin expression using antisense oligodeoxynucleotides against *Isp1* mRNA resulted in improper hatching and implantation was affected [41]. It still remains to be defined what protein(s) in the ZP are targeted by the lysis activity of ISP1. Moreover, it would be informative to confirm this mechanism in genetically modified mice in which conditional ablation of *Isp1* in the embryo would result in impairment of in vitro hatching and subsequent implantation failure upon Δ*Isp1* blastocyst transfers in the uterus of recipient female mice.

46.2 Assisted Hatching: Historical Background and Current Clinical Applications

46.2.1 History of Assisted Hatching

In the field of assisted reproductive technology (ART), the procedure of assisted hatching (AH) consists of the chemical/mechanical manipulation of the ZP before embryo transfer to facilitate the escape of the embryo from the ZP and its subsequent implantation in the uterine lining [42, 43]. Within the realm of AH, several techniques were developed over the past few decades [44], which include chemical drilling of the ZP with acidic Tyrode's medium; ZP thinning using acidic Tyrode's; mechanical piercing of the ZP using a microneedle, known also as partial zona dissection (PZD); mechanical expansion of the ZP via injected hydrostatic pressure; carving a hole in ZP via piezoelectric pulses; and laser-assisted *zona* drilling.

Early reports on the application of artificial manipulation of the ZP using acidic Tyrode's were performed in mice in 1986 [45]. Although the primary goal of these proof-of-concept studies was to facilitate mouse fertilization in vitro, the authors obtained positive results on implantation as well [45]. In 1988, a successful pregnancy was achieved in the human when PZD was also performed to facilitate sperm penetration [46]. From these pioneer studies, it was hypothesized that an artificial manipulation of the ZP could have assisted the embryo to escape from the ZP, which in turn would have resulted in higher implantation rates. Indeed, in 1990, a subsequent compelling study reported a significantly higher implantation rate (n = 8/15; 53%) when the *zona* of 8-cell embryos was mechanically pierced with respect to the non-manipulated control (n = 3/15; 20%) [47]. In subsequent studies [48], artificial ZP manipulation was applied to 4–8

cell embryos following in vitro fertilization (IVF) from patients with basal FSH levels (≤15 mIU/ml) that presented a ZP thickness ≥15 μm and exhibited low implantation prospects. Cohen and colleagues concluded that the reason behind the lower implantation and pregnancy rates observed could have been the restriction of a thicker ZP that may have impeded normal embryo escape. To address this hypothesis, embryologists applied topically, over a ~30 μm area of the ZP, acidic Tyrode's solution to chemically drill a hole in the ZP and reported upon transfer a significant increase of implantation rate (n = 70/278; 25%) compared to the non-manipulated controls (n = 51/285; 18%). Of interest, embryos presenting a thinner zona (average thickness ≤13 μm) did not benefit from the procedure; instead chemical AH had adversely impacted embryos resulting in 25% (n = 5/25) implantation compared to the non-manipulated embryos (n = 13/26; 50%) [48].

With time, alternative mechanical approaches were developed and adopted. Initial mechanical techniques for AH involving PZD using a microneedle to perforate the ZP resulted in inconsistent openings [47, 49]. AH was also accomplished using a piezo-micromanipulator where piezoelectric pulses producing vibratory movements are repeatedly applied to drill a hole in the ZP [50]. This approach has proven effective on "good-quality" embryos (embryo grade based on Veeck's classification [51]), resulting in a better implantation rate (n = 13/67; 19.4%) compared to the non-hatched controls (n = 4/68; 5.9%), but had no significant effect on low-quality embryos [50]. Another interesting and more recent approach involved simulating the natural expanding effects of blastocysts on the ZP by injecting HTF-HEPES medium into the perivitelline space of 8-cell stage embryos to induce internal hydrostatic pressure, which in turn would have assisted a more physiological escape of the embryo from the zona [52]. This novel approach resulted in a relatively total low implantation rate (n = 25/178; 14%), although significantly higher when compared to the non-hatched control (n = 14/90; 7.4%).

Of all the above-listed techniques, laser AH has been reported to be the most effective and noninvasive procedure [44, 53]. Laser beams offer high precision and control when thinning or drilling the ZP [44]. As of today, laser AH remains the most popular technique as it minimizes overall risk of visible injury to the embryos [44], and although it is not recommended as a routine clinical procedure, it has been reported to improve pregnancy and implantation rates in poor prognosis patients [54].

46.2.2 Clinical Applications

Clinical cases that might benefit from AH techniques include embryos that have less chance to normally implant due to a suggested failure to properly expand/contract and subsequently fail to reduce the thickness of the ZP down to ~3 μm at the blastocyst stage [55]. Advanced maternal age, in vitro culture conditions, and cryopreservation procedures have been associated with an increased number of embryos presenting low elasticity of the ZP, a still molecularly uncharacterized *zona*-hardening effect, and an impairment of normal ZP thinning [56].

46.2.2.1 Advanced Maternal Age and Increased Zona Thickness

Embryos from infertile female patients of 38 years of age and above present sharply declining developmental performance and significantly reduced fertility potential. Many factors have been suggested to be the cause of this decrease in fertility including diminished ovarian reserve and oocyte quality and in addition embryos presenting with aneuploidy and/or poor morphology. One more factor proposed is a still biochemically uncharacterized *zona* hardening affecting poor morphology embryos [57] that might restrict and prevent the blastocyst from escaping the ZP. While there is no molecular evidence showing that these embryos present a prematurely cleaved ZP2 or any other molecular signs of *zona* hardening, recent studies report that the application of laser AH improves embryo escape and implantation rates (18.36% vs. 11.36% of the non-hatched embryos) [56] in this cohort of patients. Other than advanced maternal age, patients with an elevated day 3 follicular stimulating hormone (FSH) level ranging from ≥7 mIU/ml to ≥15 mIU/ml are likely to show poor ovarian response [58]. Under this scenario, early studies have showed a higher implantation rate upon AH on 4–8-cell embryos from patients with elevated FSH basal levels (AH, 26% of 38 embryos; control, 10% of 40 embryos) [48].

Excessive ZP thickness has been a matter of concern and has been observed also in female patients less than 38 years of age. However, two studies have shown no correlation between the ZP thickness on embryo development and implantation [59, 60], and indeed when AH (performed by acidic Tyrode's solution) was applied to embryos with a ZP thickness ≥13 μm, implantation rates were not improved [61].

46.2.2.2 Cryopreserved Embryos

Upon cryopreservation, it has been proposed that a biochemically uncharacterized ZP hardening occurs [62, 63]. In early studies, we and others have documented a slight improvement of implantation rates upon AH performed on cryopreserved embryos [64, 65]. The first report included 125 embryos which underwent cryopreservation; AH was performed on 64 thawed embryos, 10 of which (16%) resulted in viable implantation, whereas only 6 out of 64 total in the unhatched control group (9%) successfully implanted [64]. Comparable results were observed in a subsequent study where AH was performed on 269 cryopreserved and thawed embryos, 37 of which implanted upon transfer (13.7%), whereas only 15 out of 284 (5.3%) implanted successfully without AH [65]. More recently, similar implantation rates were observed using AH performed by acidic Tyrode's solution applied to 136 cryopreserved embryos, which resulted in a higher implantation rate (11.4%) than the non-hatched control (5.8% of 117 embryos) [66]. Even *zona* thinning was having a positive

impact on the implantation rate of cryopreserved embryos, resulting in a 16.7% implantation rate versus 7.3% of the "non-thinned" control (200 total frozen embryo cycles) [67].

When in frozen embryo transfer cycles, AH seems to benefit the implantation rate of the cryopreserved embryos, studies which analyzed hundreds of clinical cases of fresh cycles have concluded that there are no strong evidence supporting a necessary role for AH in improving fertility outcomes (extensively reviewed in [68, 69]). However, with novel and emerging time-lapse video imaging, a high heterogeneity in the human embryos populations appears. We and others have observed different developmental patterns and implantation potential, even among embryos from the same cycle [70–72], which could have been the result of heterogeneity in embryonic genetics and physiology. Although further studies are needed to explore this heterogeneity, it might be reasonable to assume that although presenting similar characteristics (comparable age, morphology, culture conditions, etc.), different embryos might perform differently in developmental outcomes upon AH.

46.2.2.3 Repeated IVF Failure

Recurrent failed IVF cycles may be due to several causes which include reduced endometrial receptivity and endometriosis, embryonic developmental defects, genetic mutations inherited from the parental gametes, and aneuploidy. Oftentimes, the cause of IVF failure is unknown, and recurrent idiopathic IVF cycle failure is correlated with IVF failure in subsequent cycles.

46.3 Risks Associated with Assisted Hatching: Comparative Studies on Humans and Animal Models

Studies on animal models may inform clinicians on how the artificial induction of embryo hatching from the ZP may impact the cellular physiology of the embryo and the subsequent fertility outcome. Animal models offer an almost unlimited number of embryos and reagents that can be used as a platform to investigate the best conditions for assisted hatching and to provide insights on the possible physiological side effects that have been associated with this procedure.

A number of studies [73–75] in mouse have indicated conditions to perform a most effective assisted hatching of the mouse early embryo. While the use of acidic Tyrode's [76] solution has been largely replaced by less-invasive laser-assisted technologies [46], the impact of laser photoablation on the blastomeres adjacent to the ZP has been the matter of concern [77]. To avoid involuntary laser ablation of valuable blastomeres, some studies evaluate the possibility of thinning versus complete opening of the ZP and the pattern of embryo hatching on the procedure's outcomes, which include the development of the inner cell mass (ICM) and the rates of hatching, implantation, and pregnancy. In carefully designed studies, investigators have compared laser-assisted *zona* thinning with complete laser-assisted *zona* opening, using naturally conceived, genetically inbred, International Cancer Research (ICR) mouse embryos. As a negative control, intact-*zona* embryos were adopted [78, 79]. Assisted hatching was performed at the 8-cell stage followed by embryonic development and hatching pattern recording by time-lapse video imaging. Of interest, "*zona* thinning" only slightly improved the hatching rate of blastocyst, resulting in 39.3% of embryos hatched, which was comparable to the hatching rate of the negative control (33.9%), consistent with clinical data obtained in humans (200 patients), showing that thinning of the ZP (when performed chemically) does not improve implantation rate [80]. Indeed, a complete opening of the mouse ZP resulted in a 94.4% hatching rate. Another study used embryos from the same mouse strain (ICR), but assisted hatching was performed at the 2-cell stage. The results showed laser-assisted *zona* thinning to be more efficient than the previously described study, obtaining a similar number of hatched-blastocysts compared to laser-assisted *zona* hatching. One possible interpretation of the inconsistency of results between these two studies is that embryos may develop "better" in vitro if, since fertilization, they are not under the restriction of a constraining ZP.

Another compelling biological question that has intrigued the field in the past decades is the reason behind the ~2–12-fold [81, 82] increase in the incidence of monozygotic twinning in patients undergoing assisted reproductive technologies, particularly with assisted hatching, compared with natural conception. The phenomenon of monozygotic twins seems to be induced by physical, molecular, and mechanical factors, and it does occur in nature in several conventional and nonconventional animal models. For example, the 9-banded armadillo produces naturally identical quadruplets. These twins are the result of two binary fissions of a single fertilized egg [83] that develops normally up to the hatching blastocyst stage and then remains in diapause for 7 months; after that the epiblast undergoes two binary fissions, resulting in four conceptuses [84, 85]. Other vertebrate models show an association of a delayed embryo development with the insurgence of monozygotic twins. In particular, artificial modulation of oocyte and embryo development in vitro such as decreasing incubation temperature in fish [86], reducing oxygen availability in mice [87], or delaying ovulation in rabbit [88] may induce a rise in the insurgence of monozygotic twins. Moreover, an artificially induced mechanical split manipulation of the preimplantation embryo at different developmental stages has been associated with the birth of monozygotic twins in cattle (blastocyst) [89], pig (morula and blastocyst) [90], and rhesus monkey (2-cell, 4-cell, and blastocyst) [91].

In humans, insurgence of monozygotic twins has been attributed to hormonal ovulation induction (natural 0.45% vs. ART 1.2%) [92], natural or induced modification(s) in the architecture of the ZP (perforation upon ICSI, assisted hatching) [93–95], and extended in vitro culture conditions [96, 97]. The mouse model shows a comparable incidence of monozygotic twinning (1–1.75%) [98, 99], and their embryos

make a useful proxy for the investigation of the possible causes of monozygotic twinning in assisted reproduction.

There have been two case reports showing human blastocysts herniating from small breaches in the ZP generated upon sperm injection [94, 95], resulting with a so-defined 8-shaped hatching (representative schematic and picture in Fig. 46.1c, d), which resulted in double ICM-like masses in two blastocoels [100, 101], one of which yielded a monozygotic twin pregnancy [100]. The "herniation" hypothesis was also supported by a recent study performed in the mouse [102], where it was shown that extended in vitro culture led to a high frequency of "8-shaped" hatching patterns in both embryos conceived in vivo and in vitro; this hatching pattern leads to an increased occurrence of split ICMs, positive for OCT4 expression, a transcription factor that is exclusively expressed in the ICM cells in the embryo and that maintains ICM cells' pluripotency [103].

While it has been shown that mechanically induced splitting of the mouse morula [104], 2–8-cell stage human embryos [105], and mouse blastocysts [102] results in monozygotic twinning, other factors such as culture media/conditions might cause the embryo to be more likely subjected to splitting in vitro upon mechanical insult, perhaps through induced modification of their epigenome [106]. For example, we occasionally observe zona-free embryos developing into two separate blastocysts (Fig. 46.2a). In this instance, no herniation induced by the ZP could be inferred (as indeed, no ZP was present). These findings are consistent with previous studies showing that the complete removal of the ZP prior to blastocyst transfer does not reduce the incidence of monozygotic twin pregnancies [107]. Because culture media have been shown to induce epigenetic alterations in mouse and human embryos [108–110], one could hypothesize that culture conditions might promote the embryos to "split" at some point during development and perhaps sometimes develop two ICMs, one more visible plus an extra cryptic one, made of few cells and not clearly visible under the microscope, which could continue dividing and eventually be the basis for monozygotic twins (Fig. 46.1e, f). If this hypothesis is correct, we could envision experiments using embryos from transgenic mutant mice with constitutive epigenetic alterations at defined genetic loci (alterations normally induced under in vitro

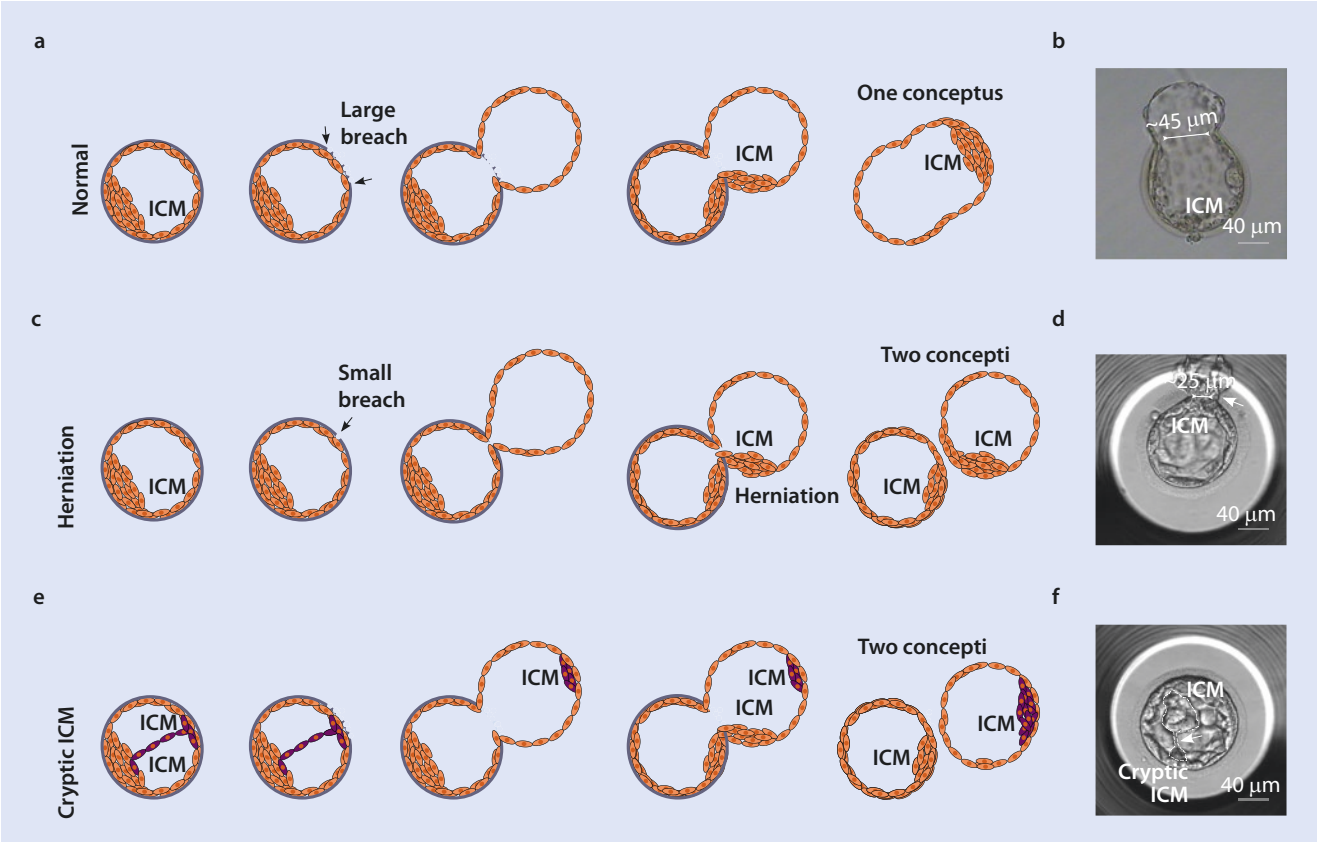

Fig. 46.1 Possible outcome upon laser-assisted hatching. **a** Hatching blastocyst escapes from the manipulated ZP, encountering no obstacles. **b** Representative picture of a hatched blastocyst which successfully implanted. The opening generated was ~45 µm. **c** Small breaches in the ZP may lead to monozygotic twins. Blastocyst escaping through a small (~25 µm) breach in the ZP may undergo ICM herniation and split, with the generation of two genetically identical blastocysts. **d** Representative picture of an "8-shaped" hatching blastocyst. Picture from time-lapse video recording (Embryoscope, VitroLife). Arrowhead shows the herniation of the ICM during embryonic escape from the ZP. **e** ICM bridges. During the completion of cavitation, ICM bridges are occasionally observed. This event could be associated with the presence of a "cryptic" ICM which could eventually result in the development of a second conceptus. This event has been observed to raise the question independently of the AH procedure. **f** Representative picture of an ICM bridge and a possible cryptic ICM

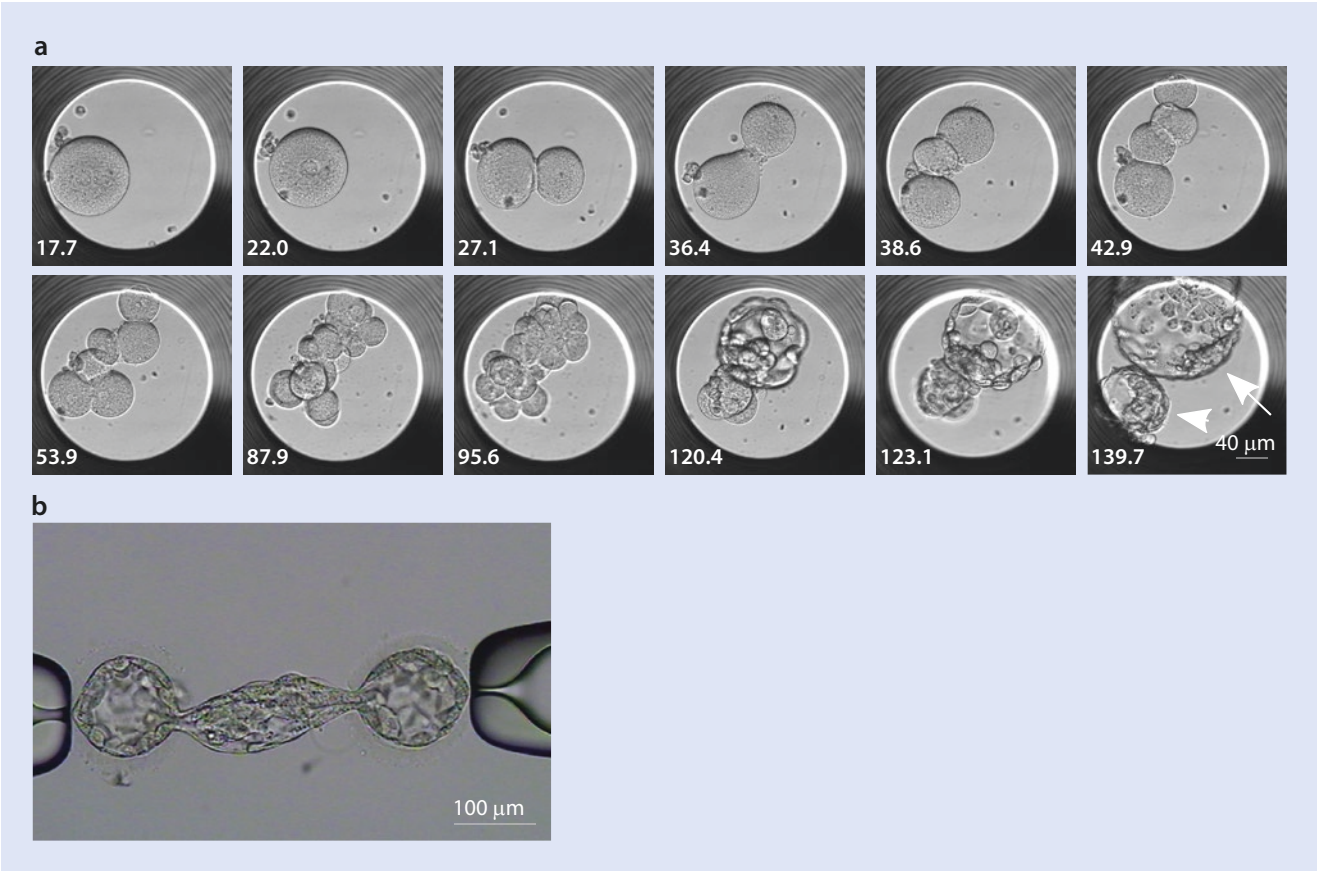

Fig. 46.2 Cases from our fertility treatment programs. **a** Time-lapse imaging frames show an embryo without ZP dividing and splitting into two embryos which ultimately proceed through compaction and cavitation independently and form two disjoint blastocysts (white arrow and arrowhead) which were cryopreserved 5 and 6 days post insemination. As of the date of the drafting of the present manuscript, these two blastocysts were not transferred as the patient became pregnant with a third single blastocyst transfer. Captions are hour post insemination. **b** Embryos cocultured and fusion: hatching embryos at the 8-cell stage that are cocultured may potentially lead to blastocyst fusion as they hatch from their separate ZPs. Although feasible using laser technology, at this stage it might be challenging to divide the blastocysts while preserving their viability. Ongoing studies at our practice are performed to prevent this reoccurring phenomenon

culture conditions) that should activate or silence signaling pathways that may lead to the development of this second "cryptic" ICM and consequentially a higher incidence of monozygotic twins in their litters.

46.4 Current Methodologies for Assisted Hatching

Implantation requires embryo-endometrium contact as the blastocyst hatches out of ZP in the uterus following embryo transfer. Failure of the embryo to escape the ZP is believed to be related to low implantation rates for poor prognosis patients and the main goal of AH is indeed to overcome this obstacle [111]. Here, we describe protocols for the different AH methodologies reviewed above, which include mechanical (partial zona dissection), chemical (zona drilling), and laser AH techniques.

Traditional AH treatments, including mechanical and chemical AH, were mostly performed at the cleavage stage (day 2/3) after fertilization prior to embryo transfer and blastomere biopsy, while the newer laser AH technology is routinely performed prior to blastocyst transfers and trophectoderm biopsies [111]. Mechanical AH or PZD involves making a small slit opening in the ZP using a simple microneedle. A holding pipette is used to hold the embryo in place at 9 o'clock, with the largest perivitelline space at 12 o'clock. The needle is then pierced through the ZP into the perivitelline space at 1 or 2 o'clock position and out the other side of the zona at 10 or 11 o'clock position. The holding pipette suction is released, and the embryo is held by the needle. The holding pipette is rubbed against the pierced area of the zona until it is completely opened in a slit-like fashion [49, 112]. An improvement of this technique is the three-dimensional PZD, where a second slit is made in the ZP at a right angle to the first cut, leaving a cross-shaped hole. This allows a larger opening while still protecting the embryo during transfer [44, 49].

Chemical AH treatment uses acidic Tyrode's solution to create a hole in the ZP. An AH dish is prepared using aseptic techniques, with a large 30–60 µl drop of medium supplemented with 10% protein in the center of the dish. Using a clean pipette, a ~10 µl drop of Tyrode's solution is placed

above the medium drop, and both drops are overlaid with mineral oil. Micro-tool setup includes a holding and hatching pipette correctly positioned and aligned on the micromanipulator. The embryos selected for AH are moved into the hatching dish and placed in the medium drop. The dish is placed on the heated stage of the microscope, and the embryo placed in the center of the view field at 40× magnification. The holding pipette is lowered into the drop and suction is applied to hold the embryo at the 9 o'clock position on the bottom of the dish. The hatching pipette is preloaded with the acidic Tyrode's solution, and is brought close to the ZP in an area near the perivitelline space and away from any blastomeres. Holding pipette, hatching pipette, and embryo should all be in focus in the field of view, with ≤5 μm space between the opening of the hatching pipette and the *zona* surface. The solution is then gently expelled against a small area of the ZP until a hole is made (~30 μm), which should take no more than 10 s. The hatching needle is gently moved up and down to ensure the acid is dispersed over a section of the ZP. Once the desired hole is achieved, suction is applied by the hatching pipette to prevent any acid from entering the embryo. The embryo is then immediately rinsed off several times and placed back in culture [44, 66].

Laser AH has grown in popularity since the 1990s with its advanced technology and ease of use in the IVF laboratory. This technique uses a noncontact 1.48 μm diode laser beam and computer software to breach the ZP in a controlled manner. The laser technology allows for easier AH of both day 3 embryos and fully expanded blastocysts for transfer. Selected embryos need to be artificially shrunk down away from the ZP prior to AH to "allow space" for the laser. The target on the laser software is moved over the selected portion of the zona, placing it in the path of the laser beam. Repeated pulses of the laser using a computer mouse or footpad produce the desired size of *zona* breaching [111].

A laser AH protocol for day 3 embryos requires only an inverted microscope outfitted with a 1.48 μm diode (Hamilton Thorne-Zilos) laser and software (Fig. 46.3a). The selected embryos are moved to a separate well in the culture dish and placed on the heated stage. The desired location for AH is selected based on the largest perivilline (PV) space away from any blastomeres (Fig. 46.3b). The embryo is then positioned in the middle of the microscope field of view on the laser-grade objective lens displaying the laser target. With the laser power set at 300 mW and 260 μs pulse duration, the target is placed over the outside edge of the ZP, and the laser is applied to create the first hole (Fig. 46.3b). Using the stage manipulator, the target is positioned immediately next to the first hole and the laser is applied again. This is repeated until the PV space is reached. Using this procedure, a breach of ~40–45 μm diameter should be opened to later avoid ICM herniation (Fig. 46.1a, b). Once all selected embryos have been hatched, the dish is placed back into the incubator. Under these conditions, when we culture ≥2 embryos in the same dish, we occasionally have observed two blastocysts attempting to merge (Fig. 46.2b). At this point, it is challenging to separate the two blastocysts, and this condition may lead to the discard of both embryos.

To prevent this issue, we also perform AH at the blastocyst stage. As per our protocols, laser AH of expanded blastocyst requires a pre-made 0.2 M sucrose solution to artificially collapse the embryo (Fig. 46.3c). A ~50 μl drop is placed in the lid of a Falcon® dish, and overlaid with mineral oil. The drop is aspirated and refreshed with fresh solution prior to hatching to prevent evaporation. The blastocysts are transferred into the sucrose drop, and the drop is drawn down to place the embryos on the bottom of the dish. The dish is then placed on the heated stage of the inverted microscope with the laser. Once the embryos have collapsed away from the ZP, the stage manipulator is used to reposition the target, and the laser is fired in a straight line to cut off a

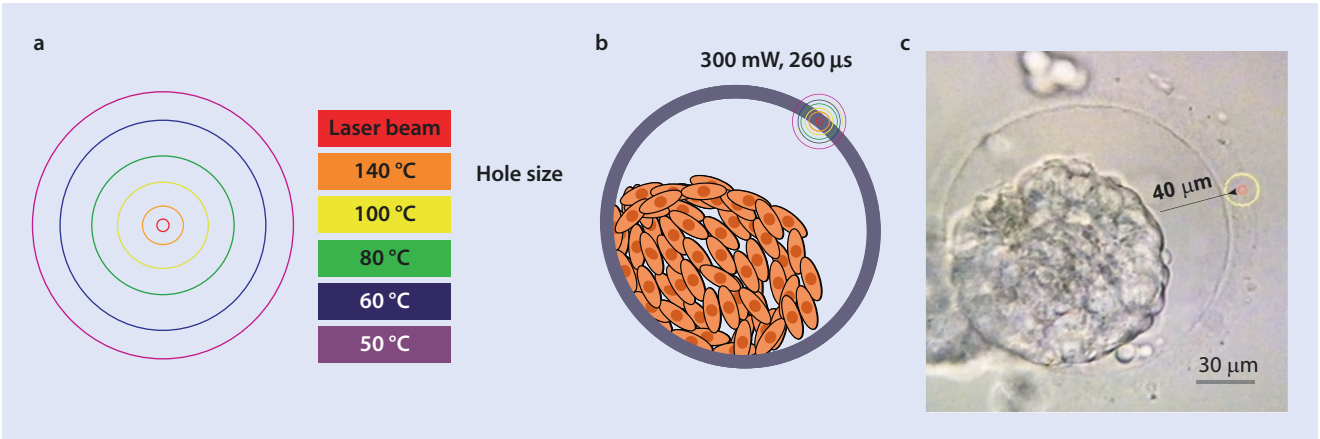

Fig. 46.3 Laser-assisted hatching. **a** Schematic of predicted thermal profile of the Hamilton Thorne Isotherm Rings™ which shows the temperature that the tissue and cells around the center hole (orange) may potentially be exposed to. **b** Schematic shows the conditions we have adopted for laser AH. A laser power of 300 mW and pulse duration of 260 μs help protect a collapsed embryo from the exposure of laser-generated heat. **c** We estimate that maintaining the blastomeres/trophectoderm ~40 μm away from the center hole of the laser prevents the embryo from exposure to the laser-induced heat, which guarantees minimal to no physiological stress to the embryo and consequently no impact on survival and implantation potential

Table 46.1 Cycle outcomes from transfer of non-hatched day 3 embryos (2010–2015)

portion of the ZP. After this process is completed, the embryos are rinsed 2–3 times before being placed into their culture dish.

As clinical tools, all of the AH procedures have their benefits and drawbacks. It is crucially important to minimize the time the embryos are exposed to atmospheric air during the procedure. The goal of AH is to generate a breach in the ZP in an efficient manner while keeping proper pH and temperature [44]. The more traditional techniques of PZD and zona drilling require extensive technical skills to achieve consistent results. PZD can be performed relatively quickly but results in inconsistent sized holes in the ZP. Indeed, small breaches in the ZP can lead to entrapment and herniation of the developing blastocyst, possibly increasing the chances of monozygotic twinning in the case where the ICM is pinched in two. On the other hand, large breaches can result in blastomere expulsion during the transfer [44, 111, 113]. *Zona* drilling using acidic Tyrode's solution creates larger and more consistent holes in the ZP, but involves possible exposure of the embryo to the acidic solution and must be performed quickly. Each embryo must be quickly and extensively rinsed to avoid unnecessary exposure of the cells to acidic medium, which increases the time needed to perform this technique [44, 111]. Laser AH requires a microscope equipped with a laser system, and lately, most laser systems have been designed to be easily adaptable to existing inverted microscopes. Laser AH is highly efficient, is technically easy to use, generates consistent results, and has no apparent negative impact on the embryo developmental performances [44, 49, 111, 114, 115].

46.5 Assisted Hatching on Fresh and Frozen Embryo Transfers from Poor Prognosis Patients: Current Data from Shady Grove Fertility Clinical Programs

We extensively investigate the effect of AH on patients clustered by age, over the period 2010–2015 in our fertility clinics, and here we report tables summarizing the data (Tables 46.1, 46.2, 46.3, 46.4). A general overview would suggest that AH might negatively affect implantation rate and pregnancy outcome (Table 46.3) when compared with embryos to which AH was not applied (Table 46.1). However, AH is routinely used with "poor" prognosis cases: a few examples are embryos that present a "poor" developmental pattern, embryos that failed to be fertilized using conventional insemination and are re-inseminated using ICSI, embryos from patients with recurrent failure of infertility treatments, and embryos from oocytes of 38 years of age or above. These studies present a number of limitations that may affect the validity of the study outcome [68]. For example, to assess the effect of AH on any embryo, it would be necessary to include as control sibling embryos with a comparable developmental pattern to which AH was not applied.

One more instance in which we routinely adopt AH is when cryopreserved embryos are being transferred. Table 46.5 summarizes the fertility outcomes from our fresh and frozen embryo transfer (FET) cycles over the period 2010–2015.

Table 46.2 Pregnancy outcomes from transfer of non-hatched day 3 embryos (2010–2015)

Pregnancy outcomes from "poor prognosis" patients ≥38 years of age, from 2010 to 2015. The current trend from our data seems to indicate better implantation rate when frozen cycle is performed. *CIG* clinical intrauterine gestation

While we find it hard to select appropriate controls in our clinical settings, we have found no detrimental effect of AH using our protocols. Based on the data collected over the past few years (Table 46.5) and in the light of data from previous reports showing that AH is ordinarily applied to embryos that have likely less chances to successfully implant [68], we adopt AH as a precautionary technique to assist embryos to escape from the ZP before implantation.

Acknowledgments We apologize to colleagues whose work could not be cited because of space limitations. We wish to thank our colleagues Maria Thompson (Shady Grove Fertility of Pennsylvania), Wayne Caswell (Shady Grove Fertility Center and Donor Egg Bank, USA), and Dr. Ameer Taha (University of California, Davis) for critical reading of the manuscript. We are grateful to the unique staff of Shady Grove Fertility for the continuous effort, dedication, and compassion in providing a most excellent fertility care, nationally and internationally.

Review Questions

1. What is the most recent general understanding on the mechanisms of fertilization, zona hardening, and embryo hatching?
2. How many assisted hatching procedures are being currently adopted and which is the most effective and less-invasive approach?
3. Does assisted hatching improve implantation and fertility outcome in all clinical cases or just in specific cases?

Learning Objectives

- What kind of equipment is required for polar body biopsy?
- When is the best time to perform polar body biopsy?
- How is zona opening best accomplished?
- How is the biopsy procedure performed?
- What are potential pitfalls during biopsy?
- How are polar bodies harvested for later analysis?
- What is the current status of polar body biopsy?

The chapter closes with questions that review the major aspects of the learning objectives.

47.1 Introduction

Polar body biopsy was first introduced in 1990 by Verlinsky and collaborators [1]. Since then, several groups have applied polar body biopsy to a variety of diagnostic applications such as detection of single gene disorders [2–4], translocation analysis [5], HLA typing [6] and detection of X-linked disorders [7]. However, to date, most cases of polar body diagnosis are performed for aneuploidy screening [8–11].

Polar bodies are by-products of the meiotic division. Removal of the first and/or second polar body is an indirect approach allowing the genetic status of the oocyte to be inferred from that of the polar body. The first polar body is not required for successful fertilization or normal embryonic development. The second polar body, which is extruded from the oocyte after initiation of the fertilization cascade by the spermatozoa, is similarly not required for subsequent embryo development, although it does persist up to the blastocyst stage [12]. Therefore, removal of both polar bodies for the purposes of genetic diagnosis is considered having no deleterious effect on the developing embryo.

47.2 Technical Aspects of Polar Body Biopsy

The most relevant parts of polar body biopsy are the timing of biopsy, the atraumatic opening of the zona pellucida and the removal of the polar bodies.

47.3 Equipment for Polar Body Biopsy

Like all other manipulation procedures, polar body biopsy requires an inverted microscope with a heated plate and micromanipulators. Based on the current practice, a non-contact near-infrared diode laser system should be part of the setup for opening of the zona pellucida prior to biopsy [13]. A holding capillary – similar to that used for intracytoplasmic sperm injection (ICSI) – and a bevelled and flame-polished capillary for polar body biopsy with an inner diameter of approximately 18 µm are required for the actual manipulation and biopsy of the polar bodies. A stereomicroscope, dishes, pipettes and other labware are part of the standard laboratory setup; however, a special pipette may be needed for transfer of polar bodies into reaction tubes.

47.4 Timing

An oocyte presenting a first polar body is usually considered to be in metaphase II. However, recent investigations using polarization microscopy have shown that some oocytes may be still in telophase I due to the presence of a connective spindle strand between the first polar body and the oocyte [14] (Fig. 47.1). Such a spindle bridge is a remnant of the meiotic division and is only present for a limited time period of 1–2 h after extrusion of either the first or the

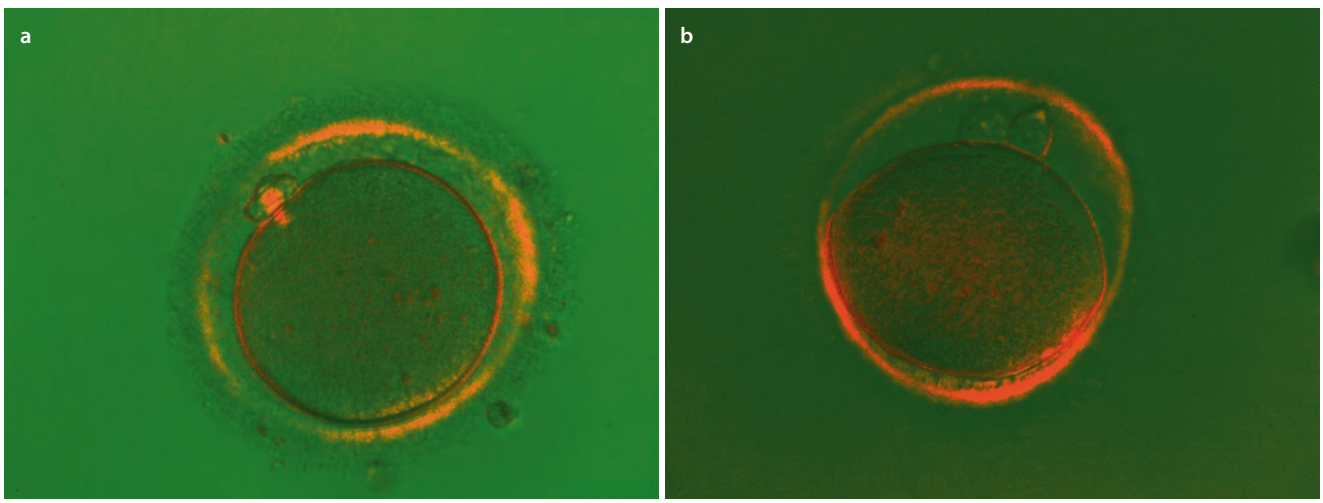

Fig. 47.1 **a**, **b**: For an optimized biopsy of the first and/or second polar body, the presence of a connective spindle bridge between one of the polar bodies and the oocytes can be visualized by polarization microscopy. If a spindle is present **a** the biopsy should be performed 1.5–2 h later, as the remnants of the spindle still may connect to chromosomal material, which imposes the risk of complete or partial removal of DNA during biopsy. The absence of a spindle **b** denotes that polar bodies are no longer connected by spindle strands and can be removed with such a risk

second polar body. Therefore, it is important not to biopsy polar bodies within a too short time period after their formation, because chromosomal material from the oocyte may still be attached to these spindle fibres and pulled out during biopsy. For the first polar body, this does usually only apply if one considers performing the biopsy prior to or immediately after the ICSI procedure – unless one can control for the presence and location of the spindle by using a polarization microscope. The risk is higher for the second polar body, which usually is extruded within 1.5–3 h after ICSI [15].

In view of this, several biopsy strategies have been discussed for polar body biopsy [13]. Removal of the first and second polar bodies can be done at separate time points or at the same time point. The sequential approach has the clear advantage that one can always distinguish the first and second polar bodies – which is of uttermost importance for diagnosis of monogenetic diseases. However, care has to be taken to remove both polar bodies through the same opening (see Pitfalls of polar body biopsy).

Simultaneous biopsy of the first and second polar bodies requires only one manipulation and helps reduce stress to the oocyte and is best accomplished in a time window of 8–14 h after fertilization. Too early biopsy bears the risk of spindle remnants in the second polar body, and too late biopsy may result in a first polar body that already started disintegration or degeneration. The latter problem is especially important if the analysis is based on fluorescence in situ hybridization (FISH) as it may contribute to diagnostic failures [8].

Regarding isolation of polar bodies for aCGH, the timing of biopsy of the second polar body seems to influence the amplification results. It was reported that too early biopsy of the second polar body (4–6 h post ICSI) may slightly lower the amplification efficiency, and this effect disappeared after adjustment to later biopsy times (>8 h post ICSI) [16].

Independent of whether a sequential or simultaneous approach has been chosen, it is mandatory to biopsy and to analyse both polar bodies. It has been shown in younger women that the first polar body is more prone to meiotic errors causing aneuploidies than the second polar body, whereas the opposite holds true in older women [17]. Hence, one could be tempted to conclude for chromosomal screening that analysis of the first polar body is more important in younger women and of the second polar body in older women. However, a reliable diagnosis can only be based on the analysis of both polar bodies, and results from clinical studies on the concordance of PB 1 and 2 analysis and the corresponding oocyte gave direct proof to this [18].

47.5 Zona Opening

Various methods have been proposed for the opening of the zona pellucida and subsequent removal of polar bodies: chemical, mechanical and laser-assisted opening.

47.6 Chemical Opening

Acidic Tyrode's solution was the first method ever used for opening of the zona pellucida by chemical means [19]. Although acidic tyrode can be applied at the embryo stage, there was an inhibitory effect on embryonic development when oocytes were exposed to acid tyrodes [20]. Therefore, since both the oocyte and polar body are sensitive to the effects of acid, zona drilling by acidic Tyrode's solution is unsuitable for polar body biopsy.

47.7 Mechanical Opening

A very efficient mechanical technique was elaborated by Cieslak et al. [21] and is based on three-dimensional zona dissection and subsequent biopsy. For this procedure, the oocyte is affixed to the holding capillary. Using a sharp needle, a slit is made close to the area where the polar bodies are located. After turning the oocytes by 90°, a second slit is made by creating a cross-like incision in the zona, which allows accessing the polar bodies. This method can be performed with simple glass tools; however, multiple steps including dissection, release and rotation of the oocyte are needed. Therefore, this procedure is technically difficult and requires extensive experience.

Another approach is the use of a bevelled micropipette (12–15 µm in diameter), which due to its sharpness assists in opening the zona. For this technique, the oocyte is oriented so that the polar body is located at the 12 o'clock position. The bevelled micropipette is passed through the zona and into the perivitelline space tangentially toward the polar body, which can then be aspirated into the pipette. This method works very well if only one polar body is biopsied; however, it is more tedious if the first and second polar bodies need to be biopsied and if both are not lying close to each other. Naturally, this method bears a certain risk of damaging the oocyte due to the sharpness of the needle.

47.8 Laser-Assisted Opening

The ultimate way of opening the zona pellucida is by a laser beam. Lasers were initially used to assist fertilization in cases of severe male factor infertility. The introduction of laser-assisted zona opening [22] has entered the field of polar body [11, 23] and embryo biopsy [24] and has helped in reducing the rate of biopsy damages as well as the time required [25]. In a recent expert survey among embryologists, laser-assisted zona opening was considered to be the only methodology that should be applied for polar body biopsy [13] as it offers a very fast access to the perivitelline space and allows to perform the required manipulations within a minimum of time.

47.9 Biopsy Procedure

The whole procedure of simultaneous laser-assisted polar body biopsy is illustrated in Fig. 47.2. Laser-assisted polar body biopsy is best accomplished when the oocyte is affixed

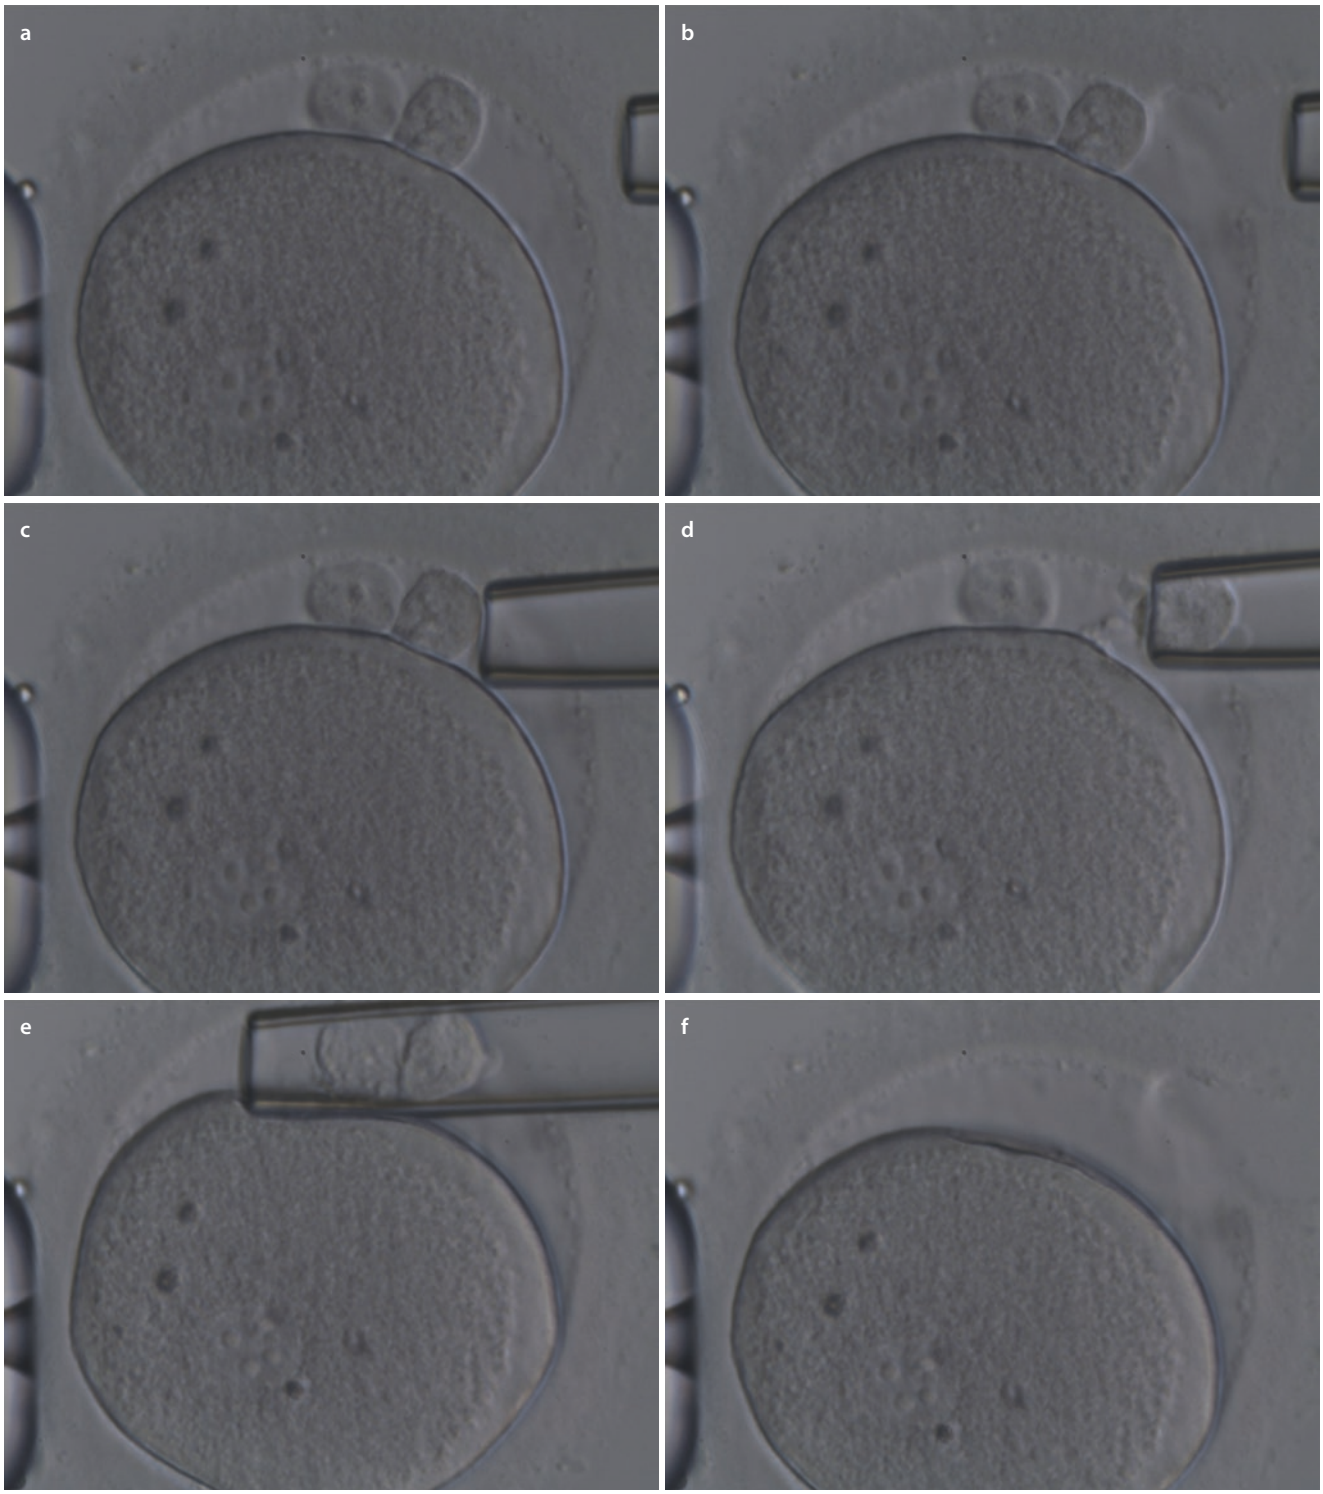

Fig. 47.2 **a**–**g**: Polar body biopsy following polarization microscopy For biopsy, the first and second polar bodies were aligned with a holding capillary so that the second PB faced to the biopsy capillary **a**. Using a non-contact 1.48 µm diode laser, an opening was introduced into the zona pellucida using 2–3 laser shots **b** through which the biopsy capillary could be easily introduced **c**. The second polar body is usually connected to the oolemma via a cytoplasmic strand **d**. In order to remove the second polar body without damaging the oocyte, it is *not* recommended to suck the second PB into the capillary, as shown in **d**. Instead, the capillary is pushed slowly over the second PB and toward the first PB **e**. Once the first PB enters the capillary, the strand between the second PB and the oolemma breaks due to shear stress, and both polar bodies can be easily removed **e**, leaving the oocyte without any damage **f**. Polar bodies should be placed in one droplet for further processing for FISH analysis **g** or in two different droplets if a PCR-based analysis is performed

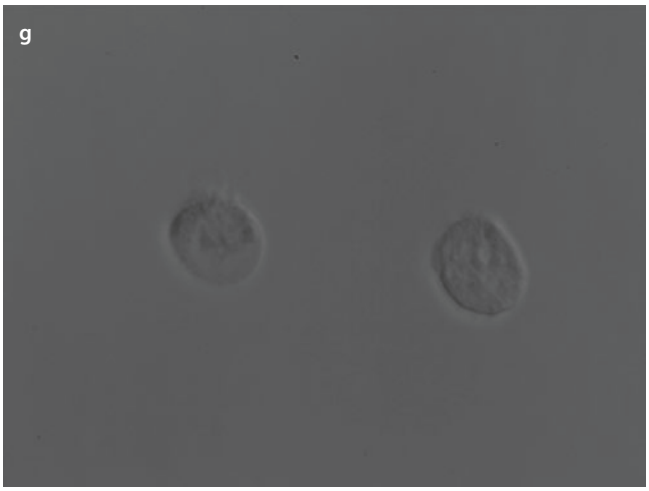

Fig. 47.2 (continued)

to the holding capillary with the first polar body at the 12 o'clock position and the second polar body located right of the first one but in the same focal plane. An opening of 18–25 µm is drilled at 2–3 o'clock, and by pushing the biopsy capillary into the perivitelline space, both polar bodies can be removed simultaneously. The positioning of the second polar body next to the aspiration capillary allows pushing the second polar body far to the left side toward the holding capillary. This stretching movement usually is sufficient to break the cytoplasmic bridge between the second polar body and the oocyte. Due to the use of a blunt-ended capillary, even manipulation in direct vicinity to the oolemma does not damage the oocyte.

In general, the size of the drilled opening is usually in the range of 20 µm or less, but it can be easily adjusted to the diameter of the aspiration capillary. As the capillary can be introduced through the laser-drilled opening, there is no need for a sharp aspiration needle. This allows the use of flame-polished, blunt-ended aspiration needles and greatly reduces the risk of damaging the polar body or the remaining oocyte. The procedure is accurate, reproducible and safe, and it also reduces the number of cells that cannot be reliably diagnosed as a result of technical problems during the biopsy procedure [26]. Another benefit is that laser drilling and subsequent biopsy can be performed without changing the capillaries in contrast to mechanical zona drilling where one either needs a double capillary holder for the drilling and the polar body biopsy capillary or another setup for subsequent biopsy.

47.10 Pitfalls of Polar Body Biopsy

The different approaches to generate an opening in the zona pellucida do result in different characteristics of the shape of the openings as well as the behaviour of the corresponding oocytes and embryos. To date only the effect of laser drilling has been studied intensively.

Although the use of laser seems to be easy and straightforward, it is still essential that the technique is trained properly in order to avoid possible pitfalls [27]. Laser opening of the zona can be performed at a very high precision, giving reproducible results. Consequently, it was shown that laser-assisted biopsy does not interfere with further development of mouse embryos [23] as long as the laser is used in a proper way [27], and a few examples will be given below.

Laser-drilled openings stay permanently in the zona, and therefore gentle handling during subsequent transfer of oocytes to other media droplets and even during the embryo transfer is strongly recommended.

Depending on the size and position of the laser openings, inappropriate hatching may occur at the blastocyst stage [27]. If the biopsy of both polar bodies is done in a sequential approach at different time points, one should avoid drilling another opening. If polar bodies were retrieved through separate openings, problems may arise at the time of hatching because the embryo could hatch through both openings simultaneously and therefore may get trapped within the zona [27] and either split or get stuck and degenerate.

While introducing an opening in the zona, care should be taken to generate a sufficiently large opening which allows consecutive hatching at the blastocyst stage, because smaller openings (<15 µm) may also cause trapping of the embryo followed by splitting or degeneration [27].

Independent of the method used for biopsy, it is extremely important to note the shape of the polar body. Especially, a fragmented polar body should be classified as that because this does require special care during later transfer for further evaluation. If fragments are lost, one will get an incomplete diagnosis or even a misdiagnosis.

47.11 Preparation of Polar Bodies for Subsequent Analysis

Once polar bodies are biopsied, they need to be transferred for further analysis by FISH or amplification of the DNA for subsequent analysis by aCGH, NGS or SNP array. This transfer is a crucial step as it bears the risk of loss of material or even of contamination.

47.12 Transfer for FISH

Immediately after biopsy of an oocyte, the corresponding polar bodies are placed in a neighbouring droplet of medium until all oocytes are biopsied. For FISH, it is not essential to place the first and second polar bodies in different droplets, as they can be visually distinguished during fluorescence evaluation. Due to the small cytoplasmic content of the polar bodies, a special pretreatment such as hypo-osmotic swelling or proteinase/pronase treatment prior to FISH is

not necessary. For transfer onto the glass slide, polar bodies of one oocyte are removed from their drop and transferred into a tiny drop (0.2 µl) of water placed on a clean glass slide. The small volume guarantees that the polar body attaches to the slide within a small area and that the fluid dries out very fast, which reduces the risk of a dislocation of the polar body on the slide. It is recommended to use for this transfer the biopsy capillary and to perform the complete procedure under visual control at the microscope. Placing the polar bodies directly at the bottom of the slide prevents floating and rupture of the polar bodies. The drying process should be observed under a stereomicroscope, and the final location of the polar body after air-drying should be marked on top of the slide by encircling with a diamond marker. With some experience, polar bodies from 6 to 10 oocytes can be placed within a round area of 10 mm, each encircled with a diamond marker. Subsequent fixation can be performed with 2–3 drops of 10 µl methanol:acetic acid (3:1, ice-cold −20 °C) followed by another fixation after air-drying using methanol at room temperature for 5 min [28].

47.13 Transfer for PCR

In contrast to the isolation for FISH, the differentiation of the first and second polar bodies is crucial for any PCR-based evaluation, either for monogenetic diseases or for screening. Therefore, the first and second polar bodies are released after biopsy in different droplets with medium in a dish covered with mineral oil. This facilitates the subsequent transfer of both polar bodies into separate reaction tubes. Using a high-contrast stereomicroscope, polar bodies can be easily identified in the medium droplets and aspirated for immediate transfer by using an unbreakable plastic capillary with a fine tip, similar to those used for oocyte denudation, which has a diameter ranging between 80 and 140 µm. If a standard low-volume pipette (0.2–2.0 µl) is used, care should be taken to use droplets for polar body sampling of at least 10 µl of volume as this facilitates to aspirate the polar bodies without sucking up any mineral oil.

It is important to note that the subsequent DNA amplification procedure, which is performed in the reaction tubes, requires a well-defined volume and a special medium base (e.g. phosphate-buffered saline, PBS). Therefore, polar bodies should be transferred with a minimal carryover of the sampling medium (which is usually HEPES- or MOPS-based culture medium). A standard setting is to pre-fill reaction tubes with 2.1–2.3 µl of PBS and to transfer polar bodies with 0.4–0.2 µl of medium into this solution to give a final maximum volume of 2.5 µl. Following the transfer into the reaction tube, it is advisable to rinse the capillary in the sampling droplet in order to verify that the polar body has been placed in the reaction tube, as this process cannot be directly visualized due to the plastic material of the tubes.

47.14 Current Status of Polar Body Biopsy

FISH technology is nowadays less applied for diagnosis in PGS programs but may still be found in combination with polar body biopsy. A major problem of such an approach is the interpretation of FISH results, especially for the first polar body. It is unknown at what time the first polar body has been extruded during the final maturation of the oocyte. Therefore, the chromatin of the first polar body is more prone to an ageing process compared to the second polar body, whose formation and ageing can be precisely controlled as a result of the time point of injection. Ageing affects the quality of the DNA, the coherence of the chromatids, its dispersion after isolation on a slide and hence hybridization efficiency. In contrast, isolation and amplification of DNA from the first (and second) polar body for PCR-based diagnostic methods can be accomplished with over 90% success rates even from polar bodies that show signs of degeneration.

Independent of the diagnostic approach, the use of polar bodies only allows a diagnosis of the maternal contribution, whereas the paternal factor remains inaccessible.

Despite these shortcomings, polar body biopsy has been discussed in recent years as a potential alternative to blastomere biopsy on day 3 [29].

Whereas some studies report a high or acceptable correlation for predicting aneuploidy based on polar body and aCGH [18, 30], others question the accuracy of polar body diagnosis due to the high incidence of post-zygotic errors [31, 32]. Another conflicting topic is the occurrence of reciprocal chromosome aneuploidy results in the first and second polar bodies of an oocyte. This was considered as a negative factor, but a recent study showed that this situation mostly gives rise to normal euploid embryos [33], and the birth of a healthy child has been reported from an oocyte with reciprocal aneuploid polar bodies [34]. These findings illustrate the difficulty in the interpretation and diagnosis of polar body-based results.

In combination with comprehensive chromosome screening methods such as aCGH or NGS, polar body biopsy and subsequent diagnosis is the most expensive approach that can be chosen. First, not every oocyte develops into a viable embryo. Even if the diagnosis is postponed to a stage that allows a better judgment of the developmental potential of an oocyte and the corresponding embryo, still both polar bodies from every oocyte should be initially biopsied and sampled. Second, both polar bodies should be separately analysed, which inevitably doubles the costs of the diagnosis.

47.15 Summary

Polar body biopsy is the initial step prior to investigation of the first and second polar bodies regarding genetic dispositions or structural and/or numerical chromosomal disorders. Polar body diagnosis allows concluding on the genetic/chromosomal constitution of the oocyte. The most frequently

used biopsy method is the laser-assisted biopsy followed by mechanical biopsy using zona dissection.

Isolation of polar bodies depends on the methods used for diagnosis. For FISH analysis, both polar bodies can be simply placed in a water droplet on a glass slide, whereas any PCR-based approach requires separate processing of the first and second polar bodies under sterile conditions.

Accurate timing and technique of biopsy are important for optimal results and reduction of oocyte trauma. Differences in techniques may explain differences in the success of polar body diagnosis for PGS reported by different studies. Polar body biopsy requires a proper training in order to achieve good results. However, the need to analyse both polar bodies for genetic as well as for chromosome screening methods in order to get the full picture is a cost-driving factor and a clear disadvantage compared to other methods such as trophectoderm biopsy [35].

Review Questions

1. What kind of equipment is required for polar body biopsy?
2. When is the best time to perform polar body biopsy?
3. How is zona opening best accomplished?
4. How is the biopsy procedure performed?
5. What are potential pitfalls during biopsy?
6. How are polar bodies harvested for later analysis?
7. What is the current status of polar body biopsy?

Cleavage-Stage Embryo Biopsy

Alan R. Thornhill

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_48

Learning Objectives

- To describe the need for embryo biopsy
- To present the options at what embryonic stages can biopsy be performed
- To review the technical requirements to perform embryo biopsy
- To provide a detailed description on how cleavage-stage embryo biopsy is performed
- To present the applications of cleavage-stage biopsy

The first PGD cycles were carried out in late 1989 in a series of couples at risk of X-linked disease and involved cleavage-stage embryo biopsy [1]. Theoretically, PGD can be accomplished at any developmental stage between the mature oocyte and blastocyst, but to date, only three discrete stages have been proposed: polar body, cleavage-stage, and blastocyst. Clearly, each of these stages is biologically different, and thus, the strategic considerations have both advantages and disadvantages [2] (Table 48.1). However, cleavage-stage biopsy has remained the most widely practiced form of embryo biopsy worldwide (according to the ESHRE PGD Consortium) accounting for approximately 90% of all reported PGD cycles to date [3]. Currently, this embryo biopsy strategy requires the removal of one or more cells from each embryo, making it comparable to amniocentesis or CVS at fetal stages since the primary aim is the removal of sufficient embryonic tissue to allow diagnosis. Cleavage-stage embryo biopsy is a two-step micromanipulation process involving the penetration or removal of part of the zona pellucida surrounding the oocyte or embryo followed by the removal of one or more cells. Many of the biopsy techniques currently in use for human embryos [4] were pioneered in animal models, notably the mouse [5–7]. While the total number of human embryos biopsied in clinical cases is vast, relatively little work has been published to define the relative merits of different biopsy methods and their safety and efficacy in clinical application (Table 48.2). This chapter focuses on cleavage-stage embryo biopsy since the majority of PGD centers and clinical cases reported have employed this technique [3].

Table 48.1 Advantages and disadvantages of cleavage-stage embryo biopsy

Stage	Advantages	Disadvantages
Cleavage-stage accuracy (blastomeres)	Diagnosis of maternally and paternally inherited disease	Chromosomal mosaicism compromises accuracy
	Gender determination possible	Choice of blastomere is critical
	Large body of clinical data available	Time for analysis may be limited
	1–3 cells available for analysis	Most cells in interphase (no karyotypic data)
	Biopsied embryos develop into normal blastocysts	Single-cell-sensitive analysis required
		Reduced embryo implantation potential post-biopsy
2–4 cell	95% embryo cohort available for analysis	Detrimental effects of acid/reduced cell mass
		Possible selected cell allocation to TE/ICM
6–10 cell	1 or 2 cell removal still results in viable development	Reduced embryo cohort on the day of biopsy
		Possible selected cell allocation to TE/ICM

48.1 Penetration of the Zona Pellucida

Until the advent of noncontact lasers for use in micromanipulation (see below), two basic methods were employed for zona pellucida penetration. Both methods were pursued initially as a means to enhance fertilization rates with oligozoospermic men and have now been superseded for this purpose by intracytoplasmic sperm injection (ICSI).

48.1.1 Mechanical Zona Penetration

The first approach, partial zona dissection (PZD), employs a fine needle to penetrate the zona at two separate points around the circumference. The oocyte or embryo is then detached from the holding pipette as it is effectively held on the needle and a gentle rubbing action is made against the side of the holding pipette used to make a slit between the two apertures generated by the needle taking care to avoid damage to the oocyte or embryo [8]. Although a narrow-diameter micropipette can be pushed through such a slit, it is difficult to use one large enough to aspirate cleavage-stage blastomeres, and with the human embryo, pressure on the zona can lead to the lysis of blastomeres and/or, where a slit has been made, force blastomeres out through the slit. The latter approach is used for embryo biopsy in some centers, but requires highly skilled micromanipulation, can be difficult to control, and does not allow precise selection of blastomeres, and the risk of lysis can be high. A modification is to make two slits to create a "flap" or "cross" in the zona that can be flipped open, allowing more flexibility in the size of the opening created. This method is effective for both blastomere and polar body biopsy [9].

Table 48.2 Cleavage-stage embryo biopsy methods—benefits, limitations, and factors critical to success

Zona penetration method	Benefits	Limitations	Factors critical to success
Mechanical	Least invasive to embryo (safer)	Difficult to learn	Operator skill essential
	Improved survival after freeze–thaw?	Operator dependent	Appropriate microtools needed
	Inexpensive	Time-consuming	
Chemical (acidified Tyrode's solution)	Relatively inexpensive	Operator dependent	Acidified Tyrode's solution pH 2.2–2.4
		Difficult to limit aperture size	Sensitive control of acid
	Widespread clinical experience	Effect on cryopreservation?	Rinse acid from embryos
		Double tool holder optimal	
Laser (1.48 µm noncontact diode)	Rapid and reproducible	Capital cost (30–60,000 US dollars)	Laser alignment and calibration
	Simple to use	Not all systems portable	Pulse duration and number
	Documentation/measurement software	Invisible thermal damage/stress	Distance between laser and zona
Cell removal method			
Aspiration	Ability to select cell	Cell lysis during aspiration	Appropriate microtools needed
			Sensitive suction device
Fluid displacement	Aspiration pipette does not contact cells	Limited ability to select cell	Operator skill essential
Mechanical displacement	Aspiration pipette does not contact cells	Limited ability to select cell	Operator skill essential
		Damage to non-biopsied cells?	

48.1.2 Chemical Zona Penetration

In general, mechanical methods for zona penetration are time-consuming and require skillful micromanipulation, possibly making them inaccessible to some IVF laboratories. As an alternative, zona drilling using acidified Tyrode's solution (pH 2.2–2.4) to dissolve the zona glycoproteins has been extensively used and is commercially available from most culture medium manufacturers. This method developed in the mouse embryo model, with the aim of improving fertilization rates with low sperm densities [10], was of limited value when using human oocytes, as an increased fertilization rate was offset against developmental arrest in the zygote, presumably consequent to changes in intracellular pH [11]. With zona drilling, the effect of the acidified Tyrode's solution is localized to a small area of the zona (generally between 20 and 30 µm) using a fine micropipette, with an inner diameter of 5–10 µm. The pipette is placed very close to or in direct contact with the zona pellucida at the desired position and the acidified solution gently expelled from the pipette until the zona thins, and an aperture is drilled (in some cases, the zona can be seen to "pop" as an aperture is made). The flow, facilitated via oil-filled syringe (hydraulic), air-filled syringe (pneumatic), or by using a mouth pipette, must be carefully directed and controlled to limit the size of the zona breach. The human zona is bilayered, and the zona drilling process must be carefully monitored as the outer layer dissolves more rapidly than the inner layer. Moreover, there is great variation in zonae pellucidae both between and within cohorts of human oocytes and embryos. The final diameter of the aperture made will be determined by a combination of the above factors. An excessively large aperture may result in the unwanted loss of blastomeres but, more significantly, may indicate that the blastomeres were exposed to potentially damaging quantities of acid, which could compromise further development. Physiologic pH of the medium was originally maintained by employing phosphate-buffered saline but is now routinely maintained using modified culture medium buffered with either 4-morpholine propanesulfonic acid (MOPS) or 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES). When the drilling is complete, the micropipette is immediately withdrawn and, if necessary, excess acidified Tyrode's solution aspirated from the biopsy drop.

48.1.3 Noncontact Laser (Thermal Ablation of the Zona)

Since the first PGD cycles reported by the ESHRE PGD Consortium, there has been a marked shift across centers worldwide from zona drilling using predominantly acidified Tyrode's solution [12] to laser ablation of the zona pellucida with the laser now accounting for more than 70% cleavage-stage embryo biopsies [3]. This shift may be more to do with the ease of use and elimination of the need for a double tool holder and batch testing of acidified Tyrode's solutions rather than any measurable improvement in safety or efficacy.

The preferred model of laser is the near infrared (NIR) solid-state compact diode 1.48 μm laser. The advantage of using light as a cutting tool is that it obviates the need for a double tool holder and either disposable or reusable cutting tools. It is extremely precise and, if used appropriately, provides consistent, reproducible, and rapid results. Furthermore, the likelihood of introducing contamination or pH changes in the medium surrounding the embryo is greatly reduced as neither microtools nor reagents are required to dissect the zona. The 1.48 μm diode laser is small but, at the appropriate pulse duration, can emit light at power levels sufficient to cause selective thermal disruption of the zona pellucida glycoproteins and is not absorbed by water. This noncontact laser can be inserted into the body of the microscope on which the manipulations take place or be integrated in a special objective and the beam delivered to the target through the dish.

Since the laser beam travels up through an objective which lies below the sample, localized heating causes denaturation of the zona proteins in a cylindrical spot where the laser beam is focused, and the size of the aperture created is controlled by adjusting the laser pulse duration. The thermal energy created produces a groove in the zona perpendicular to the microscope stage, rather than a circular aperture. However, an "aperture" is produced in the zona at the point at which the zona is perpendicular to the microscope stage (Fig. 48.1). The size of the aperture (or more accurately, the width of the groove at its widest point) created in the zona ranges from 5 to 20 μm and is governed by the pulse irradiation time (ranging from 3 to 100 ms) or the accumulation of pulses along the length of the zona margin. The precision of the laser is illustrated by the fact that drilled mouse and human embryos show no sign of extraneous thermal damage under light or scanning microscopy [13].

Clearly, such equipment may be used for assisted hatching as well as PGD [14], and if used appropriately, there appears to be no detrimental effect of the laser itself on the development to the blastocyst stage or pregnancy rates in animal and human studies [3, 15–17]. However, studies of the immediate effects at the blastomere level in a mouse model [18] and following assisted hatching in a clinical program [19] have shown that the laser can cause damage if used inappropriately. Certainly, if the laser beam is fired in an area in direct contact with a blastomere, its viability is always compromised. However, as the pulse length, and therefore localized heating, is increased, the distance between the laser beam and blastomere required to avoid damage increases [18]. Hence, care is required to drill the zona away from underlying blastomeres and from as far away as possible and also to use minimum pulse lengths to restrict any damaging effects. Several practical guidelines have emerged to ensure safe and effective use of the laser for human embryo biopsy as follows. Wherever possible, a single aperture only should be made for cellular aspiration. Double or multiple apertures may cause problems during embryo hatching as the embryo will attempt to hatch out of multiple openings which could compromise further inner cell mass (ICM) development or lead to increased monozygotic twinning. To generate the desired aperture, several pulses of short duration are preferable to a single pulse of long duration (with higher energy),

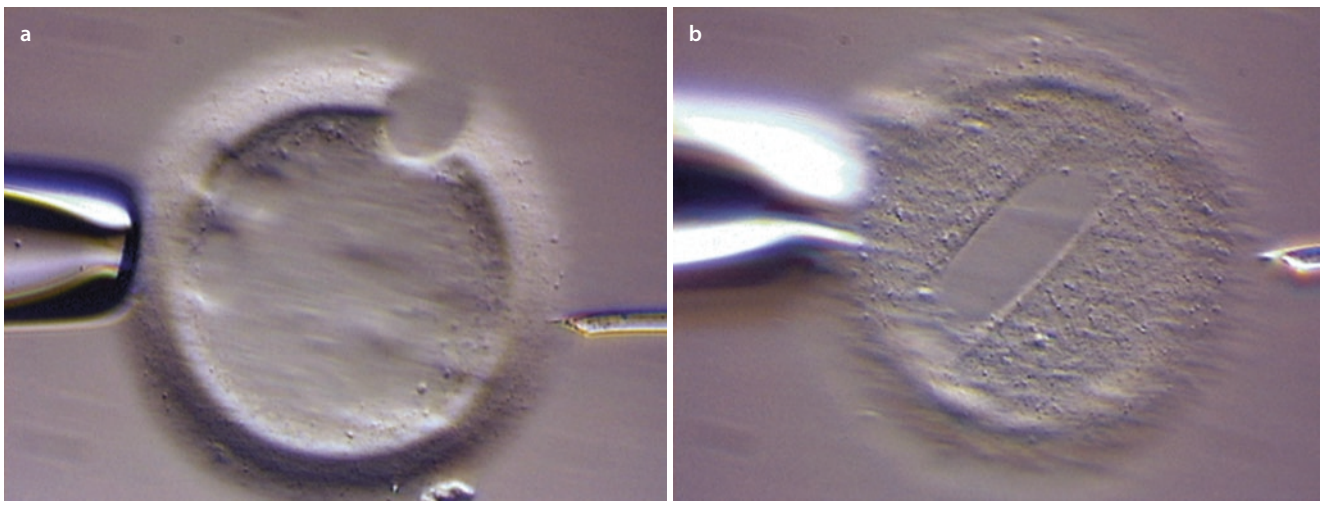

Fig. 48.1 Empty human zona pellucida after thermal ablation using noncontact laser. (**a**) Cross-sectional view as used during biopsy procedure indicating the aperture through which biopsy aspiration pipette is passed. (**b**) The same zona pellucida rotated through 90° to show the path of the laser

which could cause thermal damage. During laser use, it is imperative to maintain the oocyte or embryo as close to the bottom of the biopsy dish as possible to allow a focused beam to ablate the zona pellucida. As the embryo is raised above the dish surface, the beam energy is diffused and can create localized heating or simply prevent effective ablation of the zona. The use of the laser is deceptively simple, and it is imperative that the operator is constantly aware of the possible detrimental effects to the embryo of unnecessary or misplaced ablations.

48.2 Blastomere Removal

Having created an aperture large enough for the safe passage of one or more blastomeres, the operator must select a method for cell removal. The most frequently used method of blastomere removal is aspiration, but other methods have been described and used clinically, although no studies have been conducted to compare their relative safety and efficacy.

48.2.1 Aspiration

If performing aspiration in conjunction with zona drilling using acidified Tyrode's solution, it is easier to use a double tool holder containing a second aspiration micropipette (internal diameter of 30–40 μm depending on the cell size) filled with biopsy medium [2] rather than changing the micropipette in a single tool holder for each biopsy procedure. A single micropipette may be used for both drilling and subsequent aspiration, but care is needed to prevent overexposure to acid [20, 21]. Any advantage accrued in terms of speed of the procedure may be offset by potential damage as a result of overexposure to acid.

A typical procedure for cleavage-stage biopsy using laser and blastomere aspiration is illustrated in Fig. 48.2. Briefly, following laser ablation of the zona pellucida adjacent to the blastomere selected for analysis, the blastomere is aspirated by gentle suction using a finely polished "sampling" pipette. The aperture may be sited adjacent to either a selected blastomere or a sub-zonal space between blastomeres. The pipette is placed through the aperture, close to the blastomere to be aspirated. By gentle suction, the blastomere is drawn into the pipette while the pipette is withdrawn from the aperture. The aperture of the sampling pipette is critical for successful biopsy. If the internal diameter is too large for the cell being removed, the pipette will have little purchase on that cell and may result in unwanted suction on non-biopsied cells. Conversely, an undersized pipette will cause the biopsied cell to be squeezed unnecessarily, resulting in blebbing on the cell membrane and ultimately lysis, which will likely reduce the chances of a successful diagnosis in that embryo. Similarly, use of a holding pipette with an internal diameter of 30 μm (i.e., larger than a regular ICSI holding pipette) ensures safe and reliable suction on the zona particularly during difficult biopsies.

Once the blastomere is free of the embryo, it is gently expelled from the sampling pipette. Following biopsy, the embryo should be rinsed in culture medium at least twice to remove residual embryo biopsy medium before returning to the culture. The blastomere should be washed extensively in handling medium before proceeding to the analysis.

Fig. 48.2 Human cleavage-stage embryo from which a single blastomere with a single visible interphase nucleus is being removed by micromanipulation after laser ablation of the zona pellucida

48.2.2 Alternative Methods of Blastomere Removal

In the extrusion method, after zona pellucida drilling, the blastomere is extruded through the aperture by pushing against the zona at another site (usually at 90° to the aperture) using a blunt pipette [6]. The slit in the zona pellucida can be introduced using mechanical means, chemical (acidified Tyrode's solution) exposure, or laser ablation as described above.

Another variation in the method of cell removal involves fluid displacement whereby culture medium surrounding the embryo is used to displace individual cells following a zona breach. This method was pioneered in mouse embryos by introducing a slit in the zona with a sharpened needle and, through a second puncture site, injecting medium to dislodge the blastomere through the first puncture site [7]. This method requires the production of two separate apertures and considerable skill to displace the blastomere of choice but has been successfully modified for clinical application [22]. A challenge common to both of these methods is to ensure that only the selected cell or cells are removed.

48.3 Practical Considerations for Embryo Biopsy

48.3.1 Preparation Prior to Biopsy

ICSI is still recommended for all PGD cases involving DNA amplification to reduce the chance of paternal contamination from extraneous sperm attached to the zona pellucida or non-decondensed sperm within blastomeres [23]. Similarly,

as far as is practically and safely possible, all cumulus cells should be removed before biopsy as these cells can contaminate both fluorescence in situ hybridization (FISH) and polymerase chain reaction (PCR)-based diagnoses. Embryo and blastomere identity (individual drops or dishes) should be checked throughout the procedure so that diagnostic results can be reliably linked to specific embryos [23–26]. The use of standard IVF culture medium during biopsy is acceptable, but its effectiveness may be highly dependent upon the developmental stage of the embryo biopsied with compacting eight-cell embryos proving more difficult to biopsy. Commercially produced calcium- and magnesium-free (Ca^{2+}/Mg^{2+}-free) medium which temporarily reverses calcium-dependent cell–cell adhesion [27] is widely available and is used by many centers for routine clinical biopsy with the benefit of reducing the frequency of cell lysis [23] combined with a shorter time needed to perform the biopsy procedure.

48.3.2 Timing of Biopsy

Most of the cleavage-stage biopsy takes place on the third morning following insemination, although the exact timing varies according to timings of procedures in different laboratories and may be patient-specific or even cohort-specific for particular patients. One variation, allowing more time for genetic analysis, is to alter the timing of ICSI to allow cleavage-stage biopsy at the same embryonic stage but late on day 2 since biopsy at earlier cleavage stages on day 2 may adversely affect embryo development [28]. In cases where retarded development is observed, the possibility of delaying the biopsy procedure to allow diagnosis of a larger proportion of the embryo cohort should be considered. The use of Ca^{2+}/Mg^{2+}-free medium has also facilitated later biopsy (i.e., beyond eight-cell stage) making the laboratory timings more flexible. Furthermore, the increased use of sequential media and blastocyst culture and transfer has led to the routine delay of transfer until day 4 or more commonly day 5. This extended culture period allows additional time for diagnostic analysis and allows more opportunity to preferentially select the most developed embryos for transfer with the aim of improving pregnancy and implantation rates during a fresh transfer cycle and facilitating elective single embryo transfer to reduce multiple pregnancy rates [29].

Most laboratories exclude very poor-quality embryos or those not reaching a predefined cell stage from the embryo biopsy procedure. Of the centers surveyed, most will consider only embryos at the five-cell stage and beyond only for biopsy [12]. Biopsy at the four-cell stage in mouse results in a distorted allocation of cells to ICM and trophectoderm and abnormal postimplantation development [30], while human embryos biopsied on day 2 show cleavage rate retardation and smaller blastocysts [28]. Conversely, four-cell stage human embryos surviving freeze–thaw procedures with the loss of one or more blastomeres can develop, implant, and result in live birth, albeit at a reduced rate compared with nonfrozen embryos [31, 32]. Stringent biopsy policies have the benefits that fewer embryos need to be biopsied and fewer cells prepared and tested with only developmentally competent embryos considered with relatively little loss in pregnancy potential for that cycle. On the down side, an opportunity to identify genotypes on a full cohort of embryos may be lost.

48.3.3 Number of Cells to Remove During Cleavage-Stage Biopsy

In deciding how many cells to biopsy from cleavage-stage embryos, it is axiomatic to balance diagnostic accuracy with the potential to implant and develop, which is progressively compromised as a greater proportion of the embryo is removed [33]. There is no consensus on the number of blastomeres that can be safely removed during cleavage-stage embryo biopsy. In many centers, a second blastomere is removed from embryos having seven or more cells regardless of the type of analysis involved, but this approach has been criticized as compromising the implantation potential of the biopsied embryo based on extrapolation from frozen–thaw embryo implantation rates [32]. The decision to remove one or two cells is based on many factors including the embryo cell number and the accuracy and reliability of the diagnostic test used. Removal of two cells should only be considered on embryos with six or more cells [34]. While the removal of two blastomeres decreases the likelihood of blastocyst formation, compared with the removal of one blastomere, day 3 in vitro developmental stage is a stronger predictor for day 5 developmental potential than the removal of one or two cells. The biopsy of only one cell significantly lowers the efficiency of a PCR-based diagnosis, whereas the efficiency of the FISH PGD procedure remains similar whether one or two cells are removed [35]. However, a recent trial demonstrated that live birth rate was compromised at a level of 1 birth for every 33 cycles of two-cell embryo biopsy suggesting that, ideally, one-cell biopsy should always be performed unless the diagnostic test is suboptimal [36].

In the case of lost or anucleate blastomeres and failed diagnosis, rebiopsy of embryos is possible, but embryo cell number and timing of rebiopsy should be considered to avoid excessive harm to the embryo. Although technically challenging, the original zona breach site should be accessed to prevent later problems, including monozygotic twinning, possibly the result of embryos hatching via multiple sites. No specific recommendations for time limits for embryos out of the incubator are available, but ideally, biopsy should be performed as quickly as possible (certainly less than 5 min in total and, ideally, 1–2 min per embryo) to ensure pH, temperature, and osmolality are maintained. A documented record for biopsy timings should be maintained for quality assurance purposes [26, 27].

48.3.4 Success Rates After Biopsy

The reliability of cleavage-stage biopsy has now been established in many centers, and in a recent ESHRE PGD Consortium report, the efficiency of successful embryo biopsy is 98% in over 150,000 cleavage-stage embryos in clinical PGD cycles [3]. Pregnancy rates after PGD are notoriously difficult to assess between different indications and centers. Nevertheless, in the largest series analyzed in detail to date, mostly following cleavage-stage biopsy, pregnancy rates are only 22% per oocyte retrieval and 30% per embryo transfer on average [3]. The reasons for the apparently low success rates are manyfold but unsurprising considering that a proportion of embryos cannot be transferred because they are diagnosed as affected, and in many countries, the number of embryos transferred is limited to a maximum of two. To demonstrate the possible detrimental effects of embryo biopsy alone, one would need to conduct a clinical trial involving biopsied and non-biopsied embryos which would be transferred after selection on purely morphological grounds post-biopsy (i.e., without any genetic selection). Such a trial could be considered unethical. However, data from a recent trial provides some insight into the possible detrimental effects of biopsy with a reduction in implantation potential evident in undiagnosed biopsied embryos compared with non-biopsied control embryos [37, 38].

It is well established in mammalian embryos that as an increasing proportion of the embryo is removed or destroyed before transfer, implantation and fetal development rates decline, suggesting a lower limit of embryo mass compatible with implantation and development [39]. Reduction of 50% or more of the cell mass frequently results in cell proliferation in the absence of normal differentiation; thus, it is important to minimize the cellular mass removed at biopsy. However, cell reduction within this limit is compatible with normal embryo metabolism, blastocyst development, and fetal growth, while cell numbers in the trophectoderm (TE) and ICM of blastocysts were in proportion to the cellular mass removed at biopsy, making cleavage-stage biopsy for PGD a viable option [40]. Hence, human cleavage-stage biopsy is delayed until just before the beginning of compaction, the process of intercellular adhesion, and junction formation, which progressively makes the removal of blastomeres more difficult and eventually impossible without causing damage to the embryo. Generally, cells identified as having completed the third cleavage division (on the basis of their size) are selected for biopsy. Theoretically, therefore, each blastomere removes only one-eighth of the cellular mass of the embryo. As zona drilling for assisted hatching may be beneficial for some indications [41], it is also possible that the hatching process itself offsets to some extent the adverse effects of reducing the cell mass of the embryo.

In frozen embryo transfer (FET) cases, viable pregnancies are routinely achieved, albeit at a reduced rate compared with fresh transfer cycles. Moreover, no increase in fetal abnormalities has been reported following the transfer of cryopreserved embryos in which some cells have been destroyed by freezing and subsequent thawing of cleavage-stage embryos [42, 43]. Indeed, estimates of the loss of implantation potential have been made based on outcomes following FET involving cleavage-stage embryos with one or more nonviable cells after thawing [31, 32], although it is clear that the growth rate of viable cells may be more important than the loss of cells per se [31, 42]. It is now apparent that cleavage-stage biopsy should be considered a "cost" to the embryo, and this must always be weighed against the potential benefit to the embryo of any diagnostic testing.

48.3.5 Selection of Cells in the Cleavage-Stage Embryo

Biopsy at cleavage stages is based on the principle that at these stages, the blastomeres remain totipotent and equivalent such that the removal of a single blastomere will (a) provide a representative sample of the entire embryo and (b) compromise the embryo only to the extent of one-eighth of the embryo mass rather than removal of a developmentally crucial blastomere. The importance of selecting a blastomere with a single visible interphase nucleus cannot be stressed enough (Fig. 48.2). Aside from the increased diagnostic efficiency observed in mononucleated blastomeres [44], mononucleation is a marker for and directly correlates with implantation potential [45]. Nevertheless, embryos containing blastomeres, all of which have no visible nucleus, should still be considered for biopsy as nuclear material is likely to be present and should yield results in molecular tests [44]. After micromanipulation skills, blastomere selection is probably the most challenging aspect of effective cleavage-stage biopsy. Time spent in careful examination of the embryo and orientation to selectively remove specific blastomeres is essential to attain the high diagnostic efficiencies required for clinical effectiveness. The reasons for this are that, first, an interphase nucleus is essential for FISH analysis since the nucleus is prepared on a slide by a process of cell lysis in which individual chromosomes from a metaphase plate may not be visible and are likely to be lost during cell preparation [46]. Second, post-zygotic chromosomal mosaicism arising during cleavage is known to be associated with nuclear abnormalities [47]. The exception is binucleate blastomeres, in which there are two normal-sized nuclei. In most cases, these are generated through failure of cytokinesis, and both nuclei contain the normal diploid chromosomal complement for that embryo [48]. In general, multinucleate cells should not be selected at biopsy if FISH analysis for aneuploidy detection follows, and the removal of mononucleate cells only is recommended [23]. The dilemma with this selection procedure is that in a chromosomally mosaic embryo (which contains significant proportions of both normal diploid and aneuploid cells), removal of only mononucleate cells (which are more likely to be chromosomally normal) may result in only the chromosomally abnormal multinucleated cells

remaining in the embryo. For accuracy during FISH-based diagnosis, it is advisable to only use bi- or multinucleated cells as a last resort in the absence of mononucleated cells. This may be less critical for PCR-based testing in which presence or absence of a specific parental chromosome is important rather than copy number per se. However, even with careful blastomere selection, diagnostic efficiency is not 100%, and aneuploid results are common even in mononucleate blastomeres primarily as a result of chromosomal loss and mitotic nondisjunction, leading to chromosomal mosaicism [48]. Biopsy of two nucleated blastomeres is only possible in good-quality embryos at a sufficiently advanced stage, such that even with a two-cell biopsy policy, a mixture of embryos with one or two blastomeres for analysis is common [34]. Where possible, one of the smaller blastomeres should be selected to minimize the reduction in mass, and the relative sizes of cells may provide an indication of recent mitosis. This may also reduce the risk that a cell in metaphase will be taken; the chromosomes of which could be lost during the fixation process.

48.3.6 Safety of Cleavage-Stage Embryo Biopsy

As with any micromanipulation procedure involving human gametes or embryos, every reasonable precaution should be taken to minimize cellular damage and stress during the procedure. General precautions include the correct installation, calibration, and maintenance of all micromanipulation equipment (particularly the laser). In advance of all clinical procedures, one should ensure that all appropriate reagents and micromanipulation tools are available, sterile, and within their expiration date. Biopsy and cell preparation should be performed by a suitably qualified and trained person. Regular reviews of key performance indicators [26, 27] such as the rate of biopsied cell lysis, post-biopsy survival, morphology, and cell numbers of untransferred embryos provide an indication of the possible harm as a result of biopsy as do pregnancy rates after biopsy—particularly those not progressing beyond the biochemical stage. Clearly, effects on postimplantation development should also be closely monitored as any increase in fetal malformations or congenital abnormalities would be unacceptable. To date, studies of pregnancies and children born after PGD have identified no significant increase in abnormalities above the rate seen in routine IVF [3, 49–51]. The main problem in terms of diagnostic efficiency with cleavage-stage biopsy is the presence of chromosomal mosaicism, which is reported to occur in up to 80% cleavage-stage embryos [52–54]. A full discussion of the impact of chromosomal mosaicism on the accuracy of PGD is beyond the scope of this review, but its impact on both diagnostic accuracy and clinical effectiveness of PGD can be significant. Mosaicism is thought to be the primary reason for the high rate of false positives depleting the pool of chromosomally "normal" embryos for transfer and hence significantly lowering the chance of live birth following preimplantation genetic diagnosis of chromosomal aneuploidy (PGS) compared with controls in a recent randomized controlled trial [37]. However, the impact of mosaicism on the misdiagnosis rate when performing PGD by PCR analysis appears to be less significant [55]. While polar body biopsy appears to offer a solution to the problem of mosaicism by focusing on maternal mutations and/or meiotic errors—acknowledged to be the main source of aneuploidy in human IVF—the approach does not address either paternal mutations, meiotic errors, or post-zygotic errors arising in the embryo [2]. Blastocyst biopsy has been proposed as a solution to the problem of cleavage-stage mosaicism and has been used successfully in the clinical setting [56–59]. While its use is becoming more widespread, it is still unclear whether or not any residual mosaicism reduces diagnostic accuracy and hence clinical effectiveness at this developmental stage, although its use in aneuploidy detection appears to be superior to that of cleavage-stage biopsy and analysis [59]. Since blastocyst biopsy focuses on only the most developmentally competent embryos within a cohort, diagnostic costs may be lower, and the outcomes per biopsied embryo improved; however, a comprehensive diagnosis of the embryo cohort is not possible.

As an alternative to blastocyst biopsy, it is possible to coculture blastomeres biopsied at cleavage-stages with the biopsied embryo [60]. Over a period of 3 days, division and development of the biopsied blastomere mirrors the behavior of the parent embryo. Hence, if the embryo reached the blastocyst stage, in most cases, the blastomere divided and developed into a small TE vesicle. On average, those blastomeres that divided and formed these vesicles divided two or three times, resulting in an average of 5.6 ± 0.6 (n = 13) cells for single eight-cell-stage blastomeres and 9.1 ± 1.1 (n = 11) cells where two blastomeres were biopsied and encouraged to form a single morula. In this approach, the behavior of the cleavage-stage biopsy in vitro could predict the potential for the biopsied embryo [61], thereby avoiding the difficulties and damage of biopsy at the blastocyst stage itself and the possibility of having no embryos to biopsy, if one elected for blastocyst biopsy alone.

48.3.7 Cryopreservation of Embryos Following Cleavage-Stage Biopsy

A major challenge at present is to develop an effective standardized method for cryopreservation of biopsied embryos. Attempts to use established protocols either in the mouse model or in humans have shown extensive damage after thawing, presumably because of the loss of protection from ice crystals in the medium provided by an intact zona pellucida [62, 63]. However, recently, several improved slow-freezing protocols for biopsied cleavage-stage embryos have been reported in which damage is much reduced [64, 65]. However, following successful application in animal models, vitrification looks set to replace slow freezing for both cleavage- and blastocyst-stage embryos after polar body or embryo

biopsy [59, 66–68]. With the high rate of multiple pregnancies reported after PGD, it is imperative to develop effective methods of cryopreservation that will (1) allow storage of unaffected embryos for later transfer so that the numbers transferred can be limited to two or even single embryo transfers and (2) provide additional time to perform more extensive diagnostic tests.

48.4 Future Developments

With the introduction of quality management systems and accreditation in IVF laboratories [25–27], safer and more effective biopsy should be achieved through agreed definitions of successful and safe biopsy, standardized training and procedures, and validation of new techniques as well as calibration of new and existing instruments such as the laser. It has become clear that embryo biopsy, as with any form of invasive testing or manipulation, exacts a cost to the embryo in the form of cellular depletion and metabolic stress. Thus, it is imperative to assess the potential benefit to the embryo itself in terms of improved selection or disease-free status before performing embryo biopsy. However, in the future, it may be possible to diagnose inherited diseases or chromosomal imbalance in early human embryos by noninvasive analysis of the secretome or metabolome in spent culture medium, an advance which would shift the cost–benefit ratio heavily toward potential benefit. At present, noninvasive analyses are likely to be used as an adjunct to assess embryo quality and viability with the genetic test requiring biopsied cellular material [69]. For the time being, it is critical that the diagnostic laboratory optimizes the use of each single biopsied blastomere. Whole genome amplification is one such optimization allowing the testing of multiple loci, repeat testing, sample sharing for external quality assessment, and archiving for later assessment of additional loci. A sufficiently large amount of DNA is generated following this process such that microarray-based testing is possible from a single cell for detection of either chromosome, single gene, or a combination of both [70].

In conclusion, blastomere biopsy of human cleavage-stage embryos remains the most commonly performed form of biopsy for genetic diagnosis of the early embryo. The various techniques used appear to be largely safe in terms of pregnancy outcomes and health of children, but it is clear that biopsy of even a single blastomere has some degree of cost to that embryo, manifested as reduced implantation potential. For this reason, the benefit of the possible diagnosis should always be weighed against the "cost" of the embryo biopsy. The noncontact laser has largely overtaken other methods for breaching the zona pellucida and has made embryo biopsy techniques accessible to any embryology laboratory with micromanipulation capabilities. The comparative ease with which the laser may be used should be carefully considered to avoid any inadvertent damage to embryos through misuse. The combined introduction of the laser and large diagnostic laboratories providing PGD services on a satellite basis to embryology laboratories worldwide has greatly improved access for patients to PGD services. The biggest change in practice in future is a shift away from cleavage-stage biopsy, in which chromosomal mosaicism is an occupational and biological "hazard," toward more trophectoderm biopsy from blastocysts in which greater accuracy and diagnostic reliability is predicted.

Review Questions

1. Please define what are the objectives of embryo biopsy.
2. Please describe the required settings for cleavage-stage embryo biopsy.
3. Please explain what the options are to get the zona pellucida open and have access to embryonic cells/blastomeres.
4. Please describe the procedure of embryo biopsy, the removal of the blastomere(s), and its preparation for genetic testing.

Current andNovel Methods forChromosome Testing

Sarthak Sawarkar and Santiago Munné

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_49

More than 50% cleavage and blastocyst stage embryos produced in vitro are found to be chromosomally abnormal, increasing up to 80% in women over 42 years of age [1]. While some abnormal embryos arrest during culture, most do not. Embryos with numerical chromosomal abnormalities are usually not compatible with either implantation or birth, with and up to 70% of spontaneous abortions being chromosomally abnormal, clearly highlighting the detrimental effects of aneuploidy. Thus, we hypothesized that the selection of normal (euploid) embryos for transfer should improve the success rate of IVF [2]. This process of selection against aneuploidy is known as preimplantation genetic diagnosis (PGD) of aneuploidy (PGD-A) or preimplantation genetic screening (PGS).

49.1 PGS Version 1 andIts Limitations

Early strategies for PGS involved using fluorescent in situ hybridization (FISH) to analyze day-3 blastomere biopsy or polar bodies biopsied from oocytes and/or zygotes [3]. FISH allowed the analysis of anywhere between 5 and 12 chromosomes per sample but a complete evaluation of the chromosome complement. Even with this limited coverage, FISH detected more than 80% of chromosomally abnormal embryos. Another limitation of FISH was the need of fixing the cells, which required dexterity, and some methods were better than others [4] but not used widely. More importantly, cleavage-stage biopsy required as much skills, and although experienced centers showed improved results in clinical randomized trials (CRTs) [5], on the other hand, it could reduce implantation potential by half [6–8]. Thus, while some studies showed an improvement in implantation rates, reduction in spontaneous abortions, and take-home-baby rates [9–18], others showed no improvement or even a detrimental effect of PGS [6, 19–21].

The most likely cause explaining the inter-center differences in PGD outcomes are variations in biopsy and genetic techniques employed. For example, one of the studies showing detrimental effects of PGD used a two-cell biopsy [22]. However, the same group later reported a detrimental effect of a two-celled biopsy compared to the one-celled biopsy from cleavage-stage embryos [23]. Biopsying even a single cell in sub-optimal laboratory conditions has been shown to be extremely damaging to the embryo potential. Mastenbroek et al. (2007) reported a very high rate of diagnostic failure (20%) resulting in many of the embryos included in the study being transferred without a diagnosis. The implantation rate of these non-diagnosed embryos was 59% lower than the control. In this case, the only difference between the control and the test group appears to be the biopsy. This suggests that embryo viability was drastically reduced by sub-optimal biopsy procedures used in that clinic.

The second factor in obtaining good outcomes with FISH is a low error rate. Error rates varied widely between PGD laboratories, 2–7% [10, 24, 25] to 40–50% [26, 27], due to varying practices in PGD laboratories in the steps after the biopsy of the embryo. Higher error rates have been shown to decrease implantation rates [28]. When FISH was performed using appropriate, well-validated methods, it detected over 80% of chromosome abnormalities detected by a CGH [9, 29].

The primary argument made to explain the detrimental effect of PGS by the groups with poor results was mosaicism. However, although mosaicism is common in cleavage-stage embryos, most of these embryos have chromosome abnormalities in every cell [10]. In this case, the biopsied cell is chromosomally different to the remaining cells in the embryo but still correctly classified as abnormal. However, bad fixation methods could increase the error rate dramatically. With good fixation methods, mosaicism produced about 7–10% misdiagnoses [10].

Overall, although some PGD laboratories had consistent results with FISH and cleavage-stage embryos and improved outcomes, the field of PGD/PGS has moved away from those techniques. Most PGT is now being performed at blastocyst stage on days 5–6 of development, which seems to be more resilient to technical manipulation [8]. In addition, FISH has been replaced by more comprehensive methods of DNA analysis, which detect all numerical chromosomal abnormalities (except polyploidy). These techniques constitute what we call PGS version 2.

49.2 Biopsy Techniques

For PGD, oocytes obtained during ART are stripped from their surrounding cumulus cells, because these cells can potentially provide a source of non-embryonic DNA, which could cause contamination during PGD [30, 31]. Intracytoplasmic sperm injection (ICSI) is used most routinely to fertilize oocytes in order to reduce the rate of fertilization failures and also to prevent any contamination caused by DNA from residual sperm attached to the zona pellucida [31, 32]. Post fertilization, the embryos can be biopsied at different stages of their development, and one or more cells can be retrieved or polar body biopsy can be performed to obtain the first and second polar bodies extruded from the oocyte [22].

49.3 Polar Body Biopsy

Genetic material for PGD can be obtained pre-fertilization by the removal of the first polar body from the mature (metaphase II) oocyte. The first polar body can be used to deduce the genotype of the oocyte before fertilization, while upon fertilization, the second polar body can also be obtained and tested [33]. Polar body PGD was first applied by Verlinsky and colleagues [34] for PGD and Munné et al. for PGS [2], and the accuracy of the method has been shown in a large number of PGD cases [35]. It should be noted that PGD for single gene disorders requires that both the first and second polar body are tested, since meiotic recombination can lead to unclear (heterozygous) results in the first polar body. Polar

body biopsy was also widely used for aneuploidy screening of the oocytes [36]. The benefit of this method is that it does not involve biopsy of the embryo and is apparently non-invasive (although the egg can be harmed during second PB if a bridge between the metaphase and PB persists). Furthermore, in some countries (e.g. Germany), where testing of embryos is forbidden or highly restricted, it is still the main choice for obtaining material for PGD. However, polar body biopsy only provides information regarding the oocyte genotype [37], and any chromosomal aneuploidies inherited from the sperm or arising post-mitotically will not be detected [38].

49.4 Cleavage-Stage Biopsy

Cleavage-stage biopsy used to be the most popular method used in PGS but now has been replaced mostly by blastocyst biopsy.

Cleavage-stage embryo biopsy is performed by breaching the zona pellucida with either acid Tyrode's solution or laser or mechanically [39]. At the day-3 stage, the embryo typically contains 6–12 cells which are totipotent [33]. One or two blastomeres are extracted and used for PGD. The removal of two cells has proven to be clearly detrimental decreasing the implantation potential and reducing the rate of blastocyst formation [22, 40]. Suitable embryos are selected and transferred to the uterus of the woman on day 4 or day 5 post fertilization. Compared to polar body biopsy, day-3 biopsy permits checking the embryo for genetic disorders inherited from both parents and mitotic chromosomal imbalances. A challenge for cleavage-stage and blastocyst biopsy is mosaicism, or the presence of two or more distinct cell lines with different chromosomal constitutions in the same embryo that occur due to errors that happen during mitosis after zygote formation – especially during the first three mitotic divisions [41–44]. The incidence of mosaicism in cleavage-stage embryos, assessed through FISH, was about 30% [10] and with use of CCS methods was similar or higher [45, 46]. Therefore, a single blastomere biopsied from a day-3 embryo might not always be representative of the rest of the embryo. However, studies on mosaic embryos have shown that a majority of day-3 mosaic embryos have all their cells abnormal and the error rate caused by them is about 7–10% [10]. Mosaicism in spontaneous miscarriage specimens is seen at a degree of <10% [47], while for first trimester, the incidence in ongoing pregnancies is even lower (1–2%) [48]. It therefore seems that mosaicism disappears prior to the period of first trimester through mechanisms that involve loss of mosaic embryos or euploid cells taking over abnormal cells [49].

49.5 Blastocyst Biopsy

Blastocyst culture, vitrification, and blastocyst biopsy techniques have improved considerably in the last 10 years and are an essential aspect of ART [50]. Frozen cycle transfers accounted for almost 30% of transfers in North America, while over 50% cycles in Nordic countries are frozen transfers and is routinely performed for cases undergoing PGS.

The most popular option nowadays for obtaining genetic material from the embryo is through blastocyst biopsy reached at days 5–6 of development. At this stage, the inner cell mass that gives rise to the fetus has differentiated from the trophectoderm, which later develops into extraembryonic tissues [33]. Approximately 3–10 cells are removed during biopsy at the blastocyst stage. Biopsy of the trophectoderm is advantageous because no cells are extracted from the inner cell mass, and in contrast to the other two biopsy strategies, this method obtains multiple cells for carrying out PGD/PGS, which leads to improved accuracy. Moreover, blastocysts are robust compared to the earlier embryonic stages and tolerate biopsy better than cleavage-stage embryos [8]. Two drawbacks of this method are that only about 50% of the embryos growing in vitro reach the blastocyst stage [51] and the time left for diagnosis after biopsy is limited since the embryos need to be transferred by day 6 [30]. However, the introduction of vitrification as a method to cryopreserve blastocysts [52] and the high survival rates obtained even after biopsy [53] make blastocyst biopsy increasingly attractive for PGS. Theoretically, cryopreservation of biopsied blastocysts allows for an unlimited amount of time for PGS to take place. Furthermore, vitrification of blastocysts and their transfer later on during a natural ovulatory cycle rather during a hormonally stimulated cycle has been found to result in a better clinical outcome [54]. As in cleavage-stage embryos, mosaicism is detectable in blastocysts [41, 47]; the incidence however is found to be considerably lower (4–35%) depending on the technique used [41]. Through data collected from different studies, it is suggested that a proportion of mosaic embryos undergo developmental arrest before reaching the blastocyst stage [47, 55]. This explains the lower rates of mosaicism at the blastocyst stage when compared to day-3 embryos, while it also suggests that culture to the blastocyst stage might be advantageous since it would identify embryos of increased developmental competence. Furthermore, the possibility of misdiagnosis is believed to be considerably lower since, now with NGS, they can be identified when the number of abnormal cells is between 20% and 80% [56–58], preventing a large degree of the transfer of mosaic embryos, which would possibly have a negative effect on IVF outcome.

Blastocyst biopsy is not completely benign, and some forms may be detrimental. For instance, there are two studies reporting adverse effect on implantation potential if 10 or more cells are biopsied [59]. Also there are two modalities of blastocyst biopsy, one described by [60] in which the zona is breached on day 3 and the herniating TE is biopsied on days 5–6 and the other described by [61] in which the blastocyst zona is breached on days 5–6 and then the TE is biopsied. There are no studies yet comparing which method is better; plus within each method, the number of laser pulses vary from lab to lab.

49.6 Screening Techniques Used inPGS v2

A variety of PGS v2 technologies are currently being used in PGS laboratories for comprehensive chromosome screening. In this part of the chapter, we will cover CGH, array CGH, SNP arrays, and next-generation sequencing (NGS) techniques that are routinely being used for testing embryos. The advantages and disadvantages for every technology will be discussed alongside the technique itself. Microarray CGH (array CGH or aCGH) and single-nucleotide polymorphism (SNP) microarrays can be used for comprehensive chromosome analysis of single cells from day-3 biopsy and day-5 embryos. NGS, however, has been validated only for blastocyst biopsies.

49.6.1 CGH

The first technique employed was comparative genome hybridization (CGH), a molecular cytogenetic technique that allowed for the performance of a global assay to find chromosomal gains and losses in embryos [62]. CGH was initially used in day-3 embryo biopsies. However, CGH as a technique has several pitfalls. CGH is labor intensive and time consuming. This makes day-3 biopsy and day-5 transfers (fresh transfer) logistically infeasible. During the early days of CGH, embryo freezing was not very efficient and the survival rates of embryos post thawing were low. Hence, CGH was temporarily abandoned and not reused till vitrification was a standard procedure. CGH has been clinically applied to blastocyst biopsies and polar body biopsies. Vitrification along with CGH significantly improved the implantation rates from 46.5% to 72.2% in cycles with screening, with almost 100% of blastocysts surviving the embryo biopsy [53].

49.6.2 aCGH

Array CGH (aCGH) is widely used for the cytogenetic analysis of prenatal and postnatal samples [63–66] since it is rapid and cost-effective and allows chromosomal regions to be screened at high resolution. Several types of aCGH platforms are available for the purposes of aneuploidy screening. The variety most commonly used for the purpose of PGD utilizes bacterial artificial chromosome (BAC) probes, about 150,000 bp in length, covering all chromosome bands and giving a 4 MB or lower resolution. Even higher resolutions are achievable but not recommended since, at that level, the difference between clinically significant duplications/deletions and normally occurring copy number variations is less clear. The microarray validated for PGD had 4000 probes and thus covered ~25% of the genome sequence [67]. aCGH provides a quantitative analysis based on comparing the relative amount of DNA from two different sources, one from the clinical sample (e.g., a cell from an embryo) and another from a chromosomally normal individual. DNA samples from the two sources are differentially labeled and hybridized to either metaphase chromosomes (CGH) or probes on a microarray (aCGH). In the case of aCGH, each probe reveals the relative amounts of these two DNAs at a single chromosomal site. Since multiple copies of each probe are placed on the microarray and each chromosome is tested at several distinct loci, the diagnosis is very accurate.

Chromosome imbalances (aneuploidies, unbalanced translocations, deletions, and duplications) are easily detected by aCGH, but a limitation of these approaches is that diploidy cannot be distinguished from changes involving loss or gain of an entire set of chromosomes (e.g., haploidy, triploidy, tetraploidy, etc.). How important is this? We report (personal communication) that about 7.7% (n = 91,073) of the supposedly 2PN embryos tested by FISH were polyploid or haploid, but the majority of them had additional abnormalities detectable by array CGH, and only 1.8% of all embryos were homogeneously polyploid or haploid. Furthermore, of those embryos, the majority arrested by day 4, leaving only 0.2% of developing embryos uniformly polyploid or haploid. This suggests that failure to detect polyploid embryos may rarely lead to a misdiagnosis but is unlikely to have a significant impact on the clinical efficacy of the screening using aCGH.

aCGH has been used in multiple PGS studies [53] including a randomized clinical trial showing a significant improvement in pregnancy rates over no PGD [68].

49.6.3 SNP Arrays

Single nucleotide polymorphisms are areas of the genome where a single nucleotide in the DNA sequence varies within the population. Most SNPs are biallelic, existing in one of two forms, and are found scattered throughout the genome. By determining the genotype of multiple SNPs along the length of each chromosome, a haplotype (a contiguous series of polymorphisms on the same chromosome) can be assembled. This ultimately allows the inheritance of individual chromosomes or pieces of chromosomes to be tracked from parents to embryos. Current SNP microarrays simultaneously assay hundreds of thousands of SNPs, while utilizing powerful software to distinguish how many copies of each chromosome was inherited by an embryo [67, 69, 70].

Chromosome screening methods (CGH, aCGH, SNP microarrays, and NGS) rely on whole genome amplification (WGA) to amplify DNA from the single cell or small number of cells removed from a developing embryo [71]. CGH can be performed in combination with a variety of WGA methods; however, SNP microarrays are more sensitive to the type of amplification technique used and are not compatible with all methods. WGA methods like multiple displacement amplification (MDA), GenomePlex, and PicoPlex are most commonly used for SNP microarrays. These amplification methods allow for better overall coverage of the genome compared with earlier WGA methods (e.g., degenerate oligonucleotide primed PCR) and are less inclined to preferentially amplify some parts of the genome while leaving others unamplified or under amplified. While the technologies differ greatly, both types of arrays (CGH-based and SNP-based) and NGS are trying to

answer the same underlying question: how many copies of each chromosome is present in a sample? The small size of the SNP array probes can lead to poor hybridization efficiencies and low signal intensities for individual probes. This factor, coupled with the failure of WGA methods to amplify the entirety of the genome, can lead to many probes yielding no result (i.e., a low "call rate"). Also, allele dropout (ADO) and/or preferential amplification (PA) of one SNP allele versus another can lead to a great deal of "noise" in the system, which requires sophisticated interpretation. Several methods for the cleanup of data from SNP microarrays have been developed: (1) qualitative methods, looking only at the inheritance of specific SNPs and requiring comparison with parental DNA samples; (2) quantitative approaches, assessing only the intensity of SNP calls; and (3) techniques combining qualitative and quantitative methods, using both SNP intensity calls and inheritance patterns. For qualitative approaches, it is necessary to assess parental DNA prior to clinical embryo testing. The key requirement is the deduction of the four parental haplotypes for each chromosome. Embryo testing is then focused on detecting the individual parental haplotypes, revealing how many chromosomes were inherited from each parent, i.e., karyomapping [67]. This approach has the disadvantage that mitotic abnormalities, in which only two haplotypes are present in a trisomy (i.e., caused by duplication of one of the two chromosomes in the embryo after fertilization), will not be detected [72]. This can misdiagnose a substantial amount of embryos since 30% of aneuploid embryos contain mitotic abnormalities (mosaics). Qualitative SNP approaches are still used for PGD of gene defects with the karyomapping approach [43] but not for PGS alone (Table 49.1).

A quantitative approach compares the intensity of each SNP against the other SNPs. A purely quantitative approach for aneuploidy screening may not require parental testing ahead of the cycle; however, this approach would not be compatible with combination testing of single gene defects with aneuploidy screening (discussed below). This approach is currently the least developed. A qualitative/quantitative approach has also been applied clinically and probably can obviate the issues mentioned above for purely qualitative or quantitative approaches [69, 70]. All these approaches still share one limitation and that is the diagnosis of tetraploidies. In a tetraploid cell, only two haplotypes are present (i.e., a postmeiotic duplication of a euploid cell); therefore, all SNPs will have the same intensity. SNP-based microarrays do offer some advantages over aCGH: (a) if qualitative analysis is employed, SNP-based microarrays can also detect the parental origin of any chromosomal abnormalities. This may be valuable in rare instances of young couples producing many chromosome abnormalities but of little relevance to cases of advanced maternal age where at least 90% of the aneuploidies will be maternal in origin, and those of paternal origin are most likely mitotic errors where the paternal chromosome was randomly recruited as the extra chromosome [72]. These errors offer no predictive value for other embryos in the cohort or for future cycles; (b) SNP microarrays applied to PGD for chromosome rearrangements can differentiate between normal and balanced (carrier) embryos. However, because the rate of abnormalities in translocation cases is generally very high (>80%) [73], the great majority of PGD cycles do not have a surplus of embryos with a balanced chromosome constitution. In most cases, whatever balanced embryos are available are needed for transfer, (c) SNP arrays can directly produce a fingerprint of the embryo, allowing for assessment of which of the transferred embryos led to a pregnancy. With SET of blastocysts becoming the trend in PGS, this is of little use except to determine misdiagnoses. (d) Finally, qualitative SNP arrays can also detect uniparental disomy (UDP), although this is a very rare event (e.g., UDP 15 occurs in 0.001% of newborns (OMIM)).

A major disadvantage of a qualitative or combination approach to SNP array analysis is the need to assess parental DNA ahead of the PGD cycle. This complicates patient management, adds substantially to the cost of the test, and precludes ad hoc decisions on biopsy for PGD. Approximately 20% of IVF cycles with planned PGD are canceled on day 3 due to low embryo numbers. Thus, these patients would have spent money on pre-cycle parental testing that was ultimately unnecessary.

Table 49.1 Comparison of techniques

	% embryos	FISH	qPCR	aCGH	Embryo Vu	SNP array	hr-NGS
Labs performing test		100s	2	180	1	11	5
Total independent data signals*		11	96	2,700	26,000	32,000	700,000
Resolution in Mb		Arm	20M	6M	20M	6M	3M
Misdiagnosed aneuploidies (a-f)		7%	1%	2%	3% d	2%	0%
Unbalanced translocations (g)	2%	Custom	No	Yes	No	Yes	Yes
Partial aneuploidies	5%	No	No	Yes	Some	Yes	Yes
Polyploidy	2%	Yes	No	No	No	Yes	Yes
Mosaicism (h, i)	20%	20%	No	4%	No	No	20%
Miscarriage rate (j, k)		10–20%	20%	13%	Unk	Unk	11%

49.6.4 qPCR

The qPCR method was developed as a rapid, 4-h chromosome aneuploidy screening technique [74, 75] to enable comprehensive chromosome screening in fresh embryo transfers (FET). One of the key factors unique to this method is its independence from whole genome amplification methods. Ninety-six loci were identified and then amplified for this method. The threshold for amplification was representative of the amount of DNA template and hence the chromosome number in the sample. The significant advantage of this particular method also lies in the low amount of time required to perform the assay and complete the analysis. As we have discussed above, CGH-based methods are not suitable for fresh embryo transfers. The qPCR method for aneuploidy screening is an ingenious repurposing of a method traditionally used to perform gene expression studies, where relative transcript quantities are determined. Parental DNA is not required for this technique. qPCR for PGS is well validated and has promising results from CRTs [8, 76]. The major disadvantages of qPCR are the inability to detect structural abnormalities and the low resolution due to amplification of only four loci per chromosome (>20 Mb). Similarly, mosaics cannot be detected with this method.

49.6.5 High-Resolution NGS

Massively parallel genome sequencing, also known as next-generation sequencing (NGS), is the latest and currently the most popular technique being utilized in PGS laboratories throughout the USA. Compared to the older techniques, like the SNP array (32,000 reads) and aCGH (2700 reads), high-resolution NGS (hr-NGS), which is currently being used in the laboratory, derives about 700,000 reads per sample. hr-NGS utilizes similar upstream technology as aCGH and SNP arrays. Biopsy of the trophectoderm from the embryos is used as starting material. Whole genome amplification is performed on the biopsy. At this stage, the protocol for hr-NGS deviates from aCGH and SNP. One of the major advantages of NGS is the ability to scale up and run a large number of samples together by multiplex sequencing, thereby reducing the cost per sample for every procedure. Multiplexing is the ability to run multiple samples on a single run on the sequencing machine. NGS makes this a possibility by virtue of the addition of "barcodes." Barcodes are small (6–10 bp) sequences that are unique oligonucleotides that ligate to the ends of the fragments of the DNA (derived from the blastocyst day-5 biopsy) being sequenced. Barcodes help differentiate between different samples when sequenced. The possibility to scale up as a result of multiplexing is the first major deviation between the processing of samples for SNP/aCGH and hr-NGS.

In most cases, DNA sequencing unlike aCGH and SNP array isn't limited in coverage to the areas of the genome that are attached to the chip. The process of DNA sequencing involves processing one base at a time. Sequencing is performed on DNA that has been randomly amplified during WGA stage. These sequences are aligned and compared to a reference or a master sequence, which is a database of previously sequenced genomes. Post-alignment in hr-NGS, the sequenced fragments are then mapped back to each chromosome.

49.6.6 Targeted NGS

Another modification of the next-generation sequencing technique is the targeted NGS approach. This approach like the qPCR approach does not include the whole genome amplification step [77]. Instead scientifically defined pieces of the genome are amplified using the PCR method, and then the amplified product is sequenced. These strategies are usually lower in resolution due to selection of limited defined regions. However guaranteed coverage of the specified sequences (desirable genes and polymorphisms) enables detection of haploidy, triploidy, specific pre-selected microdeletion targets, uniparental disomy (UPD), and mitochondrial DNA quantification [77]. It is important to keep in mind that detection of microdeletions, UPD, and mitochondrial DNA is impending on the selection of the targets before sequencing. This is different from the hr-NGS technique where whole genome amplification is random in nature and prediction of the said abnormalities is inaccurate. Additionally, since each chromosome is examined at fewer sites, fewer reads are utilized which allows for more samples to be run simultaneously and in turn lower the cost per sample. Another advantage of the targeted approach is its ability to detect imbalances with chromosome rearrangements [77].

49.6.7 Validation ofPGD V2 Techniques

Due to the intrinsic and often unforeseen problems with every new technology, a novel method should always be validated against other more established methods [78]. Assessing a new approach against itself may preclude the detection of technique-related flaws. Validation by inadequate methods is possible and may lead to false assumptions when (1) the analysis of cell lines with defined chromosome abnormalities which cannot mimic mosaicism and other peculiarities of the cell being tested, (2) analysis of embryos by one technique and the remainder of the embryo by the same technique which precludes identifying abnormalities not detectable by that technique, (3) blindly replacing undiagnosed embryos (either by single embryo transfer or fingerprinting the embryo) and following pregnancies and clinical losses determine the fate of each tested embryo, which does not account for the status of non-implanted embryos. In addition, the use of analysis tools that are qualitative in nature will miss the presence of two chromosomes of the same grandparental origin, and the errors caused by mosaicism will not be taken into account in this validation mode, resulting in bogus 99.9% confidence results. In our opinion, the optimal method for validating any new technique is to reanalyze those embryos

that were not transferred to the patient. The reanalysis of these embryos should be done with another well-established technique, i.e., the "gold standard." This would discern shortcomings of the new method under evaluation and account for issues related to embryo biology, such as mosaicism. To simplify comparison between studies, an error should be classified as diagnosing an embryo as euploid when reanalysis shows that it was abnormal or vice versa. Due to the extent of mosaicism, an error rate per chromosome has questionable relevance and no clinical importance compared to an error rate per embryo. SNP microarrays have undergone a variety of validation experiments, such as comparison of PGD results and analysis of babies born [70], SNP microarray reanalysis of embryos previously analyzed by SNP arrays [79], and using data from one set of SNPs as internal controls for another set of SNPs. To date, no studies have confirmed the original diagnosis by reanalyzing the remaining embryonic cells with a different technique.

Microarray CGH for PGD has been validated by analysis of single cells from known cell lines (Dagan Wells, personal communication) and by analyzing eggs with aCGH and comparing them to the results obtained using aCGH of the corresponding PBs (Montag and Gianaroli, personal communication). Day-3 embryos analyzed by PGD with aCGH that were not replaced because of chromosome or morphological abnormalities were reanalyzed in most of their remaining cells by FISH using 12 probes for the most common chromosome abnormalities plus probes for any chromosomes found abnormal according to aCGH. Only 1.9% of embryos were found to be incorrectly diagnosed [67]. This is lower than the 7% error rate expected solely from mosaicism as calculated in FISH studies [10].

The qPCR technique validation is probably one of the most complete validation techniques for PGS technologies. Validation was performed in several phases. The first phase included randomized blinded samples from cell lines with previously determined karyotype by a gold standard g-banding method. An overall consistency of 99.90% (1007/1008) and an overall 24-chromosome diagnosis consistency of 97.60% (41/42) were observed in this phase [75]. No false negatives were observed. In the following phase, 71 embryos with reliable SNP microarray-based 24 chromosome aneuploidy screening results from double biopsies were biopsied again, randomized, and blinded for analysis. The validation of this technique in embryos had an overall chromosome-specific consistency of 99.94% (1703/1704) and an overall 24-chromosome diagnosis consistency of 98.6% (70/71). There were no false positive aneuploid chromosomes observed or inaccurate predictions of sex. Results from the cell line and the embryo phase were also found to be concurrent for the qPCR technique.

hr-NGS validation was recently performed by Fiorentino et al. in 2014 and Kung et al. in 2015 [80, 81]. In these studies, dependability of NGS-based 24-chromosome copy number assignments was gauged with previously established array-CGH–based diagnoses of the same WGA products at the level of individual chromosome copy numbers for the entire 24 chromosomes of each sample tested and also for the overall diagnosis of euploidy or aneuploidy. NGS specificity for an aneuploidy call (consistency of chromosome copy number assignment) was observed to be a 100% with a sensitivity of 100%. NGS specificity for an aneuploid embryo call (24-chromosome diagnosis consistency) was also a 100% with a sensitivity of 100%. An overall error rate of 0% was observed during the validation of NGS.

Table 49.2 RCT studies using PGS v2

Implantation rate				
	Technique	no PGT	PGT	
Yang et al. 2012	aCGH	46%	69%	$p < 0.001$
Scott et al. 2013	qPCR	63%	80%	$p < 0.001$
Forman et al. 2013	qPCR	40%	58%	$p < 0.001$
Rubio et al. 2017	aCGH	28%	53%	$p < 0.001$

49.6.8 Clinical Results

Initial CGH and aCGH studies [53, 82–84] were not randomized but showed improving ongoing pregnancy rates. Two studies [54] showed high implantation rates, avoided cleavage-stage embryo biopsy, and transferred embryos that had previously been cryopreserved in a later cycle. In addition to the potential benefits of transferring euploid embryos, there may be additional advantages associated with transfer in a non-stimulated cycle [85]. Loss of blastocyst-stage embryos after devitrification in the study by Schoolcraft et al. was minimal (0.7%) [53] . Blastocysts are more resilient than the day-3 embryo [86]. This resilience seems to increase the overall implantation rate by almost 20% when day-5 blastocyst biopsies are used instead of cleavage-stage biopsies. It is important to remember that despite the available data, biopsies are subject to differ greatly between operators, which in turn would alter the success rates greatly too.

The first randomized clinical trial (RCT) using PGD v2 was performed by [68] using aCGH in a group of young patients, showing a significant improvement in ongoing pregnancy rates. Two other RCTs using SNP arrays followed: one by [8] also showing significant improvement in ongoing pregnancy rates in a group of good prognosis patients and another RCT by [76] which showed that replacing one euploid blastocyst achieved the same ongoing pregnancy rate than replacing two untested embryos (Table 49.2). Two meta-analyses show that overall PGS v2 produces a significant improvement in ongoing pregnancy rates [87, 88]. Most recently, [5] published a RCT using aCGH combined with day-3 biopsy in AMA patients showing a significant improvement in ongoing pregnancy rates and showing that even with day-3 biopsy, if performed by a center with experience, it can produce an improvement in results.

49.6.9 Mosaicism

hr-NGS has an increased dynamic range which enables the detection of mosaicism in multicellular samples [80]. Chromosomal mosaicism is an established and relatively common phenomenon in the preimplantation embryo which has both diploid and aneuploid cells [89]. About 21% embryos are observed to be mosaic in the clinic [90]. When clinical losses of aCGH-analyzed euploid embryos were reanalyzed by hr-NGS, almost 50% of the cases ended up being mosaic [90–93] and showed that mosaic embryos have lower rates of implantation than euploid embryos but can implant as previously shown by [94]. So far, all babies born from embryos classified as mosaic at blastocyst stage have resulted in unaffected children (unpublished), and the current hypothesis is that these embryos will not implant or will miscarry depending on the load of abnormal cells, and if the embryo has enough normal ones, those will take over [49]. In humans, the same tendency seems true [90]. As proposed by [90, 95] and PGDIS, mosaic embryos have an intermediate pregnancy outcome potential between euploid and aneuploid and should be deprioritized for transfer but can be replaced if no euploid ones are available. Initial studies comparing aCGH to hr-NGS seem to indicate an advantage of the second over the first by not replacing mosaic embryos (Friedenthal et al. 2017, ESHRE).

49.6.10 Chromosome Abnormalities AreCenter-Dependent

Not all chromosome abnormalities are due to maternal age. We described a long time ago that sub-optimal culture conditions could produce more post-meiotic abnormalities [96]. In a recent study, we compared the rate of aneuploid embryos derived from egg donors from different fertility centers. The only variable that differed between these centers was the center itself, and we detected rates of aneuploidy that ranged from 20% to 60% [97]. These differences could be attributed to differences in stimulation protocol from one IVF lab to another, media differences from one manufacturer to another-temperature and pH could also potentially be affecting the final outcomes-or which follicles are retrieved (i.e., small and immature ones may result in more abnormal embryos). Such variables need to be further controlled in future studies to improve IVF techniques and therefore PGS can be used as quality control [98].

In summary, data on the clinical application of comprehensive chromosome analysis techniques suggests a better prognosis for patients undergoing ART with increased implantation rates, on-going pregnancy rates, and decreased miscarriage rates.

Review Questions

1. More than _____ in vitro embryos are found to be chromosomally abnormal.
   A. 10%
   B. 25%
   C. **50%**
   D. 35%

2. Embryos from which of the developmental stages may be used in obtaining biological material for genetic testing of embryos?
   A. Polar body biopsy
   B. Blastocyst biopsy
   C. Blastomere biopsy
   D. **All of the above**

3. Multiplexing of a large number of samples is possible in next-generation sequencing. This is possible due to
   A. **Addition of barcodes, 6–10 bp unique oligonucleotides**
   B. High number of reads possible during a sequencing run
   C. Blastocyst biopsy samples being used for NGS compared to polar body or blastomere biopsy samples
   D. None of the above

Learning Objectives

- To describe the rationale for blastocyst-stage biopsy in comparison to biopsies performed at earlier embryo developmental stage.
- To review the settings where blastocyst-stage embryo biopsy can be performed.
- To provide a detailed description on how blastocyst-stage embryo biopsy is performed.
- To present the applications of blastocyst-stage biopsy.
- To review the objectives and means of single gene testings using embryonic cells.

This chapter sets out to examine the major recent advances in embryo biopsy, specifically blastocyst-stage biopsy and preimplantation genetic testing and diagnosis (*PGD*), which are transforming singleton live birth rates in families at risk of passing on monogenic diseases or chromosomal translocations.

50.1 The Development of Embryo Biopsy

Embryo biopsies for clinical PGD generally were performed on day 3, when the embryo typically was at the six- to eight-cell stage, and involved the removal of one or two blastomeres. The zona was breached by dissolving the protein with acid Tyrode's solution. The embryo was incubated in a calcium-/magnesium-free medium to reduce cell–cell interactions and make the removal of cells easier. There has been debate about the impact of removing multiple cells, and in general, it was considered that two-cell removal was more detrimental than removing just a single cell and should not be performed—although the reliability of amplification of two cells was considered less prone to allele dropout. An alternative biopsy approach involved the removal of either the first or second polar bodies—either sequentially on day 0 and day 1 or both on day 1. PCR analysis of blastomeres or polar bodies involves amplification of a single allelic copy of the target. Similarly, analysis by FISH is a single-cell test. Biopsy at the blastocyst stage, when embryos typically comprise upward of 100 cells, enables the removal of 3–5 trophectoderm cells without significant cell mass depletion. Putting several cells into a PCR reaction should decrease the likelihood of amplification failure (allele dropout, or ADO) and, with FISH analyses, should provide an opportunity to confirm signal patterns.

During the early 2000s, Genea (formerly Sydney IVF) moved comprehensively to blastocyst culture and blastocyst-stage transfers and cryostorage and experienced a corresponding increase in take-home baby rates, substantial reductions in multiple pregnancies, and reduced rates of miscarriage [1–7]. In 2004, we described the first clinical application of blastocyst biopsy to routine PGD practice [1]. Embryos were "hatched" on day 3 using a Hamilton Thorne ZILOS-tk near-infrared laser and were then incubated for another 2 days to enable blastocoel expansion and herniation of trophectoderm cells through the opened zona for biopsy [1, 6]. Suitable embryos were placed in 5 μL drops of standard medium under oil. A holding pipette, the same as used in ICSI practice, was employed to immobilize the embryo, while a 30-μL biopsy pipette was used to collapse the blastocyst cavity and hold the tissue sample. Several pulses with the laser set at low level loosened cell–cell interactions, permitting a small piece of tissue to be teased off the exposed trophectoderm. The embryo was then removed and placed into fresh medium for further incubation (until the results were known and the embryo was transferred, cryostored, or disposed of). The tissue piece was washed and placed into PCR tubes or fixed to glass slides for analysis using FISH.

The advantage of moving from cleavage-stage to blastocyst-stage PGD was demonstrated by comparison of embryo biopsies performed (a) at the day 3 cleavage stage and followed by the transfer of embryos that went on to blastulate successfully, with (b) embryo biopsies taken *at* the blastocyst stage (day 5–6) and followed by almost immediate transfer [7]. This study, in other words, *examined the efficacy of day 3 biopsy* vs. *day 5 or 6 on the embryo while controlling for the embryo's ability to blastulate*; patients in this trial had PGD not for infertility or miscarriages but to prevent further propagation of a serious monogenic family disease. The outcome (Table 50.1) implies that, in comparison with the biopsy of blastocysts, day 3 cleavage-stage PGD reduces the implantation potential of at least some embryos. (The same could still also be true of blastocyst biopsy but appears to be to a much lesser extent.)

Table 50.1 shows the technical outcome data for the embryos biopsied (595 for day 3; 656 for days 5–6), with an

Table 50.1 Embryos available for testing for monogenic disease mutations by biopsy on day 3[a] and on day 5–6

	Egg retrievals	Embryos biopsied	Inconclusive test result	Conclusive, favorable test	Embryos transferred fresh	Tested embryos cryostored
Day 3 biopsy + day 5–6 transfer[a]	91	595 av. 6.5 embryos	61 (10.3%)	261 (43.8%)	103	158 (60.5%)
Day 5–6 biopsy + day 5–6 transfer	177	655 av. 3.7 embryos	46 (7.0%)	305 (46.5%)	121	184 (60.3%)

See McArthur et al. [7] for more detailed interpretation of the data
[a]All embryos were developed to blastocysts before transfer

Table 50.2 Clinical outcomes following biopsy at the cleavage stage vs. biopsy at the stage of blastocyst, each with transfer of embryos fresh on day 5 or 6

	Embryos transferred *n*	Transfer procedures *n*	Pregnancy per retrieval	Implantation per embryo[a]	Miscarriage	Live birth or ongoing pregnancy	Multiple at confinement		
							Single	Twin	Triple
Day 3 biopsy + day 5–6 transferred *n* = 91 retrievals	1	38	11	11	4	7	7

Data from McArthur et al. [7]
[a]The implantation rate for blastocysts biopsied from the trophectoderm as blastocysts (48.8%) was highly significantly better than the implantation rate for blastocysts biopsied using a single cell removed at the day 3 cleavage stage (26.2%, $P < 0.01$)

average of 6.5 embryos biopsied and tested per retrieval at cleavage, compared with an average of 3.7 embryos biopsied and tested per retrieval when the blastocyst stage was awaited before performing PGD. The proportion of embryos with a conclusive test and with a normal result, thus suitable for transfer, was still approximately 50% in each series, which means that taking the biopsy later in embryo development conferred appreciable laboratory and clinical efficiency through not having to test embryos whose development was compromised. The late-biopsied blastocysts had almost twice the chance of implanting than did the blastocysts that had been biopsied on day 3.

Table 50.2 shows the outcomes of the embryo transfer procedures. In spite of a lower average number of embryos transferred (1.1 vs. 1.5 per transfer procedure), and without taking into account later further pregnancies from cryostored, biopsied embryos, the day 5–6 biopsy transfers resulted in fewer miscarriages and a higher absolute ongoing pregnancy rate, as well as the expected lower rate of multiple pregnancy. There was one obvious monozygotic twinning event, involving an embryo biopsied on day 3. In about 60% of cases in each series, additional embryos that had tested normally were cryostored for further attempts at pregnancy.

50.2 Preimplantation Screening for Aneuploidy

It has been known for more than 15 years that IVF embryos show a high rate of chromosome aneuploidy [8]. It has also been understood for many more years that a chance acquisition of an abnormal number of chromosomes is a frequent event in human conception and, in particular, is the commonest cause for pregnancies to miscarry. It might therefore be expected that screening IVF embryos for aneuploidies before selecting an embryo to transfer should materially improve the chance of pregnancy, reduce the risk of miscarriage, and (by enabling embryos to be transferred efficiently and efficaciously one at a time) greatly reduce the multiple pregnancy rate, thus lessening perinatal morbidity and mortality. The target—improved live birth rates from IVF and less costs for community—is worthy and logical.

50.3 Aneuploidy Risk

Several authors have reported that the age of the woman undergoing IVF has a significant bearing on the extent of aneuploidy in the resulting embryos. Studies on the origin of nondisjunction chromosome anomalies have suggested that most of the abnormalities originate predominantly from female meiosis, especially meiosis I, although analysis of preimplantation embryo polar bodies with FISH has indicated that meiosis II errors could be similar in number [9]. Analysis of later-stage embryos would therefore be able to identify both meiosis I and meiosis II errors (as well as reveal aneuploidies brought by the fertilizing sperm). Generally, a predisposition to aneuploidy beyond maternal age effect has been hampered by the fact that few studies have looked for or been able to identify genetic causes; rare recessive genetic states that interfere with meiosis have been described [10]. While not extensive, there have been a number of reports suggesting that among women undergoing IVF and experiencing subsequent implantation failure, the chromosome

abnormality rate in their embryos is quite high compared to the other IVF cohorts [11–13]. Screening embryos for aneuploidy could reduce the number of embryos subsequently needed to initiate a successful and continuing pregnancy [14]. The efficacy of the screening process must obviously take into account any detrimental aspects of the biopsy and culture processes to be considered truly beneficial for the patient's progress.

50.4 Aneuploidy Screening in IVF Programs

Examination of a restricted number of chromosomes using FISH for aneuploidy screening as a routine may not be helpful in all cases and in fact can be harmful if biopsy procedures are not efficient. Mastenbroek et al. showed that biopsy of day 3 (cleavage-stage) embryos for limited PGS—screening for aneuploidy of chromosomes 13, 16, 17, 18, 21, X, and Y—can reduce the chance of an ongoing pregnancy in women aged 35–41 having in vitro fertilization (IVF) [15]. Our considerations above (Tables 50.1 and 50.2) suggest that interfering with an early embryo might lie behind this detrimental result, but other factors could also be important. For the Mastenbroek study, these included such straightforward concerns as the time the embryos spent being manipulated in potentially altered culture conditions across the variety of IVF clinics where the biopsies were performed. They also include more complex issues, such as the inadvertent exclusion from transfer of mosaic embryos in which the biopsied cell happened to be the only cell with trisomy (a situation that can follow a mitotic nondisjunction event) [9].

Between August 2004 and November 2006, we studied the impact of screening for aneuploidy in younger infertile women (<38 years, median 33.5 years), employing biopsies of blastocysts [5]. All women were in their first or second attempt at IVF. Agreement to have one embryo transferred (eSET) was a precondition for entry. Patients were withdrawn from the study if there were fewer than eight ovarian follicles over 1 cm diameter at 8–10 days of stimulation, fewer than four embryos with seven or more cells on day 3 of culture, or fewer than three blastocysts for biopsy on day 5 or 6; no women had cycles canceled because of a poor response. The biopsies consisted of 2–9 trophectoderm cells and were tested by at least five-color fluorescent in situ hybridization for, at minimum, chromosomes 13, 18, 21, X, and Y. We compared outcomes between the screened group (Group A, normal [3]five-color pattern in all the removed trophectoderm cells for the transferred embryo) and the principal control group (Group B, with zona opening but no biopsy); we also made comparisons with the women who were withdrawn from the study before randomization because of suboptimal responses to stimulation (Group C) and with women who were eligible but elected not to take part in the study (Group D). Table 50.3 gives the results up to the time the trial was suspended. Pregnancies are clinical pregnancies with a normal fetal heart rate on ultrasound scanning in the first trimester. The clinical pregnancy rate (pregnancies with a normal fetal heart rate at 6 weeks' gestation) was high (46.4% of egg retrieval procedures overall), irrespective of whether PGS was performed or not, and is consistent with results we [2, 6] and others [16] have reported previously for elective single blastocyst transfers.

Table 50.3 Pregnancy rates after preimplantation genetic screening for aneuploidy from biopsy of blastocysts on day 5 or 6 of development using five- or seven-color FISH

Group A. Biopsy				Group B. No biopsy (control)			
N	P	NP	%P	*n*	P	NP	%P
56	25	30	45.5%	48	26	20	56.5%
Group C. Poor response, withdrawn				Group D. Eligible, nonparticipating			
N	P	NP	%P	*n*	P	NP	%P
107	36	71	33.6%	1194	564	630	47.2%

From Jansen et al. [5], with permission
P pregnant; *NP* not pregnant

Among the women who underwent biopsy for aneuploidy screening (Group A), the pregnancy rate at 45.5% was insignificantly less than among women who were eligible for the trial but did not take part (Group D, 47.2%) and was trending to be higher than among women who were withdrawn from the trial prior to randomization because of a suboptimal response (Group C, 33.6%; $c^2 = 1.7$, $P < 0.1$, 1-tailed). We could thus find no evidence of clinically important detriment from blastocyst biopsy in women of normal reproductive age. The pregnancy rate compares favorably, with the 25% clinical pregnancy rate reported by Mastenbroek et al.

Unexpectedly, Group B, the embryos subjected to zona opening by near-infrared laser, a standard preparatory step for biopsy and performed on day 3 or 4 (see above), produced the highest clinical pregnancy rate of the groups (56.5%). While the results in Group B were not statistically significantly different from either the biopsied embryos (Group A, $c^2 = 0.8$) or the eligible but nonparticipant women's embryos (Group D, $c^2 = 1.2$), the trend was opposite to that required to disprove the null hypothesis, and the clinical trial was stopped.

The reason for the strong performance of the embryos in the principal control group, if it is true, is not clear. Assisted hatching by opening of the zona, while advocated from time to time for the embryos of older women to facilitate hatching and implantation, has not been shown to be beneficial among women under 40 or with good blastocyst development. More likely, a too strict set of criteria for assumed meiotic nondisjunction led to overinterpretation and rejection of some blastocysts that would, if left unscreened, have developed normally and contributed to the total number of embryos suitable for transfer.

50.5 Testing for Chromosomal Translocations

Reciprocal translocations occur in about 1 in 625 newborns and usually result from the exchange of two terminal segments from different chromosomes, ordinarily resulting in a genome that is balanced. Exchanges can also take place close to the centromeres of two acrocentric chromosomes; these Robertsonian translocations, which occur in about 1 in 900 newborns, also ordinarily provide a balanced genome and bring the overall prevalence of balanced translocations among newborns to about 1:380 [17]. When diploid germ cells with these karyotypes eventually undergo meiosis, however, the chromosomes involved segregate abnormally and yield a varying but significantly high level of unbalanced haploid states among oocytes and spermatozoa—an unbalanced state that is continued into the embryo and which results in implantation failure, miscarriage, stillbirth, or abnormalities at birth. Balanced translocations are ten times more common among couples presenting for treatment with IVF [18].

With *reciprocal translocations*, homologous pairing during meiosis 1 produces a tetravalent structure instead of the usual bivalent. Subsequent segregation to respective daughter cell spindles takes one of three modes: *2:2 alternate segregation* (producing alternately a normal or a balanced abnormal complement, the latter perpetuating the familial condition but both with a balanced genome); *adjacent 1 and 2 segregations* (producing segmental monosomies and trisomies); and, comparatively rarely, 3:1 *segregations* (involving nondisjunction of a whole chromosome and producing more complete monosomies and trisomies) [19]. Overall, 75% of embryos from a parent with a balanced reciprocal translocation show partially or fully aneuploid chromosome complements (14 different unbalanced combinations compared to two balanced combinations), considerably reducing the number of otherwise healthy appearing embryos available for transfer after PGD.

In *Robertsonian translocations*, a trivalent structure is formed during meiosis 1, with three main segregation modes possible (and nine different chromosome combinations), namely, *alternate* (which returns dosage to its balanced state), *2:1 segregations* (producing complementary monosomies and trisomies), and *3:0 segregation* (producing double trisomy or double monosomy).

Traditional PGD for translocations involves FISH, utilizing either breakpoint-spanning probes (which require access to extensive probe libraries and complicated workups) or (much more simply) combinations of commercially available, quality-controlled centromeric, locus-specific, and subtelomeric probes attached to standard fluorochromes. The use of PGD to screen balanced from unbalanced chromosome sets in the embryos then significantly reduces the failure rate for implantation and should result in fewer miscarriages among the embryos available for transfer [13, 20]. Again, to be truly beneficial, the process of biopsy must do the least amount of harm to the embryo's continued development and to its ability to implant. Table 50.4 shows our experience with cleavage- and blastocyst-stage biopsies among couples with recurrent miscarriage attributable to a balanced reciprocal translocation in one of them. The live baby results have been lower compared to those we obtain after testing for monogenic disease (Table 50.2), possibly reflecting the large decrement in transferable embryos seen with reciprocal translocations following the demonstration of unbalanced cells by FISH-based PGD. These apparent unbalanced outcomes can be of biological origin but can also be false, due to inherent error rates observed with FISH-based protocols [21] or reflective of a benign mosaic state,

Table 50.4 Clinical outcomes of PGD for balanced translocation using FISH and from using STR-based PCR

	Reciprocal translocations		Robertsonian translocations	
	FISH	STR-PCR	FISH	STR-PCR
Patients	54	22	17	7
Mean age	35.2	33.1	36.0	33.3
Cycles with egg retrieval	112	22	51	6
Cycles with embryo biopsy	73	22	31	6
Biopsied embryos	320	61	142	17
Actionable PGD result	304	60	136	17
Embryos for transfer	74 (23%)	20 (33%)	44 (31%)	13 (76%)
Embryo transfer cycles	54	13	27	5
Embryos transferred	1.2	1	1.2	1
Total embryos transferred	62	13	32	5
Positive pregnancy test	20	7	14	3
Implantation rate/embryo (%)	32	54	44	60
FH-positive pregnancy rate per transfer	15 (24%)	6 (46%)	12 (38%)	2 (40%)
FH-positive pregnancy rate per egg retrieval (%)	13	27	24	33

Data from McArthur et al. [7] and Traversa et al. [22]
All embryos were biopsied and transferred at the blastocyst stage. Results do not include pregnancies from the embryos cryostored

but in either case contributing to false-positive interpretation of FISH signals and leading to the exclusion of otherwise normal embryos.

In our published series for translocations using FISH [7], 95 egg retrievals were performed and led to biopsy and testing among couples with a *balanced reciprocal translocation*; there were 10 pregnancies among 26 patients who had day 3 biopsies, seven of which went to term—a miscarriage rate of 33%. Of the 12 pregnancies among 21 couples for whom biopsy was performed on day 5–6, eight miscarried (38%). Twenty-three egg retrievals among 15 couples with a *Robertsonian translocation* led to biopsies and testing; there were three pregnancies among seven couples with day 3 biopsies, each of which went to term, and eight pregnancies among seven couples with day 5–6 biopsies, one of which miscarried and one of which was an ongoing monozygotic twin pregnancy. Combining day 3 with day 5–6 biopsies, the miscarriage rate after PGD for Robertsonian translocation exclusion was 18%, whereas PGD for excluding unbalanced reciprocal translocations was followed by a miscarriage rate of 45%.

50.6 Monogenic Diseases

Monogenic diseases considered appropriate for PGD are those uncommon or rare, fatal, or chronically disabling familial conditions that occur as a result of mutations in a single gene. The location of the mutation can be in an exon, a splice point, or within the control regions and affects the functioning of the specific gene. Inheritance is Mendelian, and classically there are three major classes of phenotypic expression:

1. *Dominant inheritance*, where every individual who inherits the single gene change is likely to be affected by the disorder and will carry a 50% chance of passing on the affected gene to offspring. An example is Huntington's disease. PGD analysis for such mutations must be reliable in detecting a mutation change in a background of normal DNA sequence.
2. *Recessive inheritance*, where carriers of mutations themselves are not affected by the disorder but who partner with another carrier for a mutation in the same gene then produce a reproductive risk for their offspring of 25% for an affected child and 50% for a carrier child. An example is cystic fibrosis. Mutation analysis for these conditions needs to address the ability to analyze for a mutation in a homozygote state or often in a compound heterozygous state.
3. *X-linked inheritance* where, essentially, mutations on the X chromosome typically result in female carriers who have a 25% risk of producing affected male offspring and a 25% risk of reproducing the carrier state in female offspring. An example of a recessive X-linked gene disorder is hemophilia A. An example of an incompletely dominant X-linked disorder is fragile X syndrome, which causes severe mental retardation in males but which also has a heterozygous female phenotype that includes premature ovarian failure. Analysis must be reliable but, unlike other recessive diseases or the dominant diseases, there is no normal background DNA sequence for males. Female carriers contribute a nonmutated X chromosome, so confidence with the analysis must be the same as for the autosome mutations.

The starting point for PCR in the case of a single cell from a day 3 biopsy is usually just a single copy of DNA (there is obviously more DNA available with multicellular trophectoderm biopsies). In principle—and regrettably sometimes also in practice—failure of the mutated DNA to amplify (ADO) produces a false-negative result, leading to an incorrect conclusion of a normal state. Any biopsy testing process must be as reliable as possible to avoid any miscalls.

50.7 The Near Future for Translocation Testing

50.7.1 STR-Based Molecular Strategies

Our experience, above, revealed no obvious advantage for blastocyst-stage biopsies compared with day 3 cleavage-stage biopsies when FISH is used to infer balanced chromosomal patterns for either reciprocal or Robertsonian translocations. In each case, miscarriage rates remain particularly high for apparently balanced reciprocal translations. We have since reported a molecular strategy utilizing PCR for PGD in translocation carriers that examines highly polymorphic short tandem repeat sequences (STRs), application of which has significantly improved outcomes after biopsies at the blastocyst stage [22].

Using STR profiling to identify chromosomal segments on either side of the known breakpoints, in conjunction with standard cytogenetic segregation tables to predict each unbalanced state, we directly identify the monoallelic and triallelic states that are the direct cause of the phenotypic abnormality and reproductive loss which results from these malsegregants and, in turn, is the immediate pathogenic mechanism behind the reason PGD is offered to translocation carriers. The method requires extensive screening of chromosome-specific STRs to define those markers for which the carrier is heterozygous and where alleles are not shared with the partner. To make this PCR-based test efficient, chosen markers are multiplexed to obtain results within primary or secondary amplifications. The method also lends itself to other PCR-based PGD objectives conducted simultaneously, such as monogenic disease exclusion. Verification of the method has come from the rebiopsy of embryos diagnosed as unbalanced: in each of six cases in which samples were assessed for segmental chromosomal gains and losses using conventional CGH (see below), the predicted malsegregations were confirmed.

Conclusive results in our hands rose to 99% using STR profiling, compared with 93% with blastocyst-based FISH.

Any apparent mosaicism seen in the trophectoderm sample has the potential to complicate the interpretation of the translocation state, especially when using FISH, where any visible abnormality tends to disqualify the embryo for transfer, on the subjective basis that failure of a chromosome to hybridize or to hybridize ambiguously is always possible. STR profiling, on the other hand, encompasses multiple loci on each side of the translocation point, reducing ADO-based errors (false monoallelic states from diploid alleles, false biallelic states for trisomic alleles).

Table 50.4 compares our FISH-based blastocyst biopsy experience with our STR-PCR experience. Patients with reciprocal translocations still show the expected predominantly unbalanced segregation patterns predicted by theory, but fewer embryos are falsely disqualified from transfer. Patients with Robertsonian translocations also fare better. Robertsonian translocation carriers can be prone to uniparental disomy, especially when chromosomes 14 and 15 are involved (see [22]); STR-PCR, unlike FISH, enables biparental inheritance to be looked for and to be confirmed or excluded. Finally, the time needed for actionable results with STR-PCR is just 4–5 h, compared with the 6–16 h required for FISH hybridization and interpretation.

50.8 The Near Future for Aneuploidy Screening

The majority of aneuploidies arise during female meiosis. The minority are brought to the embryonic genome by the fertilizing sperm and are equally pathogenic. A small number take origin in the first few cleavage divisions through mitotic nondisjunction. The latter lead to mosaic states in the embryo: clearly, the later this happens, the smaller the proportion of triploid cells and the more patchy the distribution among inner cell mass and trophectoderm derivatives. There is a large body of published knowledge on the recognized outcomes, such as confined placental mosaicism. In the embryo proper, trisomic cells will be at a disadvantage compared with their euploid neighbors as tissues and organs develop. Our experience with karyotyping 82 cell lines derived from inner cell masses of slow and stalled embryos, assumed to disproportionally display aneuploidies, provides an indication of this process (Bradley et al., manuscript under review). Sixty-nine (84%) displayed only a normal, diploid karyotype, indicating likely self-correction of mitotic nondisjunction-based mosaic states; a limited number tested showed no cases of loss of heterozygosity, which would indicate uniparental disomy as a consequence of self-correction of meiotic errors. The 13 cellular outgrowths that were cytogenetically abnormal included six single trisomies, a double trisomy, a monosomy, three triploidies, a triploidy with an additional chromosome 22, and a balanced reciprocal translocation. In each of the trisomies, meiotic nondisjunction was confirmed by demonstrating triallelic states for STRs on the affected chromosome. There were no mosaic cell lines.

Thus, for reasons of both relative numbers (mitotic trisomies are from the start mosaic states, whereas meiotic trisomies are pure) and, possibly, a qualitative difference between independent aneuploid states compared with diploid states, the key objective of screening for aneuploidy should be less to count chromosomes than it is to recognize dominant original parent of origin states for any of the 24 chromosomes.

50.9 Fluorescent In Situ Hybridization

Specific staining of embryo chromosomes with FISH has been the preferred method to identify the chromosome copy number in a fixed cell preparation. The probes bind to defined regions on the cell chromosomes immobilized on a standard microscope slide, usually at interphase. Generally, the probes are purified cloned regions of the specific chromosome, subtracted for repetitive sequences. These probes are labeled with a unique fluorophore, which can be visualized with fluorescence microscopy. The preparation and quality control of such material generally means that a commercial supply of the probes is the preferred choice for routine clinical use.

There are limitations to commercially available probe sets. The number of fluorophore colors falls far short of the minimum of 24 required. The fluor needs to be chemically active to attach to the DNA probe and also stable enough to remain attached during the hybridization process. Once hybridized, the color must be able to be visualized using, typically, UV excitation and filtered emission. High-energy wavelength excitation can result in rapid photo bleaching of the fluorophore and hence insufficient time to enumerate the hybridization pattern. The commercial suppliers have limited their probe labels to a very small set that meet manufacturing standards and the exacting requirements for clinical use. These fluors must be spectrally separable using specific but simple microscope filters. In practice, this means that only 5–7 or so chromosomes can be checked in one hybridization event. Consequently, the number of chromosomes that are there to be counted using FISH means that multiple cycles of hybridization, enumeration, probe stripping, and rehybridization are needed. Each cycle runs the risk of target loss and/or degraded target sites, either of which can result in incorrect chromosome enumeration and thus a misreading of chromosome number—technical considerations that preclude more than two or three rounds of hybridization. Temporally, adding more than a very few hybridizations would take too much time to permit the transfer of IVF embryos fresh.

Single blastomere biopsy from day 3 embryos gives a single, simple answer: a normal chromosome complement or an abnormal complement. The problems of mosaicism and technical difficulties discussed above, however, still lead to embryos being incorrectly classified and then being excluded from transfer. Biopsy at the blastocyst stage does not resolve these problems but does offer an opportunity to see multiple

hybridization signals for a set of cells. Nonetheless, a conservative reading of those signals has meant that observation of mosaic states in multicell biopsies has resulted in the exclusion of embryos that are likely to be substantially normal and suitable for transfer. The policy of disqualifying an embryo for transfer on the basis of one or two aberrant cells might need to be reexamined.

All other current karyotyping methods applicable to extremely low copy numbers of chromosomes, including analyses of single cells with day 3 embryo biopsies and of typically fewer than ten cells with blastocyst trophectoderm biopsies, require preliminary amplification of DNA copy number.

The first way to satisfy this challenge is to greatly increase the number of chromosome targets to be amplified, enabling any genomic shortcomings in genome-wide amplifications to be overcome by averaging. Over the last few (very few) years, advances in whole genome amplification has advanced the place of the technique of *comparative genomic hybridization* (CGH) by increasing its resolving power within chromosomes as well as improving its quantitative reliability in estimating preamplification DNA copy number.

50.10 Comparative Genomic Hybridization

Developed as a chromosomal screen to analyze genomic changes in cancers almost 20 years ago [23], CGH reveals copy amounts of all 22 autosomes and the 2 sex chromosomes to a resolution of 10 million base pairs or so. The technique uses a combination of molecular and cytogenetic approaches to evaluate chromosome complements. Testing cancers with CGH is simpler than testing embryos, however, because generally with cancer samples there is no shortage of extracted DNA to be tested, whereas embryo biopsy specimens are much more limited.

Wells and Delhanty reported CGH analysis of individual cells from human day 3 embryos a decade ago [24]. Wilton and others reported the first successful clinical preimplantation use of CGH technique a year later [25]. While the use of CGH promised to deliver a total chromosome aneuploidy screen and the possibility of identifying any chromosome imbalance in an embryo, its labor intensity and its time-consuming nature (which required the embryos to be frozen while testing proceeded over periods of many days) precluded transfer of embryos during the biopsy cycle. There were only a few further reports over the ensuing 6 years [26–28]. Often, what was observed were relatively complex chromosome combinations; these then were given causal roles to explain implantation failure, but screening out aneuploid embryos did not improve embryo implantation rates. In spite of its promise, CGH has not been reported to be in routine use by any group. Recently, however, a report from Wells et al. has reported high implantation rates for blastocysts biopsied and analyzed with CGH after improved whole genome amplification [29]. The embryos were transferred after vitrification and later thawing and produced an impressive thawed blastocyst implantation rate of 67%—which would warrant routine use, at least in selected patients.

The use of classical CGH on metaphase chromosomes demands high levels of skill, many days of analysis, and the freezing of biopsied embryos until the karyotype is known. One approach to minimizing labor requirements and shortening the testing time has been to employ DNA microarrays [30]. On the one hand, the timing suits polar body analyses and day 3 cleavage-stage biopsies, but both of these sample types offer only a single-cell genome for amplification and analysis, whereas blastocyst biopsy offers several cells to average out the amplification biases more effectively. On the other hand, the additional expense of CGH, however performed, is coming to be more generally appreciated as another reason for identifying embryos that can blastulate before biopsy and testing, in effect providing a self-screening process that reduces the costs of the testing for the individual patient. A pilot study looking at the analysis of polar bodies for aneuploid detection of female origin has been commenced by a consortium from the European Society of Human Reproduction and Embryology. Implantation rates and pregnancy outcome data are still to be collected. Recent advances combining blastocyst-stage biopsy, micro-array CGH, and vitrification have produced high embryo implantation rates and clinical pregnancy outcomes allowing a viable clinical service to be offered [31].

To date, therefore, it is blastocyst-stage biopsy that has given valuable improvement in implantation rates, and it waits to be seen whether the still prevalent day 3 biopsies and day 0–1 biopsies of polar bodies can achieve the same outcomes. With the use of a DNA amplification-based approach, the interpretation problems associated with low-level somatic mosaicism common in embryos and seen with FISH are partially overcome. The tissue sample, typically consisting of 3–5 cells, is analyzed as a whole (and is taken to represent the embryo as a whole), thus producing an averaging effect for the constitutional chromosomes under investigation.

Review Questions

1. Please define the rationale of blastocyst-stage embryo biopsy.
2. Please describe the required settings for blastocyst-stage embryo biopsy.
3. Please explain the procedure of blastocyst biopsy and the removal of trophectoderm cells.
4. Please describe the general principles of single gene mutation testing (PGD or PGT-M) and the reasons for performing it.

Learning Objectives

- To understand the indications, principles, and significance of sperm cryopreservation.
- To provide knowledge of different cryoprotectants and understand the mechanism of action, as well as the advantages and disadvantages of different categories of cryoprotectants.
- To provide basic knowledge of the gradual decrease in the temperature of the sample for the conventional slow cryopreservation method.
- To discuss the changes in sperm parameters after thawing.
- To discuss the ART outcomes in the use of cryopreserved spermatozoa.

51.1 Introduction

The term cryopreservation is derived from the Greek word κρύος (krýos, "icy cold, chill, frost"). This technique is used to preserve structurally intact living cells and tissues using very low temperatures. The origin of cryopreservation dates back to 1776, when Spallanzani froze sperm in snow and demonstrated their motility after rewarming. One century later, Mantegazza reported the survival of human sperm frozen at −17 °C for more than 4 days (for review [1]). In 1949, with the discovery of glycerol as a cryoprotective agent [2], it was possible to freeze viable spermatozoa for longer periods. In 1957, the first piglet was born from frozen-thawed porcine sperm [3]. In the 1970s, cryopreservation progressed significantly when freezing in dry ice and liquid nitrogen vapor was introduced [4]. However, the success of cryopreservation was achieved with the introduction of controlled rate freezing.

Following the first attempts in 1964, successful cryopreservation of human spermatozoa was then reported in 1973 for the first time [5]. Sperm cryopreservation, when properly performed, allows long-term storage in a state of metabolic arrest that prevents cellular aging while maintaining viability and fertilizing potential and is a critical part of assisted reproductive technology (ART) as it allows these spermatozoa to be used when needed. This process can be divided into three steps: (i) collection of the sample, (ii) freezing, and (iii) long-term storage in liquid nitrogen (LN_2) at extremely low temperatures of −196 °C.

The creation and maintenance of sperm cryobanks is regulated by the World Health Organization (WHO) [6]. Preservation of fertility is one of the main goals of sperm cryopreservation and, in some cases, the only opportunity for some couples to have children in the future. Consequently, it is also considered prior to any medical procedure that may potentially affect the fertility of the individual, for example, in some cases of malignant or non-malignant diseases. Cryopreservation is recommended for sperm donors or, in cases of absent partner, traveling husbands or men serving in the military. Moreover, freezing of sperm can be used to avoid the stress of multiple testicular or epididymal sperm extraction, as well as semen collection in cases of fertility treatment, thus avoiding the necessity of synchronization with female ovulation. Finally, this technique is recommended in cases where fertility may be compromised through medical interventions such as vasectomy and gender selection. In cases of pediatric illness, testicular tissue can be preserved. However, the use of testicular tissue for fertilization purposes still requires more optimization.

51.2 Principles of Cryopreservation

51.2.1 The Cryoprotectants

The cryoprotective effects of glycerol were accidentally discovered in 1948 [2]. Eventually, this discovery, and later on the discovery of dimethyl sulfoxide [7], led to the cryopreservation of many different types of cells. For the cryopreservation of spermatozoa, scientists, in 1952, reported the use of a hen egg yolk-sodium citrate buffer equilibrated with glycerol [8]. Besides glycerol and dimethyl sulfoxide, ethylene glycol and 1,2-propanediol have also been used as cryoprotectants.

Cryoprotectants protect cells, including spermatozoa, from the damage caused by ice crystal formation during the freezing process by decreasing the freezing point and thereby reducing the amount of salts and solutes [9]. On the other hand, such cryoprotective substances can have toxic properties, and it is therefore essential to understand not only their possible toxic effects but also the efficiency of the freezing process and the effect of cryoprotectant on spermatozoa. Thus, the success of cryoprotectants will depend on factors such as concentration or incubation time of the cryopreservation process [9].

51.2.2 The Temperature Changes

Selecting a most suitable cryoprotectant is important, but equally important is the proper selection of the cryopreservation method. The success of cryopreservation depends on the ability of the cryoprotectant to protect spermatozoa from freezing damage, which is reflected in the quality of the sperm after thawing. Based on cooling rates, i.e., the rate by which the temperature is decreased, different sperm freezing methods can be distinguished. The slow-freezing method is based on a slow, gradual decrease in the temperature of the sample, and it can be performed either manually or using an automated system. Sperm vitrification, the non-crystalline, amorphous solidification, is the preservation at extremely low temperatures without freezing. This method is relatively new and the protocol requires further evaluation and standardization for use in spermatozoa. These two methods will be discussed in greater detail below.

51.3 Cryopreservation of Male Gametes

51.3.1 Ejaculated Spermatozoa

The collection of the ejaculated semen after masturbation represents the major part of cryopreservation of male gametes for fertility treatments. The preservation of ejaculated spermatozoa should always be the first option when possible and is indicated whenever a patient can provide a semen sample, which should be collected by masturbation in a sterile plastic container after 2–3 days of sexual abstinence [10]. After a minimum of 20 min of liquefaction at 37 °C, a basic semen analysis should be performed [10]. The semen of the donors must be of good quality according to the WHO guidelines. However, for patients, any sample with adequate spermatozoa motility should be frozen [11]. Since it is possible for men with poor semen quality to have a child by injecting a single sperm into the oocyte (intracytoplasmic sperm injection; ICSI) [12], there is no minimum requirement for semen parameters from patients. Therefore, all samples can be cryopreserved, even those with a low sperm concentration. For men with a disease that affects fertility, the stress of knowing the diagnosis of the disease is itself a physiological and emotional factor contributing to unsuccessful fertilization with an ejaculated specimen, and sometimes, it could even be the reason for the poor quality of the sample. Furthermore, patients who are unable to achieve an ejaculation due to many reasons (social, medical, or religious) and prepubertal adolescents who may be unfamiliar with masturbation can also be considered as candidates for cryopreservation of semen samples. In these cases, it is necessary to use other techniques for sperm collection such as penile vibratory stimulation or electro-ejaculation [13].

51.3.2 Epididymal Spermatozoa

In 1994, Craft and Shrivastav [14] described for the first time percutaneous approaches to retrieve sperm from the epididymis. In cases where a man is diagnosed with azoospermia, it is necessary to use surgical techniques to collect spermatozoa from the testis or the epididymis. In patients with an absence of the vas deferens or an obstruction thereof, epididymal sperm retrieval is indicated. This technique can be performed on the same day when the partner is ovulating or the samples can be frozen prior to the assisted reproduction procedure. Microsurgical epididymal sperm aspiration (MESA) and percutaneous epididymal sperm aspiration (PESA) are the two most commonly used techniques, both of which require local anesthesia.

MESA is a microsurgical technique that requires a small incision in the superior hemiscrotum. The epididymal fluid is aspirated into a tube with sperm medium and subjected to microscopic examination. In contrast, PESA is the direct percutaneous extraction of sperm through the scrotal skin from the epididymis without a microscope. During this procedure, a small-gauge needle is inserted in the caput of the epididymis, and with pressure for several minutes, a clear fluid is aspirated into a syringe. If no sperm are detected in this fluid in a microscopic examination, the needle will be redirected and passed several times through the caput epididymis. With this technique, it is possible to select the most motile sperm from the epididymis. The procedure can be repeated in different parts of the epididymis. If sperm retrieval using MESA fails, either a testicular sperm aspiration (TESA) or testicular sperm extraction (TESE) may be used as alternative procedures.

51.3.3 Testicular Spermatozoa

The retrieval of spermatozoa from men with obstructive azoospermia or non-obstructive azoospermia is restricted to testicular surgery. In cases of obstructive azoospermia at the level of efferent ducts, the sperm can be obtained by TESA or a TESE. Similar to the epididymal retrieval of spermatozoa, TESE can either be performed at the same time as the partner's oocyte aspiration or prior to the oocyte aspiration with subsequent cryopreservation. Previously, TESA was used for diagnostic purposes to evaluate whether or not spermatogenesis takes place in azoospermic patients [15]. To perform a TESA, a needle is inserted in the testicular parenchyma through the scrotal skin, and a negative pressure is applied to aspirate fluid from the seminiferous tubules. Complications related to this procedure are minimal (bleeding (1%) and infection (1%)), and the recovery time is approximately 24 h. In contrary, TESE is a more invasive technique. The procedure for TESE is like that of TESA, but a larger gauge needle is used to obtain multiple biopsies of the testis, and a scalpel is used to make an opening on the scrotal skin. The main risk of this technique is hematoma, and the recovery time is between 24 and 48 h.

51.3.4 Prepubertal Patients and Testicular Tissue Cryopreservation

In 2013, the incidence of cancer in children between the ages of 0 and 14 years was 1% of all the new cancer cases diagnosed in the USA [16]. With safety and efficacy of treatments being established as well as improved survival rates, it is necessary to consider the future quality of life of these children, which includes the preservation of their fertility. However, fertility preservation in children diagnosed with cancer is not yet a standard of care. Besides diagnosis of cancer, some children with non-malignant diseases such as Klinefelter syndrome should be considered for fertility preservation [17].

Since there is no sperm production before the onset of puberty, options for fertility preservation in prepubertal patients are very limited. However, the preservation of

testicular tissue with diploid spermatogonial stem cells has recently been investigated and, to date, has been found to be the only option for this cohort [18]. Immature testicular tissue can be cryopreserved with slow-freezing protocols using dimethyl sulfoxide combined with sucrose or with ethylene glycol as cryoprotectants [17, 19]. Testicular extraction of immature tissue for cryopreservation in boys aged between 3 and 14 years has not shown any acute adverse effects [19]. However, the approaches currently available for gamete maturation are methods that are not well established yet. Therefore, the future fertility of prepubertal patients with frozen immature testicular tissue relies on development of novel methodologies. Although many methods for fertility restoration in young and adolescent male cancer survivors such as auto-transplantation of spermatogonia into the testis, growth and maturation of spermatogonial stem cells in vivo, and auto-transplantation of frozen testicular tissue are already established, these methods need to be further investigated in terms of the fertility potential of these cells. It is also still unclear whether these cells are safe for clinical use.

51.4 Methods for Sperm Cryopreservation

51.4.1 Slow-Freezing

The slow-freezing principle is based on dehydration of cells [20], where slow cooling is combined with low concentrations of a cryoprotectant to achieve an equilibrium. Using this method for cryopreservation, ice crystals are formed at a certain temperature as the temperature is gradually decreasing. The slow cooling is achieved either by a programmable freezer or by manually lowering the samples into liquid nitrogen vapor. Freezing starts with keeping samples at −20 °C for approximately 20 min and then at −86 °C for an additional 60 min. Finally, samples will be stored in liquid nitrogen at −196 °C [6].

Slow-freezing can be performed with fresh, whole ejaculates or washed spermatozoa. It is the preferred method for preservation of human spermatozoa as this method can also be performed with surgically retrieved spermatozoa as well as testicular tissue.

51.4.1.1 Cryoprotectants and the New Generation of Cryopreservation Buffers

Cryoprotectants are used to protect spermatozoa and testicular tissue from damage caused by the ice crystals. The main characteristics of these chemicals are low molecular weight, high cell membrane permeability, and minimal toxicity. The method how the cryoprotectant is added to and removed from the samples is essential to reduce osmotic shock and minimize possible toxic effects. Dimethyl sulfoxide, glycerol, ethylene glycol, and 1,2-propanediol are the more commonly used cryoprotectants. Besides the need for cryoprotection, there is also a need to add cryoadditives. These supplements, also called extenders, have antioxidant effects and are used to improve post-thaw sperm functional parameters such as post-thaw motility, viability, and reducing DNA damage [21].

Glycerol is the most common cryoprotectant used while egg yolk is the most common extender. Since egg yolk contains phospholipids and cholesterol, it increases the tolerance of spermatozoa to cryopreservation [22]. However, one has to consider that extenders from animal origin are a potential source for the transmission of infectious diseases. During the past few years, anti-freeze proteins have been developed with the ability to lower the freezing point, modify the ice crystal formation, avoid recrystallization, and interact with the plasma membrane at low temperatures [23]. However, the use of these proteins for sperm cryopreservation requires further studies and clarification.

51.4.1.2 Slow-Freezing in Vapor Versus Liquid Nitrogen

There are two methods of storage of the cryopreserved samples: immersing in the vapor phase of liquid nitrogen and directly submerging in liquid nitrogen. The option for the storage in the vapor phase seems a more economical option. However, the higher temperature in the vapors may affect the quality of cryopreserved samples. This option can be considered if the samples are kept well within the height of 17 cm from the liquid nitrogen surface and for not more than 3 months [21]. In contrast, storage of the samples directly in liquid nitrogen (−196 °C) is the standard method for long-term storage of semen samples [21]. At this temperature, cellular metabolism and physiological reactions have been slowed down tremendously. Short-term storage of spermatozoa in the vapor phase can replace direct storage in liquid nitrogen to achieve the same results in motility, morphology, and sperm-zona pellucida-binding capacity after thawing [24] (◘ Fig. 51.1). A problem with this method is the possibility of cross-contamination of samples with pathogens from infected samples stored in the same liquid nitrogen container [25]. For this reason, since 1999, the guidelines of the British Andrology Society for the Screening of Semen Donors for Donor Insemination require that cryopreserved gametes have to be stored in sealed vials free from external contamination. Samples that are negative from screened donors have to be stored separately from unscreened individuals [26].

51.4.2 Slow-Freezing Method

Ejaculated semen samples should be collected in a sterile plastic container and liquefied at 37 °C for at least 20 min. After liquefaction, a semen analysis should be performed and freezing must be completed within 1 h. The following protocol (◘ Figs. 51.2, 51.3, 51.4, 51.5, 51.6, 51.7, and 51.8) is for the

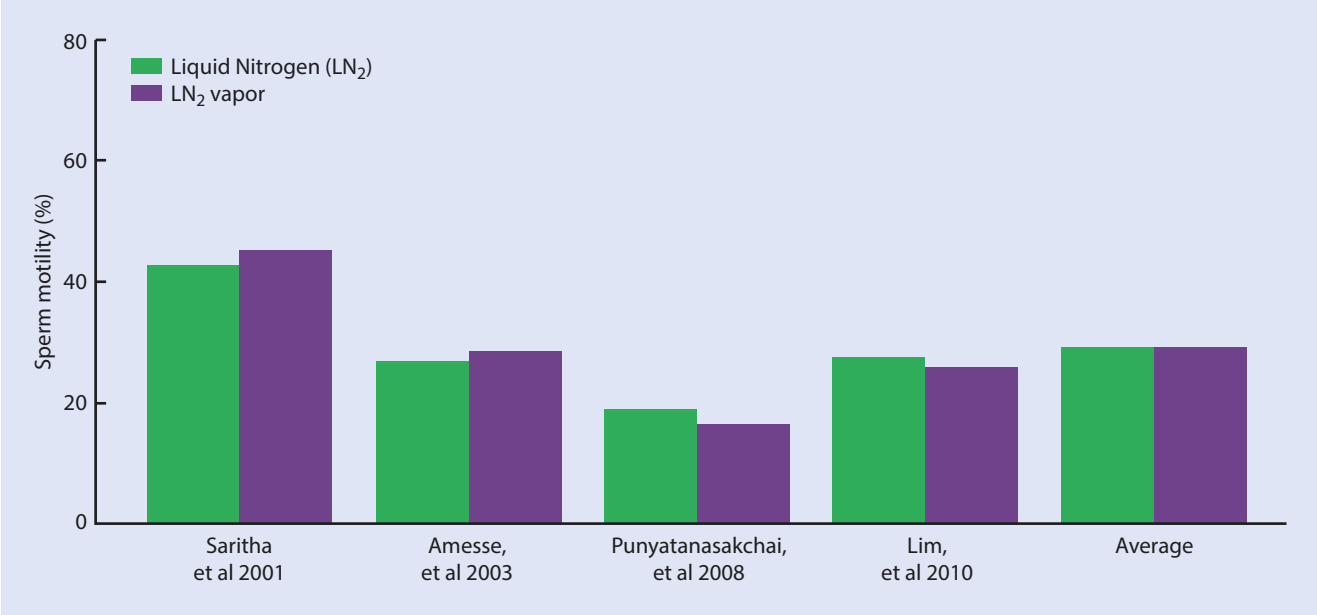

Fig. 51.1 Graphical representation of the effect of sperm preservation in liquid nitrogen compared to liquid nitrogen vapor on sperm motility. The represented studies show no differences between the two options of cryopreservation

Fig. 51.2 A volume of TEST-yolk buffer at 37 °C, equal to 1/4 of the sample volume should be added, then the specimen plus the TEST-yolk buffer is gently rocked for 5 min

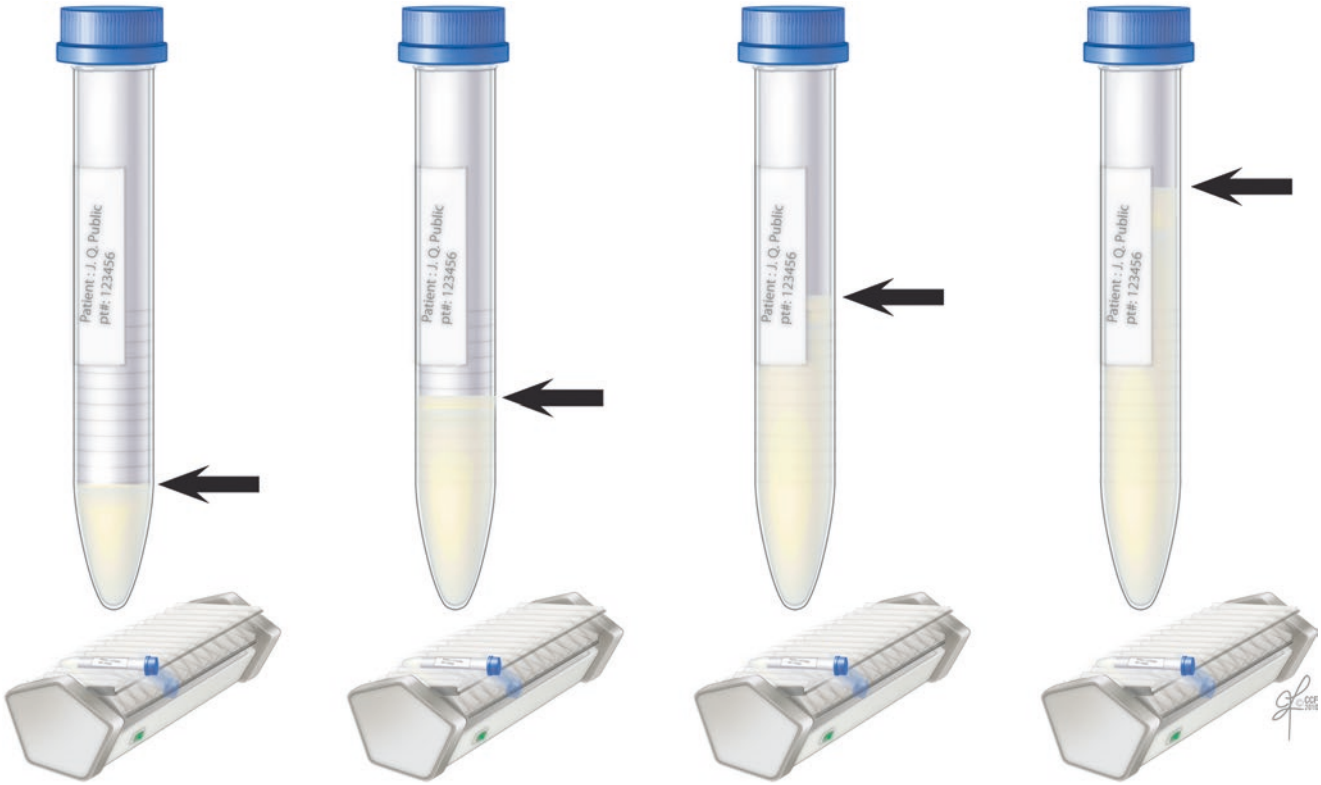

Fig. 51.3 Step-by-step addition of TEST-yolk buffer to the sample. The volume of TEST-yolk buffer should be equal to ¼ volume of the sample

Fig. 51.4 Distribution of the specimen with the freezing medium into cryovials

Fig. 51.5 The cryovials should be placed into the cryocanes before immersion in liquid nitrogen vapors

use of tris, sodium citrate, and fructose (TEST)-yolk buffer as freezing medium supplemented with gentamicin as antibiotic. A semen volume will be diluted with 25% of TEST-yolk buffer at 37 °C and gently rocked for 5 min (Fig. 51.2). This procedure must be repeated three more times until the volume of the freezing medium is equal to the volume of the original semen sample (Fig. 51.3). Subsequently, the samples should be stored in cryovials with a volume not larger than 1.8 ml per cryovial (Fig. 51.4). The tubes should be placed at −20 °C for 8 min (Figs. 51.5 and 51.6) and then kept for at least 2 h in liquid nitrogen vapor (−80 °C) (Fig. 51.7). Finally, the vials have to be transferred into the liquid nitrogen for long-term storage (Fig. 51.8). After 24 h, an aliquot of the frozen sample should be thawed and analyzed [10].

51.4.3 Vitrification

The vitrification process is based on an extremely high cooling rate that prevents ice crystal formation and produces an amorphous, glass-like solid state [27]. Contrary to the slow-freezing method, the effects of the cryoprotectants in spermatozoa are eliminated since this method is cryoprotectant-free. This method of cryopreservation is more commonly used for oocytes and embryos [21], whereas vitrification of spermatozoa is still a challenge, which is attributed to their very specific characteristics. The advantages and disadvantages to slow-freezing method can be found in Table 51.1.

Fig. 51.6 Upright storage during 8 min at −20 °C of the cryovials, with cryocanes and cryosleeves

Fig. 51.7 Vapor phase step in the cryopreservation by slow-freezing process

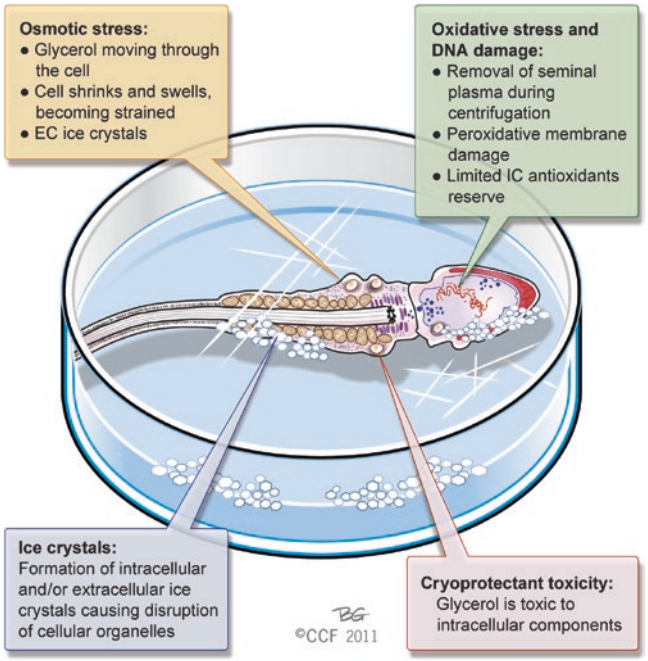

Fig. 51.8 Long-term storage of the samples in liquid nitrogen

Table 51.1 Advantages and disadvantages of slow-freezing vs vitrification

Technique	Advantages	Disadvantages
Slow-freezing	Standardized protocol Fully validated for human spermatozoa storage Approved by the Food and Drug Administration	Expensive and time consuming Use of cryoprotectant Requires a post-thawing process Possibility of cross-contamination
Vitrification	No need for cryoprotectant Simple and quicker Less expensive Free of pathogens Does not require post-thawing process	Inability to preserve larger volumes of sperm Not completely validated for human spermatozoa storage

Since spermatozoa are osmotically sensitive, the use of cryoprotectants can be cytotoxic and cause DNA fragmentation [28]. Isachenko and collaborators reported a cryoprotectant-free vitrification method showing less cryoinjures in human spermatozoa using capillaries [29]. The other limitation of vitrification is the inability to preserve large volumes of sperm. Some studies reported the successful cryopreservation of spermatozoa by vitrification in straws and cryoloop droplets for small volumes [30–32].

For vitrification of sperm, a semen sample can be processed by swim-up and loaded into straws or to a cryoloop container, which ensures that the sample is rapidly cooled by direct contact with liquid nitrogen (−196 °C). After loading the straws or cryoloops, the next step includes the direct contact of the sample with precooled aluminum blocks for a long storage in liquid nitrogen or with a surface of a cryochamber (−180 °C). To the best of our knowledge, no study has reported differences in sperm motility using vitrification compared to slow-freezing (Fig. 51.9).

51.5 Effects of Cryopreservation on Sperm Quality

Intracellular ice formation, osmotic stress, oxidative stress, and cryoprotectant toxicity are some of the factors responsible for the damage in cells during cryopreservation/thawing [33] (Fig. 51.10). Although most of the damage occurs during the thawing process [34, 35], cells can also be damaged due to the formation of intracellular and extracellular ice

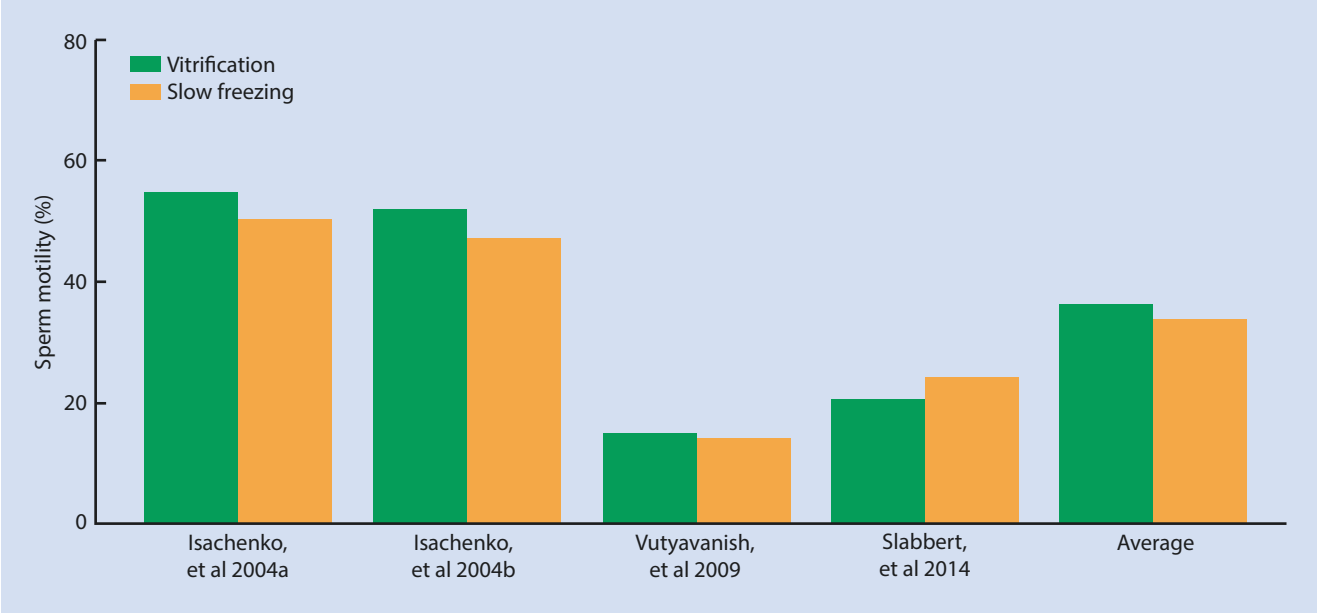

Fig. 51.9 Graphical representation of the effect of sperm cryopreservation using vitrification compared to slow-freezing on sperm motility. The represented studies show no differences between the two options of cryopreservation

Fig. 51.10 Damages in the spermatozoa during cryopreservation

crystals and osmotic stress [36, 37]. These damages cause an imbalance in reactive oxygen species that will affect metabolism and cell signaling, DNA integrity, mitochondrial function, and membrane integrity [31]. The toxicity of the cryoprotectants can be influenced by the slow metabolism of the cells at lower temperatures [38] (Fig. 51.8).

51.5.1 Sperm Parameters

In 1992, MacLaughlin and collaborators [39] reported a decrease in sperm motility after thawing (results from other studies are depicted in Fig. 51.11). Until now, motility is known to be the most affected by cryopreservation/thawing (Table 51.2). A decrease in sperm motility is proposed to be a consequence of mitochondrial damage, sperm tail abnormalities, and changes in the sperm membrane content, such as phospholipids, glycolipids, and sterols [40–42]. It is estimated that sperm cells lose 25–75% of motility after thawing [24, 43–47] (Fig. 51.9). Among the glycolysis taking place in the cellular cytoplasm, mitochondria are also producers of ATP that is essential for sperm motility [21]. Mitochondrial membranes are vulnerable to cryopreservation and consequently the impairment of mitochondria can explain the loss of motility [48]. The fact that the decrease in sperm motility is higher in patients with poor semen quality at the time of sperm banking has to be considered as well [38, 43]. Similar to motility, normal morphology may also decline after thawing [40, 45–47, 49, 50]. Moreover, numerous studies report that the number of viable sperm also significantly decreases after cryopreservation [40, 45–47, 49, 50] (Table 51.2).

51.5.2 Effects on Sperm DNA

The integrity of spermatozoa is an important factor for fertilization. DNA integrity is maintained by the packaging of the DNA in a sperm nucleus. A recent study has attributed the decrease in sperm quality after thawing to sperm DNA fragmentation [21] (Table 51.2), a parameter that, like other basic sperm parameters such as motility, significantly varies from sample to sample [65]. In cryopreserved sperm, DNA integrity can be assessed using a variety of methods. While methods such as terminal deoxynucleotidyl transferase dUTP nick end labeling (TUNEL) directly measure DNA damage [47, 66, 67], the sperm chromatin dispersion

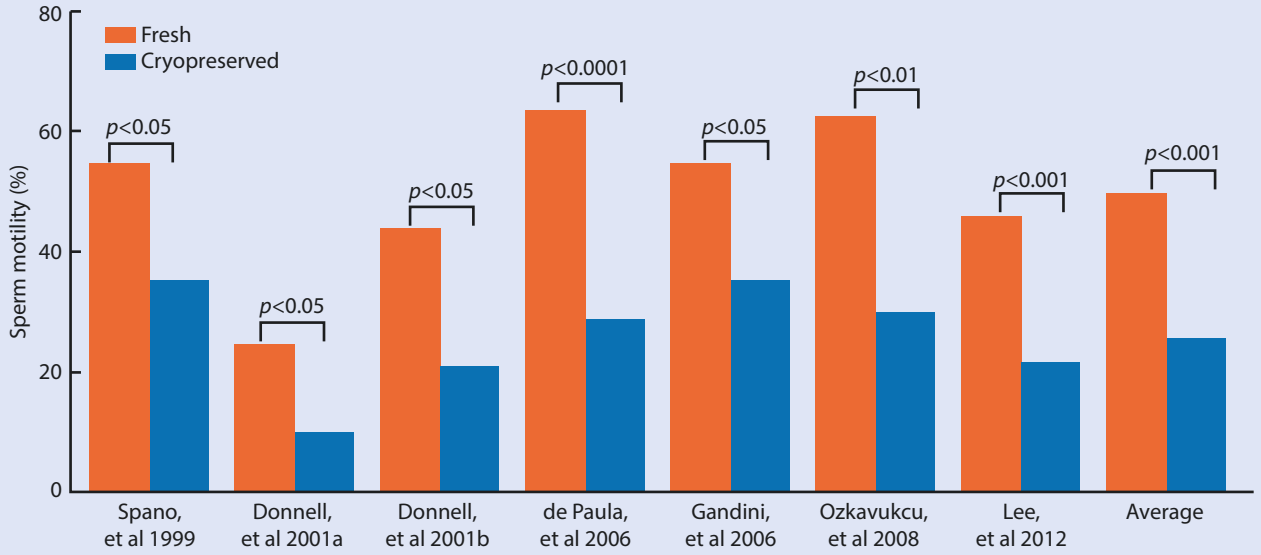

Fig. 51.11 Graphical representation of the effects on sperm motility in fresh spermatozoa and after thawing. A decrease in post-thaw motility was found in all the studies. Significant values found were for $p < 0.05$, $p < 0.01$, and $p < 0.001$

test (SCD) or the COMET assay measure the damage after denaturation [67, 68]. There are also other methods available, which are based on emission spectra of dyes sensitive to the status of DNA-associated protamines, such as the acridine orange assay [67, 68]. Since the oxidant levels are increased in sperm after cryopreservation [69], this results in oxidative stress, which is mainly responsible for increased DNA fragmentation [34, 55] in cryopreserved sperm [55, 70]. Sperm from infertile men or men with poor semen quality have more DNA damage after cryopreservation [11, 55, 70], while samples from infertile men per se have an increased state of oxidative stress [71–73].

51.5.3 Effects on Pregnancy Outcome

Many studies have reported pregnancy outcomes after using fresh or frozen ejaculated spermatozoa [21, 38, 74] (Table 51.3) (Figs. 51.12, 51.13, 51.14 and 51.15). A study in patients with non-obstructive azoospermia using frozen-thawed spermatozoa showed higher implantation and pregnancy rates when compared to fresh spermatozoa [75]. In contrary, a more recent study in 2016 found no differences in ART rates after ICSI between fresh or cryopreserved spermatozoa from patients with Klinefelter syndrome [76]. Meta-analyses comparing the use of fresh vs frozen spermatozoa in ICSI reported no statistical differences in the assessment of clinical fertilization and pregnancy rates between the two groups [74, 77].

ART performed with cryopreserved spermatozoa obtained before gonadotoxic treatment in patients with cancer is reportedly successful. However, the success rate in patients with cancer related to lymphoma or the testis is slightly lower [52, 78, 79]. Some studies report lower or no statistical differences in the fertilization rates with cryopreserved testicular/epididymal spermatozoa from azoospermic men, when compared with freshly obtained germ cells [74, 80]. Besides the use of frozen or fresh spermatozoa, the quality of spermatozoa at the time of usage and the ART technique used are crucial to achieve a pregnancy with success [38, 81–83] (Figs. 51.12 and 51.13).

Table 51.3 Reported effects of cryopreservation in fertilization and pregnancy rates

51.5.4 Length of Freezing and Effects on Sperm Quality

The most common reason for long-term storage of sperm is cancer. Semen and spermatozoa from these men can be cryopreserved before cancer treatment [18, 38, 95]. A study conducted in 2013 reported the birth of twins after in vitro fertilization using semen stored 40 years ago [96]. Some long-term follow-up studies are reporting on sperm quality after thawing of cryopreserved semen from oncological patients [52, 79, 97–99]. Meseguer and collaborators reported that sperm characteristics after approximately 3 years of storage show no differences after thawing in total

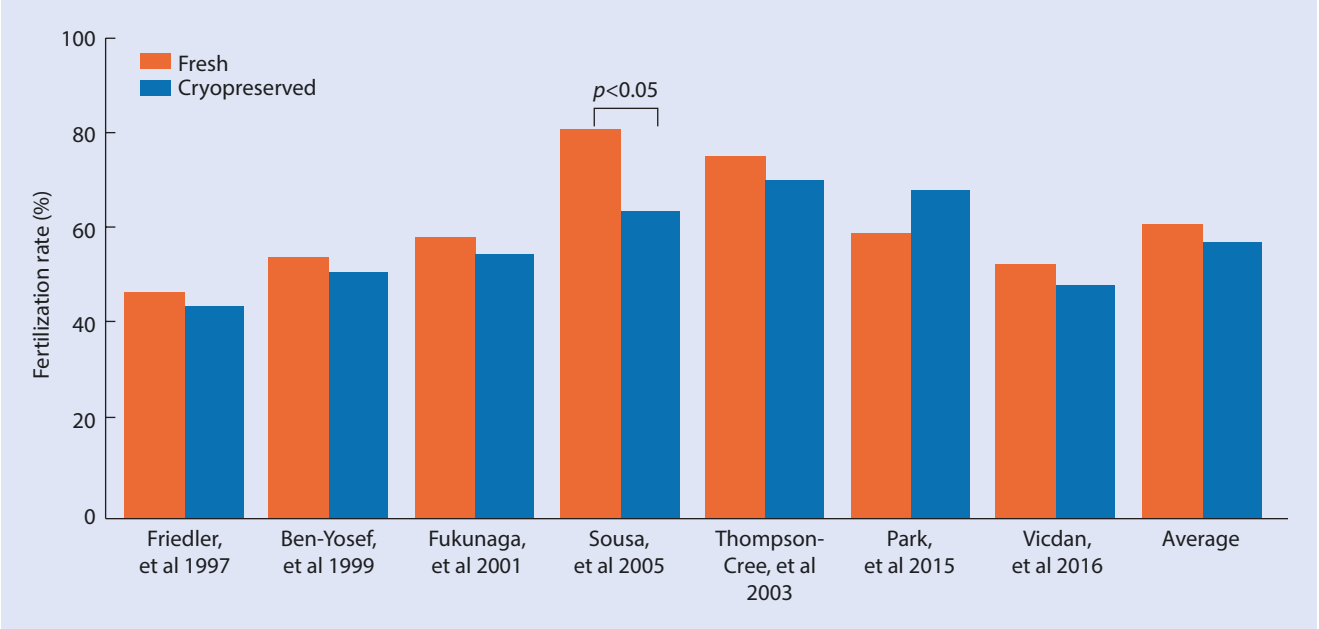

Fig. 51.12 Graphical representation of the fertilization rate in ART using fresh spermatozoa in comparison to cryopreserved spermatozoa. Only one study (Sousa, et al. 2005) reported a higher fertilization rate using fresh spermatozoa, with a $p < 0.05$

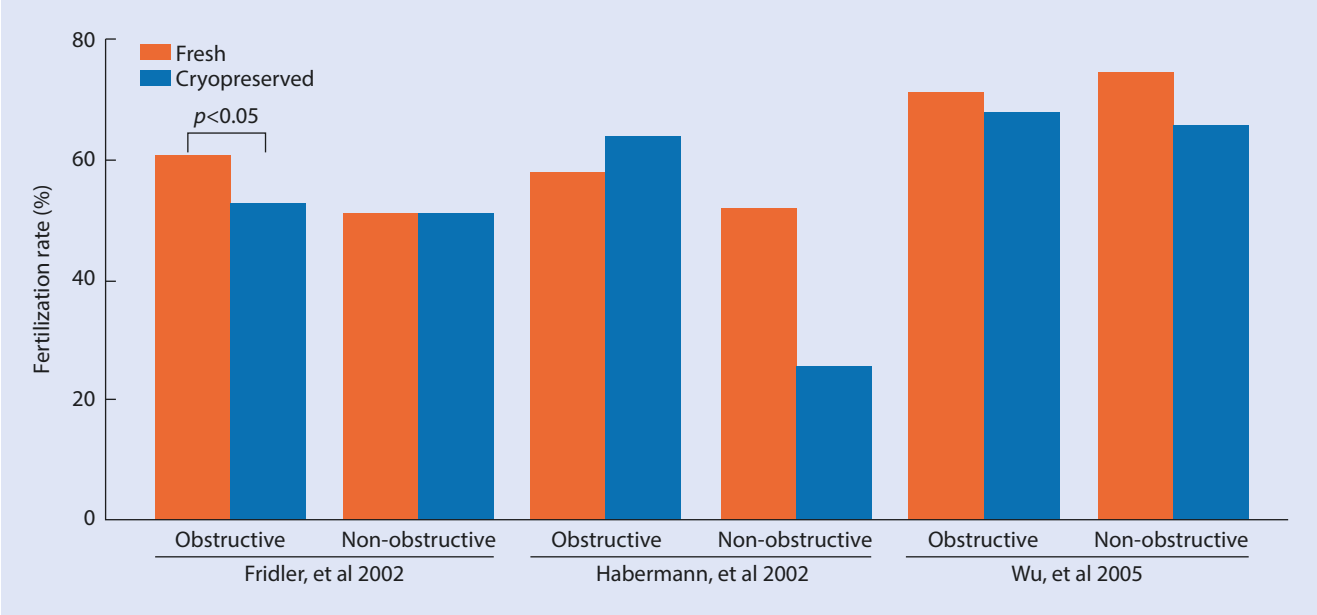

Fig. 51.13 Graphical representation of ART fertilization rates using obstructive and non-obstructive azoospermia and comparing the use of fresh and cryopreserved spermatozoa in each case. In case of obstructive azoospermia, only one study (Fridler et al. 2002) reported a higher fertilization rate using fresh spermatozoa, with a $p < 0.05$

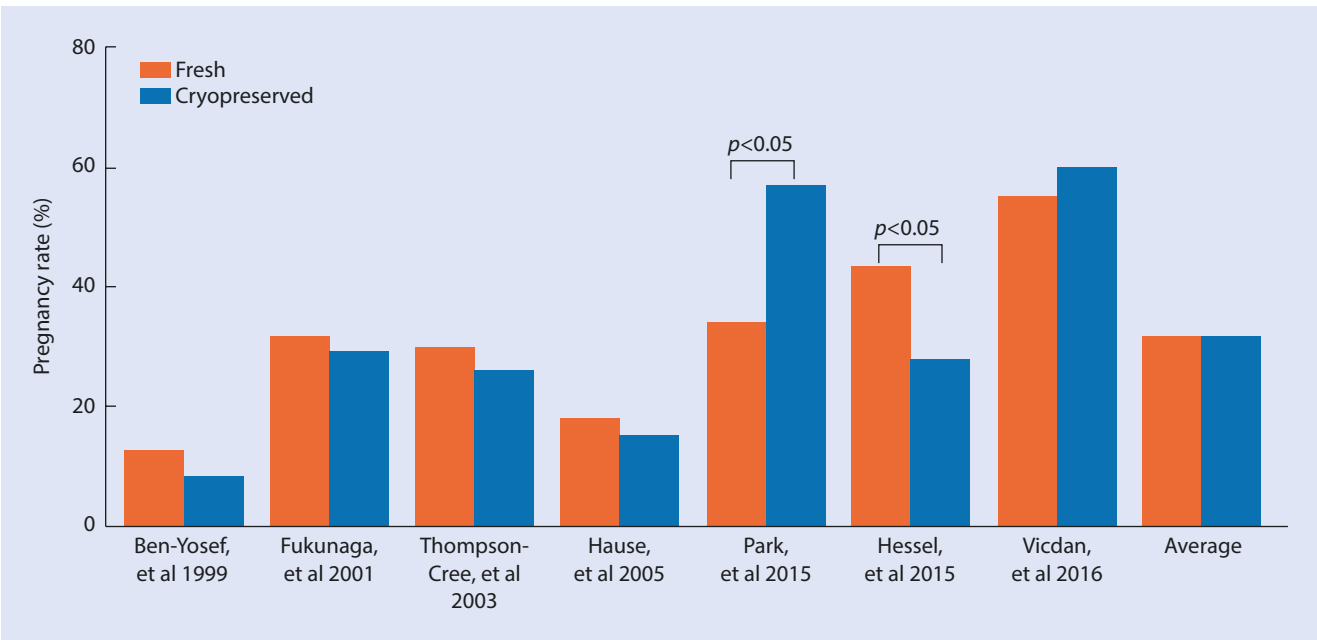

Fig. 51.14 Graphical representation of pregnancy rates in ART comparing the use of fresh vs. cryopreserved spermatozoa. Two studies show contrary results: Park et al. (2015) showed an increase in pregnancy rates using cryopreserved spermatozoa, while Hessel et al. (2015) reported a decrease in pregnancy rates, with a $p < 0.05$

sperm count and motility between cancer patients and controls [51]. Yogev and coworkers reported no differences in motility between different lengths of cryopreservation [100]. Another study also reports no differences between sperm parameters from men with testicular cancer, Hodgkin's disease, and other cancers after approximately 10 years of cryopreservation [101].

51.6 Sperm Cryopreservation

51.6.1 Sperm Donors

Currently, the use of donor sperm in assisted reproduction programs is a common practice [5, 6, 26, 102, 103]. It is mandatory to screen the donors for any infection or

genetic disorders. For a semen sample to be accepted, the concentration of progressively motile sperm after thawing is the most important parameter to be considered [104]. Among the examples of couples who request sperm donor samples are partners of patients with azoospermia, genetic diseases, HIV-positivity, and same-sex couples. In the USA, some agencies provide extensive non-identifying information [105, 106]. These agencies will counsel recipients of sperm donations about the cultural and psychological background of the donors, and when the child reaches the age of 18, the agencies will provide the name and other details of the donor [103, 105, 106]. This will allow the offspring to find the father, if they should so desire [103, 106].

51.6.2 Cancer Patients

Cancer is the major reason why men cryopreserve their gametes [107, 108], and an estimate of 900,000 men in the USA were expected to be diagnosed with cancer in 2018 [109]. Despite the fact that exposure to chemo- and radiotherapy is responsible for the loss of fertility in men undergoing cancer treatment [107], only 48% of the physicians discuss the possibility of sperm banking with the patients and only 25% with cancer patients [108]. This loss of fertility may be permanent or temporary [110, 111]. Therefore, sperm banking before cancer treatment is always recommended, even when the sperm parameters are poor, as it is in the case of reproductive cancers [107, 108]. When cancer is diagnosed in pediatric patients, where the adolescents have not achieved puberty, cryopreservation of testicular tissue is an option [112–115], which should always be discussed with the parents and the child [38, 116].

51.6.3 Other Diseases

There are several non-reproductive diseases, such as Klinefelter syndrome [76], which can be responsible for the impairment of fertility, in which case sperm banking is recommended as soon as possible. Infertility can also be caused by the treatment of a condition, such as autoimmune disorders [117], diabetes, or heart transplant where gonadotoxic drugs [118, 119] are used. In these cases, sperm banking is recommended prior to therapy [120, 121].

51.6.4 Traveling Partner

Sperm cryopreservation in case of a traveling partner allows the utilization of male gametes at the time of female ovulation. This can be an option when the partner is absent at the time of ovulation, due to deployment in the military, or due to frequent or long business trips [121].

51.6.5 Pre-vasectomy

Vasectomy is a male contraceptive method where the *vas deferens* is cut and the ends closed or cauterized (blocked) resulting in the absence of spermatozoa in the ejaculate [122]. Many men who go for vasectomy want to perform sperm banking prior to vasectomy [123]. This option allows them to have their biological children later on, should their life circumstances or demographics change [38].

51.6.6 Transgender

Male-to-female transsexualism (transwomen) results in an irreversible sterile condition. Furthermore, transwomen often wish to become biological parents and start a family, like other people at the reproductive age. It is only in the last 10 years that these individuals are also eligible for this option to preserve their fertility [124]. It is also known that parenting is one of the preventing factors for suicide in transwomen [125]. Now, transwomen can preserve their fertility using the sperm banking option before undergoing any medical transition procedures [126].

51.7 Postmortem Utilization of Cryopreserved Semen

Viable sperm can be retrieved from a cadaver up to 24–36 h postmortem and can still be frozen [127, 128]. The use of posthumous sperm raises many controversial, ethical, and legal concerns about the ownership of the sperm [108]. High fertilization rates (40–100%) using postmortem sperm have been reported [129]. In cases of patients who cryopreserved spermatozoa prior to a medical treatment, in case of death, clear and precise instructions about the use of the sample and an informed written consent that is recognized by law have to be obtained from these patients [130].

51.8 Future Developments of Cryopreservation in Male Patients

When using conventional sperm cryopreservation protocols, a decline in viability, chromatin integrity, motility, and mitochondrial potential is observed. It is accepted that most of the damages occur during the thawing process. Optimization of the freezing medium with antioxidant supplements is a promising option. Newer freezing techniques such as vitrification also appear to be promising as they are less time-consuming and require minimal processing of the sperm. Still, the size of the sample and cross contamination are major concerns with the use of open devices for this technique. Therefore, further studies are necessary to assess the fertilization and pregnancy rates using vitrified sperm. Another technique with potential, though still in the development phase for

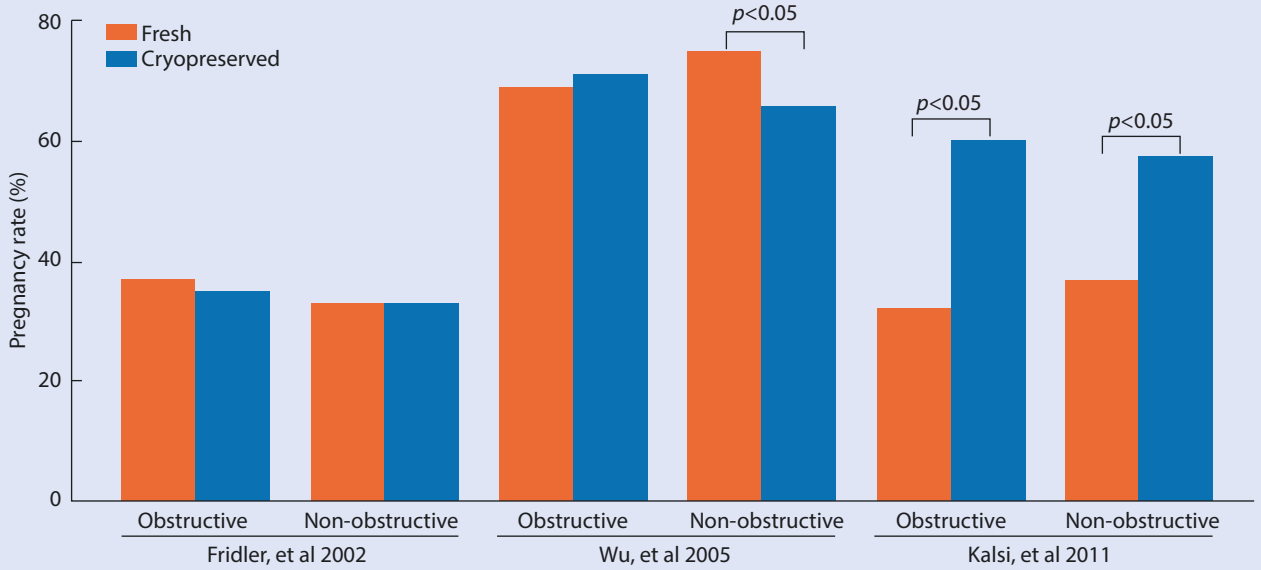

Fig. 51.15 Graphical representation of the pregnancy rates in ART using obstructive and non-obstructive azoospermia and comparing the use of fresh and cryopreserved spermatozoa in each case. In case of obstructive azoospermia, only one study (Kalsi et al. 2011) reported a higher pregnancy rate using fresh spermatozoa, with a $p < 0.05$. In case of non-obstructive azoospermia, Wu et al. (2005) demonstrated a decrease in pregnancy rates using post-thaw spermatozoa, while Kalsi et al. (2011) found increased pregnancy rates using post-thaw spermatozoa, with a $p < 0.05$

human spermatozoa, is lyophilization (freeze-drying) of sperm where the samples can be stored at 4 °C [21, 131]. After lyophilization, the spermatozoa are immotile, but the DNA damage is less when compared with liquid nitrogen freezing [132]. However, since the spermatozoa are immotile, lyophilized sperm can only be used in ICSI.

51.9 Conclusion

Cryopreservation of male spermatozoa is the standard of care for fertility preservation in patients undergoing to gonadotoxic treatments, such as chemotherapy/radiotherapy. There are other scenarios where a couple or an individual patient will need to cryopreserve the spermatozoa, for example, before vasectomy or in cases of a traveling husband. With the development of medicine and research, newer opportunities for cryopreservation have been explored. The option for cryopreservation of testicular tissue in cases of pediatric cancer provides hope for patients of fathering a child in the future. With modern societies being more open and liberal, the wrong sexual identity of individuals is considered a problem, and these individuals do try to have their physical gender changed. Consequently, transwomen should have an opportunity to cryopreserve spermatozoa before undergoing gender reassignment.

The conventional cryopreservation (slow-freezing) protocol is standardized and widely used. However, challenges remain in terms of functional sperm parameters including motility after the thawing. Although new methods to preserve spermatozoa are promising, they still need validation before being routinely used for cryopreservation of spermatozoa in an assisted reproduction program. These new methods include the necessity for the development of new cryoprotectants and new antioxidants to improve sperm quality after thawing. Vitrification is a new technique of cryopreservation, which is being investigated in recent years. While this method is commonly used for oocytes and embryos, for spermatozoa, challenges remain due to the special characteristics of male germ cells. This technique is further limited as only small volumes with small numbers of spermatozoa can be cryopreserved. Lyophilization of spermatozoa is another method that is still being investigated. The problem associated with this technique is the fact that male germ cells are completely immotile after lyophilization and can therefore only be used for ICSI. Hence, future research needs to be conducted not only on the optimization and safety but also on the health of the offspring.

Review Questions

1. Which of the following characterizes a good cryoprotectant?
   (a) Low toxicity
   (b) High toxicity
   (c) High pH
   (d) None of the above

2. Short-term storage of cryopreserved samples in vapors can be considered as an option with the following conditions:
   (a) Height of 3 cm from the liquid nitrogen surface and for not more than 17 months
   (b) Height of 7 cm from the liquid nitrogen surface and for not more than 3 months
   (c) Height of 27 cm from the liquid nitrogen surface and for not more than 7 months
   (d) Height of 17 cm from the liquid nitrogen surface and for not more than 3 months

3. The estimated percentage loss of motility after thawing is between:
   (a) 15 and 65%
   (b) 5 and 20%
   (c) 25 and 75%
   (d) 80 and 100%

4. It is mandatory to freeze the sperm from a donor in order to:
   (a) Allow time to screen for any infection
   (b) Allow time to screen for genetic disorders
   (c) Allow time to analyze the physical characteristics of the donor
   (d) a and b are correct

5. To avoid concerns about the legal ownership of the cryopreserved sample in case of use of posthumous sperm:
   (a) An informed written consent recognized by law should be provided to the patient.
   (b) An informed written consent should be provided to the patient.
   (c) An informed oral consent recognized by law should be provided to the patient.
   (d) An informed oral consent recognized should be provided to the patient.

Learning Objectives

In natural conditions, the egg and embryo are subjected to ever-changing dynamic processes. However, the routine assisted reproductive technologies (ARTs) used today involve the use of static in vitro culture systems. The objective of this work is to determine whether there is any difference in the viability of embryos after in vitro culture under static and mechanical microvibration conditions.

52

52.1 One Hundred and Twenty Years of Cryoprotectant-Free Vitrification of Human Spermatozoa

As noted by Parkes [1], Davenport reported in 1897 that human spermatozoa would survive freezing down to −17 °C. However, these extremely interesting data were forgotten for 40 years.

In 1938, Jahnel cryopreserved human spermatozoa at −79 °C, at –196 °C (with 52 h of storage in liquid nitrogen), and at −269 °C (with 3 h of storage in liquid helium). For cooling containers he used vials of Duran glass (today this polymeric material, invented shortly before 1938, is known as plexiglass). In these tubes, native spermatozoa were directly plunged into the cooling agent. After warming the samples at 37 °C for some minutes, the author noted that some spermatozoa displayed high activity similar to that in fresh ejaculate.

In 1940, Shettles repeated the experiments of Jahnel [2], but cooling of the sperm was performed in capillaries 0.2 mm in diameter. A few of the spermatozoa that were revived after warming were viable (cited by Parkes [1]).

In 1942, Hoagland and Pincus described freezing of human and rabbit spermatozoa, using a bacteriological loop to cool small specimens in rabbit serum with rapid cooling. They obtained up to 40% viable human spermatozoa after cooling a sperm film in liquid nitrogen followed by rapid warming of these microvolumes [3].

The subsequent decrease in interest in cryoprotectant-free vitrification of human spermatozoa can probably be explained by the beginning of the era of permeating cryoprotectant use in cryobiology.

In 1937, Bernstein and Petropavlovski reported that spermatozoa of many mammalian species (bulls, rams, stallions, boars, and rabbits) were cryopreserved successfully with cooling down to −22 °C, using 0.5–2.0 M glycerol.

In 1949, Polge et al. [4] used glycerol for deep freezing of fowl spermatozoa. From that time until now, in the management of human male infertility, cryopreservation of spermatozoa by conventional freezing with permeating cryoprotectants has become a routine and effective technique.

Sixty years after the publication of the report by Hoagland and Pincus [3], the results of investigations aimed at comparing the effectiveness of three methods of cryopreservation of human spermatozoa—conventional freezing with permeating cryoprotectants, cryoprotectant-free vitrification, and vitrification with permeating cryoprotectants—were published [5].

In these experiments [5], ejaculate samples containing at least 20 million spermatozoa per milliliter, with at least 50% progressive motility and 15–30% morphologically normal spermatozoa after swim-up, were frozen "slowly" and vitrified.

For "slow" (programmable or conventional) freezing the samples in both groups (native and swim-up-prepared spermatozoa) were divided into four subgroups: native spermatozoa without cryoprotectant, native spermatozoa with cryoprotectant, spermatozoa after swim-up without cryoprotectant, and spermatozoa after swim-up with cryoprotectant. Test-egg-yolk buffered-glycerol freezing medium (TYBG; Scandinavian IVF Science, Gothenburg, Sweden) was used. After 1:1 dilution with TYBG, 0.25 mL of the sperm suspensions was pipetted into standard 0.25-mL insemination straws and kept at room temperature for 10 min. Then the straws were placed in a programmable freezer and cooled at −10 °C/min. Thawing of the samples was performed by plunging the straws into a water bath at 37 °C for 50 s.

For cryopreservation by direct plunging into liquid nitrogen (vitrification), samples from both groups were divided into four subgroups: native spermatozoa without cryoprotectant, native spermatozoa with cryoprotectant, spermatozoa after swim-up without cryoprotectant, and spermatozoa after swim-up with cryoprotectant. TYBG medium, in the same concentration as that used for slow freezing, was used for vitrification with cryoprotectant. Samples of the spermatozoa were placed onto copper loops 5 mm in diameter (drops 20 μL in volume) or into standard 0.25-mL insemination straws. The loops and straws were plunged into liquid nitrogen.

Thawing of the loops was performed by plunging them into a 15-mL tube with 10 mL of strongly agitated culture medium at 37 °C. After thawing of five loops in one tube, this tube was put into a CO_2 incubator at 37 °C for 5–10 min. Then the spermatozoa were concentrated by centrifugation at 380 × *g* for 10 min. The pellet was resuspended in 100 μL of culture medium.

Thawing of the straws was performed by plunging them into a water bath at 37 °C for 50 s. The test for evaluation of dead and acrosome-reacted spermatozoa was performed according to the method described by Talbot and Chacon [6], with staining in 2% trypan blue, fixation in 3% glutaraldehyde, and staining with Bismarck brown. The colors of the acrosomal and postacrosomal regions of the spermatozoa were evaluated. Dead spermatozoa have a dark blue to black postacrosomal region and a pink or white acrosomal region. Live spermatozoa without an acrosome reaction at the time of fixation have a light brown postacrosomal region and a pink acrosomal region. Live spermatozoa with a normal acrosome reaction at the time of fixation have a light brown postacrosomal region and a white acrosomal region. Sperm morphology was assessed according to strict criteria [7].

Also, the ability of fresh (control) spermatozoa and spermatozoa vitrified without cryoprotectant to fertilize oocytes was evaluated.

It was established that the motility rates of the spermatozoa were 55% in the fresh native sperm samples and 87% after swim-up. Ten minutes after dilution with TYBG, the rates of motility were nonsignificantly reduced to 42% in native spermatozoa and significantly reduced to 73% in swim-up-prepared spermatozoa. These data demonstrated that addition and removal of cryoprotectant can negatively influence the motility of spermatozoa. Programmable freezing without cryoprotectant reduced the rates of sperm motility significantly to 1% in native spermatozoa and 0.2% in swim-up-prepared spermatozoa. After this type of cryopreservation using cryoprotectant, in comparison with nonfrozen samples, the rates of motility were reduced to 16% in native spermatozoa and 36% in swim-up-prepared spermatozoa. The proportions of spermatozoa with normal morphology were decreased to 12% in native spermatozoa and 12% in swim-up-prepared spermatozoa.

After vitrification in standard 0.25-mL straws, nearly all spermatozoa (98%) were immotile. The highest motility rate after vitrification was achieved with swim-up-prepared spermatozoa on copper loops without cryoprotectant (50%). This rate was lower (38%) after conventional freezing of swim-up-prepared spermatozoa with cryoprotectant. For conventional freezing with cryoprotectant, the highest post-thaw rates of motile spermatozoa recovery were obtained with native spermatozoa (45%) and swim-up-prepared spermatozoa (55%).

After vitrification on copper loops, the highest post-thaw rate of motile spermatozoa recovery was achieved with swim-up-prepared spermatozoa without TYBG treatment (57%). The highest proportion of morphologically normal spermatozoa was obtained after conventional freezing of TYBG-treated/swim-up-prepared samples (27%). After vitrification of swim-up-prepared spermatozoa without cryoprotectant, this parameter was not significantly different (26%).

The proportions of "viable" cells were comparable (59%) after programmable freezing and after vitrification of swim-up-prepared spermatozoa without cryoprotectant. The highest proportion of acrosome-reacted cells was found in swim-up-prepared samples after vitrification without cryoprotectant (38%). It was shown that preservation of the fertilization properties of spermatozoa after vitrification resulted in a higher rate of embryo formation than that observed in native (control) spermatozoa.

It was concluded than cryoprotectant-free vitrification of human spermatozoa is a perspective direction of cryopreservation [5].

52.2 Conventional Freezing and Vitrification with Permeating Cryoprotectants Versus Cryoprotectant-Free Vitrification

Conventional freezing with permeating cryoprotectants leads to mechanical cell injury, which is a consequence of intracellular and extracellular ice crystal formation and osmotic damage due to extensive cell shrinkage. Subsequent rewarming and thawing of the cells can cause further deterioration in their viability through possible excessive osmotic swelling [8–10]. As a result, the average velocity in terms of the percentage of motile spermatozoa drops significantly after cryopreservation relative to that of fresh sperm (Watson et al. 1995; [11–14]).

It has been established that the production of reactive oxygen species leads to an increase in lipid peroxidation after cryopreservation of spermatozoa [15] and that this event is associated with a loss of sperm motility [16, 17]. This type of cryopreservation with permeating cryoprotectants can provoke extensive chemical and physical damage in spermatozoa cell membranes as a result of changes in lipid-phase transition and increased lipid peroxidation.

Alvarez and Storey [16, 18] and Chatterjee and Gagnon [19] have suggested that the injury to human spermatozoa induced by conventional freezing occurs mainly during thawing, and it has been related to diminished antioxidant defense activity during cooling and/or structural damage to the cytoskeleton and/or antioxidant enzymes during cryopreservation [16, 18].

This suggests that conventional ("slow") freezing and thawing of spermatozoa, aside from ice crystal formation, is intrinsically deleterious. To prevent excessive cell shrinkage during conventional cryopreservation, permeating cryoprotectants are used. However, the effectiveness (prevention of intracellular ice formation) of permeating cryoprotectants during this type of freezing can be achieved only with a low cooling rate [9], which, as mentioned earlier, can be damaging in itself. Besides, the introduction (before cooling) and removal (after thawing) of permeating cryoprotectants can produce damage even at room temperature in the absence of freezing or thawing (or both). The main mechanisms of permeating cryoprotectant toxicity have been discussed elsewhere [20] and include osmotic damage, as well as chemical toxicity to cells and membranes [19, 21, 22].

Conventional freezing and thawing, with all of these negative effects, can also lead to chromatin damage. In view of this possibility, assessment of sperm nucleus integrity is very important because chromatin abnormalities have repercussions for sperm quality and male fertility status [23].

Besides, sperm DNA damage is strongly correlated with mutagenic effects of conventional freezing [24]. In fact, freezing and thawing of spermatozoa from fertile and infertile men lead to chromatin damage, as well as effects on spermatozoa morphology and membrane integrity [25–28].

It has been demonstrated that any defects in the chromatin structure of spermatozoa from infertile men showing increased DNA instability are sensitive to denaturing stress [29]. This stress may be induced by several treatments, including conventional freezing. Despite this, oocytes have the ability to repair a small amount of sperm DNA damage, although this seems to be insufficient to support subsequent embryo development [30], and DNA damage can lead to decreased conception rates or conception failure [28, 31]. The percentage of spermatozoa with fragmented DNA has also been negatively correlated with the success of

in vitro fertilization and intracytoplasmic sperm injection (ICSI) [32].

In contrast to conventional freezing ("slow" ice-forming techniques), the protocols for vitrification currently used for cryopreservation of oocytes and embryos, as a rule, involve the use of very high concentrations (25–50%) of permeating cryoprotectants and relatively high cooling rates in comparison with the rates used in conventional freezing.

At the same time, the presence of permeating cryoprotectants substantially decreases the critical rates of freezing and warming. However, it is known that high concentrations of cryoprotectants have a toxic effect [33–36].

52.3 Cryoprotectant-Free Vitrification of Human Spermatozoa Can Entail the Use of Nonpermeating Compounds: Carbohydrates, Proteins, Lipoproteins, and Antioxidants

It is known that for cryopreservation of mammalian and human spermatozoa, mixtures of nonpermeating compounds—such as proteins (e.g., in the form of human serum albumin (HSA)) for antioxidant and cryoprotectant purposes, and sucrose as the agent for dehydration of cells—can be used [37–51].

During vitrification with permeating cryoprotectants, carbohydrates play a role in compensating for the change in osmotic pressure caused by the permeating cryoprotectants, increasing this pressure during saturation with the cryoprotectants (dehydration) and decreasing during removal of the cryoprotectants (rehydration).

What roles do carbohydrates play in cryoprotectant-free vitrification when we use only isotonic solutions?

The literature answers on this question are a little unclear. Carbohydrates can stabilize the cellular membrane. For example, there is an opinion that raffinose plays the role of a stabilizer of the mouse oocyte membrane [52, 53]. Koshimoto and Mazur [52] investigated three different sugars (monosaccharide glucose, disaccharide sucrose, and trisaccharide raffinose). It was shown that protection against cryodamage during cryopreservation (freezing and thawing) depended not on the type of sugar or its molar concentration, but on the mass concentration of sugar. The positive effect of sucrose on the cell plasma membrane has been described by Rodgers and Glaser [54].

Lipoproteins in seminal plasma maintain the lipid composition of the plasma membrane and increase the viability and cryostability of the cellular membranes of spermatozoa during storage and cryopreservation [55]. Probably the same positive roles are played by lipoproteins for stabilization of mitochondrial membranes.

Antioxidant properties of seminal plasma have been described in humans [51], rats [38], and mice [41]. According to Sasaki et al. [46], the antioxidant properties of seminal plasma are attributable to low molecular weight protein fractions, whereas Liu et al. [44] suggest that antioxidant protection of spermatozoa is related to the proteins in seminal plasma.

52.4 Extremely High Viability of Viruses, Bacteria, Mycoplasmas, and Fungi After Cryoprotectant-Free Cryopreservation

What happens to microorganisms when they get into liquid nitrogen spontaneously (cryoprotectant-free vitrification) in culture medium or even in distilled water?

In fact, *viruses* (especially enveloped ones) present big problems in medicine.

Speck et al. [56] showed that certain cryoprotectant-free suspension media (skim milk, buffered saline, gelatin, rabbit serum, egg yolk, allantoic fluid) permit adequate storage of *herpes simplex virus* in dry ice (−70 °C) for many months.

Melnik [57] studied enveloped viruses (*herpes*, *measles*, *sindbis*, and *vesicular stomatitis viruses*) as well as nonenveloped viruses (*vaccinia virus*, *adenovirus*, and *poliovirus*). For cryoprotectant-free freezing, the viruses were mixed with distilled water and 20% fetal calf serum. Then samples were frozen by reduction of the temperature from 25 °C to −40 °C over an interval of 20 min. The viruses were thawed rapidly at 37 °C. It was established that enveloped viruses were fully inactivated after freezing in distilled water; however, after freezing in 20% fetal calf serum, these viruses were only partially inactivated after freezing and thawing. Even after four cycles of freezing–thawing, positive titer values were noted. Thus, it was concluded that fetal calf serum can protect enveloped viruses (during freezing in the absence of permeating cryoprotectants).

The nonenveloped viruses were not inactivated by freezing and thawing, even in the absence of protective agents (in distilled water). After cryoprotectant-free freezing in 20% fetal calf serum, two of the three tested viruses (*vaccinia virus* and *poliovirus*) were activated. The stable characteristics of these viruses are well known [58].

In our opinion, the following technology, which is intensively used in the biomedical industry, can demonstrate extremely high cryostability (cryoresistance) of viruses. This technology is freeze-drying (lyophilization) of live virus vaccines [59] and entails (at the beginning of vacuumization) the freezing of enveloped viruses in a cryoprotectant-free solution. These viruses have lipid membranes and a water volume confined by these membranes (in cells, this volume is the cytoplasm). For protection of these viruses, a number of nonpermeating compounds are used: mannitol, sorbitol, sucrose, gelatin, glutamate, HSA, and fetal bovine serum.

We would like to underline here that the most "famous" viruses (*human immunodeficiency virus* (HIV) and *hepatitis virus*) are enveloped viruses. For nonenveloped viruses, the question of cryopreservation a priori is absent because they are lipid membrane free and water free. For these viruses, "cryopreservation" means only cooling (e.g., by direct plunging into liquid nitrogen) and nothing more.

Experiments by Stringfellow et al. [60] demonstrated the high level of cryostability of *bacteria*. A cryoprotectant-free solution of 10% fetal bovine serum was inoculated with *Brucella abortus*, conventionally frozen at a cooling rate of −0.3 °C/min, and later thawed in a 37 °C water bath. It was established that the number of colony-forming units of *B. abortus* in 1 mL of frozen suspension was reduced from 213 million to only 70 million colonies per milliliter and from 213 to only 83 million colonies per milliliter after 2 weeks and after 6 months of storage in liquid nitrogen, respectively [60].

High cryostability of bacteria was demonstrated in a recent publication regarding freezing–drying (cryoprotectant-free cryopreservation followed by vacuumization) of lactic acid bacteria [61].

Mycoplasma is also a cryostable pathogen [62]. It was established that the developmental rate of *M. equigenitalium* and *M. subdolum* was not diminished by cryoprotectant-free cryopreservation by direct plunging into liquid nitrogen and storage at −196 °C for up to 30 days [62].

M. genitalium is an established cause of sexually transmitted infections. Remnants of positive original specimens were frozen without cryoprotectants and stored at −20 °C for up to 18 months. It was established that the viability rate (DNA load) of these bacteria was 90% [63].

The high cryostability of mycoplasmas was evidenced by a publication regarding freezing–drying (cryoprotectant-free freezing was the first stage of the process) of these microorganisms [64].

Various plastic cryovials and cryostraws allow cryopreservation of any types of cells and tissues without direct contact with liquid nitrogen and with no risk of cross-contamination by different pathogens.

Taking into account all of the data mentioned above, in this review we present two types of cryoprotectant-free cryopreservation of human spermatozoa by direct plunging into liquid nitrogen (vitrification): nonaseptic and aseptic.

52.5 Asepticity as an Obvious Parameter of ART (Including Cell Cooling in Liquid Nitrogen) and Hazard of Cross-Contamination by Pathogens in Liquid Nitrogen

In 1972, Piasecka-Serafin [65] described the possibility of translocation of bacteria from infected semen pellets to sterile ones via liquid nitrogen.

Numerous points of view regarding the risk of cross-contamination during cryopreservation of reproductive cells in liquid nitrogen have been presented [58, 66–81].

In the opinion of Isachenko [82], the following three facts evidence the impossibility of sterilization of liquid nitrogen (one of the methods of sterilization was published by Parmegiani et al. [83]).

Firstly, the bacterium *Deinococcus radiodurans* is extremely resistant to ionizing radiation and ultraviolet light, and is capable of withstanding an acute dose of 5000 Gy of ionizing radiation with almost no loss of viability, and an acute dose of 15,000 Gy with 37% viability. For comparison, 5 Gy can kill a human and 200–800 Gy kills *Entamoeba coli* [84].

Secondly, the colony-forming ability of ultraviolet-irradiated mycoplasma cells has been shown to completely recover after 3 h in the dark [85].

Thirdly, activation (an increase in the viability of viruses) has been shown to begin after 5 min of ultraviolet treatment, and maximal activation was noted 10 min after the beginning of ultraviolet treatment [86].

Bielanski [73] notes that "From a practical point of view, complete sterilization and maintenance of sterility in such a robust system might be a very demanding task, if possible at all. Accordingly, some ubiquitous bacterial agents can be expected in any commercially-produced liquid nitrogen. To this author's knowledge, at the present time, there is no commercial supplier of sterile liquid nitrogen or of a portable device producing liquid nitrogen suitable for assisted reproductive technologies (ART)."

52.6 Technologies for Cryoprotectant-Free Vitrification of Human Spermatozoa Involving Direct Contact with Liquid Nitrogen

Isachenko et al. [43] investigated the ability of sucrose to protect spermatozoa against mitochondrial damage, artificial cryoinduction of capacitation, and acrosome reaction. Spermatozoa were cryoprotectant-free vitrified using three different media: (1) human tubal fluid (HTF; control) medium; (2) human tubal fluid with 1% HSA; and (3) human tubal fluid with 1% HSA and 0.25 M sucrose. From each group, 30-μL suspensions of cells were dropped directly into liquid nitrogen. The cells were thawed by quickly submerging the spheres in human tubal fluid with 1% HSA at 37 °C with gentle agitation. The sperm motility, viability, mitochondrial membrane potential integrity, spontaneous capacitation, and acrosome reaction were investigated. The number of progressively motile spermatozoa was significantly higher in the sucrose-supplemented medium group (57%) than in the controls (19%). The combination of HSA and sucrose (65%) had a stronger cryoprotective effect on the integrity of the mitochondrial membrane potential than HSA alone (33%). It was concluded that cryoprotectant-free vitrification of human spermatozoa with nonpermeating cryoprotectants such as HSA and sucrose can effectively cryopreserve the cells without significant loss of important physiological parameters [43].

Two principally different methodologies were compared: freezing with permeating cryoprotectants and cryoprotectant-free vitrification [87]. For freezing, a cryovial of sperm suspension with permeating cryoprotectant was cooled in liquid nitrogen vapor at a cooling speed of about −10 °C/min. For vitrification, 30 μL of cryoprotectant-free suspension was dropped directly into liquid nitrogen. It was

established that the rates of DNA fragmentation were not significantly greater in the vitrification (16%) or rapid-freezing (17%) groups than in the control group (12%). The rates of hyaluronan binding were similar in spermatozoa in the control and cryopreserved groups. The authors noted that addition of cryoprotectant for vitrification had a neutral effect on the rates of sperm recovery. It was concluded that cryoprotectant-free vitrification has great potential for human sperm cryopreservation. However, it is not superior to freezing with cryoprotectant [87].

Chen et al. [88] collected spermatozoa from normozoospermic patients and cryoprotectant-free vitrified them with or without addition of sucrose by directly plunging a small volume of suspension into liquid nitrogen. The spermatozoa recovery rate, motility, viability, chromatin damage, and DNA fragmentation were assessed. No significant differences were observed in the spermatozoa recovery rate and motility rate between spermatozoa that were cryoprotectant-free vitrified without or with sucrose. However, spermatozoa vitrified without sucrose had greater viability and less damage to sperm chromatin and DNA than those vitrified with sucrose [88].

High effectiveness of cryoprotectant-free vitrification was shown in experiments by Agha-Rahimi et al. [89]. Sperm suspensions were divided into four aliquots: fresh sample (control); cryoprotectant-free vitrification in human tubal fluid medium supplemented with 5 mg/mL HSA and 0.25 M sucrose; patients' seminal fluid; and artificial seminal fluid. Vitrification and warming were performed according to the method described by Isachenko et al. [43]. Twenty-five-microliter aliquots of sperm suspension were dropped directly into a strainer that was immersed in liquid nitrogen, using a micropipette. After warming, sperm parameters of motility, viability, and morphology (assessed with light and transmission electron microscopy observations) were analyzed. It was concluded that seminal fluid in normal semen can act as a cryoprotectant and that cryoprotectant-free vitrification of human sperm in artificial seminal fluid can more effectively preserve the spermatozoa than vitrification in human tubal fluid supplemented with HSA and sucrose [89].

52.7 Basis for Cryoprotectant-Free Vitrification of Human Spermatozoa with Full Isolation from Liquid Nitrogen (Aseptic Technology)

In experiments [90] assessing vitrification by direct plunging into liquid nitrogen, the prepared spermatozoa were loaded onto copper loops 5 mm in diameter by dipping the loops into a sperm suspension to obtain a thin film (supported by surface tension) of 20 ± 2 μL. The volume of the sperm suspension included in the film was determined in the following way. After the loop was plunged into the suspension of spermatozoa and a film was formed, the suspension was shaken down onto the flat surface of a plastic petri dish. Then, using a micromeasurer, the researchers were able to determine the volume of the film, which had formed a droplet on the flat surface of the petri dish. The potentially negative effect of the copper on the spermatozoa was ignored, given their short contact with this material. The loaded loops were then plunged into liquid nitrogen. After storage for a minimum of 24 h, the samples were thawed by plunging the loops into a 15-mL tube containing 10 mL of culture medium at 37 °C under intense agitation. After warming of five loops in one tube, the tube was placed in a CO_2 incubator for 5–10 min. Next, the spermatozoa were concentrated by centrifugation at 380 × *g* for 10 min and processed for further evaluation.

For vitrification in liquid nitrogen vapor, the spermatozoa were vitrified and thawed according to the procedure described above, with the following modifications. Before being plunged into liquid nitrogen, the loops were cooled for 3 min in liquid nitrogen vapor at −160 °C. This was achieved by placing the loops in a Styrofoam box containing a 0.5–0.8-cm depth of liquid nitrogen, 1 cm above the liquid nitrogen level. The temperature of the vapor was determined using an electric thermometer.

The speed of cooling during the direct plunge into liquid nitrogen was calculated by introducing variables such as the geometry of the loop, the amount of attached material, and the physical characteristics of the sperm suspension [90]. The speed of cooling of the sperm suspension film on a loop frozen in liquid nitrogen vapor was determined using a method designed by the authors [90]. A loaded loop was placed in the same position in the same box containing liquid nitrogen in which the experimental spermatozoa were frozen. The film was then periodically (at 1-s intervals) pierced by a thin (27-gauge) needle at different locations (in the center, near the copper ring, and at the periphery). When the film was liquid, it was possible to punch through it many times without disruption of the film, and after the needle was removed, the film remained intact. Upon freezing, the film solidified (starting from the copper ring area and extending toward the center) and piercing without disruption of the film became impossible; the ring began to move. The time elapsed (visually indicated) from placing of the loop in the box at room temperature (23 °C) to the beginning of solidification of the suspension (−4 °C) allowed calculation of the speed of cooling of the spermatozoa.

The time that elapsed from when the suspension was at room temperature (23 °C) to the beginning of the suspension film solidification (when the ring began to move at −4 °C) depended on the place where the film was pierced by the needle: from 6 s (with piercing near the copper ring) to 10 s (with piercing at the center of the ring). Thus, the rate of cooling of the spermatozoa in liquid nitrogen vapor was in the range of 162–270 °C/min.

Both cryopreservation regimes caused about a 40% reduction in the motility of the spermatozoa in comparison with the swim-up-treated control. No statistically significant difference in this parameter between the two methods of cryopreservation was found.

In contrast to motility, the DNA integrity in both groups of cryopreserved spermatozoa was found to be unaffected by the vitrification mode. Instead of motility, three parameters of the viability of the spermatozoa after vitrification with rapid and slow cooling, compared with the control (fresh samples), were taken into account: the fertilization rate (formation of pronuclei), early cleavage of zygotes (formation of 4–6 blastomeres), and late development of embryos (formation of a blastocoel). The results of in vitro fertilization (IVF) demonstrated the approximately equal fertilization potential of the human spermatozoa that were cryoprotectant-free vitrified and frozen in liquid nitrogen vapor.

In conclusion, these results point to the feasibility of cryoprotectant-free cryopreservation of human spermatozoa by fast or relatively slow cooling, achieved by direct plunging into liquid nitrogen (vitrification) or freezing in liquid nitrogen vapor beforehand, followed, in both cases, by rapid thawing. The DNA integrity of sperm cryopreserved using both regimes was comparable to that of fresh sperm [90].

The results of the described experiments provided the grounds for creation of aseptic technology for cryoprotectant-free vitrification of human spermatozoa (with full isolation of the spermatozoa from liquid nitrogen).

52.8 Technologies for Cryoprotectant-Free Vitrification of Human Spermatozoa with Isolation from Liquid Nitrogen (Aseptic Technologies)

In experiments performed by Isachenko et al. [42], ejaculate from patients with oligoasthenoteratozoospermia was prepared using the swim-up method and divided into equal parts for vitrification using droplets, open pulled straws, and open standard straws, as well as one fresh (control) group.

The method used to cool the droplets in liquid nitrogen vapor was previously described by Dinnyes et al. [91] for vitrification of oocytes and embryos; however, in the present experiments, a massive metal block was not used. Aliquots of 40 μL of sperm suspension were placed on aluminum foil that had previously been cooled to −160 °C in liquid nitrogen vapor. During cooling, each droplet of sperm suspension adopted a spherical form. After 5 min of cooling, these solidified droplets of sperm suspension were placed into cryovials that had been precooled in liquid nitrogen, for subsequent storage in liquid nitrogen until the time of warming.

To cool the open pulled straws in liquid nitrogen, aliquots of 5 μL of sperm suspension were drawn inside the end of the open pulled straws by capillary action [92]. The straws were placed inside 0.5-mL insemination straws. The 0.5-mL straws were hermetically closed and plunged into liquid nitrogen, using the method described by Isachenko et al. [42].

To cool the open straws in liquid nitrogen, 1-μL aliquots of sperm suspension were deposited inside the ends of standard 0.25-mL insemination straws. The straws were placed inside 0.5-mL insemination straws. The 0.5-mL insemination straws were hermetically closed and plunged into liquid nitrogen, using the method described by Isachenko et al. [42].

To warm the droplets, the samples were thawed by being plunged into a 15-mL tube containing 10 mL of culture medium at 37 °C under intense agitation. After warming (with one droplet in one tube), the tubes were placed in a CO_2 incubator for 5–10 min at 37 °C. Next, spermatozoa were concentrated by centrifugation at 380 × *g* for 5 min, and the resulting pellet was resuspended in 100 μL of culture medium and used for further evaluation.

To warm the open pulled straws and open straws, these straws (after being expelled from the 0.5-mL insemination straws) were rapidly plunged into 1.5-mL microcentrifuge tubes with culture medium at 37 °C. After warming, the spermatozoa were expelled into a petri dish and were then cultured.

The three cryopreservation regimes resulted in approximately 40% reductions in sperm motility in comparison with the swim-up control. Although progressive motility was much reduced just after thawing, the motility of the spermatozoa was increased dramatically 2 and 5 h later, but it decreased again after 24 h of culture. No statistically significant differences in this parameter between the droplet, open pulled straw, and open standard straw cryopreservation regimes were found. Thus, there were no differences in the motility rates of spermatozoa vitrified using these methods during culture periods of 2, 5, and 24 h.

In conclusion, evaluation of two parameters—motility and long-term survival of spermatozoa—suggests that the three described methods are suitable for use in ART.

However, the open pulled straw and open straw methods of vitrification are preferable because they allow isolation of the spermatozoa from the liquid nitrogen, with a maximum reduction in the potential risk of microbial contamination, as described by Isachenko et al. [42].

The aims of the study by Isachenko et al. [93] were to develop and test the aseptic technology of cryoprotectant-free vitrification of human spermatozoa in large volumes (for intrauterine insemination). Each of the 52 swim-up-prepared ejaculate samples was divided into three aliquots and allocated to one of three treatment groups: group 1 was a nontreated control group; group 2 consisted of spermatozoa cryopreserved by slow conventional freezing with glycerol-containing medium, and group 3 consisted of spermatozoa vitrified in 0.5-mL insemination (“french”) straws in culture medium with 0.25 M sucrose. Sperm motility at 1, 24, and 48 h after warming; plasma membrane integrity; and capacitation-like changes (spontaneous “cryocapacitation” and acrosome reaction) were assessed after freezing–thawing. Prior to vitrification, the spermatozoa were processed by the swim-up technique and thereafter diluted 1:1 with 0.5 M sucrose. The final concentration of sucrose prepared with bidistilled water was 0.25 M. The packaging of spermatozoa for aseptic vitrification was performed in the following way. Spermatozoa suspensions were cooled in 0.5-mL plastic straws. The hermetically sealed straws were

immersed in liquid nitrogen. The warming-up of the spermatozoa was achieved by immersing the straws with vitrified spermatozoa in a water bath at 42 °C and dangling them gently in the water for 20 s. After warming, the residual fluid was removed from the straws with a paper towel and the straws were disinfected with 70% ethanol. The heat-sealed ends of the straws were cut off with sterile scissors and the suspension was expelled from the straws for immediate evaluation of sperm quality, and for loading into a catheter and intrauterine insemination. It was established that in comparison with conventional freezing, spermatozoa vitrified with aseptic cryoprotectant-free technology displayed superior functional characteristics. The motility rate and the integrity rates of the cytoplasmic and acrosomal membranes were significantly higher after vitrification than after conventional freezing (76% vs. 52%, 54% vs. 28%, and 44% vs. 30%, respectively). However, there were no differences between vitrification and conventional freezing in the presence of glycerol in terms of the percentages of spermatozoa expressing a cryocapacitation pattern (11% vs. 10%). It was concluded that basic protection from cryoinjury can be achieved for human spermatozoa using the novel technology of aseptic cryoprotectant-free vitrification in large volumes. Spermatozoa vitrified with use of this technology are free of permeating cryoprotectants and are ready for further use immediately after warming without the need for any additional treatment (centrifugation or separation in the gradient for removal of cryoprotectants [93, 94].

In investigations by Isachenko et al. [94], a couple, both 39 years old, underwent ART because of severe endometriosis and oligoasthenoteratozoospermia. The spermatozoa suspension was prepared on culture medium supplemented with 1% HSA and diluted (1:1) with 0.5 M sucrose prepared in double-distilled water. After dilution, the cell suspension was maintained at 37 °C in a 5% CO_2 atmosphere for 5 min before being directly plunged into liquid nitrogen.

Cooling of the spermatozoa was performed using a cut standard straw [95]. A 10-μL aliquot of spermatozoa suspension was deposited on the end of the inner part of the straw. Then the straw was placed inside a 0.5-mL insemination straw, which was sealed hermetically with a handheld sealer and plunged into liquid nitrogen.

For warming, the packaged cut standard straw was partly removed from the liquid nitrogen and the upper part of the 0.5-mL straw was cut off. Then, the cut standard straw was removed from the packaged straw and quickly immersed in 1.8 mL of culture medium, which had been prewarmed to 37 °C in a 2-mL centrifuge tube. In this way, very fast warming of the spermatozoa (30,000 °C/min) was achieved.

Next, the warmed and diluted spermatozoa were concentrated by centrifugation and used for further culture, evaluation, and ICSI. The freshly prepared swim-up and thawed vitrified spermatozoa were assessed for changes in the following physiological and morphological parameters: progressive motility, capacitation-like membrane changes, acrosome reaction, and mitochondrial membrane potential.

Eight mature (metaphase II) oocytes were microinjected with the vitrified–warmed spermatozoa. Eighteen hours later, six oocytes showed signs of normal fertilization. Two four-blastomere embryos were transferred to the uterine cavity.

Thirty minutes after thawing, the vitrified spermatozoa displayed 60% progressive motility (vs. 90% in freshly prepared swim-up spermatozoa); 10% were identified as displaying a "cryocapacitation" pattern and 5% were identified as displaying an "acrosome reaction" pattern (vs. 8% and 5% of freshly prepared swim-up spermatozoa, respectively). Sixty-three percent of spermatozoa were classified as having high mitochondrial membrane potential (vs. 96% of freshly prepared spermatozoa). Two healthy girls were subsequently born.

The first case of a healthy baby born after intrauterine insemination with vitrified swim-up spermatozoa from an oligoasthenozoospermic patient was reported in 2012 [84]. A 39-year-old patient underwent intrauterine insemination with spermatozoa from her 35-year-old husband diagnosed with oligoasthenozoospermia. The swim-up spermatozoa from two ejaculate samples were suspended in a culture medium supplemented with 1% HSA and 0.25 M sucrose. Three hermetically packaged 100-μL sperm portions were vitrified by being directly plunged into liquid nitrogen.

Before intrauterine insemination, all portions were warmed in culture medium at 37 °C and the spermatozoa were concentrated by centrifugation; they were then resuspended in 500 μL of culture medium and inseminated. The cell suspension used for insemination displayed 60% progressive motility. Clinical pregnancy was confirmed, and a healthy baby was born at term. These results showed that successful intrauterine insemination can be achieved with aseptic vitrification of spermatozoa [96].

The aims of the study by Isachenko et al. [97] were to develop and test the standardized aseptic technology of permeating cryoprotectant–free vitrification of human spermatozoa in capillaries (for ICSI or IVF in microvolumes). To test the effects of vitrification on basic sperm parameters, 68 swim-up-prepared ejaculate samples from oligoasthenoteratozoospermic patients were aliquoted and distributed into three groups: (1) a nontreated control group, (2) a group consisting of 10-μL samples of spermatozoa cryopreserved by slow conventional freezing with glycerol-containing medium, and (3) a group consisting of 10-μL samples of spermatozoa vitrified in 50-μL plastic capillaries in culture medium with 0.25 M sucrose.

Spermatozoa motility (at 1, 24, and 48 h after warming), plasma membrane integrity, acrosomal integrity, and spontaneous capacitation-like changes were determined after warming.

For preparation of the vitrification solution, the basic medium (culture medium +1% HSA) was diluted 1:1 with 0.5 M sucrose prepared with bidistillate water. The spermatozoa were centrifuged and resuspended with this vitrification solution. For this methodology, 50-μL plastic capillaries were manufactured from hydrophobic material as vehicles for cooling sperm cell suspensions. The capillary was filled

with 10 μL of spermatozoa suspension by aspiration. It was absolutely crucial for the inner surface of the capillary to not become moist during the packaging procedure. The authors noted that aspirating the volume of sperm cell suspension above the mark and correcting it by lowering the fluid level inside the capillary after aspiration was technologically wrong and would result in an excess volume after thawing. After aspiration was completed, the capillary was inserted into a 0.25-mL insemination straw. After sealing of both ends, the straw was plunged into liquid nitrogen and cooled at 600 °C/min.

For warming, the capillary was removed from the isolating 0.25-mL insemination straw and immersed in a 1.8-mL centrifuge tube with 0.7 mL of vitrification medium (culture medium with sucrose) prewarmed to 37 °C. The authors noted that the volume of vitrified suspension after warming was not increased. Finally, the suspension of spermatozoa was expelled from the capillary for immediate evaluation of spermatozoa quality and use in IVF or ICSI.

It was established that aseptic cryoprotectant-free vitrification showed a significantly stronger cryoprotective effect than conventional freezing. One hour after warming, the rates of motility, plasma membrane integrity, and acrosomal integrity were significantly higher than those observed in conventionally frozen spermatozoa (28% vs. 18%, 56% vs. 22%, and 55% vs. 21%, respectively) but lower than those observed in fresh spermatozoa (35%, 96%, and 84%, respectively). The rates of capacitation-like changes did not differ significantly between vitrified and conventionally frozen samples (8% vs. 9%) but were higher than the rate observed in fresh spermatozoa (2%).

It was concluded that the newly developed technology of aseptic vitrification of human spermatozoa in capillaries can effectively preserve these cells from cryoinjuries [97].

The following nonaseptic technology was used in experiments by Khalili et al. [98]. The aim of the investigations was to evaluate the effects of neat semen vitrification on vital parameters and DNA integrity of sperm from men with normal and abnormal sperm parameters.

The semen was loaded onto copper cryoloops 2.5 mm in diameter by dipping the loops in the suspension to obtain a thin film, and the loaded loops were plunged into liquid nitrogen. After storage for 7 days, the samples were warmed by plunging the loops into a tube containing 2.5 mL of culture medium at 37 °C. After warming of ten loops in one tube, the tube was placed in a CO_2 incubator for 5–10 min. Then the spermatozoa were centrifuged at 300 × *g* for 10 min, and the resultant pellet was resuspended in 100 μL of culture medium and processed for further evaluation. It was established whether each semen sample was a normozoospermic sample or a specimen with abnormal sperm parameters.

Cryoprotectant-free vitrification of the spermatozoa resulted in significant decreases in sperm motility, viability, and normal morphology after thawing in both normal and abnormal semen. Also, the rates of sperm DNA fragmentation were significantly higher in the vitrified samples than in the fresh samples in both the normal semen group (24% vs. 16%) and the abnormal semen group (34% and 23%). It was concluded that vitrification of neat ejaculate has a negative impact on both sperm parameters and DNA integrity, particularly among abnormal semen samples. The authors therefore recommended processing semen samples before vitrifying the sperm pellets [98].

The following investigation by Kuznyetsov et al. [99] used technology that could also be characterized as aseptic. The purpose of this study was to optimize cryoprotectant-free vitrification and post-thaw recovery of a small number of spermatozoa in a closed straw system in normozoospermic and severely oligozoospermic samples. Spermatozoa in 5-μL droplets of a cryoprotectant-free vitrification medium were placed in open pulled straws [92], which were then inserted into 0.5-mL insemination straws. The insemination straws were hermetically closed at both ends and plunged into liquid nitrogen. For warming, the end of each insemination straw was cut with scissors and the open pulled straw was removed with forceps. The open narrow end of the open pulled straw with vitrified spermatozoa was immediately immersed in culture medium for 10 s. The capillary flow of the warm medium allowed melting of the vitrified sample. Subsequently, the content of the open pulled straw was expelled, with the help of a syringe, into a droplet of media, and each sample was assessed to confirm the number of recovered spermatozoa and sperm motility. The overall sperm recovery rate after vitrification was 80%, with 80% viability and 42% retained postwarming motility [99].

A study by Slabbert et al. [100] aimed to compare cryoprotectant-free vitrification and conventional freezing protocols for spermatozoa cryopreservation. Washed samples of spermatozoa were split into two aliquots and cryopreserved by cryoprotectant-free vitrification or conventional freezing with glycerol.

Spermatozoa were vitrified without permeating cryoprotectants by Isachenko et al. [93] in culture medium supplemented with HSA and 0.25 M sucrose with use of 0.5-mL straws. After filling of the straws with spermatozoa suspension, the straws were hermetically closed and plunged into liquid nitrogen. The mitochondrial membrane potentials and DNA fragmentation were evaluated. No significant differences were observed in the sperm motility parameters. A significantly higher mitochondrial membrane potential percentage (12% vs. 7%) and a lower DNA fragmentation percentage (3% vs. 4%) were observed in spermatozoa after cryoprotectant-free vitrification and after freezing with glycerol, respectively. The authors concluded that cryoprotectant-free vitrification is a rapid and promising alternative to conventional cryopreservation using cryoprotectants. For thawing, the straws were immersed in a water bath at 42 °C for 20 s, in accordance with the protocol suggested by Isachenko et al. [93]. It was concluded that cryoprotectant-free vitrification of spermatozoa provides a simpler, faster, more cost-effective alternative to conventional cryopreservation methods [100].

Ali Mohammed [101] compared conventional freezing of human spermatozoa in 0.25-mL insemination straws with permeating cryoprotectant and cryoprotectant-free vitrification in a culture medium with 1% serum supplement and 0.25 M sucrose. For vitrification, 0.25-mL insemination straws were filled with 100 μL of the sperm suspension and placed in 0.5-mL insemination straws, which were hermetically closed at both ends and plunged directly into liquid nitrogen. For warming of the vitrified probes, the ends of the 0.5-mL straws were cut and the 0.25-mL straws were taken out and inserted into 15-mL plastic tubes containing 5 mL of culture medium prewarmed to 42 °C. The viability and mitochondrial membrane potential of the spermatozoa were assessed. Both cryopreservation techniques yielded similar results. However, vitrification was faster, easier, less expensive, and associated with less toxicity [101].

Mansilla et al. [102] determined the optimal temperature of warming for vitrified human spermatozoa. After centrifugation of the spermatozoa, the pellet was diluted with 1% dextran + 0.5 M sucrose. Then 100 μL of sperm suspension was packaged into 0.25-mL insemination straws. Each 0.25-mL straw was horizontally inserted inside a 0.5-mL insemination straw, which was then immersed in liquid nitrogen. After warming, sperm motility and the functionality of the sperm membranes were evaluated. It was detected that the progressive motility rates of sperm warmed at 38, 40, and 42 °C were 26%, 57%, and 65%, respectively. The plasma membrane function was better preserved by thawing at 42 °C (76%) than at 40 °C (43%) or 38 °C (65%). It was concluded that warming of the vitrified spermatozoa at 42 °C with 5 s of exposure in the thawing medium preserved highly motile cells and plasma membrane function [102].

52.9 Conclusions

The present data show extremely high viability of viruses, bacteria, mycoplasmas, and fungi after cryoprotectant-free cryopreservation in culture medium and even in distilled water. During vitrification, spermatozoa should be isolated from liquid nitrogen, and a number of such aseptic technologies have been described.

Competing interests The authors declare that they have no competing interests.

Review Questions

1. What is known about microvibration in general?
2. Is vibration a natural phenomenon?
3. Does vibration have a stimulating effect on living systems?
4. Does vibration play a role in mechanical transduction?

Slow Freezing of Oocytes

Giovanni Coticchio and Lucia De Santis

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_53

Learning Objectives

- Importance of oocyte cryopreservation programs in female fertility management.
- Importance of rigorous management systems to control cryopreservation protocols.
- Pros and cons of slow-freezing procedures.
- Objective viability evaluation of slow-cooled oocytes compared to vitrified counterparts.
- Cytoskeletal and ultrastructural assessment of slow-cooled oocytes.
- Clinical outcomes of cycles (IR, PR, and CPR) with respect to different CRSC protocols.

53

53.1 Introduction

Assisted reproduction technology (ART) is becoming an increasingly important strategy to preserve female fertility. Until a decade ago, in an ART context, the only option available to preserve fertility for a woman at risk of loss of ovarian function was embryo cryopreservation. The storage of embryos is a sound, well-established, and safe procedure but entails major downsides, such as ethical objections to the generation of conceptuses that might never be used, the need of donor sperm for the treatment of single women, and legal complications in case of separation of the couple under treatment. More recently, new avenues have been opened to preserve female fertility through ART. Ovarian tissue cryopreservation and orthotopic reimplantation have shown the potential to restore ovarian function for a period of time and offer a chance for natural conception. However, so far only a limited number of full-term pregnancies have been achieved [1]. Therefore, the efficacy of this approach remains to be established. Oocyte cryopreservation is powerfully established as an efficient ART procedure able to preserve female fertility without the implications that afflict embryo cryopreservation. Historically, control rate slow cooling (CRSC) has been the technological standard of human embryo cryopreservation. This legacy marked the early history of oocyte cryopreservation. In fact, specifically developed CRSC protocols gave oocyte cryopreservation the dignity of a routine procedure in many human IVF laboratories. Cryopreservation of slow cooling remains nowadays a viable option, although progress in the last several years has been mainly driven by vitrification (Box ► 53.1).

Box 53.1 Optimized slow freezing protocol for oocyte cryopreservation. From Bianchi et al. (2007)

Materials

- PBS (Dulbecco's phosphate-buffered saline)
- PPS (Plasma protein solution, 5% g/v) or other protein supplement
- Propane-1,2-diol (PrOH)
- Sucrose
- 4-well plates
- Freezing straws
- 1 ml syringes

53.2 Methodological Aspects of Oocyte Cryopreservation

Oocyte cryopreservation, irrespective of whether it is achieved by CRSC or vitrification, requires a rigorous management system to control technique (type of protocol, cryopreservation media) and procedure (time of oocyte culture before and after cryopreservation, oocyte manipulation, operator experience) that could affect the viability of the stored material. In terms of operative times and mobilization of resources, cryopreservation can represent a conspicuous part of the activity of an IVF laboratory. Therefore, cryopreservation and long-term storage in liquid nitrogen necessitates specific work areas. These areas should be adjacent to the core of the laboratory, accessible only by authorized staff, and equipped with systems to monitor oxygen levels and ensure sufficient air changes to prevent accumulation of nitrogen vapors. An approach to cryopreservation based on CRSC should be supported by the use of two cryofreezers, to ensure safe backup and give the opportunity to run separate cycles of freezing at appropriate times on the same day, if required. Cryofreezers produce temperature graphs of the cooling process that represent an important document of quality control for each cryopreservation cycle. Liquid nitrogen levels in dewars used for medium-/long-term storage should be monitored at regular intervals and reported in a dedicated logbook. More recently, dewars have been equipped with electronic monitoring systems to be able to send information to remote terminals, such as PC and mobile phones. Laboratory staff should be properly instructed on safety measures concerning the use of liquid nitrogen and have access to devices for personal protection. Quality control and quality assurance programs require monitoring and recording of the procedures adopted for the cryopreservation of oocytes. These data may be used at later stages for various purposes, especially to assess efficacy and reproducibility. Each laboratory should have standard operating instructions describing the cryopreservation protocols and flow charts showing the path that oocytes follow from recovery to their use after cryopreservation. All aspects pertaining to cryopreservation procedure (information for the identification of the couple, cryopreservation protocols, storage details) should be fully described and reported in a logbook and an electronic database backed up at regular intervals.

53.3 Possible Effect of Slow Freezing in Human Oocytes

Fully grown oocytes from antral follicles may be cryopreserved at the immature—germinal vesicle (GV)—or mature stage. Immature oocyte cryopreservation has been suggested to represent a possible route for fertility preservation especially in women facing the prospect of gonadotoxic therapies [2]. This option was inspired from the hypothesis that the risk of chromosome aberrations possibly associated with the process of freezing-thawing could be attenuated by the fact

that in immature oocytes chromosomes are protected inside the nucleus and the cytoskeleton is not organized in a meiotic spindle. Therefore, under these conditions, chromosome integrity and segregation should not be affected. However, recent data have shown that other important cellular structures of the immature oocyte and companion somatic cells may be subject to damage as an effect of cryopreservation. In particular, cryopreservation conditions cause physical disruption of trans-zonal projections (TZPs), axon-like microfilament-rich projections that originate from cumulus cells, cross the zona pellucida, and make contact with the oolemma [3, 4]. In the sites of contact, cumulus cells communicate with the oocyte by means of gap junctions [5]. Gap junctions are critical for the transport of small size [less than 1 kDa] cumulus-derived factors, metabolites, and signaling molecules that are necessary for immature oocytes to resume meiosis and acquire full cytoplasmic maturation and developmental competence. Therefore, the documented damage to TZPs offers a plausible explanation of the poor performance of oocyte cryopreserved at the GV stage, in terms of maturation, fertilization, and embryo developmental capacity [6–8]. Moreover, recent data describing the redistribution of mRNAs and cytoskeletal proteins during GV to MII transition confirm the importance of full maturity to support proper fertilization and development [9].

The storage of mature oocytes has gained a far larger interest as an alternative to embryo cryopreservation. The preovulatory mature oocyte is an individual entity, ready for fertilization and relatively autonomous from the cumulus cells that have accompanied and supported its development throughout oogenesis. Its cryopreservation, therefore, is not complicated by the need to maintain unaltered a sophisticated tissue and intricate cell contact, as in the case of the preservation of ovarian tissue. Nevertheless, the cellular and biochemical integrity of the single oocyte is exposed to a risk of irreversible damage during the process of cryopreservation. Rupture of the oolemma and widespread cell disruption is a relatively common event. This occurs in 20−30% of cases even with the most efficient CRSC protocols [10, 11], a frequency that has become less acceptable following the recently reported successes of the vitrification approach by which survival rates in excess of 90% can be achieved. Oocyte death may be observed immediately after freezing and release from the storage device (usually a 250 µl straw) or during exposure to thawing solutions. Clearly, this may represent an effect of physical damage caused by intracellular ice formation or osmotic stress dictated by dehydration and rehydration events taking place during replacement of intracellular water with cryoprotective agents (CPAs) and/or vice versa [12]. Cell death may occur even hours after the completion of the process of thawing and rehydration. Gook et al. [13] reported a decrease in survival rate of oocytes over the 24 h following thawing. Clearly, oocyte cryopreservation by CRSC requires further development in order to improve survival rates.

Survival after thawing is obviously crucial, but does not necessarily ensure or coincide with cell integrity. Sublethal damage may affect different cell organelles and structures and/or biochemical pathways. Transmission electron microscopy (TEM) is an investigative tool often believed either obsolete or out of fashion by many, but in fact, it is extremely valuable for the study of cell damage that may be generated by cryopreservation. In human oocytes stored by a CRSC protocol developed for human embryos, Sathananthan observed fractures in the zona pellucida, oolemma irregularities, and widespread disorganization of the ooplasm. After exposure to dimethylsulfoxide (DMSO) at 0 °C, he also found that parts of the endoplasmic reticulum, Golgi, mitochondria, and the cytosol were damaged to some extent [14]. A subsequent study showed how sometimes TEM fails to detect structural anomalies that may have significant implications for the oocyte physiology. Van Blerkom and Davies [15] described cytokinesis anomalies and cleavage arrest in embryos developed from cryopreserved human oocytes, despite the fact that electron microscopy analysis carried out after thawing had not shown gross cytoplasmic alterations. Afterward, electron microscopy studies on cryopreserved human oocytes were interrupted for over a decade, as a consequence of the inadequacy of the cryopreservation methodology available in the 1990s to ensure high survival rates. With the development of improved protocols [11, 16, 17], ultrastructural studies again attracted significant interest. By comparing fresh and frozen-thawed oocytes, Ghetler et al. [18] reported substantial decrease in the number of cortical granules (CG) as an effect of cryopreservation. This supports the inference that stored oocytes should be microinjected by intracytoplasmic sperm injection (ICSI) rather than inseminated by standard IVF to prevent possible fertilization failure caused by hardening of the zona pellucida. In effect, a few years after its introduction as a routine fertilization method, ICSI was chosen as the elective route to achieve fertilization in cryopreserved oocytes [19] and is now recognized as a standard of treatment involving cryopreserved oocytes [20–23]. Despite that, the question of a non-physiological release of CG in cryopreserved oocytes remains open. By using epifluorescence microscopy, Gook et al. [13] showed that, in comparison to fresh material, the staining specific for CG was unaffected in cryopreserved material. They also showed that in frozen oocytes, fertilization could be achieved through standard IVF [24]. The possibility of using standard IVF has been reported by other authors [25]. However, further ultrastructural analysis has confirmed that a partial loss of CG occurs following cryopreservation. This has been observed qualitatively in oocytes cryopreserved with CRSC protocols involving the use of 0.1 or 0.3 mol/l sucrose as a constituent of the freezing solution [26]. Similar findings were described by Gualtieri et al. [27]. Consistent with this, oocytes stored by a CRSC protocol including ethylene glycol (EG) as an intracellular CPA [28] or by vitrification [29] appear to be affected by a loss of CG. Recent observations provide quantitative data suggesting that about two-thirds of the original population of CG is lost and presumably their contents released in the perivitelline space, as a result of cryopreservation. This phenomenon appears therefore rather ubiquitous in cryopre-

served oocytes, irrespective of the cryopreservation approach (CRSC or vitrification) or specific protocol. Whether CG release is always sufficient to cause zona hardening in frozen oocytes is not clear, but the detection of thickening and change in texture of the inner surface of the ZP is in line with this hypothesis [28].

Another recurrent characteristic found in cryopreserved oocytes is the increased presence of vacuolar structures. The nature of these formations has not been well characterized. They may be found in fully grown immature oocytes, but in metaphase II (MII) oocytes, they are rare [30] and have been interpreted as a sign of cytoplasmic immaturity or, vice versa, aging. Because vacuoles may also derive from a general response to injury, in the case of oocyte cryopreservation, they may represent a manifestation of cell stress. Rather consistently, the presence of vacuoles was described in association with a variety of CRSC protocols [18, 26, 28]. It is tempting to hypothesize that vacuoles located peripherally may evolve from crypt-like invaginations and clusters of endocytic vesicles that form in the oocyte cortex following simple exposure to CPA [31]. However if this assumption is correct, it remains to be explained why oocytes vitrified through the cryoleaf method, which are exposed to high concentrations of CPAs, do not exhibit an increase in the number of vacuoles, as recently reported [32]. Regardless of their origin, it is possible that vacuoles may be adopted as a specific indicator of cryodamage and reduced developmental potential in cryopreserved oocyte, considering that an increased number of vacuoles [26] and a reduced developmental ability [20, 33] are concomitantly associated to certain CRSC protocols. This indication, however, has not been confirmed through a prospective randomized control trial. Evidence suggests that vitrification protocols are associated with high implantation ability [34] and a normal or low incidence of vacuoles [32].

Mitochondria and elements of the smooth endoplasmic reticulum may also be affected by cryopreservation. Individually, these two types of organelles play well-characterized roles in all cells. In particular, in oocytes, not only are mitochondria central to the energy generation process but also can produce intermediates of the tricarboxylic acid cycle and reducing equivalents that may be employed for antioxidant defense. The SER complex is instead well characterized as an organelle system competent to the translation, modification, packaging, and delivery of proteins destined to the plasmalemma or exocytotic compartments. In the oocyte, the association between mitochondria and SER elements contributes to the generation of the typical oscillations in cytosolic-free calcium that are triggered by the fertilizing spermatozoon and are interpreted by the oocyte biochemical machinery as a start signal for fertilization [35]. Magnitude and frequency of calcium oscillation have also been found to influence much later events of development, such as organogenesis and fetal growth [36]. For such reasons, mitochondria-SER aggregates are particularly important for the physiology of the oocyte. Mitochondria and SER elements, separately in close association with each other, are often found unaltered in oocytes cryopreserved with CRSC protocols relying on propane-1,2-diol (PrOH) as a intracellular CPA [26] and used in the clinical practice [20, 33]. This is a reassuring evidence in the light of the role of mitochondria-SER associations in the mechanism of intracellular calcium signaling, as discussed above. Conversely, other cryopreservation conditions may be in fact deleterious to mitochondria-SER aggregates. In particular, in oocytes cryopreserved by a CRSC protocol including EG as an intracellular CPA, pronounced disorganization of these aggregates may be noticed [28]. Why some cryopreservation conditions can generate damage to the mitochondria-SER aggregates is still to be understood. It may be relevant to this question the fact that, so far, disarrangements of mitochondria-SER aggregates have been reported only in association with the use of EG, but not PrOH. Perceptible, although moderate, underdeveloped mitochondria-SER aggregates were also observed in oocytes vitrified with a solution containing EG [32]. However, such findings are largely insufficient to conclude that EG can specifically and directly affect the constitution of mitochondria-SER aggregates.

Recently it was reported that oocyte ultrastructural dysmorphisms related to cryopreservation and possibly responsible for low oocyte fertilizability not only occur during freezing and thawing, in a strict sense, but also during post-thaw rehydration [37]. These cellular alterations, induced by low temperatures and by osmotic and chemical forces produced during cycles of dehydration-rehydration as well, may alter the distribution and activity of oocyte cellular components. In particular, although slow freezing appears to ensure a good overall preservation of the oocyte, vacuolization and CG release remain crucial limits. It seems also worth noting that all systems of ooplasmic membranes appear significantly affected by freeze-thawing but, except for CGs, their alterations seem to undergo a partial or, more rarely, an almost complete recovery after thawing, at the end of the rehydration process. In addition, the observed variations in the number of M-SER aggregates and MV complexes, occurring during freeze-thawing, suggest that a dynamic process of transition between these two forms of organelle associations may occur. In this regard, it should not be excluded that vacuole and CG membranes, and oolemma as well, may take part in the recycling mechanism. Such shuttle of membranes, starting during freezing and/or at thawing but mainly occurring during rehydration, may be related to alterations of the cytoskeletal stiffness [38] presumably due to PrOH administration and/or withdrawal [39, 40]. We cannot exclude, of course, that the described membrane restructuring is also related to calcium disturbances. From a merely morphological point of view, this recycling reveals a sort of morphogenetic multipotency of the oocyte cytomembranes, possibly eliciting membrane turnover and delivery or clearance of substances (CG content, cryoprotectants, calcium, other solutes?), as postulated for other cells [41].

Overall, these studies confirm the usefulness of TEM to investigate oocyte quality after cryopreservation.

53.3.1 In Vitro Aging

One of the factors that could cause a partial loss of oocyte viability after cryopreservation is the phenomenon of in vitro aging. In fact, only for a limited period of time, the mature oocyte is able to maintain a particular condition that is essential for successful fertilization and development. Such a condition corresponds biochemically to relatively high levels of maturation promoting factor (MPF) and microtubule-activated protein kinase (MAPK), two key regulators of the meiotic and mitotic cell cycles, and from a cellular standpoint to the arrest of the meiotic process at the MII stage. The MPF and MAPK activities can decrease either as an effect of a spontaneous biochemical decay occurring within a few hours after PBI extrusion or secondarily to extrinsic factors, such as inappropriate manipulation in vitro. Cryopreservation could interfere with the mechanism of meiotic control of the oocyte, either directly, through the stresses generated by the process of freezing-thawing (or vitrification-warming), or indirectly, because of an excessively protracted maintenance in culture before and/or after cryopreservation. Recent evidence suggests that biochemical cryodamage is not purely hypothetical. In fact, in sheep, oocytes cumulus removal and vitrification can affect the MPF and MAPK levels after in vitro maturation [42]. A similar phenomenon may occur in human oocytes after cryopreservation. In coincidence with the use of a protocol involving 0.3 mol/l sucrose as non-penetrating CPA [11], over a period of 2 h after thawing, MAPK is unaffected in comparison to fresh controls. Conversely, during the same interval, MPF activity is initially maintained unaltered but undergoes a significant decrease thereafter [43]. It is striking that the observed decrease in MPF mirrors a progressive loss in the organization of the MII spindle that is known to occur with a similar dynamic in frozen-thawed oocytes [44]. Because high levels of MPF are critical to maintain the integrity of the MII spindle, it is tempting to speculate that after thawing a decrease in the activity of the former may cause a loss in the organization of the latter.

These findings may have significant implications for the clinical use of frozen-thawed oocytes. In particular, considering the observed delayed reduction in MPF activity, it might be appropriate to limit to 1 h the period of post-thaw culture that is implemented in preparation for ICSI, thereby preventing possible losses in spindle and chromosome configuration or premature exit from the MII arrest. The importance of the time factor in oocyte cryopreservation seems to be suggested also by data that indicate that the oocyte ability to give rise to a viable pregnancy tends to decrease if the overall time spent in culture before and after cryopreservation exceeds a certain number of hours (Borini et al., unpublished observations). Other recent studies appear to confirm that an excessively protracted period of culture between retrieval and cryopreservation may have a negative impact on the developmental ability of frozen-thawed human oocytes [45, 46]. However, the problem of in vitro aging does not seem to concern oocytes cryopreserved by vitrification, at least in donor oocyte cycles. In fact, Vassena and colleagues showed that fertilization and other developmental parameters were unaffected by a number of parameters, including the time between pickup and vitrification and between warming and microinjection [47].

53.4 Clinical Outcome of Oocyte Cryopreservation

Cryopreservation strategies can profoundly affect the clinical outcome of oocyte cryopreservation and make difficult the comparison among different studies. In certain contexts, constraint of religious, ethical, or legal nature limits the number of embryos that may be produced and transferred during each cycle of treatment. In frozen-thawed oocyte (or vitrified-warmed) cycles, these restrictions can be met by thawing only a small proportion of the stored material at a time to the end of having 2–3 viable oocytes suitable for insemination, avoiding wastage of material. As an effect of a legal restriction implemented in Italy from March 2004 to April 2009, the practice established by law to thaw a limited number of oocytes for treatment cycle was adopted systematically and described in various studies [33, 45, 48]. In other studies, no limit was imposed on the number of oocytes that could be thawed and, consequently, the number of embryos that could be cultured and transferred [49, 50]. The different implications of these two strategies are rather obvious. The thawing of only a few oocytes per cycle involves a higher risk of drop out of the frozen cycle as an effect of high rates of fertilization or cleavage failure [20]. Furthermore, with only a few oocytes available, embryo selection is not applicable, and in some cases, the number of embryos available for transfer may be insufficient. This scenario, which is unlikely to occur when several oocytes are thawed at the same time, influences the clinical outcome in terms of implantation and pregnancy rates. For this reason, the comparison of implantation rates achieved in studies in which the mean number of transferred embryos was different appears rather arbitrary and non-informative [20, 51]. An example of the inadequacy of pregnancy rate per transfer as a measure of efficacy is offered by a study [48] in which by using a freezing protocol specific from cleavage stage embryo, a success rate of 16.7% was achieved. In fact, in the same study, the pregnancy rate per thawing cycle was 7.7%, as a consequence of a high incidence (50%) of cycles cancelled for failed survival or fertilization. Gook and Edgar [52, 53] proposed a more objective standard to assess the efficacy of treatments involving frozen oocytes or embryos. By considering that during an IVF treatment the initial amount of biological material (oocytes) undergoes a decrease (attrition) at different stages of the process (fertilization, cleavage, selection for freezing, and thawing), they estimated that from an original pool of 100 fresh oocytes, about five implantations from frozen embryos can be achieved. Gook and Edgar suggested that the same approach

should be adopted also for the assessment of the clinical efficacy of oocyte cryopreservation, including in the calculation all the events of pre- and post-storage loss of the original material. Only under those conditions the relative values of the diverse cryopreservation methods can emerge. For example, it is well known that a considerable increase (35–40% to 70–75%) in the survival rate oocytes cryopreserved by CRSC may be obtained by increasing from 0.1 to 0.3 mol/l the concentration of sucrose in the freezing solution [3]. A higher sucrose concentration is also beneficial to the fertilization rate [33, 48]. However, the reduced loss of material during the thawing and fertilization phases is accompanied by a decreased implantation rate in comparison to the outcome derived by the use of the protocol based on 0.1 mol/l sucrose [20, 48]. Therefore, in the final analysis, the two protocols result equivalent if assessed on the number of implantations (approximately 2.4–2.6 in both cases) that can be obtained from 100 thawed oocytes. By using other protocols, implantations rates per thawed oocytes of about 5% can be achieved, a result that makes oocyte freezing rather comparable to embryo freezing. By adopting a freezing protocol based on sodium-free media, Boldt et al. [50] reported an implantation rate per oocyte thawed of 5.3%. In that study, however, only 23 patients were included and the initial rate of success has not been confirmed by the treatment of larger series of patients. A comparable implantation rate per thawed oocyte has been reported in another study reported by Borini and colleagues [10], in which oocytes were cryopreserved with a protocol based on different sucrose concentrations in freezing and thawing solutions (0.2 and 0.3 mol/l, respectively). More recently, the same group confirmed these results reporting a success rate of 5–6% implantation rate per thawed oocyte (with obvious differences depending on female age) in a much larger study involving almost 350 patients [54]. Using such differential sucrose concentrations during freezing (dehydration) and thawing (rehydration) seems to be the silver bullet to achieve maximum performance of CRSC in oocyte cryopreservation (see enclosed protocol). In fact, with this protocol, in women younger than 38 years of age, Gook and Edgar obtained a rate of implantation per thawed oocyte of 6.3% [55]. Importantly, both in this study and that of Borini and colleagues [10], rates of fertilization, cleavage, and implantation of embryos developed from frozen oocyte were comparable to those observed in fresh control oocytes. The study of Gook and Edgar [55] was notable also because it assessed the impact of female age in oocyte cryopreservation. The inverse relationship between female age and embryo implantation potential is well known and represents the major cause of reproductive failure in women of advanced reproductive age. Consistently, Gook and Edgar observed a reduced implantation potential in embryos developed from frozen oocyte recovered from women older than 38 years of age. However, the difference in implantation rate between the groups of younger and older women was more than six fold (6.3% vs. 1.0%), a hiatus difficult to explain with the exclusive impact of female age. Rather, it is more plausible that oocytes of older women are particularly sensitive to cryodamage, which acts additively to female age to produce a drastic reduction in plantation rates. Consistent with these data produced by CRSC is a study of Cobo and colleagues [56], who reported implantation rates of 6.6% and 1.8% for embryos developed from vitrified oocytes collected by women with age <36 or >39, respectively. Therefore, oocytes of older women are particularly exposed to cryodamage, irrespective of the cryopreservation approach.

53.5 Safety of Oocyte Cryopreservation

Oocyte cryopreservation has raised health concerns derived from the possibility that oocyte cell damage secondary to freezing-thawing is a frequent event that may expose the conceptus to an increased risk of developmental anomalies. The number of babies born from cryopreserved oocytes is steadily increasing. In 2004, Borini et al. [20] described 11 births from cryopreserved embryos. These children had an average weight of 3.2 kg, normal karyotype, and no malformations. Shortly afterward, Chen et al. [49] reported the birth of five children from vitrified oocytes with normal karyotypes. Other authors [10, 21, 33, 45, 48, 50, 57] documented 65 births from frozen oocytes but did not describe details on their genotype in a systematic fashion. In the 18 births of Levi Setti et al. [21], a mean gestational age of 37.1 weeks and weight of 2807 g were observed. So far, the largest group of children from cryopreserved oocytes has been described in a preliminary study of Borini et al. [58] where 4 cases of developmental anomalies were found (Rubinstein-Taibi syndrome, 47XXX, chromosome 19 hypomethylation, and choanal atresia) in 146 births. Tur Kaspa et al. [59] analyzed more than 37 studies on children from cryopreserved oocytes. In 555 live births, 5 developmental anomalies were identified. This corresponds to a frequency of congenital abnormality comparable to the one that affects spontaneous conceptions. The criteria adopted for this analysis have been questioned. In particular, it has been objected that the overall number of births was overestimated as a result of duplication of sets of original data [60]. However, the absence of an association between oocyte cryopreservation and congenital anomalies is confirmed by a different analysis including over 900 births [61]. Eight children were found affected of various anomalies at birth, a result that, again, is comparable to the frequency occurring in spontaneous births.

The debate on the safety of oocyte cryopreservation remains open. For example, data on the frequency of spontaneous abortion are lacking. Nevertheless, current evidence does not seem to support the existence of specific health risks and legitimate the use of oocyte cryopreservation as a treatment for women requiring an assisted reproduction technology treatment.

53.6 Conclusions

Oocyte cryopreservation by CRSC has become a well-established procedure able to compete with embryo freezing, especially after recent progress in the development of novel protocols and conditions. Safety concerns have not been confirmed, although further and more rigorous studies are needed. Future development of oocyte CRSC will depend on the application of novel theoretical models that can better predict cryopreservation conditions and thereby improve oocyte quality after freezing-thawing.

Review Questions

1. What are the limitations of oocyte slow-cooling approach?
2. Are all the protocols adopted equivalent in term of survival and outcomes?
3. Are data provided from invasive methods valuable to improve SC protocols?
4. Are there any advantages in the laboratory management of female fertility preservation via slow cooling?
5. Is it time to discontinue slow freezing?

Freezing

Freezing Solutions

Freezing Solution 1:	1.5 mol/l PrOH
	1.08 ml PROH
	6.92 ml PBS
	2.00 ml PPS

Freezing Solution 2:	1.5 mol/l PrOH, 0.2 mol/l sucrose
	1.08 ml PROH
	6.92 ml PBS
	2.00 ml PPS
	684 mg sucrose

Notes

(a) Freezing solutions must be stored at 4 °C. Warmed to room temperature (24–25 °C) before use.
(b) All dehydration steps must be performed at room temperature.

Dehydration

(a) For each oocyte (or group of oocytes), dispense 0.5 ml of the freezing solutions in separate wells of a 4-well plate.
(b) Incubate sequentially oocytes in the freezing solutions according to the times indicated below.

Solution	Time
Freezing Solution 1	10 min
Freezing Solution 2	5 min

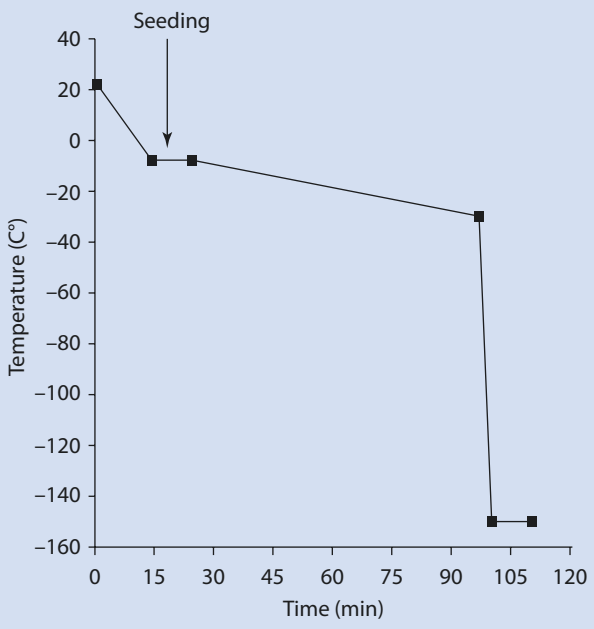
(c) Load oocyte(s) into straw(s)
(d) Seal straw(s)

Cooling to LN_2 temperature

(a) Place straws into the cryofreezer.
(b) Run the controlled rate freezing program (see below).

Controlled rate freezing program

1. Decrease temperature from +20 °C to –7 °C at a rate of −2 °C/min.
2. "Hold" at –7 °C for 10 min.
3. Perform manual seeding at about 30% of the "hold" ramp.
4. Decrease temperature from −7 °C to –30 °C at a rate of −0.3 °C/min.
5. Decrease temperature from −30 °C to −150 °C at a rate of −50 °C/min.
6. Hold at –150 °C for 10 min.
7. Transfer into LN_2 for long-term storage.



Thawing

Thawing Solutions

Thawing Solution 1:	1.0 mol/l PrOH, 0.3 mol/l sucrose
	0.72 ml PROH
	7.28 ml PBS
	2.00 ml PPS
	1026 mg sucrose
Thawing Solution 2:	0.5 mol/l PrOH, 0.3 mol/l sucrose
	0.36 ml PROH
	7.64 ml PBS
	2.00 ml PPS
	1026 mg sucrose
Thawing Solution 3:	0.3 mol/l sucrose
	8.00 ml PBS
	2.00 ml PPS
	1026 mg sucrose
Thawing Solution 4:	
	8.00 ml PBS
	2.00 ml PPS

53

Note

(a) Freezing solutions must be stored at 4 °C. Warmed to room temperature (24–25 °C) before use.
(b) All dehydration steps must be performed at room temperature.

Thawing

(a) For each oocyte (or group of oocytes), dispense 0.5 ml of the thawing solutions in separate wells of a 4-well plate.
(b) Remove the straw from LN_2 and keep at room temperature for 30 sec.
(c) Transfer the straw in a + 30 °C water bath for 40 sec.

Rehydration

(d) Release the oocyte(s) from straw(s).
(e) Incubate sequentially the oocyte(s) in the freezing solutions according to the times indicated below.

Solution	Time
Thawing Solution 1	5 min
Thawing Solution 2	5 min
Thawing Solution 3	10 min
Thawing Solution 4	10 min

(f) Transfer the oocyte(s) to 37 °C for 10 min, while in thawing solution 4 and after the initial incubation at room temperature.
(g) Transfer the oocyte(s) in medium for oocyte culture and incubate under standard conditions for 60–90 min before microinjection.

Vitrification: Methods Contributing to Successful Cryopreservation Outcomes

James J. Stachecki

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_54

Learning Objectives

- To provide a basic understanding of key cryopreservation/vitrification concepts
- To review past research leading to current methodologies
- To discuss concepts important to frozen embryo transfer success

54.1 Fundamentals of Vitrification

The only method of stable and long-term (practically infinite) preservation and storage of any perishable biological materials, particularly cells, is to keep them in the glassy (vitreous) state. This was apparent to Father Luyet when he titled his pioneering work "The *vitrification* of organic colloids and of protoplasm" and "Revival of frog's spermatozoa *vitrified* in liquid air" [1, 2]. He and other *pioneers of the cryobiological frontiers* including Lovelock, Meryman, Mazur, Polge, Smith, Levitt, Farrant, and Willadsen clearly understood some 40–70 years ago that only a glassy state would insure stable and non lethal preservation of cells [3–6]. With time, we saw the development of a variety of biopreservation methods, such as slow-cooling, ultra rapid cooling, and kinetic vitrification [7, 8]. It was Luyet's work that would make cryopreservation a science. From the outset, he recognized that ice damage must be avoided and vitrification could be a method for long-term preservation of cell viability [2].

In order to understand rapid-cooling or "modern" vitrification techniques, let us compare them to the slow-cooling method. During slow-cooling, embryos are exposed to relatively low concentrations of cryoprotectants (1.5 M PrOH and usually some sucrose, around 0.2 M), equilibrated for 10–25 min at room temperature, loaded into a straw or vial, sealed, and placed into a controlled rate freezer. Ice formation is induced extracellularly by seeding at a temperature, whereby ice can perpetuate (around −5.5 °C or lower), and, as a result of the solute gradient created, freezable water flows out of the cells, minimizing the chance of intracellular ice formation during cooling. As the temperature is gradually lowered, the concentration of cryoprotectant in the liquid phase, which includes the intracellular fluid, increases correspondingly until a level is reached at which additional formation and growth of ice crystals, although possible, are unlikely, even if the temperature drops further [9]. Rather, the liquid phase turns into a glassy substance that solidifies without further crystal formation as the temperature continues to decrease. The unfrozen liquid phase remaining within the cells when they are plunged into LN_2 should ideally consist of this glassy substance with all the original cell solutes remaining in solution [9]. This suggests that when we slow-cool cells using a penetrating cryoprotectant such as PrOH, and standard slow-cooling protocols, we are actually vitrifying the cells. Indeed, when we slow-cool human four- to eight-cell embryos, typical survival rates range between 80% and 100% for many IVF centers. These survival rates would not be possible, at least according to Mazur and company, if intracellular ice formation (IIF) were occurring [10]. This correlates well with the theory that slow-cooling is vitrification. Of course, this does not mean that IIF does not or cannot occur, it simply suggests that in conventional embryo freezing protocols, IIF should not be a major source of cell damage. However, if water efflux is inhibited and does not occur in equilibrium, as suggested, and despite a slow-cooling rate, IIF could pose a real problem [11].

IVF laboratories have been cryopreserving spare embryos for more than 30 years. There is no doubt that the technique can work and has great value in the IVF industry. Today the field has changed quite markedly from equilibrium slow-cooling [11] toward a quicker methodology of rapid-cooling. However, from a basic cryobiological standpoint, nothing has really changed. The more recent technique of rapid-cooling is called vitrification by most, despite the fact that slow-cooling was also vitrification. The confusion between slow-cooling and vitrification continues, perpetuated by inconsistencies in the literature.

The basic concept for successful cryopreservation of a cell is relatively simple. Because cells are mostly water, and upon cooling below a certain temperature, water will form ice crystals that can damage the cell, one needs to avoid this by near total dehydration of the cell or by vitrifying the cell. Near total dehydration may work for plant gametes (certain species of pollen and seeds), but has not been successful for mammalian oocytes or embryos. Therefore, the only option would be vitrification. In its most simplest form, the cell needs either (1) to be partially dehydrated, loaded with cryoprotectants (basically alcohols) that can intercalate between water molecules and inhibit crystalline formation upon cooling, and cooled at an appropriate rate to obtain a glassy state inside the cell or (2) simply cooled at an extremely rapid rate to obtain a glassy state inside the cell, without the need for dehydration or cryoprotectants (kinetic vitrification) [7, 8, 12]. Although kinetic vitrification is possible, it is far too costly and cumbersome to be used in IVF clinics today. Thus, dehydration along with the use of permeating cryoprotectants and rapid-cooling by plunging into LN_2 at room temperature is the method of choice today for human oocytes and embryos.

Rall demonstrated that mouse embryos could be vitrified and survive by cooling them in a relatively concentrated solution and cooling at either 2500C/min or 20C/min [13]. This demonstrated (similar to slow-cooling) that vitrification is not rate dependent. However, successful vitrification depends upon one basic concept: cooling and warming rate [14]. Depending on how much cryoprotectant is used (along with the other components of the media; basically salts) will determine what cooling and warming rates will be needed to minimize intracellular ice nucleation and growth.

If we look at the phase diagram (Fig. 54.1.) of a cryoprotectant solution in water, we will find several sections that are either liquid, solid, or a combination of both [14]. In the diagram, Tm = melting temperature; Th = homogeneous ice nucleation temperature; and Tg = glass transition temperature. Only liquid exists in the area above the Tm curve.

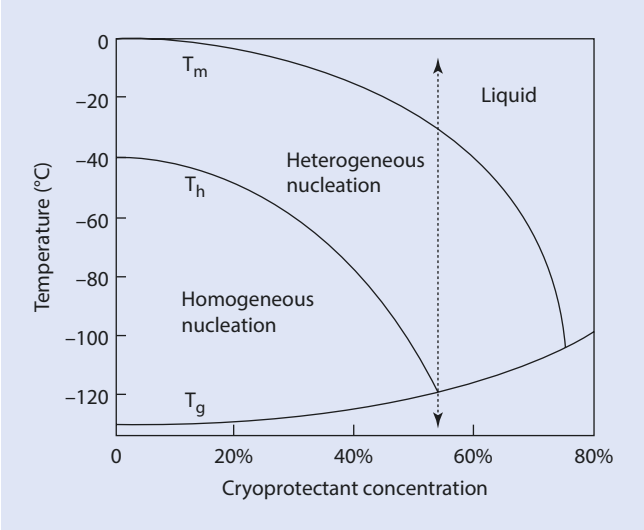

Fig. 54.1 Phase diagram of a cryoprotectant solution in water

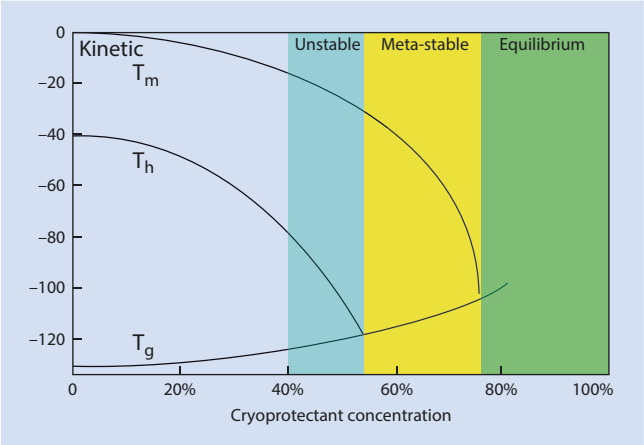

Fig. 54.2 Phase diagram of a cryoprotectant solution in water

Between Tm and Th is the meta-stable region wherein ice can nucleate only by heterogeneous means [14]; basically, nucleation on impurities in the solution (i.e., dirt particles). Below Th, both heterogeneous and homogeneous nucleations exist. Depending on the cryoprotectant concentration, ice can form in a solution upon cooling by either homo- or heterogeneous means. Once the temperature reaches the glass transition temperature Tg, the remaining solution will vitrify. Solidification of water above Tg can lead to intracellular ice formation and cell death.

In Fig. 54.2, we have separated the phase diagram into four sections representing the basic types of vitrification that can occur [14]. On the far left and extending slightly to the right (the clear section), we have kinetic vitrification wherein vitrification can only occur at extremely rapid cooling rates. The blue section, labeled "Unstable," is the area where conventional DMSO-based vitrification solutions lie. Here, we have to worry about both types of ice nucleation and need to cool at a relatively rapid rate (generally >5,000C/min) so that the remaining water in the cells does not nucleate to a great degree and grow during cooling. Also, rewarming has to occur at a rapid rate because the ice that did nucleate during cooling will grow (recrystalize) but can mostly be avoided if rewarming occurs at a fast enough rate. In the "meta-stable" region (yellow) of the phase diagram, we can cool at a relatively slow rate (approximately >20 °C/min) without having to worry about significant ice nucleation upon cooling. Furthermore, as long as rewarming occurs at a relatively rapid rate, we can also avoid recrystalization. The green and final section of the graph represents the area of "Equilibrium" vitrification. Here, one can cool at any rate and not obtain ice formation as the liquid phase transitions directly to the vitrified state upon falling below Tg.

During modern vitrification techniques, we try to avoid ice formation and maximize cell survival [12]. It is clear from looking at the phase diagram that the more cryoprotectant we have loaded into the cell, the smaller the temperature range we need to go through before reaching Tg. At a cryoprotectant concentration of around 20%, one would need to pass from somewhere just below 0 °C to below −120 °C before reaching Tg. If the cryoprotectant concentration was 60%, the range would be approximately −30 °C to −116 °C—a much smaller range. The further right we get in the diagram, the smaller the range between Tm and Tg is and thus the slower the cooling rate and warming rate that is needed to avoid a lethal amount of ice formation. Therefore, it is the cooling and warming rates that are most important and determine the type of storage container needed.

54.1.1 Vitrification Studies: Animal Research

Slow-cooling regimes have been very successful in clinical IVF, simply based on the fact that, conservatively, over 75,000 children have been born from previously frozen embryos. However, there is room for improvement, especially when it comes to storing blastocysts and oocytes. Blastocyst storage using slow-cooling procedures has met with little success for most. Studies by Fehilly et al. [15], Hartshorne et al. [16], Menezo et al. [17], and Kaufman et al. [18] demonstrated that human blastocyst cryostorage was possible; however, in the early 1990s, there was little in the literature regarding this subject. One reason is that IVF clinics, at that time, were just learning how to culture embryos to the blastocyst stage and transferring eight-cell embryos on Day 3 of culture was considered optimal [19]. Therefore, with the relative lack of experience of culturing embryos to the blastocyst stage and the fact that Day 3 storage was relatively good (around 80% survivals), the need did not exist for blastocyst storage in the late 1980s. One common problem among IVF clinics, even today, is that multiple offspring are being produced from the replacement of more than one embryo on Day 3. Multiples dramatically increase the risks and costs of a pregnancy, and thus replacing only a single embryo would be beneficial [20]. The only problem is that pregnancy rates tend to be lower with only one embryo replaced and this is not conducive to

a successful clinic. Replacing blastocysts, however, leads to very good implantation and pregnancy rates, and therefore a clinic could maintain relatively good pregnancy rates and reduce multiples at the same time [19]. As embryo culture progressed and more labs were culturing out to the blastocyst stage, to reduce the number of embryos replaced as well as the number of excess embryos that would have to be stored, blastocyst cryopreservation gained importance.

Much of the work on embryo cryopreservation by the 1990s had been done in domestic species including mouse, cow, sheep, rabbit, and pig, and these studies laid the groundwork for human blastocyst storage [21–31]. One of the first studies done was by Whittingham with mouse blastocysts [21]. Even so, many clinics still struggle with obtaining acceptable success rates by slow-cooling blastocysts [32–34]. By the 1990s, vitrification or, more accurately, rapid and ultrarapid cooling research in animal models was prevalent. The main reason was that several commercially valuable species, including bovine and porcine, were sensitive to chilling injury, and conventional slow-cooling regimes did not work [31, 35–38]. Therefore, the only way to store these cells was to rapidly cool/freeze them from elevated temperatures by direct immersion in LN2, thus avoiding chilling injury.

As vitrification became more popular, more research was done on animals, both for their importance and as model species for humans. A recent PubMed search showed that there were only about 16 papers on animal oocyte/embryo vitrification that were published from 1985 through 1990. There were 46 more the next 5 years up to 1996, and 69 through 1999. After the seminal paper by Vajta et al. in 1998 [31], the field exploded with nearly 200 papers in the next 7 years and 600 from 2006 to 2016. Of course, these numbers are not exact and do not include book chapters, abstracts, and many foreign journals, but they do demonstrate that animal models played a significant role in optimizing vitrification so that it could be used for human work.

54.1.2 Human Research

The work of Vajta et al. with bovine embryos changed history. They demonstrated that DMSO worked very well if used below a certain concentration to eliminate cellular toxicity. This meant that more water would be inside the cell; thus to avoid IIF, a rapid cooling rate was needed, as described in the previous section with a phase diagram. In order to solve the problem of rapid cooling and warming rate, they used very small volumes of media (1−2 ul) in the open end of a tiny straw and direct submersion into liquid nitrogen. Soon everyone jumped on the bandwagon of "vitrification" using DMSO and very rapid cooling rates. The effectiveness of vitrification by this new method in animals led to a flurry of human studies. The new theories soon became prevalent in the literature. Among these the most popular were that high concentrations of cryoprotectants were toxic, and exposure to the final solution with the highest concentration should be reduced to 60 s or less [39–44]; and the faster the cooling rate, the better the survival. From the early 2000s, by the simple adaptation of Vajta's methodology to human oocytes (described in a separate chapter of this book) and embryos, clinics around the globe have successfully stored tens of thousands of cells and produced thousands of "vitrified" babies. Much of the recent research has dealt with optimizing methods and media.

54.1.3 Current Vitrification Technologies: DMSO Methods

Vajta's open-pulled straw paper [31] detailed the formula and methods for successful vitrification of bovine embryos. The basic method is as follows: oocytes or embryos were pre-equilibrated for 10–15 min in 7.5% DMSO and 7.5% ethylene glycol, followed by a short 60 s incubation in 15% DMSO and 15% EG and then immediately loaded into a pulled straw and submerged into liquid nitrogen. Warming was done rapidly by removal of the straw from liquid nitrogen and submersion into 37 °C buffered media containing 1 M sucrose. The cells were then rehydrated by incubation through a series media with reduced sucrose concentration. This methodology has changed little in the past 18 years. The initial success at the turn of the century led to the commercial production of vitrification media by numerous manufacturers, all copying the same basic formula. To differentiate the different companies' products, they all had slight modifications such as using trehalose instead of sucrose, or MOPS buffer rather than HEPES, and using their own base media. One manufacturer even swapped out DMSO for PrOH in the same concentration, which was one of the biggest changes to the original formula, and surprisingly, for some groups, worked well.

If we recall from the previous section, these DMSO-based vitrification solutions lie within the "unstable" or "doubly unstable" region of the phase diagram (Fig. 54.1.), as both types of ice nucleation can occur upon cooling and warming [14]. To avoid this from occurring, or at least minimize it, the cooling and warming rate needs to be relatively high (generally >5,000C/min). In order to achieve this, several new storage devices were developed and tested. The open-pulled straw was good, but manufacturers wanted something of their own they could sell. Soon a variety of plastic straw and spatula devices were developed. Kuwayama et al., [45] measured the cooling rate for a 0.25 cc straw containing 25 ul of vitrification solution plunged directly into liquid nitrogen at 4460 °C/min; an open-pulled straw containing 1.5 ul of vitrification solution at 16,340 °C/min and a cryotop with 0.1 ul of vitrification solution at 22,800 °C/min. Similar products including electron microscope grids, cryo-top, cryo-tip,

cryo-leaf, and nylon loops that all allowed direct contact with liquid nitrogen and micro volumes were able to increase the vitrification speed considerably, in the order of >15,000 °C/min. Clinics testing these new devices soon reported high survival rates [36, 41, 43, 45–54]. Some of these devices including micro-secure, CBS high-security vitrification straw, rapid-i, and cryo-pette are closed so that the cells do not contact liquid nitrogen, thus avoiding any potential contaminants [55–58]. Although the cooling rates for closed systems tend to be slower than open systems, they still work well and achieve rates over 5000 °C/min. Today there are over 20 different micro-volume devices available.

Although the DMSO/EG method has been widely accepted and is used worldwide, the major drawbacks are the potential toxicity of DMSO, short equilibration time, large learning curve to perfect the method, and cost of the tiny plastic storage devices. DMSO is a very good vitrificant; however, it is one of the most toxic [59, 60]. Therefore, exposure of oocytes or embryos to concentration above 6 M is not recommended. More concentrated solutions, above 6 M, are toxic and lead to cell death. Exposure times for the 7.5% solutions range from 5 to 15 min. Because the cryoprotectant concentration is half of the working vitrification solution, the longer exposure time has no overt negative effect. However, when the full strength vitrification solution of 15% DMSO and 15% EG is used, the exposure time must be reduced to around 30–90 s. Longer times that would allow better equilibration (more dehydration and increased loading of cryoprotectants) prove toxic. The end result is that the cells are not completely equilibrized with the cryoprotectants and thus have more water inside. The intracellular water/cryoprotectant concentration places the cells in the "Unstable" range of the above phase diagram (see Fig. 54.2.) [14]. The technical skill in getting the timing correct and loading the cells onto/into the storage device in the allotted time period has led to variable results [61]. Furthermore, the reduced time in full strength vitrification solution is not enough to allow the cryoprotectants to reach the inner cell mass cells (ICM) and protect them. Because blastocysts are morphologically very different from a non-cavitating cleavage-stage embryo, their storage has presented different challenges. The main problem is that the blastocoel is made up mainly of water that can form ice crystals when the temperature is lowered and thus cause damage to the ICM and trophectoderm. To overcome this problem, some investigators have tried collapsing the blastocoel either by pipetting the blastocyst in and out of a fine bore pipette or by rupturing it using an intracytoplasmic sperm injection (ICSI) needle or similar device [48, 51, 62]. Although these papers report increased survival rates using these methods, the obvious drawback is that an additional procedural step is involved that is potentially damaging to the embryo. The collapse is necessary with expanding blastocysts over 150 um in size [63]. The rupture of the trophectoderm allows cryoprotectants rapid access to the ICM, allowing them to be successfully vitrified. In conclusion, DMSO systems work well despite the above-mentioned issues. Not every lab has achieved great results, and variability in success rates within and between labs still exists.

54.1.4 Non-DMSO Methods

Despite the variety of different companies that offer a vitrification system, they are all basically the same. However, not every vitrification system uses DMSO. There is one other method that is vastly different, yet very successful for vitrification of eggs and embryos. Shortly after the open-pulled straw paper came out, Stachecki developed a very different vitrification system and later published on the S^3 method [64, 65]. It was based on the fact that slow-cooling is also vitrification and that this could be achieved in a relatively large container, namely, a 0.25 cc straw. The system was developed around the simple, inexpensive, closed, sterile cryo-straw as the storage container of choice. To avoid the shortcomings of the Vajta method, no DMSO was used, thus avoiding the cryoprotectant toxicity problem. Higher concentrations of cryoprotectants were used without cell toxicity [65, 66]. Combined with longer exposure times in the final vitrification solution, the cells are better prepared for vitrification. A higher concentration of cryoprotectant and longer exposure times result in less water in the cells and a meta-stable environment, as shown in the phase diagram of Fig. 54.2. All combined, a slower cooling and warming rate is needed, allowing for larger containers and more volume to be used, while still achieving the required rates for successful vitrification. The protocol is very forgiving allowing leeway in almost every step, and almost no learning curve is required. The overall results are similar to results using the DMSO system [66].

54.1.5 Vitrification Outcomes

The efficacy of vitrification is ultimately measured by live births. There are many variables that can affect the reported outcome, such as embryo quality, day of vitrification, blastocoel collapse, and biopsy to name a few. Collectively, the results are very supportive of blastocyst vitrification. Clinical outcomes from DMSO vitrified blastocysts have been widely published. Survival and clinical pregnancy rates range upward of 99% and >65%, respectively, depending on the clinic [49, 51, 67–75]. In 2015, Sparks showed more recent blastocyst data with similar high rates [76]. Over the past 5 years, there have been numerous abstracts with reported outcomes from non-DMSO methods, namely, ICE vitrification, that were presented at three major reproductive meetings (ASRM,

Table 54.1 Clinical pregnancy rates of ICE vitrified blastocysts vs. fresh blastocysts

Age	Cryo preg. rate	Fresh preg. rate
<38	771/1300 (59.3%)	263/477 (55.1%)
38–43+	241/419 (57.5%)	42/126 (33.3%)
Donor	138/216 (63.9%)	102/178 (57.3%)

Clinical pregnancy rates (number of pregnancies/transfer) of blastocysts cryopreserved with the ICE vitrification system vs. fresh non-vitrified blastocysts. Data gathered from nine clinics between 2011 and 2016. Blastocyst survival was >93%

PCRS, and AAB) but few publications [65, 66]. We report here (Table 54.1) a collection of clinical results from nine different clinics over a 5-year span from 2011 to 2015 using the ICE vitrification system. Collectively, survival rates were >93%, and the overall clinical pregnancy rate was 59.4% in 1935 transfer cycles.

54.1.6 Emerging Concepts

During the past 15 years, vitrification has been adopted by almost every clinic in the USA and most others worldwide. With the ability of blastocyst culture and genetic testing at the blastocyst stage, vitrification of embryos as well as oocytes has revolutionized the IVF industry. The DMSO and S^3 systems were so highly successful and much better than anything else available at the time. Not surprisingly, the high rate of success has stifled innovation and further development of cryopreservation systems. Companies trying to separate their system from others have used various buffer systems, or different sugars (sucrose vs. trehalose, a disaccharide present in certain species that are able to remain vitrified for years), or even swapped PrOH for DMSO, but in the end, they are all, cryobiologically speaking, similar.

There are, however, several emerging concepts in the field that are worth mentioning. Kuwayama's split with the Kitazato Corporation led him to rethink his DMSO system, which resulted in CryoTec™, a modification of the basic DMSO system but with hydroxypropylcellulose (HPC) rather than human serum albumin (HSA) as a protein source. HPC, like albumin, is a plasma volume expander, effectively reducing water (available to form ice crystals) and increasing solution viscosity. HPC, unlike HSA, is a fully synthetic macromolecule, thus avoiding endotoxin and other possible contaminants. Coello et al. [77] and Mori et al. [78] recently showed that HPC and trehalose were safe substitutes for HSA and sucrose for vitrification of oocytes or embryos and that there was no difference between survival rates, embryo development, and pregnancy rates.

To further develop and perfect the S^3 vitrification system, Stachecki optimized protocols to reduce the time and still allow leeway in the protocol. He also introduced hyaluronate into the media (unpublished results). Hyaluronate is known for its beneficial embryo growth and development properties, as well as its ability to increase viscosity [79–84]. The new and improved system was called I.C.E. vitrification and represented a significant improvement in an already viable system [66].

Katkov has worked on developing a purely kinetic system for vitrifying sperm without the use of cryoprotectants [8]. Although he has showed feasibility, more work needs to be done if it is to enter in the human IVF field.

Recently, there have been several automated vitrification systems in the work: Gavi™ from Serono and a system from ESCO. These machines are large, complex, and, at times, not so automated. Clinical testing and continued development of these prototypes may lead to a more simplified and time-saving approach.

54.2 Beyond Vitrification: Other Factors Affecting Outcomes

54.2.1 Embryo Culture

Vitrification of human gametes and embryos is extremely successful. Published success rates and overall clinical success has changed the field and how we do IVF. This has come about due to a number of reasons; first and foremost is the improvement in culture conditions. Embryo culture to Day 5 and beyond has improved significantly in the past 15–20 years, and blastocyst transfers are now the norm, at least in the USA. Second, it has been assumed that the uterine environment, in a controlled ovarian stimulation (COS) cycle, may not be as good as in a natural cycle or with controlled preparation for a frozen embryo transfer cycle [85, 86]. If this is true (and the published evidence is rather convincing [87–94]), freeze-all cycles will avoid the transfer of fresh embryos to a stimulated uterine environment that can be suboptimal for implantation and development. The end result is that more and more clinics are using both single embryo transfer (SET) and freeze-all cycles, especially for their older (>37y.o.) patients [95]. SET has been shown to reduce multiple pregnancy rates, and the risks and costs associated with twins and multiples still maintain a high take-home baby rate [86]. Collectively, the improvement in embryo culture, improved genetic testing and blastocyst biopsy, and avoidance of transfer in a fresh cycle have perpetuated the need for the safe and efficient storage of blastocysts.

There are a number of factors that affect the overall success of vitrification, yet have nothing to do with the actual vitrification or warming process. These start with patient demographics, the stimulation protocol, culture conditions, and anything else that is associated with affecting the overall embryo quality. No matter how good the vitrification system is, poor embryo quality, either inherent or caused by user error and/or poor culture conditions will not, at least most of the time, lead to success. Because of the myriad of other factors that can influence outcomes, troubleshooting a

vitrification system is challenging. The whole system must be accounted for from egg collection through warming, culture, and transfer. Despite these issues, many clinics are obtaining better overall pregnancy rates with vitrified embryos than fresh ones.

54.2.2 Patient Preparation and Embryo Transfer

Unfortunately, many good embryos fail to produce a baby, even with good embryo culture and a good vitrification system [83, 96] [97–100]. A final piece in the overall puzzle of producing a healthy pregnancy, or at least a successful positive pregnancy with a fetal heart beat, is the embryo transfer procedure [83]. The transfer procedure can be affected by numerous factors including patient-specific issues, contamination of the catheter, retained or expelled embryos, type of catheter, media used, adjuvants, timing, etc. [83]. It is obviously important to perform the transfer correctly, but not so obvious is the proper uterine preparation [99], which has been the cause of many failed cycles. As the number of clinics increase their FET rates and/or move to freeze-all cycles, one would assume that, based upon the evidence in the literature, the pregnancy and take-home baby rate would naturally increase. However, improper uterine preparation leads to an increase in both failed and biochemical pregnancies. Because suboptimal preparation is difficult to determine, it often goes unnoticed for months. Analyzing biochemical, clinical pregnancy, and delivery rates over time and between cycles will show that something is amiss. An overall increase in biochemical pregnancies and decrease in fetal heart beats and/or delivery rates over a period of time can be a strong indicator of poor uterine preparation.

A pregnancy will initiate only when the embryo is ready to implant and only when the uterus is ready for implantation. This window of implantation, although typically 12−24 h wide, varies and can be different between patients [101]. Proper uterine preparation is key to synchronizing the implantation windows of the uterus and embryo [96, 99]. Casper and Yanushpolsky recently reviewed this topic in 2016, and their work can serve as a good source for additional information as this chapter will only briefly touch on this topic.

Endometrial morphology is an appropriate predictor of receptivity for implantation, and hormonal control of endometrial receptivity includes an estrogen priming phase followed by progesterone (P4) secretion, which leads to the necessary endometrial changes [102, 103]. Estrogen increases endometrial thickness and is given for approximately 2 weeks until thickness reaches around 7 mm. At this time, P4 administration begins for the number of days proportional to the embryo stage [104]. Thus, a Day 5 blastocyst would require approximately 5 days of P4. However, it is known that approximately 25% of women can be out of phase and would require longer P4 administration prior to embryo transfer [105, 106]. The dosage and timing is very important. For instance, it is widely suggested to do the thaw and transfer of a D5 blastocyst on D6 of P4 IM administration [105, 107]. Alternatively, we do not want to advance the endometrium using too much P4 and close the window of implantation too early. Despite the individual differences between patients, which may lead to failed pregnancies, the basic idea is to optimize the uterine preparation so that overall FET pregnancy rates are high and biochemical pregnancies remain at or below fresh ET levels.

The type of progesterone is very important and can make a difference in pregnancy rates [108–110]. However, randomized controlled studies have shown both vaginal and intramuscular P4 to be equally effectively [111–115] with an overall similarity in pregnancy rate. There are pros and cons with both vaginal and IM P4, and these should be considered prior to use. The short half-life of natural P4 (used in vaginal supplements) dictates multiple daily usages in order to maintain natural P4 serum levels. By contrast, IM P4 in oil has a continuous release over time and thus a longer half-life, requiring less administration [110, 116]. However, because of its route, it takes much longer for IM P4 to start affecting the uterus, which can lead to a longer administration period prior to ET [110].

Progesterone can also affect uterine contractility and thus influence implantation and pregnancy rates [117]. It has been shown that increased myometrial contractions are associated with decreased pregnancy rates [118, 119] and tubal ectopic pregnancies. Fanchin showed that the rate was correlated to serum P4 levels; with higher levels correlating to lower contractility and vice versa [120], therefore, performing embryo transfer during a time of low uterine contractility results in better pregnancy outcomes. Estrogen increases uterine contractility and subendometrial wave action, whereas P4 antagonizes this action. Cicinelli showed that endometrial concentrations are higher with vaginal P4 versus IM P4 [116], suggesting that the higher serum levels of P4 after IM administration may work better to reduce uterine contractions. This may be a reason that many physicians still use IM P4, despite the sometimes painful injection regimen. The gap between administration of vaginal P4 and the actual time of FET the following day can be large enough to result in a low P4 concentration in the uterus and greater contractions. This gap does not occur with IM P4, due to the continued release and higher serum concentrations. Casper therefore suggests that IM P4 may quieten endometrial activity better than vaginal P4, at least until implantation where a switch to vaginal P4 administration could be considered [110].

54.3 Conclusion

There are many factors that can affect the outcome of a vitrification procedure, from embryo quality, patient demographics, culture conditions, and laboratory quality, to the actual vitrification and warming procedure, uterine preparation, and the embryo transfer itself. All of these variables must be carefully orchestrated and managed in order to

achieve a successful outcome. Embryo and gamete storage has come a long way from the discovery of glycerol in Polge's lab to the successful cryopreservation of mouse embryos over 40 years ago to modern ultrarapid cooling techniques. From the start, animal models have provided us with most of the breakthroughs in the area of cryobiology and embryo storage. It is these pioneering studies, along with new innovative ideas, that hold the key to even more breakthroughs. Emerging methods of kinetic vitrification, as well as more robust meta-stable solutions, and simple, safe, and effective storage containers like the micro-secure will lead us into the future [7, 66, 121]. It can all be seen as one big, extensive research project culminating in the ability to successfully preserve a wide variety of mammalian embryos in a rather simplistic manner with minimal resources, namely, a set of cryoprotective solutions, a storage device, and a bucket of liquid nitrogen. Despite its simplicity, we must keep in mind that these cells were not meant to be frozen, and that any success at all is truly remarkable. Although we have seemingly conquered, or at least been very successful at storing human embryos and gametes, there is a lot we do not understand about the actual vitrification and warming process. Not all cells survive storage, and those that do, not every embryo successfully implants and continues to develop. When cells do not survive we assume it is from intracellular ice formation or osmotic effects or toxicity, but we really are just guessing [11]. We have no way of seeing what is happening inside the cell and can only make assumptions, many of which are incorrect. These unknowns and the continued push to find simpler, more effective methods of embryo storage keep us looking to the future for a deeper understanding of the complexities of human embryo vitrification.

Review Questions

1. What is the key factor(s) for vitrifcation of a cell?
2. How is slow-cooling the same as vitrification?
3. What are the two basic types of vitrification systems available today and how do they differ?
4. Besides performing basic tasks appropriately (i.e., vitrifying correctly or performing the embryo transfer correctly), what are the three key factors for a successful FET outcome?

Oocyte Vitrification and Current Clinical Applications

Ana Cobo

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_55

Learning Objectives

- To understand the basic principles of vitrification and how we can achieve it in our clinical settings
- To analyze the contribution of oocyte vitrification to clinical practice
- To describe the methodology, logistics, and technical aspects related to oocyte vitrification

55.1 Introduction

The essential role of cryopreservation in ART has become obvious since the establishment of the infertility treatment, bringing flexibility and efficiency to the practice. Semen and embryo cryopreservation has been a successful strategy, and its routine application is a reality since the onset of the IVF practice. However, in spite of numerous studies conducted over two decades, the reliability of oocyte cryopreservation is relatively recent. All of the efforts made are clearly justified, mostly because an efficient oocyte cryopreservation program is actually quite welcome and widely applied in ART, since there are many indications for this strategy, including egg-banking for ovum donation. Beneficiaries of this approach include cancer patients who need an option for fertility preservation before undergoing their oncological treatment [1], or women who wish to delay their motherhood due to a variety of reasons [2], government restrictions on IVF [3, 4], ethical reasons against embryo cryopreservation and practical reasons such us unavailability of the male gamete the day of pickup [5, 6].

Despite all of this wide diversity of potential applications, egg-banking has not been a routine procedure until relatively recent. This fact can be explained because the methodology to cryopreserve human oocytes was disappointing, with results that have not always been reproducible, especially during the 1980s and 1990s. During the early 2000s, vitrification brought efficient and reproducible outcomes to the clinical practice. Some fundamental principles of cryobiology would be helpful to understand how difficult it has been to reach the goal of safe cryopreservation of human oocytes.

55.2 Cryobiology Background

There are some reasons that could explain the low rate of successes initially observed with the first protocols available for oocytes cryopreservation. At first, the size and shape of the oocytes are intrinsic cell features that strongly challenge the outcome. These gametes are the largest cells of the human body, fact that could explain, at least in part, the great differences in cryotolerance between them and, for example, the spermatozoa. In addition, the spherical shape of the oocyte could disturb the uniform distribution of cryoprotectants (CPAs) along the cytoplasm. In addition, considering the oocytes as a unique cell, there is 50% choice of survival and 50% choice of cell death. This situation is completely different from the one observed in tissues composed of millions or thousands of cells, i.e., semen samples, in which the damage could be compensated in different proportions.

Other major factors responsible for the high oocyte sensitivity to cryopreservation include chilling injury and intracellular ice crystal formation. These factors are related to the cryopreservation method. There are two main strategies in cryobiology: slow freezing and vitrification. During the former, the cells are gradually dehydrated in the presence of CPAs, and the temperature is lowered at a very slow cooling rate (−0.3 °C) [7]. In this way, the cells are exposed to low temperatures during an extended period of time, which can lead to what is known as chilling injury [8]. At the final stage, water solidifies into ice crystals. Chilling injury can be defined as the irreversible damage following exposure of cells to low temperatures, before the nucleation of ice [9]. This detrimental event affects mainly the cytoskeleton [10] and cell membranes [11]. The ice crystal formation within the cytoplasm must be avoided at all cost in order to guarantee the survival and integrity of the cells when they are later thawed. Chilling injury can be minimized during vitrification by the use of high cooling rates [12].

Vitrification, in particular by means of methodologies that use a minimum volume, yields extremely successful outcomes, that have not been achieved with other approaches [6]. The physical phenomenon of vitrification takes place when the solidification of the solution occurs not by ice crystallization but by extreme elevation in viscosity, which is achieved by using extremely high cooling rates from −15,000 to −30,000 °C per minute, allowing to avoid the risk of chilling injury [12]. This ice-free cryopreservation method has been modified in order to optimize results. One such modification has been to reduce the volume of the vitrification solution containing the oocytes, which allows the CPA concentration and, consequently, the cytotoxicity to be decreased [13, 14]. As mentioned, this procedure circumvents the two major limiting factors for achieving optimal cryopreservation: chilling injury [14] and ice formation [15]. Chilling injury can be minimized during vitrification by the use of high cooling rates in order to avoid the range of temperature at which chilling takes place (+15 °C to −5 °C) [12]. Additionally, the velocity of the process is dependent on the volume of the vitrification solution. Thus, the smaller the volume of the sample, the higher the cooling rate. On the other hand, direct contact with liquid nitrogen also contributes to increase the cooling rate. Ice formation can be also avoided during vitrification by the use of high CPA concentrations [12], despite the fact that such high concentrations are considered toxic to cells [16]. Nonetheless, an appropriate, phased composition of CPA could mitigate the toxic and osmotic consequences of highly concentrated CPA mixtures [6]. In this way, a combination of two or three of these agents can decrease the individual specific toxicity of these agents. The most common mixture employed for this purpose consists of ethylene glycol, dimethyl sulfoxide, and sucrose or trehalose [6]. To optimize the results, in addition to an appropriate selection of CPAs, it is also helpful to use these agents

at as low a concentration as possible, while maintaining the necessary composition able to achieve vitrification. By dramatically increasing the cooling rate, the CPA concentration could be reduced. As a result, a high cooling rate avoids chilling injury, and allows the reduction of the concentration of CPA, thereby preserving the cells at nontoxic concentrations of cryoprotectant. Several approaches fit these conditions. The "minimum drop vitrification" method, proposed by Arav, uses a very small volume of vitrification solution by placing the samples on a specific device that must be cooled very quickly [17]. Extremely high cooling rates are achieved when samples loaded in minimum volume are directly immersed in LN. These methods are also known as open systems. Hermetically closed vials achieve lower cooling rates as compared with open devices. Nevertheless, it is worth mentioning that the direct contact of samples with LN has raised some concerns due to the theoretical risk of cross-contamination mainly because the LN itself is considered as a potential source of pathogen agents, even though no case of cross-contamination has ever been reported in ART in many years of practice, highlighting that such eventuality could be extremely unlikely.

A wide variety of open approaches have been reported in the literature [18–23] as well as closed ones [24, 25].

55.3 Contribution of Oocyte Vitrification to Clinical Practice

55.3.1 Ovum Donation Programs

Oocyte cryo-storage results are very useful to overcome the most common drawbacks involved with ovum donation as currently applied, such as synchronization between donors and recipients, long waiting lists subject to the availability of a suitable donor, and most importantly the absence of a quarantine period.

55.3.1.1 Management of Egg-Banking in our Clinical Setting

Egg Donor Selection

Spanish Assisted Reproduction Law is based on legislation that was passed in November 1988 (Law 35/1988) (► https://www.boe.es/buscar/doc.php?id=BOE-A-1988-27108). Although some countries already had regulations on, Spain was the first country to create a specific law to cover this area of medicine. Royal Decree 412/1996 and Ministerial Order of 25 March 1996 establish donor requirements, as well as mandatory standard screening procedures, to rule out the transmission of genetic, hereditary, or infectious diseases (► https://www.boe.es/buscar/doc.php?id=BOE-A-1996-9723). In 2006, the newly approved Spanish Law on Assisted Reproduction (Law 14/2006) (► https://www.boe.es/buscar/act.php?id=BOE-A-2006-9292) regulates the requirements for gamete and embryo use and rules on financial compensation aspects.

These are the most important topics included in Spanish Law on Egg Donation:

- *Donation of human gametes is a formal confidential contract between the donor and the reproductive medicine center. Identity of donors must remain anonymous.*
- *The donation cannot be revoked.*
- *The maximum number of children generated from a single donor's gametes should not exceed six.*

To be accepted as an egg donor, women must be aged between 18 and 35 years old and be healthy. The following steps are necessary for the admission as an egg donor in our clinics:

- *Medical History*: During the first consultation, the applicant is interviewed in order to complete the familiar and personal history.
- *Psychological Screening*: Psychological evaluation and counseling by a qualified mental health professional. The potential donor is evaluated by a psychologist, to ensure that she fully understands the benefits and risks of egg donation, and is properly motivated to become a donor.
- *Gynecological examination*: Menstrual cycles, ovaries examination by ultrasound and antral follicles count are performed. At the same time, body mass index is calculated.
- *Medical Screening*: This involves testing for blood type, antibody screening, complete blood count, hemostasis, biochemistry and infectious disease screening, such as HIV, CHV, CHV, and syphilis among others.
- *Genetic Screening*: Blood tests for karyotype and for carrier screening tests for severe recessive and X-linked childhood diseases based on NGS (549 genes implicated in 623 disease phenotypes).

Ovarian Stimulation

To initiate, an oral contraceptive pill is administered for a maximum of 21 days, which starts on day 1 or 2 of the menses of the previous cycle [26]. After a 5-day washout period after taking the last pill, donors start their stimulation protocol with 150–225 IU of recombinant FSH, 225 IU of HP-hMG, or 150–225 IU of recombinant FSH plus 75 IU HP-hMG. Regular vaginal ultrasound monitoring of donors is performed during FSH injections to measure follicle growth. Daily doses of 0.25 mg GnRH antagonist (Ganirelix or Cetrorelix) start on day 5 of stimulation. Once the leading follicle reaches 18 mm in diameter, a single dose of GnRH agonist is administered to trigger the final oocyte maturation. Transvaginal oocyte retrieval takes place 36 h later after GnRH agonist administration. Donors receive light sedation for the egg retrieval procedure to ensure their comfort, and they rest for 2 h at the clinical setting until they are discharged. In some cases, a vaginal ultrasonography scan is scheduled 2–3 days following egg retrieval [27].

55.3.1.2 Oocyte Recipients

Oocyte recipients enter our egg donation program for one of the following main diagnoses: premature ovarian failure/menopause, failure to achieve pregnancy after at least three

cycles of assisted reproduction techniques, genetic or chromosomal disorders, low response to controlled ovarian hyperstimulation, and recurrent miscarriages.

The vast majority of oocyte recipients undergoes hormone replacement therapy (HRT). In patients with ovarian function, depot GnRH-a is administered in the midluteal phase of their cycle, or GnRH-ant, administered daily with menstruation for 5 days. HRT is initiated on days 1–3 of the following cycle with oral estradiol valerate or an estradiol transdermal patch [28–30]. Recipients without ovarian function are submitted to the same endometrial preparation protocol but are not administered depot GnRH-a. On day 15 or 16 day of HRT, a transvaginal ultrasound is performed to measure endometrial thickness, and serum E2 and progesterone levels are tested. Most recipients are ready to receive embryos within 2–3 weeks after starting HRT, although administration of estradiol valerate can be maintained for a maximum of 50 days until a suitable donation becomes available. Micronized progesterone (800 mg/d, vaginally) is initiated on the day after oocyte donation, and embryos are transferred in the blastocyst stage.

The recipient continues taking estrogen and progesterone with a positive pregnancy test, and these hormonal supplements are then continued through 12 weeks of pregnancy.

Before treatment begins, the recipient undergoes preliminary testing. This assessment phase includes infectious disease screening, e.g., HIV, CHV, CHV, syphilis, and blood type, and Rh factor for both parents. In women older than 45 years old, a recent mammogram, full blood count, coagulation tests, and blood biochemistry may also be required.

55.3.1.3 Donor-Recipient Matching Process

In our center, we have developed a consistent software tool that accounts for different characteristics of the woman and her partner, as phenotypic features, blood type, etc. The tool provides a list of available donors and number of oocytes available, thus simplifying greatly the process of donor-recipient matching.

Matching is known as the time when we select a donor for a recipient after taking into account several features. We consider many different factors during donor selection: race, reproductive history, the physical characteristics that match those of the female partner, blood type, and genetic carrier screening.

The time for donors-recipients matching has changed in the last 6 years thanks to the improvement in the oocytes vitrification technique and the establishment of the egg donor bank. However, it is important to note that in our current practice, we conduct donations both with fresh and vitrified oocytes, as long as fresh donations are still allowed in our country. The decision about conducting one strategy or the other depends on different circumstances related to the availability of oocytes and the needs of the recipient.

If there is the case that the recipient requires particular rare characteristics, i.e., blood type (0 negative, AB negative), specific race, screening for specific genetic diseases, or partners who would like to have another baby with the same donor as they had before, the procedure would be as follows:

- First, we use our donor selection database and select one donor or two with the required characteristics. If there are no suitable donors undergoing ovarian stimulation by the moment of the matching, we search for another appropriate donor within the list provided by the tool after the matching process and ask them for their availability to return to initiate the ovarian stimulation for this specific donation.
- Second, all the oocytes obtained during pickup are vitrified and reserved for the recipient.
- Finally, the recipient chooses the best time to schedule embryo transfer, and we provide them with instructions to begin HRT depending on the day of the embryo transfer.
- Recipients who do not need specific characteristics:
  - The date for embryo transfer is already set.
    - First, we reserve oocytes from our egg donor bank.
    - Second, the recipient begins HRT depending on embryo transfer.
    - Finally, we have two options:
  - We use fresh oocytes when we have a donor pickup scheduled on the same date as the donation (with the same characteristics as the partner). The prior reservation of oocytes is canceled in these cases.
  - The date for embryo transfer is not set yet.
    - The recipient starts HRT and remains on the waiting list
    - If on these dates an egg donor with the same characteristics as the recipient undergoes pickup, we use fresh oocytes for the egg donation.
    - If the recipient stays on the waiting list longer than 20–25 days, we use oocytes from the egg donor bank.

55.3.1.4 Clinical Outcome

The first live birth after vitrification was achieved from a donated oocyte using an open system device (OPS) in 1999 (Kuleshova et al. [33]). Since then, numerous publications using different types of devices corroborate the effectiveness of the technique. ◘ Table 55.1 shows a list of the survival and pregnancy rates by different groups using donated vitrified oocytes.

In 2008, our group published a study aimed to assess the impact of vitrification using donated oocytes, in terms of survival and development potential when compared to fresh oocytes (Cobo et al. [1, 5]). A cohort of oocytes from a single donor was randomly divided into two groups: in the first one, the oocytes were vitrified, while in the second one, the remaining oocytes were kept in the incubator (control fresh oocytes). Oocytes were warmed up 1 h after vitrification. After two hours, we proceeded to simultaneous insemination of the fresh and vitrified oocytes. The Cryotop method employed for oocyte vitrification was that previously described by Kuwayama (22). The study included 30 donors and 30 recipients (509 oocytes; 231 vitrified oocytes and 219 fresh oocytes). After a survival rate of 96.9%, we found no differences in the rate of division in day 3 (77.6% vs. 84.6% in vitrified in fresh) or the morphological quality of embryos (80.8 vs. 80.5% of good quality embryos vitrified vs. fresh).

Table 55.1 Key publications related to donated vitrified oocytes

	Year	Device	Survival rate (%)	Pregnancy rate (%)
Kuleshova et al.	1999	OPS	64.7	33.3
Lucena et al.	2006	Cryotop	89.2	56.5
Cobo et al.	2008	Cryotop	96.9	65.2
Chang et al.	2008	Cryotop	85.4	83.3
Sher G et al.	2008	Cryoloop	96.1	81.2
Nagy et al.	2009	Cryotop	89.0	75.0

Cobo et al.	2010	Cryotop	92.5	55.4
Noyes et al.	2010	Cryotip	87.0	63.0
Trokoudes et al.	2011	Cryotop	91.4	55.6
García et al.	2011	Cryolock	89.4	61.8
Stoop et al.	2012	CBS high security	90.2	50.0
Papatheodorou et al.	2013	Vitrisafe	90.9	28.0
Solé et al.	2013	Cryotop	85.6	53.5
Figueira et al.	2014	Cryotop	77.1	37.7

Likewise, both the blastocyst rate (48.7% vs. 47.5%) and quality of embryos (81.1% vs. 70%) was similar comparing fresh and vitrified.

Another randomized, prospective, triple-blind, controlled-clinical trial, which included the largest sample size published to date, aimed to validate ovum donation via egg-banking [31]. The study included 600 donor/recipients (300 per each branch) and 3039 vitrified versus 3185 fresh oocytes. In this study we demonstrated the non-inferiority of vitrified oocytes regarding ongoing pregnancy rate by intention to treat (Odds ratio = 0.921, 95% CI 0.667 to 1.274). The overall survival rate in this study was 92.5% and ongoing pregnancy rate by intention to treat was 43.7% in the case of patients who received vitrified oocytes compared to 41.7% obtained with fresh oocytes. This study definitively confirmed our previous observations about the non-alteration of vitrified oocytes potential to develop into embryos capable of generating competent ongoing pregnancies in a similar proportion to fresh oocytes.

The availability of surplus embryos to cryopreserve after the embryo transfer in ovum donation cycles conducted with vitrified oocytes is quite common due to the high developmental potential of these oocytes. In these cases, two rounds of vitrification are involved, at MII stage and at day 3 or blastocyst stage. A study published in 2013 showed that the double vitrification has no effect on the delivery rate or live birth rates (Cobo et al. 2013). This study included 796 vitrified embryos generated from vitrified oocytes ($N = 471$ cycles) and 4394 vitrified embryos generated from fresh oocytes ($N = 2629$ cycles). The overall embryo survival rate was 97.2% (95% CI 95.9 to 98.6) versus 95.7% (95% CI 94.9 to 96.4) for double versus once vitrified embryos, respectively (NS). The live birth rate per warming cycle was 33.8% versus 30.6% (NS). As showed, the odds ratio of the delivery rate and the double vitrification had no effect on embryos regardless of whether they were in early stage development (day 3) or blastocyst stage (OR = 0.867; 95% CI 0.657 to 1.203).

A couple of years ago, we published an observational study in which our experience of 6 years with the egg-banking program (Cobo et al. [34]) was described. The analysis included 3610 cycles of oocyte donation where 42,152 MII were warmed. Survival rate was 92.6%. The impact of storage time on the survival rate and clinical outcome was calculated by establishing different time intervals from less than 6 months to over 5 years. The storage time did not impair survival or clinical outcomes in any case. We believe that this is a very reassuring information, especially for those women considering fertility preservation. The clinical, ongoing pregnancy, and delivery rates were 55.0%, 45.3%, and 37.6%, respectively, thus confirming the consistency of the results as compared to our previous findings (Cobo et al. [1, 5, 31]). The likelihood of having surplus embryos available for additional cryotransfers was very high in this series due to the mean number of oocytes donated. The possibility of further cryotransfers increased cumulative outcomes, and thus maximized the yield of a single donation cycle, which is precisely what we show herein. The cumulative delivery rate per donation cycle increased to over 70% after three cryotransfers and rose to nearly 80% after five cryotransfers. These results render the donation cycle as highly efficient.

Kaplan-Meier analysis observed in Fig. 55.1 provides interesting information about the number of vitrified oocytes consumed by a recipient (either in one or more cycles of ovum donation) necessary for a newborn. The analysis showed that the live birth rate increases exponentially and the patient can achieve a baby with a probability of nearly 100% when about three to four cycles of egg donation (around 35–40 oocytes) are completed. This result confirms our previous findings while showing the excellent efficiency of egg-banking.

55.3.2 Fertility Preservation

Vitrification of oocytes is currently being offered as an option for women who wish to preserve their gametes to allow them to have a chance to conceive in the future and to have their own genetic offspring (Cobo et al. [34]). The main beneficiaries of this strategy are cancer patients who must undergo chemotherapy or radiotherapy and patients with other diseases who require potentially gonadotoxic treatments.

The first reported case in Europe of a pregnancy after FP using vitrification of oocytes was from our group in a patient whose ovarian cortex was cryopreserved first, and after grafting, four stimulation cycles were performed to accumulate

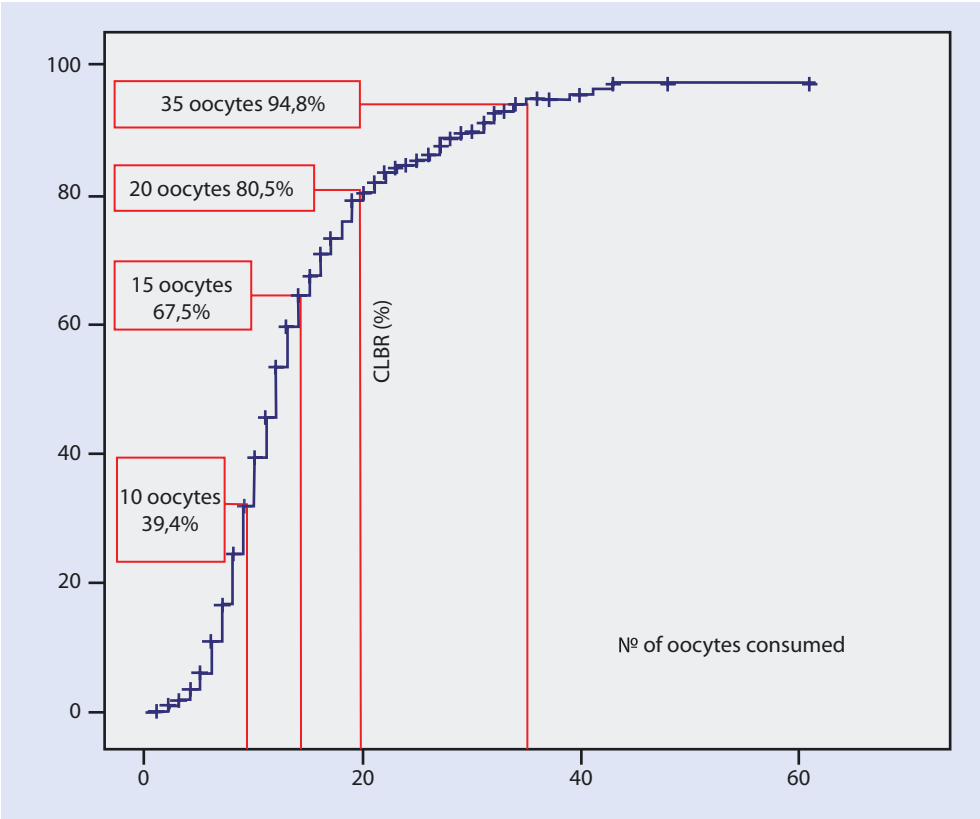

Fig. 55.1 The Kaplan-Meier curve for the cumulative live birth rates (CLBR) of at least one baby, depending on the total number of oocytes consumed

and vitrify mature oocytes; a later IVF cycle successfully ended in a twin pregnancy. Since then, various studies have reported clinical outcomes with cryopreserved oocytes for FP in cancer patients (Table 55.2).

Although FP may initially concern cancer patients, there are many other medical conditions that may compromise fertility, such as endometriosis or high risk for early ovarian failure, where an intervention as safeguarding gametes for future use is required to uphold fertility potential. In addition, age-related decline of fertility is a very common condition in assisted reproductive technology (ART). Elective oocyte vitrification for nonmedical conditions is increasingly accepted as an option to postpone motherhood (Cobo et al. [36]).

We have recently reported, in the largest series to date, our experience in FP in a population of women who electively decided to vitrify their gametes for future use (Cobo et al. [36]).

A clear, and expected, effect of female age was observed in our data. Higher outcomes were achieved in women aged ≤35 years. In this group a larger number of oocytes were retrieved and finally vitrified, and the survival and clinical outcomes were equivalent to those achieved in our egg-banking program for ovum donation, with the highest success rates in the youngest group of women (≤29 years). Otherwise, predictably fewer oocytes and worse outcomes were achieved as the age increased, resembling the results of the infertile population of similar age. There is a clear different probability of having a baby according to the number of oocytes consumed when the ≤35-year-old and >36-year-old groups are compared ($P < 0.05$) (Fig. 55.2). Obviously, the more oocytes, the higher the probability, but the relationship is not linear, as shown by the curves, and is strongly related to a powerful confounder, i.e., the age of the patient. When we looked at our data, we observed a huge difference in CLBR when using only five oocytes (15.4%) compared with using eight (40.8%), which means an 8.4% increase in CLBR per additional oocyte if women were ≤35 years old. If they were >36 years old using the same number of oocytes, the increase in CLBR was considerably more modest (from CLBR of 5.1% with the use of five oocytes to 19.9% when eight oocytes were consumed, meaning an increase in CLBR of 4.9% per additional oocyte). With 15 oocytes, the CLBR continued to increase in the ≤35-year-old group, whereas with the same number of oocytes the plateau was already reached in the group of women aged >36 years, meaning that at this point the success is independent from the number of oocytes used up. In light of this, we suggest that at least eight to ten MII oocytes should be vitrified to obtain a reasonable success rate.

55.3.3 Low-Responder Patients

A potential alternative to the management of low-responder (LR) is to create a large stock of oocytes by accumulating vitrified MII oocytes over several stimulation cycles and inseminating them simultaneously. Theoretically, this could

Fig. 55.2 Kaplan-Meier plotting of the CLBR of at least one baby, depending on the total number of consumed oocytes and categorized by age

help to increase the chances of success by "converting" poor responders into a "normoresponder-like" status.

We reported, in 2012, a study aimed to assess the efficiency of this new strategy for managing LR that takes advantage of vitrification as a way of creating larger cohorts of oocytes (Cobo et al. [37]). This study included 242 LR patients (594 cycles) whose mature oocytes were accumulated by vitrification and inseminated simultaneously (LR-Accu-Vit) and 482 patients (588 cycles) undergoing IVF/embryo transfer with fresh oocytes in each stimulation cycle (LR-fresh). The embryo-transfer cancellation per patient was significantly lower in the LR-Accu-Vit group (9.1%) than the LR-fresh group (34.0%). This result showed that this strategy is useful to avoid patients abandoning treatment due to negative results that impair their ability to cope with the situation. Live birth rate (LBR)/patient was higher in the LR-Accu-Vit group (30.2%) than the LR-fresh group (22.4%), which confirmed the efficiency of this method for managing LR patients. The positive effects of this strategy are even more evident when cumulative outcome is considered, which endorses the treatment as a successful alternative for LR patients.

Other authors also reported the evaluation of this form of vitrification in the context of standard infertile patients. Rienzi et al. [38] conducted a prospective randomized sibling-oocyte

study that included 120 fresh and 124 vitrified sibling oocytes from 40 infertile patients (mean age 35.5 ± 4.8 years). The survival rate was 97%, with a fertilization rate after ICSI of 77% (95/124) per warmed oocyte and 79% (95/120) per warmed/inseminated oocyte. Moreover, the proportions of excellent-quality embryos were the same in each group.

In another study, the cumulative outcome after the transfer of embryos derived from fresh and vitrified oocytes from a single ovarian stimulation cycle was calculated. The study included 182 ICSI cycles in which oocyte vitrification was also performed. The cumulative CPR was calculated when after failing a fresh embryo transfer, the patient underwent a second embryo transfer using embryos derived from the vitrified oocytes. Implantation rates in fresh and vitrification cycles were not significantly different for women ≤34 years (Ubaldi et al. [39]).

All these evidences suggest that vitrified oocytes are functionally similar to fresh oocytes in terms of fertilization, development, and implantation potential.

55.4 Practical Aspects of Oocyte Vitrification

55.4.1 Laboratory Procedure

The procedure described below is that developed for Cryotop. However, different methods exist on the market, and it is advisable to follow the manufacturer's recommendations.

- **Required Equipment**
  - Cryotop (Kitazato Biopharma, Tokyo, Japan)
  - Repro Plate (Kitazato Biopharma, Tokyo, Japan)
  - Cooling rack (styrene box for liquid nitrogen)
  - Liquid nitrogen
  - Storage tank
  - Stereomicroscope, stopwatch or timer, tweezers, Pasteur pipette, micropipettes, and tips

- **Solutions:**
  1. Basic solution (BS) is made of Hepes-buffered TCM-199 supplemented with hydroxypropyl cellulose (HPC), only for oocyte vitrification.
  2. Equilibration solution (ES) consists of 7.5% ethylene glycol (EG) and 7.5% dimethylsulphoxide (DMSO) dissolved in BS.
  3. Vitrification solution (VS) consists of 15% EG, 15% DMSO, and 0.5 M trehalose dissolved in BS.
  4. Thawing solution (TS) consists of 1.0 M trehalose dissolved in WS.
  5. Dilution solution (DS) consists of 0.5 M trehalose dissolved in WS.
  6. Washing solution (WS) is made of Hepes-buffered TCM-199 supplemented with HPC.

55.4.1.1 Vitrification Procedure

- **Preparation on the Day**
  1. Bring BS, ES, and VS to room temperature (24–26 °C) 1 h before application.
  2. Fill the cooling rack completely with liquid nitrogen.
  3. Write necessary information about the patient on the handle of the vitrification device.

- **Equilibration Step**
  1. Aspirate the oocytes from the culture dish and keep them at the tip of the capillar or Pasteur pipette, and transfer them within minimum drop volume to 20 µl of BS into a reproplate well (Kitazato, biomedical supply, Tokyo, Japan).
  2. Add 20 µl of ES surrounding the previous drop containing the oocytes (Kitazato, biomedical supply, Tokyo, Japan). Wait for 3 min at room temperature.
  3. Add another drop of 20 µl of ES in the same way as in the previous step and wait for 3 min more.
  4. Add 240 µl of ES slowly circling the previous drops and wait between 6 and 9 min. At the end of this step, the oocytes should be re-expanded and should recover their original appearance.

- **Vitrification Step**
  1. Dispense 300 µl of VS solution into two wells of the reproplate.
  2. After equilibrium, aspirate the oocytes at the tip of the pipette. Afterward, place them on the surface of the VS. Try to carry a minimum volume of ES solution. Note that the oocytes will float due to the high density of the VS media.
  3. Remove the ES medium just placed together with the oocytes (it will be noted clearly due to the difference in density) and wash the pipette outside the VS well. Keep removing continuously and keep on discarding the medium outside the plate. Repeat this operation as many times as possible within 30 s.
  4. Aspirate the oocytes and bring them to the bottom of the plate (the floating will stop as soon as they start to equilibrate with the medium).
  5. Repeat the same procedure in the next VS well. Place the oocytes in the bottom of the plate and move them many times around the well, repeating the washing process during 30 more seconds.
  6. Aspirate the oocytes and maintain them at the tip of the pipette within minimum volume of VS.
  7. Place the Cryotop under the microscope.
  8. Proceed to load the oocytes onto the Cryotop within minimum volume.
  9. Aspirate excess medium to make sure they are contained within minimum volume.
  10. Immerse the Cryotop directly into the liquid nitrogen container.
  11. Place the plastic protector Cryotop.
  12. Transfer the oocytes to the storage tank.

55.4.1.2 Warming Procedure

- **Preparation on the day**
  1. Warm TS vial and a petri dish up to 37 °C at least 1 h.
  2. Bring DS and WS to room temperature (24–26 °C) 1 h before application.

3. Fill the cooling rack completely with liquid nitrogen and retrieve the Cryotop from the storage tank. Keep it submerged in liquid nitrogen.
4. Drop 300 µl DS into first well and 300 µl WS each into second and third well of the repro plate.

Dilution and Warming Step

1. Remove the protective straw maintaining the Cryotops immersed in liquid nitrogen.
2. Remove the Cryotop from the liquid nitrogen container, and submerge it instantly (straight and quick movement) into 4 ml of a solution containing 1.0 M trealose (TS) (Kitazato, medical supply, Tokyo, Japan).
3. Visualize the oocytes and immediately start the countdown to 60 s.
4. Do not manipulate the oocytes within the first 40 s.
5. Retrieve the oocytes from the Cryotop with very gentle manipulations within a minute in TS solution.
6. Transfer the oocytes to the DS well in the reproplate. Aspirate the oocytes very gently, and continue to aspirate TS until the column reaches approximately 2 mm in length.
7. Take the pipette to the DS well and immerse it to the bottom. Dispense the 2 mm column at first. The column of TS within DS will be clear due to the difference in density of both. Leave the oocytes on the "top" of this column. Wait for 3 min.
8. Transfer the oocytes to well WS exactly as in the previous step. Wait for 5 min.
9. Transfer the oocytes to the next well of WS well. Leave the oocytes on the surface of this media; they will drop down immediately due to the absence of differential density between media. Wait for 1 min.
10. Transfer the oocytes to the regular culture dish and place them in the incubator at 37 °C. wait for 2 h before ICSI.

55.5 Equipment and Facilities

All our samples are cryopreserved by vitrification. This procedure, as currently performed, is entirely manual-operated, making not necessary the use of any equipment to carry out the vitrification process itself. The ease and efficiency of vitrification have been a turning point in the field of cryopreservation, making the whole process no longer than 20 min (vitrification and warming) involving very simple tools. However, the fact that the samples are vitrified mostly contained in very low volumes represents a challenge for further handling, storage, and maintenance of the vitrified samples.

The storage vessel can be the traditional liquid nitrogen tanks or vapor tanks. In our oocyte-bank facilities, we use vapor phase storage tanks (CBS V1500; Custom Biogenic Systems, Michigan, USA), which consist of an outer jacket with liquid N2. This area is responsible for cooling the storage area where the oocytes are maintained in a N_2 gas atmosphere. The cold spreads from the vacuum-insulated jacket by convection and through vents in the storage compartment that expel the nitrogen vapor downward to the bottom of the freezer, thus creating a flow of extremely cold air through the entire storage area. The exceptional uniformity of temperature allows the whole storage tank to be used, achieving temperatures below −180 °C at the upper level and −195 °C at the bottom. Samples can be manipulated in safe temperature ranges (−180 °C) thanks to the working area located on top of the storage area, thus avoiding any risk of accidental warming. An additional advantage of this storage system is that the supply of liquid nitrogen can be programmable, although it also can be performed manually. We have demonstrated the effectiveness of this storage vessel as a strategy for preventing the risk of cross-contamination due to direct contact with the liquid nitrogen (LN), showing comparable results between oocytes vapor-stored versus those stored in conventional LN tanks [31].

A temperature monitoring system is strongly advised as a part of the routine quality control (QC) of the cryolab. In our facilities, we use a system that allows continuous monitoring of the temperature of every storage tank in our unit (DataCare, ControlTemp, Barcelona). The system is able to provide numeric and graphic records and to display alarms in real time with updates every second. A record of incidents occurring during the alarm can be also easily assessed differentiating between active alarms or alarms that were active but are no longer in that state. In case of alarm, the system sends alerts and warnings messages to the authorized personnel.

On the other hand, in order to ensure efficiency, only highly skilled professionals who have to overcome a long learning curve should perform vitrification. Therefore, an adequate learning curve is also one of the most important requirements when performing vitrification that requires close attention. Our training program has produced satisfactory results since the introduction of vitrification in our clinical setting. It consists of different phases that gradually increase in difficulty. To pass to the next level, trainees must acquire the necessary skills as well as achieve a preset survival rate.

Review Questions

1. What are the reasons responsible for the ability of vitrification to rule out chilling injury and the crystallization of the cytoplasm?
2. What role does the cooling and warming rate play in vitrification protocols?
3. Which population can benefit from oocyte vitrification?
4. How can the toxicity of cryoprotectants be reduced in vitrification protocols?
5. What are the main benefits of egg-banking for ovum donation programs?
6. What factors are mainly responsible for success in the elective fertility preservation?

Slow Freezing of Embryos

Liesl Nel-Themaat, Ching-Chien Chang, Thomas Elliott, Diana P. Bernal, Graham Wright, and Zsolt Peter Nagy

This chapter is dedicated to the late Dr. Stanley Leibo. May you rest in peace knowing how many lives you touched both in the fresh and frozen state.

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_56

Learning Objectives

- Historical overview of embryo cryopreservation
- Mechanisms of freeze-thaw damage during embryo freezing
- Components of slow embryo freezing procedures
- Factors that determine embryo freeze/thaw success rates
- Applications and impact of embryo freezing in assisted reproduction
- Open vs slow cryostorage systems
- Differences between slow freezing and vitrification
- Legal and ethical considerations for freezing of embryos
- Future of slow freezing in embryo cryopreservation and assisted reproduction

56.1 Historical Overview of Embryo Cryopreservation

Cryobiology (the study of life at low temperature), as we know it today, has come a very long way to where we now can freeze and thaw living cells while maintaining viability, without any apparent detrimental effects. Currently, cryopreservation plays such a significant role in most biological fields that it is hard to imagine scientific progress without it. Examples range from the use of cryopreserved bacteria for genetic engineering, preservation of frozen tissues for transplantation, the large number of cell culture studies for disease research to assisted reproduction in humans and animals. To embark on this voyage back in time, one must consider the founding principles that led to the successes that were ultimately reported during the first half of the twentieth century. It follows a condensed representation of the history of modern cryopreservation but a more detailed review can be found in [1].

The start of this exciting journey goes back more than 300 years, to the early experiments by Robert Boyle, who was studying the effects of temperature on the volume of gasses. The foundation laid through his work led to the first Nobel Prize in chemistry, awarded to Jacobus van't Hoff, for his groundbreaking work on laws of chemical dynamics and osmotic pressures in solutions. The Boyle–van't Hoff plot still plays a fundamental role in cryobiology, as a means to describe the effect of osmotic pressure on cell volume. (The significance of these osmotic principles during freezing will be discussed in subsequent sections.)

During the same era, liquefaction of oxygen, hydrogen, and nitrogen was developed by French physicist, Louis-Paul Cailletet, which later allowed ultra-cooling of specimens. The importance of this discovery for modern-day cryobiology goes without saying.

As interest in life at low temperatures grew, so did the number of publications on the effect of cold on various biological systems. Most noteworthy of these is the work of a Swiss-born Priest named Basile J. Luyet, whose studies are best described by the title of his classic monograph "Life and Death at Low Temperatures." He proceeded to be the founder of the Journal *Biodynamica* and first president of the Society for Cryobiology. Father Luyet is thus generally known as the father of cryobiology.

The next decades saw major developments in low temperature biology, especially with spermatozoa preservation. In fact, the first observations on cooled spermatozoa occurred in 1866 by Italian military physician, P. Mantegazza, who noted that human spermatozoa became immotile when cooled in snow. He further envisioned the possibility for a deceased soldier to father a child by cooling sperm to maintain viability.

Mutual investigations by John Hammond and Arthur Walton on ejaculated and non-ejaculated sperm, respectively, showed that temperature affects ejaculated and non-ejaculated sperm differently, and that cooling of the latter could preserve its fertilizing capacity. We now know that capacitation is induced by exposure to seminal plasma, which changes membrane properties and renders spermatozoa more susceptible to temperature damage. Interestingly, Hammond predicted that "in these days of rapid aeroplane transport, it might be possible to move entire herds of animals around the world from chilled samples of semen" less than 30 years after the Wright brothers' first flight. So progressive was his thinking, that his vision today is a reality with human and animal gametes and embryos that are transported large distances, often across continents and recently even into space!

With the artificial insemination field taking off around 1930, the possible impact that the ability to freeze semen long term became widely recognized, motivating several groups to attempt long-term storage of semen by freezing in liquid gas. Success rates varied. It is notable that in 1938, Luyet and Hodapp described an experiment where spermatozoa survived vitrification in liquid air when exposed to a 2M sucrose solution. Although about 40% initially lost their motility during incubation in the hypertonic solution, cells that survived the incubation and were vitrified and warmed survived.

Despite advances, post-thaw survival rates remained typically low, until the accidental breakthrough discovery of the cryoprotective properties of glycerol by Christopher Polge and Audrey Smith under guidance of Alan Parkes in 1947 while working on fowl spermatozoa [2]. (It should be noted that in the previous year, Jean Rostand found that addition of glycerol protected frog spermatozoa from freeze damage. Fertilizing capacity of thawed samples, however, was never confirmed. Furthermore, there are unverified reports of using glycerol as a cryoprotectant for the freezing of mammal and bird semen in Russia). Polge's discovery was followed by successful freeze-thaw of spermatozoa in various mammalian species [3, 4]. Six years later, Bunge and Sherman [5] reported three human pregnancies resulting from artificial insemination with frozen sperm [5].

The second half of the twentieth century saw great improvements and refinement of the technique, while a wealth of information on freezing principles was produced. This included the necessity of water removal and the addition

of cryoprotectants and macromolecules to prevent intercellular ice crystal formation and membrane damage. We will elaborate on these topics in subsequent sections.

The next challenge investigators were facing was that of freezing the female gamete and embryo. At the end of the 1940s, M.C. Chang, who was working under Hammond at the time, started experimenting with cooling embryos and found that while slow-cooled embryos survived, rapidly cooled ones did not (Chang 1948 [6–8]). He proceeded to produce normal rabbit offspring from zygotes, cleavage and blastocyst stage embryos, all stored for at least 24 h at either 10 °C or 0 °C [8, 9]. Chang and Smith both followed these findings by experimenting with rabbit oocytes [10, 11]. Shortly after, Sherman and Lin reported birth of mouse pups from frozen-thawed oocytes that were transferred back into recipient females before being mated. These and other early studies revealed that oocytes are much more sensitive to low temperatures than embryos. During years of subsequent research, the reasons for this difference in sensitivity between oocytes and embryos were investigated but are beyond the scope of this chapter. For more information on the topic, see [12].

During the late 1950s and early 1960s, Peter Mazur turned his attention toward elucidating mechanisms involved in cell damage during freezing and thawing. His discoveries (discussed in subsequent sections) played a seminal role in the work by Whittingham et al. [13] that led to the first truly successful and repeatable freezing and warming of mouse embryos, as indicated by their high birth rate after transfer [13]. This was followed by more successes in other mammalian species [14, 15] and finally human embryos in the early 1980s [16]. Thirty-five years later, embryo cryopreservation has become an integral part of clinical embryology. The large collection of data available demonstrates that there is no single optimum technique for slow freezing and thawing. Instead, numerous different combinations of cryoprotectants, cooling and warming rates can lead to success. One thing that all these techniques do share is that they stem from the principles laid out through the diligent work of the cryobiology pioneers.

Since the first edition of this textbook almost 6 years ago, a drastic shift has occurred in the field, in that the vast majority of clinical reproductive labs now exclusively use vitrification as their cryopreservation platform. The reason for this preference of vitrification over slow freezing is not only based on perceived improved outcomes (although many studies failed to show statistical superiority of vitrification over slow cooling [17, 18]) at both cleavage and blastocyst stage cryopreservation observed following vitrification [19, 20] but also due to the significantly less time-consuming nature of vitrification protocols compared to that of traditional slow-freezing protocols. In fact, many commercial manufacturers have stopped producing their slow-freezing solutions altogether and are only selling thaw solutions, as many programs still have to thaw embryos that were frozen by slow cooling in the past on a regular basis. Therefore, knowledge of the technique is essential for any clinical embryologist.

56.2 Mechanisms of Freeze/Thaw Damage

Cells are composed of 60–85% water and a mixture of solutes and suspended particles, such as proteins, nucleic acids, and lipids. Various studies have shown that about 10% of the water in cells are bound to cellular components, rendering it incapable of freezing (Reviewed by [21]). As freezing occurs, the "free" water is removed from cells either by crystallization inside the cell or by moving out of the cell via osmosis through the semi-permeable membrane (due to hypo-osmotic conditions that occur with extracellular ice crystal formation) to crystallize extracellularly. Intracellular ice formation is the most likely cause of cryodamage, since it can rupture the cell membrane and displace or disrupt organelles. Therefore, it is desirable to dehydrate cells of their "free" water prior to freezing. This outward osmosis can be facilitated by using hypertonic freezing solutions and slow-cooling rates, which gives the water time to exit the cell as extracellular ice formation progresses. A direct consequence of dehydration is cell shrinkage, as the cell loses a significant part of its volume. In fact, cells will maintain equal chemical potential of the water inside and outside of the cell and therefore the cell volume is (in most cases) inversely proportional to the external osmolality [21]. Too rapid dehydration can cause physical stress on the membrane as it conforms to the reduced cytoplasmic volume. The same is true for too rapid rehydration, where cells swell up too rapidly and can literally burst like a balloon. This happens because during osmotic shrinkage, hydrostatic pressure draws some extracellular solution containing permeating molecules into the cell to replace the water volume that is removed. Thereby, some of the physical stress on the membrane is relieved. Thus, if a cell is inserted into a hypertonic solution, one will witness shrinkage followed by re-expansion to its original volume, as long as the solutes responsible for the high extracellular osmolarity are membrane permeable. When rehydration occurs too quickly, these replacement solutes may not have enough time to leave the cell as water moves back in before the critical volume is reached and the cell membrane gets overstretched, causing the cell to burst.

Membrane damage during freezing also occurs when intracellular ice crystals form before complete shrinkage of the cell. As ice forms, solutes in the remainder of the intracellular water cause its freezing temperature to decrease, thereby allowing further dehydration and cell shrinkage and the membrane closing in on the sharp ice crystals. This can be detrimental, since ice crystals can puncture the membrane as the cell volume continues to decrease. It is therefore crucial to not only remove as much water as possible prior to freezing but also to allow complete equilibration of the extracellular and intracellular solutions to increase the volume that will remain inside the cell and prevent the membrane from closing in on the ice crystals. This can be accomplished by high concentrations of permeable solutes in the freezing medium combined with a slow-freezing rate.

Another proposed source of freeze damage is excessive dehydration that occurs as the osmolarity of extracellular fluid increases when water is removed by ice formation. Some studies suggest that there is a maximum level of shrinkage that a cell can withstand before being damaged, and when this point is superseded during freezing, cell injury occurs [22].

There are indications that cryodamage can also result from the increased concentration of electrolytes that accompanies the "free" water crystallization, independent of the physical damage by ice. Basically, the same mechanisms that cause red blood cells to hemolyze at high salt concentrations apply. A review about this mode of damage and its variants can be found in [23].

Apart from the above discussed bursting of cells that dehydrate too quickly, thawing presents another set of challenges. In fact, some studies suggest that the majority of cryoinjury occurs during the thawing rather than the cooling process, due to recrystallization of small ice crystals into larger ones [21]. This is especially true with slow rates, which allow enough time for this ice crystal growth.

Much disagreement exists on which is the best method of thawing, which essentially represents the rate of warming. However, published works demonstrate that the ideal warming rate greatly depends on, and is proportionate to, the cooling rate that was used during freezing. Furthermore, the cell type, cryoprotectants used, and freezing technique also affect the warming method that will lead to the highest post-thaw survival rates.

56.3 Components of Slow Embryo Freezing

56.3.1 Cryoprotectants

Cryoprotectants are molecules that prevent cryodamage by reducing intracellular ice crystal formation. Their sole purpose in freezing protocols is to protect the cells from cryodamage by preventing the events described above. Two types, permeating and non-permeating cryoprotectants, are typically used in combination to dehydrate (non-permeable) and equilibrate (permeable) cells prior to freezing. The rate of diffusion of permeable cryoprotectants into the cell is slower than the rate of water exiting through osmosis, which necessitates some time for equilibration until the original cell volume has been restored. Once inside the cell, these agents prevent ice formation by lowering the freezing temperature of the cytoplasm. There are additional theories regarding the mode of protection of cryoprotectants, with strong arguments for all of them.

Some studies suggest that permeable cryoprotectants act as replacement diluents to keep relative electrolyte concentrations low when water is removed from the cytoplasm or freezing medium, thereby protecting them from high solute concentrations [24]. Others argue that they substitute the lost water fraction to keep shrinkage to a minimum and increase the unfrozen volume of the cell during freezing and thawing. Yet another school of thought is that cryoprotectants interact with phospholipids in the membrane bilayers to make them more stable. Then there is the fact that cells frozen in media without cryoprotectants are pushed into channels between forming ice crystals, while those that contain cryoprotectants in the media are encapsulated within the ice, with the latter scenario apparently less damaging. Despite the disagreements about the exact modes of protection, it is agreed that these agents are an essential component of freezing solutions. The usability of each ingredient depends on its toxicity to cells, which played a big part in optimization of freezing media for specific cell types.

Today, the most commonly used ingredients for slow-freezing human embryos are permeating 2,1-propanediol and dimethylsulfoxide for cleavage stages and glycerol for blastocysts, whereas sucrose is typically the non-permeating additive. An extensive overview of the various available cryoprotective agents and their use can be found in [25].

56.3.2 Media Formulations and Procedures

As discussed above, numerous different cryoprotectants can assist in protecting embryos against cryodamage when used appropriately. Consequently, there are various medium formulations that can lead to success. Typically, freezing medium consists of a base medium, such as M199, buffered with 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES) and supplemented with either one or a combination of permeating and/or non-permeating cryoprotectants. Commercial freezing media companies keep their formulations confidential, and they may be based on more complex media corresponding to the rest of the manufacturer's media series. However, the basic formulations of commercial brands are pretty standard and all based on published slow-freezing/thawing formulations as described above.

Conditions exerted on the embryo by these media can be detrimental if they are not introduced slowly. Therefore, cryoprotectant concentrations are usually increased systematically via a stepwise equilibration technique, allowing water to exit the cell and simultaneously allow cryoprotectants to diffuse into the cell gradually. Usually, the first solution will contain permeating cryoprotectants such as propylene glycol and DMSO, while the final freezing medium will contain a higher cryoprotectant concentration (1.0–1.5 M) and sucrose (0.1–0.3 M). Some protocols, however, use a one-step equilibration method with equally successful results, but its effectiveness depends on the species and embryo stage. Equilibrium is reached when the osmotic and chemical gradients caused by water and cryoprotectants inside and outside the cell membrane disappear. Equilibration and loading are then usually performed at room temperature to minimize cytotoxic effects of the cryoprotectants.

Once equilibration is complete, usually after 5–15 min, the embryos are loaded into a cryopreservation carrier. For slow freezing, the most commonly used devices are plastic straws that can be heat sealed after loading. They typically accommodate 0.25–0.5 mL of medium in which the embryos are suspended. It is a standard procedure to include two small air bubbles, one before and one after the section that

will include the embryos, to assist in locating the embryos upon thawing. Cryogenic vials, similar to those used for freezing somatic cells, as well as glass ampoules, have also been used successfully. Each of these has been designed to fit into an automatic, controlled-rate cooling device that carefully regulates the rate of cooling. This, however, can also be achieved by carefully layering the straws/vials at a specific distance above liquid nitrogen vapor. Naturally, the latter is less precise and much more labor intensive.

Initially, the freezing solution containing the embryos is cooled from room temperature, at a rate of 1–3 °C/min, to a slightly super-cooled state between −5 and − 7 °C. Then, seeding is initiated either manually or automatically to start crystallization in a controlled manner and prevent further super-cooling. Subsequently, the cooling process is maintained at a reduced rate of 0.3–0.5 °C/min to below −30 °C. Finally, the embryos are cooled to −180 °C at 40 °C/min before submersion in liquid nitrogen. Some protocols omit the final cooling phase and require liquid nitrogen submersion once the embryos have reached temperatures below −30 °C.

The thawing procedure can be as detrimental to embryo survival as freezing, since re-crystallization may occur in the small time window during which the liquid will transition through the melting temperature. To prevent this, high warming rates are applied. Typically, straws, vials, and ampoules are thawed either in air at room temperature or in a warm water bath at 37 °C. Once the freezing solution is completely melted, embryos are removed from the carrier and transferred into a diluent solution. This usually consists of the same medium used for freezing but without the permeating cryoprotectives and the same concentrations of sucrose to remove the permeating cryoprotectants. Rehydration is then achieved by decreasing the sucrose concentration systematically, usually in one or two steps, until all sucrose is removed from the medium. Embryos are subsequently returned to the incubator for conventional embryo culture after the final wash.

Immediate evaluation of survival is achieved visually by assessing the status of the cell membranes. In cases where embryos are cultured after thawing, the developmental competence and blastocyst re-expansion could be indicative of a successful freeze-thaw.

56.4 Factors that Determine Success

56.4.1 Embryo Stage

Over the years, research has indicated that embryos at different stages have different tolerance to cryopreservation. The reasons why embryos sometimes survive freeze-thaw better at one stage than another is not clear. Instinctively, from what we know of the effect of surface-volume ratio on cryopreservation success (for review, see [21]), we may assume that blastocysts will be most tolerant, followed by morulae, cleavage stage, and lastly zygotes, based on the size of the individual blastomeres at these respective stages. However, data clearly showed that embryos at the two-pronucleus (2PN) stage are no less tolerant to freezing and thawing than any other stage [26–28]. This becomes more baffling when one considers how challenging oocyte freezing has proven to be. Clearly, the difference in freeze tolerance encompasses more than just the volume of the individual blastomeres. So far, there is no single embryonic stage that is definitely superior in terms of outcome for a frozen embryo transfer (ET) cycle [29]. The parameters associated with assessment of success in embryo freezing are predominantly survival, subsequent development, and implantation. However, results were inconsistent when the survival rates of pronuclear versus multicellular (Day 2 and Day 3) stage frozen-thawed embryos were compared [27, 30]. Therefore, there is still no consensus as to which embryonic stage is superior for freezing tolerance, and the decision of freezing stage now primarily depends on the IVF program's management and individual patient cycle parameters. Nonetheless, it is beneficial to know the advantages and disadvantages of all embryonic freezing stages, which will be discussed below.

56.4.1.1 Pronuclear Stage

Slow freezing at the pronuclear stage has been widely used to cryopreserve human embryos, because it gives consistent survival and subsequent development after thawing [26–28]. One major advantage is that the possibility of future embryo biopsy and/or transfer at any stage is reserved when embryo freezing is performed at the pronuclear stage. The pronuclear stage embryo, however, has only one cell, which means embryo survival is either all or nothing. Furthermore, embryo quality cannot be assessed before freezing like in the case with more advanced stage embryo freezing, since the only measurable quality parameter at this stage is the presence or absence of pronuclei, and zygote scoring may not be as predictive as cleavage or blasotcyst-stage assessment. After thawing, pronuclear stage embryos are typically cultured for at least one, but usually more days to Day 3, 5, or 6, to obtain more data for embryo selection prior to ET. This requires a good number of embryos, enough to obtain the desired number of acceptable blastocysts for ET and potentially refreezing.

56.4.1.2 Cleavage Stage

Traditionally, the majority of embryo cryopreservation was performed using propanediol and sucrose to slow-freeze at the cleavage stage [31]. Survival rates of 60–88% were reported [32–34]. At cleavage stages, the widely accepted criterion for embryo survival in a clinical situation is survival of a minimum of 50% of the original blastomeres. Often, some necrotic blastomeres are present after thawing due to cryodamage. It was therefore suggested to remove those necrotic cells before subsequent culture or ET. We will discuss lysed cell removal (LCR) in subsequent paragraphs. In summary, the main advantages of freezing at the cleavage stage are that embryo cleavage potential has been confirmed before freezing, while cryodamage can be confined to individual blastomeres instead of the entire embryo, as would be at the 2PN stage. Furthermore, it preserves the opportunity to do a

Day-3 biopsy for genetic screening. It should be mentioned that the past few years have seen a dramatic shift in clinical IVF practices to predominately performing single blastocyst transfer, often in conjunction with blastocyst biopsy for preimplantation genetic screening and vitrification, and subsequent frozen-thawed embryo transfer of only euploid embryos.

56.4.1.3 Morula Stage

From all the preimplantation developmental stages, the morula has received the least amount of attention for cryopreservation and ET. However, reports of good outcomes with these procedures at the morula stage exist and the advantages cited for performing them at this stage include better selection than cleavage stages and safer assisted hatching due to the large perivitellin space [35–37]. The reason for the neglect is not due to poor results but due to its intermediate nature. Embryos are typically transferred on Day 3, at the cleavage stage or on Day 5 at the blastocyst stage. Whether embryos will be transferred on Day 3 depends on the number and quality. The advantage of extended culture is the ability to select embryos more extensively based on their developmental and differentiation potential, as well as the ability to do trophectoderm biopsy, which has become the preferred biopsy stage. However, if a patient has too few embryos or they are of suboptimal quality, Day 3 transfers may still be performed. Therefore, should embryos be assigned for Day 5 transfer, there are probably enough good quality embryos to culture all the way to the blastocyst stage, which has better selection criteria than the morula stage. It is also beneficial to reduce handling and disturbance of the culture conditions, so quality assessment on Day 4 is omitted. Thus, although rarely used, morula stage cryopreservation is an option for clinics and its utilization depends on the transfer scheme of the individual clinics.

56.4.1.4 Blastocyst Stage

Although the early successes in embryo cryopreservation were achieved at the blastocyst stage [38, 39], embryo freezing at this advanced stage was not routinely used until recent years when blastocyst culture systems became optimized. Culturing embryos to the blastocyst stage creates more selection criteria for ET and cryopreservation, due to prolonged monitoring and a more differentiated state. It further allows IVF programs to maintain their pregnancy rates despite transferring fewer embryos [29] by elective single embryo transfer often paired with preimplantation genetic testing (PGT). Even though embryos could be selected before freezing, the degree of cryodamage that may occur is hard to predict. Resumption of development is also difficult to assess in cryopreserved blastocysts, since any increase in the number of cells is very difficult to verify, and the timeframe of re-expansion for blastocelic activity assessment varies greatly. Also, due to the epithelial-like nature of the trophectoderm and compacted blastomeres of the inner cellular mass, necrotic cells are more difficult to remove from the blastocyst, which may further impede normal development. Nonetheless, blastocysts have 5–6 days of developmental history that can help to determine, with post-thaw morphology, the overall quality of the thawed embryo.

56.4.2 Embryo Quality

Several studies have shown a correlation between embryo quality and freeze tolerance. Typically, cleavage stage cell divisions are synchronized, resulting in an exponential cell number at any point before the morula stage. Non-exponential blastomere numbers are therefore indicative of asynchronous divisions, fragmentation, or degeneration of some of the blastomeres, which are all indicators of inferior embryo quality. Correspondingly, it was shown that embryos with 3, 5, 6, and 7 cells had significantly lower post-thaw survival rates than 2-, 4-, and 8-cell embryos [40–42]. A similar observation was made in the bovine model, where blastocysts of high quality survived freezing better than those of lower quality [43]. Interestingly, Check et al. [44] reported that four-cell embryos had a similar freezing tolerance to six- to eight-cell embryos, suggesting that a slower developmental rate is not included in the quality parameters that affect freeze survival [43]. Although the above-mentioned studies indicate that lower grade embryos are less prone to survive freezing, embryologists may still choose to freeze these inferior embryos to maximize the patient's number of transferable embryos in a given cycle, especially if the other quality parameters are acceptable for transfer before freezing.

56.4.3 Lysed Cell Removal

At the cleavage stage, the widely accepted clinical criterion for embryo survival is a minimum of 50% survival of the original blastomeres. However, necrotic blastomeres resulting from cryodamage are often present after thawing in embryos that are still in the acceptable survival range. These blastomeres can be removed using a technique called lysed cell removal (LCR), during which the cryodamaged blastomeres are aspirated from the embryo (see ◘ Fig. 56.1). One study found that after cryopreservation "the percentage of gestational sacs with fetal heartbeat obtained after transfer of fully intact embryos was almost three times higher than that after transfer of partially damaged embryos" [45]. The authors speculated that lysed blastomeres might produce factors as they degrade that are detrimental/toxic to undamaged cells. Additionally, lysed cells could potentially disrupt cell-cell communication between viable blastomeres. Studies in the mouse model demonstrated that LCR can restore developmental potential [46] and promote frozen-thawed embryonic development [47]. Lysed cell removal has also been used following human embryo cryopreservation at multicellular stages, and results showed that it could significantly improve clinical outcomes [48–50]. It should be noted that in the mentioned experiments, assisted hatching was performed in conjunction with LCR, a practice that was also

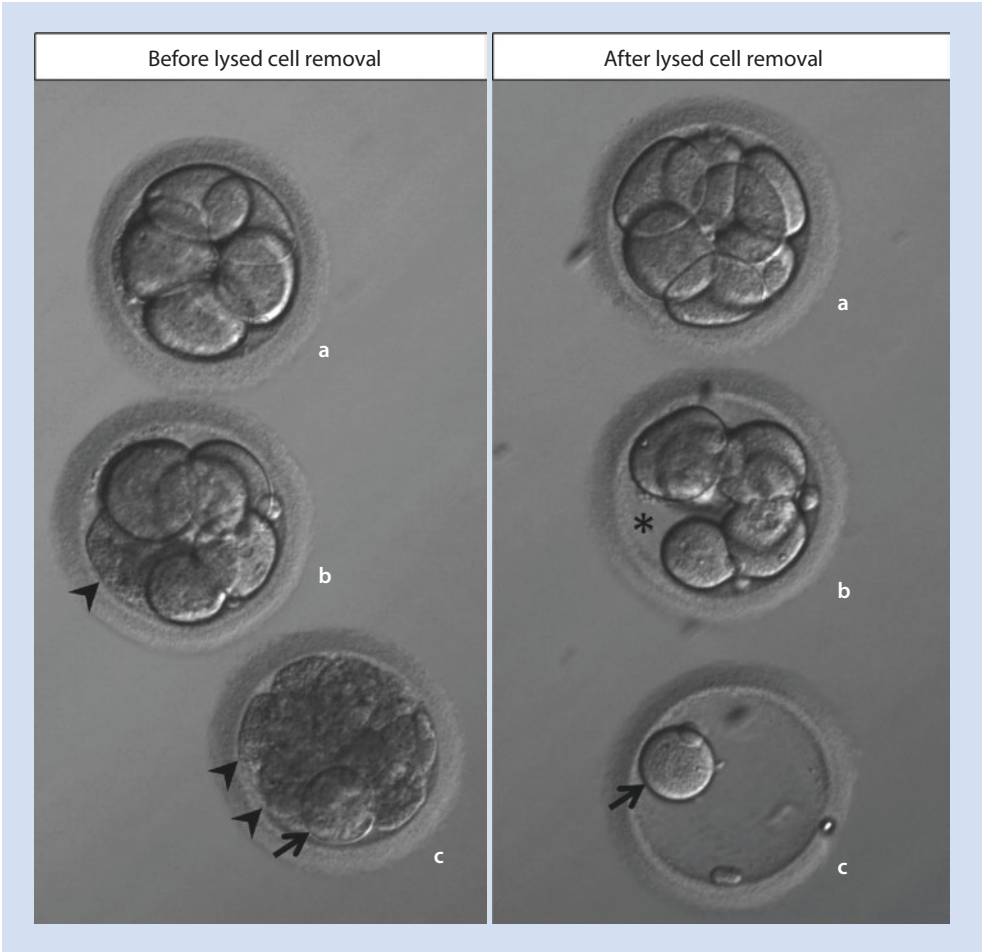

Fig. 56.1 Cleavage stage (Day 3) human embryos after slow freezing and thawing. Three embryos (**a**–**c**) are shown before (left panel) and after (right panel) lysed cell removal (LCR). Embryo **a** had no lysed cells after thawing. Embryo **b** was partially lysed (arrowhead), and these cells were removed as seen in the space present after LCR (asterix). Since only one or two cells were lysed (<50%), embryo **b** survived and is suitable for transfer. Embryo **c** had only one intact cell (arrow) after thawing, while the rest were all lysed (arrowheads) and removed. Embryo **c** therefore did not survive freezing and thawing and is not suitable for transfer

shown beneficial after vitrification and warming [51] and will be discussed in the next section. In conclusion, removal of degenerated blastomeres is a relatively simple procedure that can significantly impact implantation and pregnancy rates after cryopreservation, especially with slow freezing.

56.4.4 Assisted Hatching

Several reports have claimed that assisted hatching by thinning, breaching, or completely removing the zona pellucida prior to fresh ET significantly improves implantation and chemical pregnancy rates (for recent review, see the publication by The Committee of the Society for Assisted Reproductive technology and the Practice Committee of the American Society for Reproductive Medicine [52]). Various effective techniques have been described, including acid Tyrode's solution drilling/thinning [53], mechanical partial zona dissection [54], laser drilling [55], piezo drilling [56], enzymatic zona digestion [57], and most recently mechanical zona expansion through hydrostatic pressure [58]. Although the exact alterations that occur in the zona ultra-structure as zona hardening occurs remain elusive, oocyte exposure to cryoprotectants and freezing was shown to induce cortical granule exocytosis, zona delamination, and zona fractures [59, 60]. Similar structural changes may occur during embryo freezing, and these alterations in zona structure may prevent zona thinning and subsequent embryo hatching. Studies have demonstrated that assisted hatching following cryopreservation indeed improved implantation and pregnancy rates [61, 62]. Therefore, it is a common practice to perform assisted hatching in post-thawed embryos. Although conflicting study results and disagreement exist on the benefit for fresh ETs, the most common opinion currently is that the possible advantages of employing it for frozen-thawed ETs exceed its minute risks, and thus assisted hatching is typically performed on frozen-thawed embryos.

56.4.5 Additional Considerations

Several other factors may affect embryo survival after freezing, and those discussed below are by no means exclusive.

The technique used during execution of the freezing protocol may severely affect the success rate. One example is performing the stepwise equilibration method in a timely manner with gentle handling of the embryos to prevent mechanical damage during loading. It is thus important that technicians are properly trained to perform all the procedures the correct way.

When embryo biopsy is performed for preimplantation genetic diagnosis, embryos are subjected to crude mechanical

disruption, especially in the case of blastocysts. Although the majority of embryos recover from well-executed biopsies, the overall embryo tolerance is affected, thereby decreasing its likelihood to survive freezing and thawing [63]. However, when patients order genetic screening, embryologists have no choice but to perform biopsy and subsequent cryopreservation. Therefore, each case should be considered individually based on the total number and quality of embryos, as well as the importance of the genetic diagnosis.

Transportation of embryos has become an integral part of our field, not only to move embryos with a patient, if they relocate and switch clinics, but also for donation and adoption programs. Proper transportation technique that insures that embryos are not exposed to temperatures that can alter the frozen/vitrified stage is of utmost importance for subsequent survival during thawing. One major benefit of slow freezing is a higher tolerance to accidental warming, due to the significantly larger volume embryos are frozen in, as well as larger devices that can better maintain temperatures during fluctuations. This may be a consideration for embryo and gamete banks that ship large numbers of embryos across the nation and/or globe.

56.5 Applications and Impact

Cryopreservation of human embryos was introduced more than three decades ago, mainly as an approach to save supernumerary embryos produced and stored after ovarian hyper stimulation [16, 38, 39, 64]. The Society for Assisted Reproduction Technology (SART) and the European Society of Human Reproduction and Embryology (ESHRE) both continuously publish statistics on embryo freezing and birth rates in the USA and Europe, respectively. These are valuable data sources for seeing the overall impact of cryopreservation on clinical infertility treatment. However, the data does not distinguish between methods of freezing, rendering it impossible to determine the current success rates resulting from slow freezing alone or vitrification. Moreover, with the rapid decline in utilization of the somewhat outdated slow-freezing procedure, it is unlikely that we will see a significant number of publications on slow cooling in the future. Since vitrification is becoming more widely used, the weight that slow freezing has on overall IVF cryopreservation outcomes is likely decreasing significantly each year, as more clinics are switching over to vitrification for reasons discussed below. Therefore, we will briefly look at the impact of embryo cryopreservation as a whole.

In Europe, ESHRE reported almost 460,000 in vitro cycles in 2006, of which more than 15% were frozen ETs [65]. In 2012 (the latest available data), these numbers increased to 22% frozen transfers of over 640,000 cycles [66]. In the USA, since the publication of the first edition of this textbook, SART data indicated that although the percentage of FETs has remained roughly unchanged at about 18%, the total number of reported IVF cycles has steadily increased annually to about 188,000 cycles in 2014. About 5000 embryo banking cycles for fertility preservation were also performed (► www.sartcorsonline.com). Since many practices currently still use slow freezing and most practices perform slow-cooling procedures on a regular basis from embryo donations or embryos frozen in prior years, the impact of this technology on infertility treatment is still relevant.

One of the most common reasons a patient may opt for embryo freezing is to preserve excess embryos that were not transferred during the fresh cycle. The advantage of this is that the patient's chances of getting pregnant from a single egg retrieval significantly increases as she can have multiple embryo replacements without having to transfer more than one embryo in a single transfer. This reduces her risk of a multiple pregnancy and thus various complications.

A major drive toward elective single ET (eSET) in the field is further increasing the importance of embryo cryopreservation, allowing the patient additional opportunities for pregnancy should her first eSET not result in one. Furthermore, legislation in some European countries limits the number of embryos that can be transferred. In Germany, for example, it is illegal to culture more than three embryos from one cycle at a time, and every generated embryo must be implanted. Freezing extra embryos at the 2PN stage provides an alternative method to utilize the retrieved eggs to its full potential instead of only continuing with three fertilized eggs, as 2PNs are not considered embryos. Embryo freezing thus provides a way to store the extra embryos and makes it unnecessary for the patient to go through an entire stimulation and retrieval again and again.

Another instance in which a patient may want to freeze embryos is when the ET is cancelled due to hyperstimulation. Historically, before freezing became available, this condition required cancellation of the entire treatment cycle and loss of the embryos. Since effective embryo freezing became an option, the patient can simply return in subsequent months for frozen embryo replacements without feeling tempted to put herself at risk by having a transfer anyway.

Preimplantation genetic testing (PGT) has become a routine procedure with many clinics performing it on 100% of their patients (for a recent review, see [67]). The rapidly growing stage of choice for biopsy is Day 5/6 blastocyst, although many labs still perform day-3 blastomere biopsies, likely due to the requirement of a laser system for trophectoderm biopsy, which is a significant expense for smaller IVF labs. Although some genetic reference labs offer results in time for a fresh Day-6 transfer following a Day-5 trophectoderm biopsy, the vast majority of PGT cycles include freezing of all embryos following biopsy.

Due to a significant increase in successful eSETs coupled with highly efficient cryopreservation techniques, more and more patients may have embryos left over after delivering the desired number of babies. Many patients have ethical objections to discarding remaining embryos. A viable option for these patients is frozen embryo donation. In doing so, those patients who failed to conceive naturally or by in vitro

techniques, while eliminating the financial burden of storing embryos. Several embryo donation and adoption agencies exist, which include embryos frozen years ago by slow-freezing. Any clinic that offers donor embryo replacements from such programs are thus required to have a thorough understanding and technical training in thawing of slow-cooled embryos.

56.6 Open Versus Closed Systems

One issue that has received significant attention in the past few years is that of safety of cryopreservation for the recipient as well as the resulting babies born from these embryos. The most cumbersome is transmitted diseases, especially viruses. There are very strict regulations for egg, sperm, and embryo donations, and the donors are screened vigorously before being classified as eligible for donation. Furthermore, there have not been any reports of patients contracting diseases from frozen ETs. However, a growing concern is prompting development of closed systems for storage, where the embryos or cryomedia are never in direct contact with liquid nitrogen. This especially applies to vitrification techniques. Slow freezing is typically performed in sealed straws, ampoules, or cryovials, which all presumably prevent this exposure to potentially contaminated liquid nitrogen. Therefore, as long as the freezing carriers are used correctly, the risk of contamination of slow-frozen embryos remains dismissible. Thus, one of the most significant advantages of slow-freezing vessels is that they are completely sealed and, if used correctly, exclude any contact with liquid nitrogen (excluding what may condensate from air inside the vessel). The caveat of sealed straws and vials is that the larger volume does not allow vitrification with the current protocols and medium formulations, so slow freezing is the only reliable option when using these closed-system devices. Most vitrification systems, on the other hand, traditionally require placing the embryo on a carrier device, such as a thin membrane, with minimal amount of medium, followed by direct submersion in liquid nitrogen. These systems are highly criticized for exposing embryos to potentially contaminated fluids and storing them in communal dewars, where the risk of cross-contamination, albeit theoretical, is of concern. There are a few companies that are marketing closed-system vitrification equipment, but traditionally the higher cooling rate of these systems have been thought to yield inferior results compared to open vitrification systems.

56.7 Slow Freezing Versus Vitrification

Many factors are causing clinics to switch to vitrification instead of traditional slow freezing. Several studies suggest that vitrification results in significantly higher survival and developmental rates than slow freezing [19, 20, 68, 69]. As mentioned above, other studies failed to demonstrate a significant difference [17, 18]. A further driving force for the increased use of vitrification is the practicality of the technique. Apart from being much more cost-effective, the procedure requires significantly less time (typically about 20–30 min total) when compared to the long equilibration methods required by typical slow-freezing protocols (around 1.5–2 h). Thawing following these techniques also differs greatly, with warming a vitrified embryo taking about 15 min, versus approximately 45 min for slow-frozen embryos.

Despite these advantages of vitrification, some labs still use slow freezing, mainly because of the wealth of clinical data that supports the technique. Furthermore, recent reports on a modified, one-step slow-freezing protocol based on higher sucrose concentrations found no differences in thaw survival or subsequent outcomes between this altered slow-cooling and vitrification techniques, which significantly reduce the amount of time to complete the procedure. Paired with a less technically challenging method and a lower transportation risk that comes with larger volume vessels such as straws and vials, some labs may opt to keep using slow cooling as their primary choice for cryopreservation. Furthermore, switching a well-established, effective method for a new protocol seems intimidating, thereby preventing implementation of newer technologies in some more traditional labs. Although the number of labs that use vitrification has been steadily increasing, slow-cooled embryos are likely to be part of our field for the foreseeable future.

56.8 Legal and Ethical Considerations

The ability to store embryos for an indefinite amount of time brings up all sorts of ethical and legal issues. First and foremost, ownership of embryos has to be determined before patients that are interested in freezing are admitted to the treatment plan. This becomes very important when couples separate after freezing their embryos. It can also be an issue where family members may want ownership of leftover embryos. Patients should seek legal consultation to decide and clearly document what happens to their embryos in any of such circumstances.

Another troublesome issue for patients is that of discarding extra embryos. Often, patients are against destroying embryos but do not want any more children and also do not feel comfortable donating their embryos. These patients are left with no other option than to continue storing the embryos with the associated costs. Clinics may have difficulty collecting payments from patients after years of storage, and legally, clinics are not authorized to destroy embryos without patient consent. This can be a large burden on IVF programs, especially those with large frozen embryo collections, often from many years ago. The best way for clinics to prevent this situation is to give proper patient guidance on the subject and keep thorough records of patient consent forms before treatment begins.

56.9 Future of Slow Freezing in Cryopreservation

Embryo cryopreservation has become such an integral part of infertility treatment that it is hard to imagine that the first successful freezing and thawing of a human embryo was just over 30 years ago [16]. Slow freezing has undoubtedly played the most prominent role in embryo cryopreservation. However, because of discussed factors, vitrification is becoming the method of choice for more and more clinics, and it is only reasonable to expect that within the next decade, slow freezing for embryo preservation may be completely replaced by vitrification, despite several advantages of the technique as discussed above. Nonetheless, at the moment, many groups still rely on this much older technology for preserving embryos at all different preimplantation stages. Furthermore, slow freezing is routinely used for preservation of spermatozoa, somatic cell lines, and tissue biopsies. Therefore, although embryo cryopreservation may continue without this technology, the vast majority of clinical-freezing applications will continue to benefit from slow freezing.

Review Questions

1. What accidental discovery resulted in the first successful cryopreservation of sperm?
2. What is the most likely cause of cryodamage?
3. What are two different *types* of cryoprotectants and how does each of these prevent cryodamage?
4. What are the primary advantages and disadvantages of freezing embryos at 2PN, cleavage, and blastocyst stages, respectively?
5. How does embryo quality affect freeze/thaw survival?
6. What are the advantages and disadvantages of slow freezing vs vitrification?

Vitrification of Embryos

Juergen Liebermann

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_57

Learning Objectives

- To provide a brief overview of the principles, purposes, and goals of cryopreservation of embryos
- To discuss vitrification technique proving step-by-step protocols with special notes for the clinical embryologist
- To provide data supporting the successful application of embryo vitrification at the blastocyst stage

57.1 Brief Background

57.1.1 Principles and Purposes of Cryopreservation of Human Embryos

Since the announcement in 1972 of the survival of mouse embryos after cryopreservation at −196 °C [1], the impact of cryopreservation on the growth and improved efficiency of assisted reproduction in humans has become increasingly appreciated. Moreover, cryopreservation has also been shown to increase overall pregnancy rates while allowing for further selection of embryos. Indeed it is possible to achieve implantation and pregnancy rates with frozen-thawed embryos as high as those achieved with fresh embryos. Routine in vitro blastocyst culture and cryopreservation have been shown to increase pregnancy rates while allowing for better selection of embryos. With more reliable cryopreservation techniques, lower numbers of embryos are now being transferred, resulting in less high-order multiple pregnancies as well as increased healthy implantations.

The fundamental objectives for successful cryostorage of cells in liquid nitrogen at −196 °C can be summarized as follows:

1. Arresting the metabolism reversibly.
2. Maintaining structural and genetic integrity.
3. Achieving acceptable survival rates after thawing.
4. Maintenance of developmental competency post thaw.
5. The technique has to be reliable and repeatable.

57.1.2 The Vitrification Component

The major disadvantage of using cryostorage is that it can lead to crystallization of water and thereby can create new and unwanted physical and chemical events that may injure the cells that are being preserved. As early as 1985, ice-free cryopreservation of mouse embryos at −196 °C by vitrification was reported in an attempted alternative approach to cryostorage. Since then, vitrification techniques have entered more and more the mainstream of animal and human reproduction as an alternative cryopreservation method to traditional slow-cooling/rapid-thawing protocols. In addition, the last few years have seen a significant resurgence of interest in the potential benefits of vitrification protocols and techniques in human-assisted reproductive technologies. The radical strategy of vitrification results in the total elimination of ice crystal formation, both within the cells being vitrified (intracellular) and in the surrounding solution (extracellular). *Vitrification*, however, avoids ice formation altogether during the cooling process by establishing a glassy or vitreous state, wherein molecular translational motions are arrested without structural reorganization of the liquid in which the reproductive cells are suspended. The physical definition of vitrification is the solidification of a solution at low temperature, not by ice crystallization but by extreme elevation in viscosity during cooling [2, 3]. In general, vitrification solutions are aqueous cryoprotectant solutions that do not freeze when cooled at high rates to very low temperatures. In addition, the rate of cooling/warming and the concentration of the cryoprotectant required to achieve vitrification are inversely related. In addition, recent publications have shown the relatively greater importance of warming rate over cooling rates with regard to the survival of oocytes subjected to a vitrification procedure [4–6].

The earliest attempts using vitrification as an ice-free cryopreservation method for embryos were first reported in 1985 [7]. In 1993, successful vitrification of mouse embryos was demonstrated [8]. Furthermore, bovine oocytes and cleavage-stage embryos were vitrified and warmed successfully a few years later [9]. In 1999 and 2000, successful pregnancies and deliveries after vitrification and warming of human oocytes were reported [10, 11]. Since that time, and because it seems to be that both entities appear to be especially chill-sensitive cells in ART, blastocysts appear to have received a significant boost in survival rates by avoiding ice crystallization through use of vitrification [12].

Vitrification is very simple, requires no expensive programmable freezing equipment, and relies principally on the placement of the embryo in a very small volume of vitrification medium that must be cooled at extreme rates not obtainable in traditional enclosed cryostorage devices such as straws and vials.

It is important to mention that cryopreservation interferes without doubt with the intracellular and extracellular homeostasis and therefore poses a risk for inducing spindle abnormalities, chromatid nondisjunction, fertilization errors, and abnormal mitotic divisions during embryonic development. In addition, specific subcellular compartments containing accumulated transcripts and proteins necessary for spindle formation, epigenetic control, and chromosome alignment are also mandatory for proper spindle functionality. Although it is far too early to draw conclusions about the risk of imprinting mutations and birth defects after vitrification of oocytes and embryos, the current literature is reassuring. An increased incidence of imprinting diseases in live births after cryopreservation of oocytes and pre-implantation embryos has not been identified [13].

57.1.3 Cryoprotectant Agents

One "drawback" of vitrification considered by embryologists not familiar with the vitrification technique is the use of high concentrations of cryoprotectants, which does mean

that vitrification solutions are potentially more toxic than their counterpart solutions used for conventional slow freezing. This is necessitated by the practical limit for the rate of cooling and the biological limit of tolerance of the cells for the concentration of toxic cryoprotectants being used to achieve the cryopreserved state. It is important to note that recently published papers [14–17] have shown that the use of relatively high concentration of cryoprotectants, such as 15% (v/v) ethylene glycol (EG) used in an equimolar mixture with dimethyl sulfoxide (DMSO), had no negative effect on the perinatal outcomes from blastocyst transfers following vitrification when compared with those from fresh blastocyst transfers.

Cryoprotective agents (CPA) are essential for the cryopreservation of cells. Basically, two groups of cryoprotectants exist: (1) permeating (e.g., glycerol, EG, DMSO) and (2) non-permeating (e.g., disaccharides, proteins, and polymers) agents. The key component of a vitrification solution is the permeating agent. These compounds are hydrophilic non-electrolytes with a strong dehydrating effect. Furthermore, these CPAs are able to depress the "freezing point" of the solution. Additionally, these highly permeating cryoprotectants are also more likely to diffuse rapidly out of the cells, so that the cells quickly regain their original volume upon warming, thus preventing osmotic injury. The second component of a vitrification solution are the non-permeating CPAs such as disaccharides, for example, sucrose, which does not penetrate the cell membrane but helps to draw out more water from cells by osmosis and therefore lessen the exposure time of the cells to the toxic effects of the permeating CPASs. The non-permeating sucrose also acts as an osmotic buffer to reduce the osmotic shock that might otherwise result from the dilution of the cryoprotectant after cryostorage. Furthermore, permeating agents are able to bind with intracellular water, and therefore water is very slowly removed from the cell. During warming, using a high extracellular concentration of sucrose (e.g., 1.0 M) counterbalances the high concentration of the cryoprotectant agents in the cell, as it reduces the difference in osmolarity between the intra- and extracellular compartments. The high sucrose concentration cannot totally prevent the cell from swelling, but it can reduce the speed and magnitude of swelling [18–20].

57.1.4 Artificial Collapsing and Assisted Hatching

Most importantly, residual fluid in the blastocoel can reduce post-warming survival of embryos. Vanderzwalmen et al. [21] showed that survival rates in cryopreserved, expanded blastocysts could be improved by artificial reduction of the blastocoel cavity, and others consider that blastocoel collapse is necessary pre-vitrification on whichever day the blastocyst forms [21, 22] and the most effective strategy for promoting both permeation of cryoprotectant and dehydration [23].

Although one study has suggested that expanded blastocysts show no significant differences in viability, implantation potential, or pregnancy outcome when frozen on day 5 versus day 6 [24], our "body of data" [15–17] refutes the comparable implantation rates for blastocysts cryopreserved on day 5 or 6. And while there are several possibilities why day 6 blastocysts perform less well than day 5 blastocysts, one explanation could be that the older blastocysts are often more expanded with a significantly larger blastocoel impacting water loss and CPA absorption. Being mindful of previously published research on artificial collapse (AC) of blastocysts prior to cryopreservation, we looked for an opportunity that could potentially help us improve the outcome for day 6 blastocysts using AC of the blastocoel prior to vitrification. Because the concept showed improvement for the day 6 blastocysts, we applied to day 5 blastocysts that had well-expanded blastocoels.

AC of the blastocoel can be performed using different techniques, such as micro-needles, sucrose solutions, or lasers [25–30]. In 2003 and 2004, two groups independently reported a beneficial effect by applying AC to blastocysts prior to vitrification. Son et al. [25] observed an improved clinical pregnancy rate of 48% and an implantation rate of 29% with the use of AC. Hiraoka et al. [26] collapsed day 5 and day 6 blastocysts by manually pipetting embryos until they collapsed and achieved a clinical pregnancy rate of 50%, with an implantation rate of 33% after warming. Moreover, Mukaida et al. [27, 28] found that the survival rate of vitrified blastocysts was negatively correlated with the size of the blastocoel. They speculated that a large blastocoel may disturb the efficacy of vitrification. They collapsed the blastocoel by puncturing it with a micro-needle or by making a hole between two trophectoderm cells with a laser pulse. After applying AC, the survival improved from 86% to 97.2%. Moreover, their pregnancy rate went up from 34.1% to 60.2%, with an implantation rate of 46.7%. Iwayama et al. [29] used a laser pulse or osmotic shock resulting from exposure of the whole embryo to sucrose, and the implantation rate was significantly higher in both groups compared to the control group without AC (59.7% and 49.3% vs. 34.2%). Furthermore, Hur et al. [30] looked at the effect of AC, achieved using a 29 gauge needle or laser pulse, on clinical outcomes in fresh transfers, and they observed a significant increase in the clinical pregnancy in the study group compared to the control group (58.8% vs. 39.0%). All publications mentioned, including Liebermann and Conaghan [31] and Liebermann [32], conclude that AC has a beneficial effect both in frozen blastocyst transfers and for overall cumulative pregnancy and implantation rates. A recent study by Kazemi et al. [33] assessed the effect of pre-vitrification blastocoel fluid reduction on the survival, hatching rate, and the expression of genes related to apoptosis (*Tp53*), pluripotency (*Pou5f1*, *Nanog*), and differentiation (*Cdx2*, *Eomes*, *Gata6*) in mouse blastocysts. The survival rate of treatment groups was similar to the control group, whereas the hatching rate of artificial collapse/vitrified blastocysts was significantly higher than vitrified blastocysts.

Quantitative reverse-transcription PCR analysis revealed a considerable reduction in the expression of *Cdx2*, *Eomes*, *Gata6*, *Grb2*, and *Tp53* transcripts following artificial collapse/vitrification in comparison to the vitrification-alone group; the abundance of *Pou5f1* and *Nanog*, however, did not change. The authors concluded that artificial collapse of the blastocoel cavity before vitrification leads to relatively normal expression of apoptosis and development-related genes plus higher hatching rates.

Because of the post-thaw phenomena called "zona hardening" [34, 35] and based on recently published data [36], all thawed embryos underwent assisted hatching using a laser by removing about a third of the zona pellucida.

Warming of blastocysts occurred 1–2 h prior transfer. Both natural and hormone replacement cycles were used to increase the receptivity of the endometrium. Progesterone was supplemented on day 15 of the cycle, and blastocysts were warmed on day 6 of progesterone supplementation.

57

57.2 Brief Overview of Method

57.2.1 Materials

1. HSV (High Security Vitrification Kit) (Catalog # 022137; Cryo Bio System)
2. Heat Sealer (Cryo Bio System)
3. Polycarbonate micropipettes, 275 μm end hole (MidAtlantic Diagnostics# KFPIP-1170-10BS)
4. Brady labeler (TS 2000)
5. Brady labels (PTL-19-427)
6. 90 × 15 mm petri dish (Nunclon # 150362)
7. Center-Well Organ Culture Dish (Falcon 3037)
8. Styrofoam container
9. Visotubes 10 mm (IMV 5561)
10. Cryo Canes aluminum (Thermo Scientific 5015–0001)

57.2.2 Reagents

1. Serum Substitute Supplement (SSS) (Irvine)
2. Wash solution as a part of the Thaw Kit (Irvine)
3. Vit Kit – Freeze (Irvine Scientific #90133DSOC)
4. Vit Kit – Thaw (Irvine Scientific # 90137DSOC)

57.2.3 Equipment

1. Dissecting stereo microscope (Olympus SZX-12, Bausch Lomb or Leica) with warming stage
2. Laminar flow hood (Origio)
3. Inverted microscope (Olympus IX-71)
4. Infrared 1.48 μm diode laser (Hamilton Thorne – LYKOs laser (Hamilton Thorne Research, Beverly, MA)

57.2.4 Methods

57.2.4.1 Stepwise Blastocyst Vitrification Procedure

Vitrification of blastocysts is undertaken utilizing a "closed system" (HSV, High Security Vitrification Kit; Cryo Bio System, L'Aigle, France; FDA 510(k) clearance for cleavage-stage embryos in blastocysts) (*see* Notes 1 and 2) after a two-step loading with cryoprotectant agents at 24 °C (*see* Notes 3 and 4). If assisted collapsing (AC) is done prior to vitrification, then the blastocyst is put on an inverted microscope equipped with a laser system (LYKOS, Hamilton Thorne), the junction of two trophectoderm cells in each blastocyst is located, and one shot (100% power, 500 μs pulse length) is applied to the cell junction. The blastocyst is then moved back in the incubator for 5–10 min. Briefly, blastocysts have to be placed in equilibration solution, which is the base medium (M199) with 20% Serum Supplement Substitution (SSS) containing 7.5% (v/v) ethylene glycol (EG) and 7.5% (v/v) dimethyl sulfoxide (DMSO) (see Table 57.1). After 8 min, the blastocysts need to be washed quickly in vitrification solution, which is the base medium containing 15% (v/v) DMSO, 15% (v/v) EG, and 0.5 M sucrose, for 60 s and transferred onto the HSV using a micropipette. Immediately after the loading of not more than two blastocysts in less than a 1 μL drop on the HSV, the straws are heat sealed, then plunged in LN2, and finally stored inside 5 mL liquid nitrogen prefilled canes (Visotube Rond, IMV, France). Each single step is described in detail below:

1. Aseptic techniques are required at all stages. For equilibration and vitrification procedures, ensure the benchwarmer is at room temperature (~24 °C) (*see* Notes 3 and 4).
2. Take reagents from the refrigerator and allow them to warm to room temperature.

Table 57.1 Summary of vitrification and warming solutions (Irvine Vit Kit "Freeze" and "Warm")

	Composition		
	Ethylene glycol (%)	DMSO (%)	Sucrose (M)
Equilibration solution (ES)	7.5	7.5	0
Vitrification solution (VS)	15	15	0.5
Warming solution (TS)	0	0	1.0
Diluent solution (DS)	0	0	0.5
Wash solution (WS)	0	0	0

M-199 + 20% SSS [wash solution, WS]

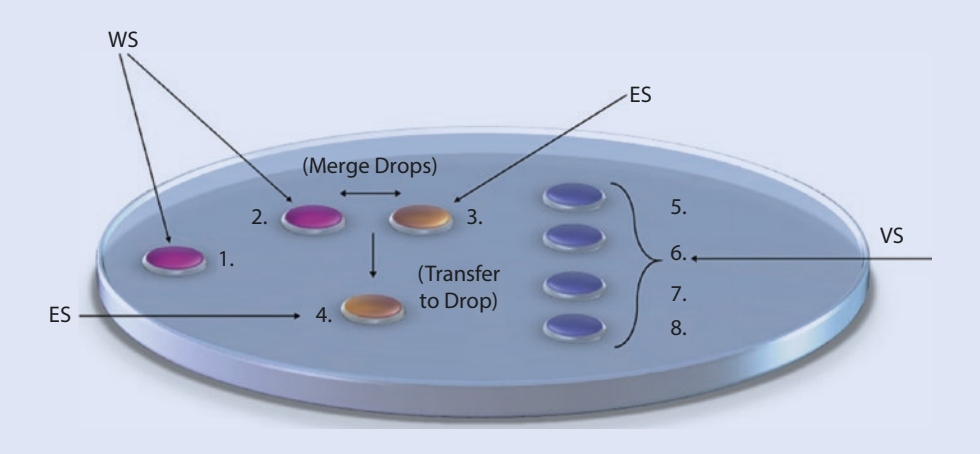

Fig. 57.1 Setup for the vitrification procedure on a plain 90 mm dish lid surface (ES, equilibration solution; VS, vitrification solution; WS, washing solution)

3. Move blastocysts to freeze into a separate well. Bring this dish to the inverted microscope, and with the embryo positioned with the laser objective, use a single pulse to hit the blastocysts between two trophectoderm cells to collapse the embryo. Place the dish back into the incubator for 5 min.
4. Label a petri dish with the patient's name under the lid as follows: washing solution (WS), equilibration solution (ES), and vitrification solution (VS). Prepare 2 × 50 µL of WS, 2 × 50 µL of ES, and 4 × 50 µL of VS (*see* Fig. 57.1).
5. Brady label should include the patients' last name, first name, accession number, medical personal identification [MPI] number, date plus number, and type of embryos.
6. Before vitrification, use a stripper tip with 275 µm end hole for loading the blastocysts on the top.
7. Fill Styrofoam container with LN_2.
8. Each sample that is vitrified will be done in a separate hood and verified by a second embryologist before proceeding. Vitrify good expanded/hatching blastocysts on days 5/6/7.
9. Remove embryos from culture dishes using a stripper tip into the WS (drop 1), gently aspirating to remove any residual culture medium.
10. Pipette from WS (drop 1) to the other drop of WS (drop 2), and immediately merge it with the first drop of ES (drop 3). Set the timer for 5 min.
11. After 5 min, transfer the embryos to the remaining drop of ES (drop 4). Set the timer for 3 min. Place the embryos on the top of the drop and let them settle to the bottom.
12. Then load the blastocysts in a VS back-loaded stripper tip, and rinse through the four droplets of VS (drop 5–8), and between each droplet, clean the tip.
13. Placement into the VS and loading of the HSV should take *less than 1 min*, so that the total incubation time in VS is 30 sec. After 30 sec, gently transfer them to the tip of the HSV by using a stripper tip to load the blastocyst(s) in as small volume (less than 0.5 µL) as possible onto the edge of the stick (*see* Note 5).
14. Visually confirm placement (*see* Note 6).
15. Before loading, apply the label to the open end of the empty straw. Load the HSV stick into the empty straw, the side with the embryos first. Use the blue handle to make sure the stick is in as far as it goes. Then, using the heat sealer, seal the open end of the stick, and plunge the whole straw into the LN_2. Place the straw in a pre-cooled aluminum cane for further storage (*see* Notes 7 and 8).
16. Store at the cane in a nitrogen tank.
17. Make sure to record cane location on the freezing worksheet and cryo inventory log.
18. Complete all paperwork, and recheck that all vial locations are logged into the Embryo Inventory.

57.2.4.2 Stepwise Blastocyst Warming Procedure

It is important to mention that regardless of the day of cryopreservation of the embryo (whether day 5, 6, or 7), at thawing, blastocysts should be treated as if they had been cryopreserved on the fifth day of development. To remove the cryoprotectants, blastocysts need to be warmed and diluted in a three-step process. With the HSV submerged in LN_2, the inner straw *should be* removed, and then the carrier with the blastocysts can be removed from the LN_2 and placed directly into a pre-warmed (37 °C) organ culture dish containing 1 mL of 1.0 M sucrose (*see* Note 9). Blastocysts can be picked up directly from the HSV and placed in a fresh drop of 1.0 M sucrose at 24 °C and immediately connected with a drop of 0.5 M sucrose for 3 min. Then connect with another drop of 0.5 M sucrose. After 2 min, blastocysts are transferred to a drop of pure 0.5 M sucrose solution and connected with drops of base medium for 3 min. Then connect with another drop of base medium for additional 2 min. When switching the embryos between different concentrations of warming

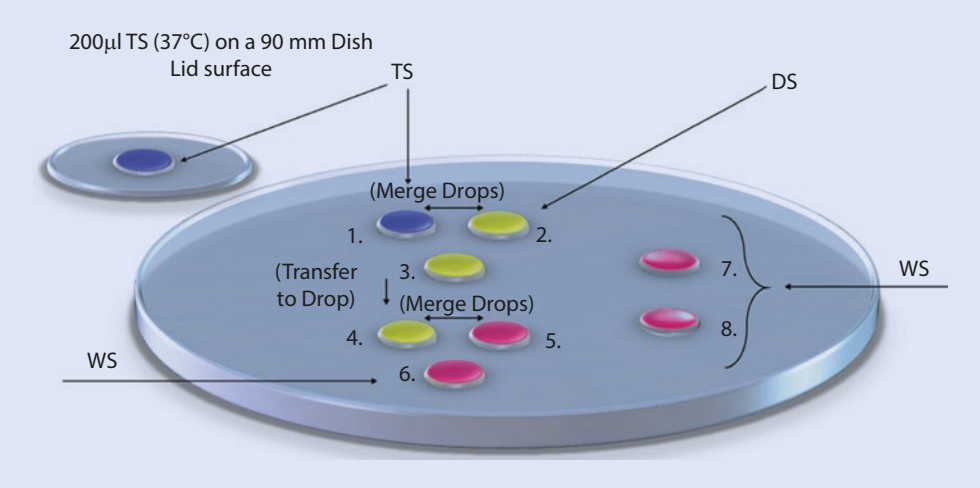

Fig. 57.2 Setup for the warming procedure on a plain 90 mm dish lid surface (TS, thawing solution; DS, diluent solution; WS, washing solution)

solutions, be sure to fill up the pipette with the next lower concentration of warming solution before picking up the cells for moving into the next dilution (*see* Note 10). Finally, the blastocysts are washed in the two drops of base medium for 1 min (at this moment, perform assisted hatching) and then returned to culture medium (SAGE+20%SSS) (SAGE blastocyst medium, Trumbull, CT, USA) in the incubator until transfer. Each single step is described in detail below:

1. Take reagents from the refrigerator and allow them to warm to room temperature. All cryoprotectants are removed at 24 °C.
2. Place a 200 µL drop of TS on a petri dish and place on a warming plate (*see* Note 9).
3. Label a petri dish (Nunc) with the patient's name under the lid as follows: TS, DS, and WS. Prepare 1 × 200 µL on a 90 mm dish and warm it up to 37 °C. Then prepare on a separate 90 mm dish lid 1 × 50 µL of TS, 3 × 50 µL of DS, and 4 × 50 µL of WS (*see* Fig. 57.2).
4. Before warming, use a stripper tip with 275 µm end hole for removing the blastocysts from the HSV tip.
5. Fill Styrofoam container with LN_2.
6. Confirm location and identification with a second embryologist before warming any HSV kit. Warm one kit at a time.
7. Each sample that is warmed is done in a separate hood and verified by a second embryologist before proceeding.
8. With the HSV kit under LN_2, open the kit by cutting the outer straw. Use the blue handle to remove the inner stick.
9. Submerge HSV kit directly in the pre-warmed 37 °C drop containing 200 TS, which should be as close as possible to the LN_2 Styrofoam container (*see* Note 11). As soon as the HSV kit contents liquefy (within 1 sec), try to locate the blastocyst(s) before removing it (them) with a stripper tip. After locating all the blastocysts, remove them from the HSV tip, and place them in the droplet of TS (drop 1) at room temperature, and then connect immediately with the first droplet of DS (drop 2). Wait for 3 min.
10. Then connect with the second droplet of DS (drop 3) for 2 min.
11. Then transfer blastocysts to 0.5 M sucrose (drop 4) and connect with first of WS (drop 5) for 3 min.
12. After 3 min, connect with second drop of WS (drop 6) for 2 min. Finally, rinse through a series of two additional drops of WS (drops 7 and 8).
13. Perform assisted hatching on the warming dish before placing the blastocysts into a culture dish, and put them back in the incubator for subsequent culture.
14. Record the survival and appearance of all blastocysts. Update log with warming data, and notify the physician of result (*see* Note 12).

57.3 Successful Application of Blastocyst Vitrification

Between 2004 and October 2016, the Fertility Centers of Illinois "IVF Laboratory River North "(Chicago) has vitrified 32,769 blastocysts from 8141 patients (Table 57.2). The majority of blastocysts were vitrified on day 5 (55.0%), 43.5% on day 6, with a minority on day 7 (1.5%). After 13 years of vitrifying blastocysts using an open (Cryotop) as well as closed (HSV) system, and close to 6700 FETs with an average number of 1.7 embryos transferred, the perinatal outcomes are as follows: number of babies from 1914 deliveries until January 2015 equals 2336 (1203 girls and 1133 boys) (Table 57.3). No abnormalities were recorded.

Table 57.2 Retrospective data from 8141 patients (average age 34.6 ± 6.0) with blastocyst cryopreservation by vitrification between 2004 and November 2016

	Day of development			
	Day 5	Day 6	Day 7	Total
Number of blastocysts vitrified	18,087 (55.0%)	14,211 (43.5%)	471 (1.5%)	32,769 (100%)

The outcomes with regard to day of development and age of the patient including donor-recipient cycles, between 2004 and October 2016, are summarized in Tables 57.4 and 57.5. In patients under 35 years old when transferring day 5 blastocysts, an ongoing pregnancy and implantation rate of 49.2% and 45.1% was noted (Table 57.4). In contrast, transferring day 6 blastocysts in patients younger than 35 of age, an ongoing pregnancy and implantation rate of 36.0% and 32.4% was recorded (Table 57.5).

In October 2007, the Fertility Centers of Illinois "IVF Laboratory River North" moved forward from the use of an open carrier system (Cryotop – embryos are in direct contact with liquid nitrogen) to a closed system (embryos are sealed before contact with liquid nitrogen). Using a closed carrier (High Security Vitrification Kit, HSV) for aseptic vitrification, the following data from day 5, day 6, and day 7 blastocysts were observed and are summarized in Table 57.6: (1) clinical pregnancy rate (cPR), 54.8% vs. 42.5% vs. 18.2%; (2) ongoing pregnancy (oPR), 46.3% vs. 33.3% vs. 15.9%; and (3) implantation rate (IR), 44.0% vs. 31.9% vs. 12.5% (Table 57.6). As shown in Table 6, oPR, cPR, and IR occurring in the day 5 blastocyst group were significantly higher than transferring day 6 or even day 7 blastocysts.

Between 2007 and October 2016, the Fertility Centers of Illinois "IVF Laboratory River North" (Chicago) performed 2765 vitrified blastocyst transfers (VBT) without collapsing prior to vitrification, with a mean patient age of 35.7 ± 4.9 years (group A), and in 2765 VBT (group B) with a mean patient age of 35.5 ± 4.8 years where artificial collapse was performed prior to vitrification (Table 57.7). On average, 1.6 vs. 1.5 embryos were transferred in group A vs. B, which means 40–50% of all VBT were single embryo transfers. Survival in group A versus group B was not significantly different (98.8% vs. 99.3%). However, there was a significant improvement in group B compared with group A for the following: (1) clinical pregnancy rate (cPR), 57.0% vs. 43.7%; (2) ongoing pregnancy rate (oPR), 48.5% vs. 34.7%; and (3) implantation rate (IR), 46.1% vs. 33.5% (Table 57.7).

When the vitrified-warmed blastocysts were divided into day 5 and day 6 groups, the following data were observed (Table 57.8): in 1622 VBT transferring day 5 blastocysts from group A (mean age of 35.5 ± 5.0), the IR, cPR, and oPR were 38.4%, 48.9%, and 40.0%, compared to 49.0%, 59.7%, and 51.5% of day 5 blastocysts from group B ($n = 1930$; mean age of 35.2 ± 4.8). As shown in Table 57.8, implantation, cPR, and oPR occurring from the day 5 blastocysts in group B were significantly higher than from the day 5 blastocyst in group A (χ^2; $P < 0.001$, respectively).

Table 57.3 Perinatal outcome of vitrified blastocysts after 6662 transfers between 2004 and October 2016 (babies delivered until January 2015). Values are numbers unless otherwise described; percentages are indicated between brackets

		Day of development		
	Day 5 + day 6	Day 5	Day 6	Day 7

[a,b,c,d] $P < 0.001$; *VET* vitrified embryo transfer

If we compare day 6 in group A ($n = 1143$; mean age of 36.1 ± 4.8) with day 6 outcome in group B ($n = 835$; mean age of 36.4 ± 4.7), the following data in terms of implantation, cPR, and oPR were observed: 26.6%, 36.4%, 27.3% vs. 39.7%, 50.7%, and 41.6%, respectively (Table 57.8). As shown in Table 8, implantation, cPR, and oPR occurring in the day 6 blastocysts of group B were significantly higher than transferring day 6 blastocysts from group A (χ^2; $P < 0.001$ for any comparison, respectively).

In Table 57.9, the results for patients under 35 years in groups A (no assisted collapsing) and B (assisted collapsing) are summarized. Comparing day 5 from group A ($n = 760$; mean age 31.4 ± 2.3) with day 5 from group B ($n = 950$; mean age 31.4 ± 2.3), we found the following for IR, cPR, and oPR: 41.5% vs. 53.0%, 52.0% vs. 62.7%, and 45.0% vs. 55.3%. Looking at day 6 outcomes for group A versus group B, we observed the following for IR, cPR, and oPR: 30.2% vs. 44.1%, 40.6% vs. 55.8%, and 32.9% vs. 46.5% (see Table 57.9).

Table 57.7 A comparison of retrospective data from the cryopreservation program (*Fertility Centers of Illinois, Chicago*) of vitrified day 5 and day 6 blastocysts without artificial collapsing (group A) and with artificial collapsing day 5 and day 6 blastocysts (group B) using aseptic vitrification technology between 2007 and October 2016. 57.4 Conclusions and Future Directions

Vitrification is a very promising cryopreservation method with many advantages and an ever increasingly consistent clinical track record. A standardized vitrification protocol applicable to all stages of the pre-implantation embryo may not be realistic because of (1) different surface-to-volume ratios; (2) the pattern of the movement of water and cell-permeating cryoprotectants that is rather more stage specific; (3) differing cooling rate requirements between oocytes, zygotes, cleavage-stage embryos, and blastocysts; and (4) variable chill sensitivity between these different developmental stages. Currently, however, the most widely used protocol applied to any embryo stage is the two-step equilibration in an equimolar combination of the cryoprotectants ethylene glycol and DMSO, at a concentration of 15% each (v/v) supplemented with 0.5 mol/l sucrose. For the adoption of vitrification in ART, as with all new technologies, there has been initial resistance; but as clinical data has been accrued, this technology is becoming more commonly adopted as standard procedure in many IVF programs worldwide. With this increased use in human-assisted reproduction will come evolution of the vitrification process as it is fine-tuned to clinical needs so pushing forward its development to higher levels of clinical efficiency, utilization, and universal acceptance.

Table 57.8 A comparison of retrospective data from the cryopreservation program (*Fertility Centers of Illinois, Chicago*) of vitrified day 5 and day 6 blastocysts without artificial collapsing (group A) and with artificial collapsing (group B) using aseptic vitrification technology between 2007 and October 2016. 57.5 Practical Implications Vitrifying at the Blastocyst Stage

Our data have shown that freezing at the blastocyst stage provides excellent survival, implantation, and clinical pregnancy rates. To achieve these outcomes, consider these points: (1) without a successful blastocyst vitrification storage program, extended culture should never be attempted; (2) the blastocyst is composed of more cells and is therefore better able to compensate for cryoinjury; and (3) the cells are smaller, which makes cryoprotectant penetration faster. On average, fewer embryos per patient are cryostored, but each one has a greater potential for implantation when thawed.

57.6 Addendum: Special Notes for the Clinical Embryologist

1. Special care must be given to the selection of the vitrification carrier type. It is necessary to use types of carrier or vessel material with rapid heat transfer that also support the process of uniform heat exchange to achieve higher cooling rates.
2. In addition, although no reports of contamination in human IVF following cryopreservation exist, the user should be encouraged to choose a closed carrier system, which in our experience works for blastocysts without any problems.
3. To minimize the toxicity of the cryoprotectant, a stepwise exposure of cells to precooled concentrated solutions (approximate room temperature of 24 °C) is recommended.
4. Utilizing higher concentrations of cryoprotectant allows shorter exposure times to the cryoprotectant – but be careful: the potential toxicity of the cryoprotectant increases at higher concentrations. As almost all cryoprotectants are toxic to some extent, it is important to carefully monitor the duration of exposure to the final cryoprotectant before plunging into liquid nitrogen.
5. To facilitate vitrification by higher cooling rates, it is also necessary to minimize the volume of the vitrification solution (VS) as much as practical (preferably less than 1 μL). From this point of view, it is very important to use a small pulled pipette. Furthermore, by collecting the blastocysts in one place and loading no more than two blastocysts at the same time in the pipette, it is possible to keep the volume small. However, if the load of media is too large, it can still be reduced before plunging in LN_2 by "drawing down" the droplet to flatten the blastocysts slightly while removing all surplus vitrification solution.
6. To make sure that the blastocysts are loaded on the carrier, perform the loading process under a stereomicroscope. Always confirm the number of loaded blastocysts.

7. After sealing the carrier, submerge the carrier loaded with the blastocysts directly in liquid nitrogen by passing rapidly through the vapor phase (nitrogen gas).
8. Store the cryo-cane in a pre-chilled PVC cryo-sleeve sitting in the goblet in the dewar. It is essential to maintain exposure of the HSV to LN_2 at all times to eliminate risk of warming and de-vitrification.
9. Before moving the carrier quickly from the liquid nitrogen into the warming solution, have a stripper tip (micro-pipette) ready. Fill the pipette with a small amount of the first warming solution (TS). When using the HSV as the vitrification carrier, rinse the open edge of the straw after placing into the pre-warmed (37 °C) 1.0 M sucrose; because the droplet is so small, it warms immediately, and it is essential to pull/stir the blastocysts off the carrier surface as soon as possible to avoid any toxic effect of the VS. A stirring motion is recommended when plunging into the warm TS to agitate the cell off the carrier surface without the need to remove it actively.
10. When switching the cells between different concentrations of warming solutions, fill up the pipette with the next lower concentration of warming solution, before picking up the blastocysts to move into the next concentration (dilution effect).
11. In general, during vitrification and warming, the LN_2 Styrofoam box needs to be as close as possible to the working area to minimize any lag in cooling and warming rates.
12. Be aware of the expiration dates of the vitrification and warming media; once opened, the shelf life is 6 (six) weeks (according to recommendation of Irvine Scientific).

Acknowledgment Juergen Liebermann wants to thank the physicians at the Fertility Centers of Illinois (FCI) and the embryologists at the FCI IVF Laboratory River North (Jill Matthews, BS; Sara Sanchez, BS; Rebecca Brohammer, BS; FanjingMeng, PhD; Alina Diamond, BS; Janna Schwab, MS; Ivana Elzy, BS; Jordan Machlin, BS; and Laura Baranyi, BS) for their invaluable contributions and support in pushing vitrification to become our standard protocol for cryopreservation of human oocytes and blastocysts within our program since 2004 as well as my dear friend and colleague Dr. Michael Tucker for introducing me to "vitrification" more than 15 years ago.

Review Questions

1. Please summarize the five fundamental objectives for successful cryopreservation of cells.
2. What has the most impact on the successful vitrification/warming of eggs and embryos: cooling or warming rates or both?
3. What would be a major disadvantage of cryopreservation if not done properly?
4. What is the most important characteristic of vitrification, if performed properly?
5. Name the two different groups of cryoprotectant, and provide the name of two cryoprotective agents for each group.
6. What role does sucrose play during the vitrification as well as warming procedure?
7. At what temperature should vitrification of eggs or blastocysts be performed?
8. Describe two procedures that might support survival and successful implantation of blastocysts: one being applied before vitrification of blastocysts, and one after warming before transfer.

Ovarian Tissue Cryopreservation

Pasquale Patrizio and Sherman Silber

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_58

Learning Objectives

- Limitations of conventional freezing of oocytes and embryos for fertility preservation.
- Ovarian tissue freezing and re-transplantation should become routine procedures.
- How to perform ovarian tissue harvesting and where to re-transplant.
- Methods to evaluate ovarian tissue for presence of cancer cells.
- Assessment of return of ovarian function and the hormonal testing.
- The difficulty of whole ovary transplant.
- Update on the number of births after ovarian tissue cryopreservation.

58.1 Introduction

As cancer survival rates keep improving, women of reproductive age need options to preserve their future fertility from the gonadotoxic doses of chemotherapy and/or radiotherapy [1–4]. Freezing embryos and oocytes are now established methods of fertility preservation. Embryo freezing has a long track record of success, and women can expect excellent pregnancy rates from cryopreserved embryos, with success rates in the United States ranging from 19% to 36% depending on a woman's age at the time of embryo freezing [5, 6]. However, the disadvantage of this method is that a woman needs a husband, or male partner, or donated sperm. For women wishing to preserve fertility but without a male partner or not interested in donor sperm, oocyte cryopreservation is a viable option. Pregnancy rates from oocytes cryopreserved by vitrification have been approaching that seen from cryopreserved embryos in some centers, and it is no longer considered experimental [7–9]. However, freezing oocytes requires a delay in the cancer treatment, and generally only one cycle of ovarian stimulation can be offered.

This chapter will focus on the cryopreservation and re-transplantation of ovarian tissue [10–12]. While this method of fertility preservation is still considered experimental as opposed to embryo or oocyte freezing, it does offer important advantages, and, in our opinion, as well as those of others [13], it should no longer be considered as "experimental." Contrary to embryo or oocyte cryopreservation, which requires approximately 10 days of ovarian stimulation, potentially resulting in high serum estradiol levels, ovarian tissue can be harvested and cryopreserved on short notice. It can be offered to women who need an almost immediate start chemotherapy or who have an estrogen-responsive cancer such as some types of breast cancer. It can also be offered to pre-pubertal girls, who are increasingly surviving from childhood malignancies, yet they may lose their fertility as a result of chemotherapy [14–17]. Indeed, ovarian tissue cryopreservation may be the only viable option for children with malignancies who need to undergo gonadotoxic treatment and wish to preserve future fertility. Finally, there will be a brief review of the experience with whole ovary cryopreservation, keeping in mind, however, that whole ovary is nowadays no longer an advocated method for fertility preservation, being replaced by the freezing of ovarian cortical tissue.

58.2 Cryopreservation of Ovarian Cortical Strips

Ovarian tissue for cryopreservation can be extracted either by laparoscopy or by minilaparotomy, and both these types of surgery can be performed at any point in a woman's menstrual cycle [10, 18]. The ovarian cortex harvested during laparoscopy or minilaparotomy is cut thin in 1 mm strips, either after removing approximately half the ovary in a block of cortical tissue or by taking small 5 mm biopsies. A different approach is to remove one ovary (unilateral oophorectomy) and then excise cortex "on the bench" in the lab. The use of cautery must be avoided during ovarian cortex harvesting. Due to the unpredictable assessment of the risk for chemo-/radiotherapy-induced gonadotoxicity, some women can be expected to have some ovarian function remaining or returning after chemo or radiotherapy; therefore, it is prudent to leave behind one ovary. With an experienced surgeon, the median operating time is 30 min. The complications from harvesting ovarian cortical strips or performing unilateral oophorectomy, via laparoscopy or minilaparotomy, are minimal and not different from any other ovarian surgery.

The ovarian cortex contains a multitude of primordial and immature follicles, and cryopreservation of the ovarian cortex is able to safeguard these large numbers of follicles to be used at a later time. The primordial and immature follicles are undifferentiated and not metabolically active [19, 20]. The small water content, the high surface-to-volume ratio, and the absence of the zona pellucida may mean that primordial follicles are less susceptible to damage during the process of cryopreservation. However, as the ovarian cortical strips are frozen without their vascular supply, they rely on neovascularization for their post transplant survival. Depletion of follicles in fact may occur when the ovarian graft is reimplanted until a new vascular supply (generally after 3 days to a week) is established to perfuse the graft [21–24]. Slow freeze has been shown to result in a 60% loss of oocytes compared to vitrification, which results in reduced oocyte loss. But oocyte loss may not matter clinically, because there are hundreds of thousands of oocytes in just one ovarian cortex [25].

Successful fresh as well as frozen ovarian cortex transplants in humans were first published in 2004 and 2005 as case reports, and many other case reports have subsequently followed [10, 11, 26–30]. There is now a rapidly growing interest in cryopreservation of ovarian cortical tissue prior to sterilizing cancer treatment followed years later by re-transplantation after cancer has been cured. It is estimated that some 100 births have been achieved and reported in either official publications or personal communications. The possibility is also looming of preserving fertility and even hormonal function against the natural decline caused by

aging and to delay menopause [31–33]. Furthermore, ovarian tissue cryopreservation may also find future indication to allow healthy young women to electively preserve their future fertility instead of using oocyte freezing. However, the main benefit of ovarian tissue over oocyte cryopreservation remains for cancer patients who need to start their chemo-/radiotherapy promptly and cannot afford to wait around for two or three cycles of IVF to accumulate and bank sufficient number of oocytes and knowing that the pregnancy rate per single oocyte is only about 4–5% [34]. With ovarian tissue freezing and subsequent re-transplantation, they can potentially get pregnant naturally and preserve several hundred thousand oocytes.

The first human applications of ovarian tissue freezing and re-transplantation were preceded by a long history of animal experimentation. As far back as 1954, Deanesly showed in rats and, in 1960, Parrott showed in mice that ovarian tissue could be successfully frozen and autografted resulting in live births [35, 36]. Interest in human applications began after Gosden's report of successful pregnancies in sheep in 1994 [19]. Recently, one of the most interesting case reports in humans involved rejuvenating menopausal ovarian cortex with cryopreserved autotransplantation [37]. Interest in cryopreserved ovarian cortical transplantation is rapidly growing, although only two reports to date have clearly stated its success rate [38, 39]. No systematic report had been published from one center comparing fresh donor transplants and cryopreserved ovary autografts, and little had been gleaned from studies of these procedures on analysis of ovarian function and resting follicle recruitment prior to a recent publication [39]. A recent worldwide survey of 37 babies born from cryopreserved transplants still could not establish a clear success rate [32]. However, a summary of cases from a single series of both fresh and cryopreserved transplants from one center, carried out with the same technique and assessed uniformly over follow-up, with the aim of improving our understanding of resting follicle recruitment, demonstrated the clinical robustness of the procedure [30, 39]. All of the recipients had normal return of hormonal and menstrual ovarian function at about the same time after surgery (4.5 months).

The duration of function of *fresh* grafts was directly related to the original ovarian reserve of the donor. In all cases, only one-quarter to one-half of the donor ovary was transplanted and most of the tissue cryopreserved for future use. All grafts functioned for more than 2 years, over one-half of them for over 6 years, and two of them already for over 8 years. Thus, if the donor's ovarian reserve is high, these grafts can last for a long time despite reduced AMH levels [25, 31]. That has very important implications for understanding the mystery of primordial follicle recruitment.

The relationships among FSH levels, menstruation, and AMH levels in donor and recipient in fresh transplants are indicative of resting follicle recruitment and ovarian reserve [40]. As recipient FSH levels returned to normal within 130–170 days, the low AMH level of recipients then began to rise in response to an increasing number of mature gonadotropin-sensitive follicles [39]. The AMH of recipients continued to rise to well above the normal baseline AMH level of the donor. In the fresh allograft recipient shown, although FSH decreased to normal levels by day 133 and normal menstrual cycling resumed, AMH levels rose far above normal (higher than the donor) shortly thereafter. Despite the transplanted graft continuing function, AMH then returned to low levels. This analysis of both donor and recipient data after transfer is rare and useful in its demonstration of no significant long-term change in donor AMH levels despite loss of an ovary. The rise of recipient AMH levels above donor AMH levels reflects over-recruitment of resting follicles in the recipient compared with the donor. Contrary to what might have been expected based on earlier studies [21], no evidence was found of significant loss of follicles from transplantation ischemia, as each patient had FSH levels return to normal as AMH levels rose far above normal. Despite continued function of the transplanted graft, AMH then returns to low levels [30, 39]. Preservation of follicles was supported by our observation of substantial follicle recruitment with many eggs produced in the two patients who underwent IVF during the window of high AMH levels. Quantitative studies have also supported this finding in bovines [41].

The autotransplantation of *frozen* ovary tissue yielded results almost identical to fresh transplantation. As with fresh ovary transplants, FSH levels returned to normal by about 150 days in all cases, and menstrual cycles resumed shortly before that. The return to normal did not differ between slow freeze cases and vitrification cases. In all of the cryopreserved cases, just as with fresh transplants, AMH rose to high levels shortly after FSH returned to normal, at around 130–170 days. Then, exactly as with fresh transplant cases, AMH dropped to a lower baseline level by about 240 days and remained at that lower level [12, 30]. Eight of the eleven cryopreserved autotransplant recipients had a follow-up of over 1 year, which allowed the assessment of pregnancy potential. Seven of these eight patients spontaneously conceived, although one spontaneously aborted. The other six were healthy singleton pregnancies. In fact, there are now even 3 more healthy babies from 11 frozen transplants followed for over a year. Therefore, cryopreserved and fresh transplantation were similar in hormonal function and high pregnancy outcome. Functional hormonal results thus far have demonstrated a remarkable degree of repeatable concordance in all 22 cases of fresh ovary donor transplantation and cryopreserved ovary autotransplantation. Thus, the spontaneous pregnancy rate overall reached 75% [39].

58.2.1 Orthotopic or Heterotopic Re-transplants?

In humans, cryopreservation of ovarian cortical strips as a method of fertility preservation has emerged over the last 15 years [12, 30, 39] and ovarian cortical strips have been autotransplanted either into the pelvis (orthotopic) or outside the pelvis (heterotopic) [10, 12, 26–29, 42–44]. Orthotopic

autotransplantation involves transplanting the thawed ovarian cortex onto the remaining ovary or into a peritoneal window in the pelvis. The transplantation surgery can be done laparoscopically or microsurgically through minilaparotomy. The first pregnancy and live birth from fresh ovarian cortical tissue was achieved in 2004 after orthotopic transplantation [10]. A 25-year-old with stage IV Hodgkin's lymphoma underwent a laparoscopy to biopsy the cortex of the left ovary. Five biopsies were taken and then cryopreserved. The patient received chemotherapy and radiation and then became amenorrheic. Five years later, the ovarian cortex was thawed and then transplanted into a peritoneal window that had been created 7 days earlier to help promote angiogenesis. Eleven months after reimplantation of the ovarian cortex, an intrauterine pregnancy was documented, and the patient went on to deliver a healthy son.

When thawed ovarian cortex is transplanted onto a remaining ovary or on nearby peritoneum, there is not always need for follicular aspiration and assisted reproductive techniques, as the fallopian tube can pick up and transport the spontaneously ovulated oocyte. However, if the ovarian cortex is transplanted elsewhere, then follicular aspiration and in vitro fertilization are required. Initially, controversy existed because it could not be proven in the cases of orthotopic transplantation that the live birth was not a result of residual ovarian function from the remaining ovary. However, this initial skepticism is subsiding as so many of live births from the procedure have been reported.

Overall, at least 100 live births have been described after orthotopic transplantation of frozen-thawed ovarian cortex ([30, 39] and personal communications), and some were after spontaneous conception and others after in vitro fertilization but all except one from orthotopic re-transplants.

Heterotopic transplantation of ovarian cortex tissue to other sites such as the forearm or subcutaneous abdominal tissues has been described [44, 45]. Only one successful heterotopic transplantation has led to the birth of a healthy baby after oocyte production, fertilization, and transfer [45]. As live births after heterotopic ovarian cortex transplantation are extremely rare, this approach to ovarian tissue reimplant is nowadays rarely recommended.

58.3 Risks

One major concern of cryopreserving tissue from patients with a malignancy, and later reimplanting this tissue, is the risk of ovarian metastasis from the primary cancer [46]. Although thus far there have been no cases of transmission of cancer cells from transplanting back-thawed ovarian tissue, there is potential concern with leukemia [47, 48]. However, even with leukemia, if the ovary is removed and the cortex frozen, while the patient is in remission, there will be no viable cancer cells in the tissue [39]. In contrast, in a Danish study, in which females with leukemia had ovarian cortex cryopreservation, six of eight patients had PCR evidence of leukemic cells in the ovarian tissue [47]. Molecular markers of malignant cells allowed detection of small numbers of cells by PCR which could not be detected by histologic examination [49].

Another group examined ovarian cortex biopsies of a patient with CML and did not find evidence of malignant cells by routine histologic methods, but again, identified some evidence of malignant cells by PCR. It is unclear whether this PCR evidence of malignant cells came from the ovarian biopsies or from contaminating blood [46]. The viability of these malignant cells is unknown.

Advanced-stage breast cancer (stages III and IV) can metastasize to the ovary, and in patients with known advanced metastatic breast cancer, it may be prudent not to cryopreserve and then reimplant cortical strips. In contrast, more than ten women with Hodgkin's lymphoma have received reimplanted ovarian cortex tissue, and no relapses have been documented so far [50–52]. At any rate, ovarian cortex tissue should always be examined for malignant cells, and as new molecular technologies to assess minimal residual disease become available, they should be used to assess the ovarian tissue prior to being reimplanted.

Of note, one of the authors (S.S.) has been freezing ovarian tissue since 1996 for 100 young women with solid organ cancer, or with a great risk for POF, of whom 16 had spare frozen tissue subjected to detailed viability testing before cryopreservation and after thawing. All had histologic review by a variety of pathologists. Only one had ovarian metastasis, a young woman with widespread breast cancer metastasis throughout her entire body. Otherwise, none of the other cases had any tumor cells in their ovary. Andersen et al. have also noted a complete lack of ovarian metastasis, even in the majority of leukemia cases. The reason for the remarkable absence of ovarian metastasis might possibly be due to the fibrous avascular nature of the ovarian cortex [52, 53]. In fact, the reason why fetal ovarian tubules (which in the fetal male become seminiferous tubules) invade the fibrous cortex and become follicles is that the dense fibrous tissue of the cortex (which in the fetal and adult testis is just tunica albuginea) is needed to suppress the resting follicles from developing all at once prematurely [53].

58.4 Whole Ovary

Cryopreservation of ovarian cortical strips, thawing, and then reimplantation leads to some follicular loss secondary to ischemia; however, this does not affect successful results. An alternative to cryopreserving ovarian tissue has been the cryopreservation and transplantation of a whole human ovary. In theory, by re-establishing a quick vascular supply, there should be less follicular loss. However, many challenges had to be overcome including optimizing methods for cryopreservation of large organs such as the ovary, which can be difficult as cryoprotectants do not diffuse well into whole organs and intravascular ice formation can cause vascular injury. Also, the technical aspect of harvesting and reimplanting a whole ovary requires a skilled surgeon to preserve a long and intact vascular pedicle at the time of harvesting

and then again a skilled microsurgeon to perform the vascular reanastomosis at the time of reimplantation.

Whole ovary autotransplantation was first described using fresh ovaries in various animal models, including rats, sheep, and monkeys. The first and only successful whole ovary transplant in humans was reported by Silber et al. by using a fresh whole ovary [54].

The preceding work in animal models involved sheep ovaries, which were autotransplanted into the abdominal wall with microsurgical vascular anastomosis of the ovarian to the inferior epigastric vessels. After 7 days, the ovaries were removed and noted to have surviving follicles [55].

In a rodent model, successful transplantation of ovaries, fallopian tubes, and the upper segment of the uterus en bloc after cryopreservation was reported in 2002. In four out of seven attempts at transplantation, the rat ovaries survived 60 days or more, and one pregnancy was achieved [56]. Recently, adult female sheep have become a standard model to study intact ovary cryopreservation [57, 58]. Arav et al. described transplantation of frozen-thawed intact ovaries in eight sheep by artery and vein anastomosis to the contralateral ovarian artery and vein. From 24 to 36 months after the ovary was reimplanted, progesterone activity was detected in three sheep. Oocyte retrieval was successful in two sheep, and in embryonic development, up to the 8-cell stage was noted [59]. Bedaiwy et al. described restoration of ovarian function in frozen-thawed sheep ovaries reimplanted with microvascular anastomosis. Yet, 8 of 11 ovaries failed due to thrombosis at the pedicle site [60]. In 2006, a live-born lamb was reported after orthotopic microvascular reanastomosis of a whole cryopreserved ovary [61]. Whole ovary cryopreservation in the sheep has been attempted through both slow-cooling and vitrification methodologies [58, 59, 62–64]. Recently, ovarian function of cryopreserved and transplanted whole sheep ovaries has been demonstrated 6 years after transplantation. This is the longest reported ovarian function of frozen-thawed whole ovaries [65].

In humans, the first report of cryopreservation and then thawing of a whole ovary was described by Martinez-Madrid et al. in 2004 [66]. They found that the percentage of live follicles was 99.4% in fresh tissue, 98.1% after cryoprotectant exposure, and 75.1% after thawing, and they also reported high survival rates of stromal cells and small vessels after thawing [66]. Bedaiwy et al. have recently described that successful cryopreservation of the human ovary in two premenopausal women with overall viability of the primordial follicles was 75% and 78% in intact cryopreserved-thawed ovaries [60]. Further, Patrizio et al. reported on successful whole human ovary cryopreservation with the vascular pedicle utilizing a Multi-Thermal-Gradient device and a slow-cooling, rapid-thawing protocol (Fig. 58.1) [67, 68]. The ovaries were thawed after cryopreservation for 2–4 days, and the frozen-thawed ovary was histologically similar to the fresh contralateral ovary used as a control and modest increase in markers of apoptosis. In three cases, the fallopian tube was cryopreserved along with the whole ovary, and after thawing, the histologic architecture was intact [69].

Fig. 58.1 Seeding of whole ovary in the glass tube prior to being loaded in the Multi-Thermal-Gradient device for cryopreservation

Table 58.1 A comparison of cryopreservation of cortical strips vs. whole ovaries

	Cortical strip	Whole ovary
Laparoscopic harvesting possible	Yes	Yes
Preserves ovarian stroma	No	Yes
Loss of follicles after cryopreservation	Yes	Yes
Loss of follicles due to ischemia	Yes	Yes
Microvascular anastomosis possible[a]	No	Yes
Short-term endocrine function	Yes	Yes
Long-term endocrine function	No	Yes

Adapted from Bromer and Patrizio [68], with permission
[a]In the event of anastomosis failure, the whole ovary will be lost. Cortical strips offer an advantage here because multiple strips are harvested and transplanted. If the loss of one cortical strip occurs, the others may remain viable

At the time of this writing, however, no cases of reimplanting a frozen-thawed whole ovary resulting in a live birth have been reported in humans. It is possible that the risks of whole ovary transplantation are greater than with ovarian cortical strips, as transplantation of a whole ovary may result in a higher risk of metastasis. Also, when transplanting organs such as a whole ovary, if the vascular anastomosis fails, then the whole ovary is lost. This compares to the transplantation of cortical strips, which can be reimplanted in batches so that if the initial procedure fails, it can be repeated with the remaining cortical strips. See Table 58.1 for a comparison of the cryopreservation of whole ovaries versus cortical strips.

58.5 Conclusions

There is a large need for fertility preservation options for cancer survivors, and the time has come to consider ovarian tissue cryopreservation for fertility preservation no longer an experimental option. Ovarian cortex banking and re-transplantation has been shown to be successful with a large number of live births even after many years after cancer has been cured. Further research to perfect methods of cryopreservation of ovarian tissue should aim at enhancing follicular survival after thawing and to discover methods to activate complete folliculogenesis in vitro on the cortical strips. Concerning the whole ovary, at this time, there is interest in researching methods to carry out in vitro perfusion of the organ and induce folliculogenesis in vitro, but not for re-transplanting whole ovaries [70]. The current outlook is hopeful that soon ovarian tissue cryopreservation will be an accepted, established treatment option for fertility preservation.

Review Questions

58

1. What are the limitations of conventional freezing of oocytes and embryos for fertility preservation?
2. Why should ovarian tissue freezing and re-transplantation become routine procedures?
3. How to perform ovarian tissue harvesting and where to re-transplant?
4. What are the methods to evaluate ovarian tissue for presence of cancer cells?
5. How to assess the return of ovarian function after re-transplant?
6. What are the difficulties of whole ovary transplant?
7. Have live births been documented after ovarian tissue re-transplantation?

Establishing and Managing Donor Oocyte Banking

Kathryn J. Go, Paula Dwan, and Linda Hillis

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_59

Learning Objectives

- Array of resources required to establish a donor oocyte bank
- Strategy for oocyte donor recruitment and compensation
- Processes for screening and acceptance of prospective oocyte donors
- Validated and effective clinical and scientific standard operating procedures for donor ovarian stimulation and method for oocyte cryopreservation (vitrification), respectively
- Federal regulations regarding donor reproductive cells and tissue
- Utility and advantages of donor oocytes in family building for some patients
- Development of marketing of inventory to recipients

59.1 Introduction

For almost four decades following the birth of the first IVF baby in 1978 [1], in vitro fertilization (IVF) and the array of assisted reproductive technologies (ART) have made it possible for countless individuals to realize the dream of having a family. Remarkable technical advances in IVF were rapidly made to enhance fertilization and optimize embryo implantation and utilization. The catalogue of ART evolved to include freezing (cryopreservation) of cleavage-stage embryos [2] as well as zygotes (fertilized eggs) and blastocysts, assisted hatching [3], intracytoplasmic sperm injection (ICSI) [4], and embryo biopsy for preimplantation genetic testing for single-gene mutations and/or chromosome copy number (aneuploidy screening) [5, 6]. What eluded inclusion in this repertoire for many years was the ability to cryopreserve eggs despite an early report of a live birth [7].

Multiple advantages are afforded by egg freezing. In providing an alternative to freezing *embryos* in a treatment cycle, the patient who elects to freeze her supernumerary eggs and her partner can avoid the ethical dilemma of the disposition of potential "surplus" embryos, i.e., more embryos than are needed to build their family. In instances when sperm are not available on the day of retrieval, the eggs can be frozen, deferring the insemination. Egg cryopreservation, importantly, offers the prospect of fertility preservation to reproductively aging women as a strategy to manage ovarian loss or function from gonadotoxic treatments such as surgery or chemo- or radiotherapy and potential loss or injury during military service or from an accident or against declining ovarian reserve with age.

A significant contribution to ART is the success of egg freezing in fulfilling an obvious need in third-party reproduction, or family building requiring donor gametes and gestational carriers. While the availability of frozen donor sperm through commercial banks or private clinics had been well-established for treatment with home insemination, or intra-uterine insemination (IUI) or ART, infertility therapies requiring donor eggs were realized with the advent of IVF and the use of eggs from "fresh" donation, i.e., ovulation induction of and egg retrieval from the egg donor [8]. Treatment was comprised of the selection of an egg donor from those available through specialized agencies or clinics by the recipient, the egg donor's ovarian stimulation and egg retrieval in a treatment cycle hormonally synchronized with the egg recipient's, and, finally, transfer of the resultant embryo(s) to the recipient's uterus with optimal endometrial preparation.

Fresh egg donation offered excellent prospects for clinical pregnancy and live birth rates for recipients as reflected in the annual infertility clinic reports of the Society of Assisted Reproductive Technology (► https://www.sartcorsonline.com) but entailed a high cost per treatment cycle or attempt (typical total fees for one attempt can be approximately $35,000), the contracting with an anonymous donor through an agency or clinic, and coordination of the donor's stimulation and monitoring of hormonal and ovarian follicular response to achieve synchronization with the recipient's. Given the significant commitments of time and effort by the donor to the cycle, the recipient was necessarily dependent on her availability to undergo the stimulation and retrieval, introducing inconvenience and potentially, a protracted waiting time. Cost-efficiency and convenience were not hallmarks of this treatment modality: there was a clear need to have donor egg availability achieve better access.

Effective egg freezing opened the door to egg "banking." The advantages are multiple: (1) with the advantage of distributing eggs from a single retrieval cycle among multiple recipients, cost-efficiency for each donor stimulation is achieved; (2) the temporal burden of donor and recipient cycle synchronization is eliminated, offering significantly greater convenience; and (3) greater access afforded by frozen egg banks increased the opportunity to many more patients whose reproductive treatments required donor eggs [9–13].

The availability of a reliable egg cryopreservation method readily fulfilled two clinical needs: the ability of reproductively aged women to preserve their fertility and the creation of donor egg banks analogous to sperm banks. The latter was an obvious opportunity to provide a significantly more convenient and affordable option and greater access to individuals desiring donor eggs for family building compared to identifying a suitable donor whose stimulation and retrieval cycle was dependent on her availability as well as possible synchronization with the recipient's cycle to afford optimal timing for embryo transfer. While egg freezing and storage for a clinic's patient for her own use (autologous egg freezing) follow the same model as that applied for cryopreserved embryos created through a treatment cycle, commercial *donor* egg banking entails more resources.

The establishment and management of a cryopreserved donor egg bank are multifactorial processes and require an array of expertise and operations. The establishment must include (1) a laboratory that has acquired, validated, and implemented the laboratory methodologies of egg vitrification and inventory management, is registered with and accredited and licensed by all appropriate regulatory agencies, and has an electronic database that captures and tracks

outcomes for each donor's eggs from number of eggs acquired to number of live births to achieve quality assurance and control; (2) a systematic approach for (a) recruiting, screening, and accepting appropriate egg donors; (b) the medical and clinical expertise for appropriately and thoroughly evaluating the donor candidates; and (c) managing the donors from ovulation induction cycle through egg retrieval; (3) an organizational plan that provides (a) an administrator and manager who oversee the development of the bank and its catalogue by building and nurturing relationships with its donors and clients and (b) a business director responsible for the financial and fiduciary management of the bank and oversight of its contracts and agreements with partners; and (4) a multidisciplinary leadership team attuned and attentive to the bank's continued development and quality.

This chapter provides a framework for establishing and managing a donor egg bank by addressing each of these elements, presented in ◘ Table 59.1.

59.2 The Science, the Technology, and Laboratory Requirements

Identifying a consistent and reliable method for freezing eggs, unlike sperm, was a challenge. Although a report of a pregnancy from thawed eggs frozen by slow cooling appeared in 1986 [7], the method could not be immediately replicated.

The slow-cooling method that proved successful for the freezing of zygotes (di-pronucleated fertilized eggs), embryos, and blastocysts involved equilibration of the samples with cryoprotectants and cooling in programmed freezing machines to achieve gradual reduction in temperature, e.g., rates such as 0.3° per min. Thawing or warming was achieved with a brief exposure to room temperature followed by equilibration in thawing or warming solutions to achieve stepwise rehydration of the zygote, embryo, or blastocyst.

Encouraging outcomes from egg freezing by slow cooling were reported [14–16], but it was the application of the ultrarapid freezing achieved by vitrification that catalyzed the emergence of a reproducible methodology for freezing and warming eggs with acceptably high recovery, survival, and potential for fertilization and embryo development.

Vitrification, in contrast to slow cooling, entails the equilibration of the egg with much higher concentrations of cryoprotectants followed by immediate immersion (plunging) of the sample into liquid nitrogen. The effective freezing rate with vitrification is the ultrarapid −20,000° per min, producing a glassy or vitreous intracellular environment and avoiding all ice crystal formation and its attendant damage to the cell [17, 18]. This technique was successful in addressing the unique challenges posed by eggs owing to their large diameter, high water content, and intracellular architecture, i.e., the meiotic spindle, requiring protection against disruption and the result risk of aneuploidy [19–22].

Warmed eggs do require fertilization by ICSI [23], reflecting potential low-temperature-induced changes to the zona pellucida precluding fertilization by conventional insemination.

Meticulous technique in vitrification must also be applied to achieve the desired post-warming survival, fertilization, and developmental potential for effective egg banking. Cryopreservation-related damage can result from nonadherence to the technical protocol that is specific in duration of equilibration intervals in cryoprotectant solutions and the loading of the eggs onto the carriers (the plastic appliances holding the vitrified eggs for storage). In addition, appropriate handling of the carriers must be achieved during transfer from storage vessel to vessel, e.g., storage tank to shipper, and shipper to storage tank. Best practices will prevent unintended warming of the eggs that will negatively affect their integrity, survival after warming, and ability to be fertilized and develop into embryos. Effective and validated training in conjunction with a solid foundation in reproductive biology and the principles of cryobiology will foster the quality assurance and quality control that contribute to the success of the bank. Thus, the prospective laboratory of the egg bank must ensure mastery of the technology with a structured training plan documenting practice by and validation of each scientist who will participate in egg retrieval, evaluation of maturity, and vitrification of mature (Metaphase II) eggs for addition

◘ **Table 59.1** Organizational and checklist chart for establishment and management of an egg bank

Scientific/laboratory	Medical/clinical	Administrative/business
Effective and validated egg freezing methodology Training for quality and consistency Appropriately equipped laboratory Storage facilities System for distribution Licensure and accreditation Registration with FDA Quality assurance/quality control programs	Compliance with ASRM guidelines Medical, psychological, and social history criteria for acceptance as an egg donor Application database Donor candidate evaluation and vetting (genetic screening, ovarian reserve screening) Risk factor assessment, infectious disease testing, physical examination Achieving safety for the egg donor and recipient	Egg bank's mission and values Development of contracts and business agreements Financial management of bank Provision of guarantees to recipients Development of business for growth and enhanced services to recipients/clients

to the bank's inventory. These professional scientists are likely to be clinical embryologists, well-versed in collecting eggs from ovarian follicular fluid, enzymatically removing the cumulus cells surrounding the eggs and evaluating the eggs for nuclear maturity. The mature eggs, that is, eggs at Metaphase II, are those that will be frozen.

With the burgeoning of favorable clinical experience and reports of pregnancies and live births from vitrified eggs in the medical literature, the American Society for Reproductive Medicine lifted the qualifier, "experimental," from egg vitrification in 2013 [24]. Subsequent reports reflect that egg freezing by vitrification has become firmly incorporated among the ART available to patients [25, 26] and has been deployed to commercial as well as autologous egg banking.

59.2.1 Storage and Distribution

An egg bank must have adequate storage capacity and meticulous maintenance of the storage containers, a redundant system for inventory management, e.g., both electronic and hardcopy versions, and a system for tracking inventory and accounting for the disposition of all samples – eggs that are in storage, shipped to other sites, or removed and discarded.

A database containing details of egg warming, specifically number of eggs surviving thaw and undergoing ICSI and number fertilized; number of embryos or blastocysts that developed and were transferred, cryopreserved, or discarded; and the clinical outcomes of any transfers, whether fresh or from a frozen embryo transfer (FET) cycle, must be in place for quality assurance and control. These data are central in the management and development of the bank's inventory, administering any guarantee programs and rendering decisions on the recycling of the egg donors, or conversely, the discontinuation or withdrawal of donors.

For shipment of eggs to other centers, dry shippers that have been validated through a program documenting that appropriate internal temperature is maintained over multiple days are used. If recipient centers send their tanks to the egg bank for loading of the samples, then the bank must inspect these to ensure they are fully functional. The use of colorimetric markers to reflect maintenance of the internal temperature over time is an excellent tool for routine use during shipping.

59.3 Compliance with Regulatory Agencies

The US federal government is clear in its rules for bank or establishment registration with the Food and Drug Administration (FDA) and the procurement, processing, storage, and distribution of donor cells and tissues: these are provided in the Federal Register, 21 CFR Part 1271 [27]. Donor eggs are considered and regulated as reproductive HCT/P – human cells, tissues, and tissue-based products. The ultimate objective of the regulations is to prevent the transmission of infectious disease by treatments using the cells or tissue. Fulfillment of these rules is achieved by the infectious screening of blood samples drawn from the candidate donor and the medical review of the outcomes that underpins whether an individual is eligible or ineligible as a donor.

The donor egg bank must register each year as an HCT/P-producing center, describing each type of product from the bank, and is subject to unannounced inspections by FDA officials. Included in the inspection are a survey of all the documents, procedures, and policies of the bank, interviews with its personnel, inspection of its facilities, and review of all donor records. Penalties for failures in compliance can be severe, with the possibility of closing of the bank's operations.

Complementing the federal regulations are the requirements by individual states that the egg bank must apply for a license as a tissue bank. Each state's application will vary in the breadth of information that must be provided to qualify for initial and renewed licensure.

While an egg bank could have an independent laboratory dedicated solely to egg retrieval, processing, vitrification, and storage, it is more frequently the case that the bank exists within and is part of an IVF clinic. While the egg donors can undergo ovulation induction and cycle monitoring at remote physician's offices or other centers, egg retrieval will occur at the bank where the eggs can be vitrified in its laboratory. ART laboratories for egg banks must have licenses as tissue banks, be registered with the FDA, and be certified as compliant with CLIA 88, the Clinical Laboratory Improvement Amendment of 1988, as well as the American Association of Tissue Banks (AATB), depending on state-specific requirements. As well, the laboratory is likely to be a member of the Society for the Assisted Reproductive Technologies (SART) of the American Society for Reproductive Medicine (ASRM).

59.4 Donor Recruitment, Evaluation, and Selection

In addition to the laboratory component, a donor egg bank requires both administrative and clinical staff working in conjunction toward bringing in young, healthy egg donors for ovarian stimulation. Administrative personnel and nurses work together to advertise to and recruit donors, review donor applications for clinical contraindications, accept applications contingent upon donors passing screening tests, coordinate screening tests, and ultimately stimulate the egg donor to produce a large cohort of oocytes.

A key component in establishing and maintaining a donor oocyte bank is the recruitment and screening of egg donors [28–30]. This is best accomplished through online advertising, social media, and local recruitment efforts. Knowing the target audience is crucial. The ideal age of donors is 21–30 years of age. Recruitment strategies must be focused toward healthy, young women, with a sense of altruism who would benefit from the compensation. They must be healthy, motivated, compliant, eager, and, ideally, educated. Initial online screening should be focused on the following areas: age, body mass index, health status, family history, and level of education. If the prospective donors do not meet

these basic criteria, it is not worthwhile to expend additional energy. If the prospective donors do meet these criteria, a much more extensive online application is the next step. Donors must submit demographic information, specific personal and relationship information, lifestyle information, detailed medical and surgical history for the donor, detailed medical history for first and second degree family members, as well as subjective information such as favorite subjects in school, hobbies and interests, and a personal statement about why they are interested in egg donation.

Donors may be disqualified at this second level of screening for poor lifestyle choices, personal or family history of autoimmune disorders, cancers at young age, or any other host of medical or social concerns. It is important to remember the attributes that donor recipients may be looking for when they undertake the donor selection process. If a recipient is not likely to choose a donor, then it does not make sense to continue further testing for that prospective donor.

Once the donor application has been vetted, it is then imperative for the nurse(s) to coordinate and perform ovarian reserve testing, genetic screening, psychological screening, infectious disease screening, risk factor screening, and physical examination including a detailed list of the donor's piercings and tattoos. Ideal egg donors will have a high normal ovarian reserve, not be carriers of common or high impact genetic diseases, be psychologically sound, be free of infectious diseases, and possess no limiting risk factors. All rules and regulations with respect to tissue banking must be adhered to in accordance with FDA policies.

Donor screening must be stringent. It is estimated that only 1–2% of women applying to be egg donors will actually meet all of the criteria set forth. Once the donors have been vetted, it is necessary to provide appropriate, detailed information about the egg donation process, including risk and benefits, time commitment, and compensation. All egg donors will need to complete informed consent. All prospective donors must be thoroughly educated about how to administer medications and subcutaneous injections, expected side effects, expected schedule for testing by blood draw and ultrasound, as well as the egg retrieval procedure and related anesthesia or sedation used to perform the egg retrieval.

It is the role of the nurse to provide the majority of the education regarding the treatment plan and medications used to stimulate the donor's ovaries. Ovarian stimulation protocols may vary, but must take into account the age and relatively high ovarian reserve potential of donors. Also, it must be remembered that these women are not considered infertile. As is the case in most IVF treatment cycles, the nurse(s) will provide overall education and day-to-day contact with the egg donor for medication instructions as the ovarian stimulation progresses. Detailed written medication and injection instructions are strongly recommended and will allow the donor to follow along and reduce medication errors on the part of the donor. Many donors will appreciate receiving their daily instructions via email, rather than verbally. Most donors have email accounts on their cellular phones and prefer this method of communication. Although most stimulation medications are now given by subcutaneous injections, minimizing the number of injections and length of time the donor will be subjected to medications and injections is imperative. The nurse will also provide preoperative instructions prior to the egg retrieval and postoperative follow-up after the egg retrieval. Nurses must ensure that donors feel well-cared for throughout the process if they hope to retain donors for subsequent donation cycles. Meeting with the donor on the day of the egg retrieval or soon after, thanking her for the donation and gift, and providing her with the compensation are strongly recommended.

According to guidelines set forth by the American Society for Reproductive Medicine, donors may participate in up to a maximum of six donation cycles [31]. It is financially beneficial for donor egg banks to utilize donors multiple times to offset the time and financial costs inherent in repeated screening.

59.5 Development of the Egg Bank and Future Prospects

The successful development of a donor egg bank must include the continual replenishment and expansion of the catalogue to offer potential recipients a greater array of donor phenotypes. As some ethnicities and mixed-ethnicities may be underrepresented among donors, an effort to recruit among these groups may fill potential voids in availability.

Every clinical and scientific technique should be subject to constant effort to achieve improvement, measured in terms of efficiency and/or efficacy. The safety of the donor during ovulation induction can be realized from innovations in controlled hyper-stimulation. With respect to the freezing method, constant revisions in cryoprotectant formulations or the technical steps of processing the eggs to achieve even higher survival, fertilization, and embryo development rates could lead to a reduction in the number of eggs needed to comprise a "lot" (the number of eggs purchased for a single treatment) consistent with leading to embryo transfer and live birth and potential supernumerary embryos for cryopreservation and future FET cycles. Potential improvements in design or function of cryopreservation storage tanks or shipping containers would also be advantageous to an egg bank for efficient operation.

59.6 Conclusion

The advent of effective egg freezing through vitrification with high survival and developmental potential offered significant advantages to individuals seeking fertility preservation as well as an improved model for patients using donor eggs. Advantages of lower cost, higher convenience, and greater access compared to the established model of fresh donor eggs were realized. The establishment and effective management of a donor egg bank is the result of careful planning and organization to ensure solid technology underpinned by committed quality assurance and control, a program of medical, genetic,

and psychological screening that is both regulation compliant and dedicated to the safety and protection of both donor and recipient, and a responsible and accountable administrative and business infrastructure for optimal donor and consumer relationships and financial management. A committed and dedicated team comprised of business, administrative, clinical/medical, laboratory, and marketing personnel is central to achieving success in the area of donor egg banking.

Review Questions

1. List the components that comprise a donor oocyte bank.
2. Describe the strategy for recruiting oocyte donor candidates.
3. Outline the processes for screening and acceptance of prospective oocyte donors.
4. Describe the clinical and scientific methods involved in creating an inventory of donor oocytes.
5. Identify the federal legislation that covers donor reproductive cells and tissues and summarize how a donor egg bank complies with this law.
6. Outline the advantages of cryopreserved donor eggs to a recipient.
7. Propose a viable marketing plan for the donor oocyte bank.

Learning Objectives

- The advantages and disadvantages with SET
- The ideal patient for SET
- Indications for DET

Assisted reproduction technology (ART) is the single most effective method to treat infertility [1]. This high success rate has generally been achieved through replacement of multiple embryos resulting in a high multiple births rate, being 25% of all ART live births in the USA in 2014 [2, 3]. In the USA, the *ASRM practice committee* [4] recommended that between one and five embryos be replaced depending on the maternal age, number of IVF cycle, quality of the embryo, and/or the prognosis. It has been advocated that it should be up to the infertile couple and their physician to decide how many embryos should be transferred. In contrast, other countries like Sweden, Finland, Belgium, and Turkey have promoted a stricter line in the form of legislation/recommendations restricting the use of multiple embryo replacement. In those countries, the trend has been steadily toward reducing multiple pregnancies through the use of single embryo transfer (SET). Globally, however, there are large variations between how SET has been implemented, and even though countries like the USA have moved from 1% (2004) to 21% (2014) [3, 5], the rate of twin gestation has plateaued and 36% of all twins and 77% of higher-order multiples are still due to ART [6]. The annual expenditures for these iatrogenic preterm deliveries total 26 billion dollars of healthcare costs in the USA [7–9]. A situation likely to persist unless there are major changes in the way ART is viewed, funded, and legislated.

60

60.1 Multiple Pregnancies

The most important reason for decreasing the number of replaced embryos is the need to decrease the high incidence of multiple gestation and multiple birth rates (MBRs) produced through ART. In the USA, it has been estimated although ART only accounts for 1% of all births, ART births are 18% of all multiple births [10]. Despite that the majority of children born after multiple pregnancies are healthy, there are significant problems linked to multiple births both obstetrical and neonatal [11]. The obstetrical risks include hypertension, preeclampsia, preterm labor, anemia, and an increased Cesarean section rate. The neonatal risks include increased mortality, lower gestational age, low birth weight, and respiratory distress syndrome along with numerous other complications associated with preterm birth. In addition, long-term neurological complications have been associated with preterm birth along with the strain such a birth puts on the family both psychologically and financially.

Multiple births are associated with increased costs for the society compared to singletons. It has been estimated that the total cost of ART-associated preterm deliveries in the USA is approximately one billion dollars annually [2]. In the Netherlands, it has been estimated that lifetime extra healthcare costs of a twin pregnancy add up to €30,000 [12].

What can be done to reduce MBR in relation to IVF? Embryo reduction has been used to escape the complications associated with higher order of multiple pregnancies. Although embryo reduction is a relatively safe method, it however is not a solution for the quantitatively largest problem of twins, which are normally not reduced to singletons.

The only realistic way of avoiding multiple pregnancies in IVF is to reduce the number of embryos replaced. The problem with this approach is that in order to really reduce the multiple pregnancies, only one embryo should be transferred. By doing so, the total delivery rate will be affected negatively [13]. The question is then what is an acceptable delivery rate per transfer or started cycle? The attitude among patients as well doctors working with IVF is that the delivery rate should be as high as possible. With such an attitude, more than one embryo should be transferred. However, growing evidence indicates that by doing so, the problem with the high MBR in IVF will never be solved.

60.2 Pregnancy Results After SET

Pregnancy rates calculated per transfer are understandably the golden standard on success as it relates to an output parameter that is easily understood, gives fast feedback to the clinic on its performance, and relates the fresh cycle most commonly performed in IVF. There are of course many ways of comparing results and success. One other way of determining success is to calculate the cumulative birth rate per oocyte retrieval. Such an approach decreases the emphasis on the fresh transfer adding the increasingly important factor of cryopreservation of human embryos.

60.3 Results from Studies Comparing SET and Double Embryo Transfer (DET)

Comparing pregnancy results of SET contra multiple replacements has been reported in numerous randomized prospective trials [14–20]. The RCT studies show a clear advantage of transferring two embryos as compared to one. DET produces a significantly higher ongoing clinical pregnancy rate (44.5%) than SET (28.3%) [13].

Several studies show, however, that comparable ongoing clinical pregnancy rates can be achieved by transferring two embryos, one at a time [17, 18, 21]. However, such an approach requires a very good cryopreservation program. Improved techniques for cryopreservation have dramatically increased both the survival rates and the ongoing pregnancy rates.

Generally, RCTs are very valuable in clinical research, as their study design results in a similar distribution of confounding variables over the study arms. However, the normal IVF clinic cannot be a never-ending RCT study; it is a mixture of many different embryo transfer regimes that have been established over time. Those cohort studies that have been published reflect this reality [22–25]. They have

compared SET vs. DET and show no significant difference in the ongoing pregnancy rate, while there is a 30-fold decrease in the twinning rate in the SET group.

60.4 The Swedish Experience of SET

Due to the high MBR, resulting in criticism from obstetricians and neonatologists, Swedish IVF clinics already in 1993 on their own initiative started to reduce the number of transferred embryos from three to two. This resulted, as expected, in a dramatic drop in triplets, whereas the twinning rate remained unchanged at around 20%. Due to the known less favorable outcome for twins as compared to singletons shown in large follow-up studies of all IVF children born in Sweden between 1982 and 1995 [26], voices were raised that only one embryo should be transferred in the majority of cycles. Due to the debate concerning the high MBR clearly related to the number of transferred embryos and unchanged twinning rate, a multicenter randomized controlled trial was set up in Scandinavia by a group in Sweden [17]. The aim of the study was to compare one fresh embryo and, if no live birth occurred, adding another embryo transfer from the frozen thawed embryo, with transfer of two fresh embryos. The results did not show any difference in pregnancy rates between the groups with one fresh plus one frozen/thawed, as compared to the DET group. However, the twinning rate was 0.8% and 33%, respectively [17]. Without waiting for the final result from the above-mentioned study, the Swedish IVF legislation was revised with regard to the number of embryos that could be transferred. Thus, the Swedish National Board of Health and Welfare in their new guidelines in 2003 stated that only one embryo should be replaced in the majority of cases. However, the guidelines did not state in which situation only one embryo was allowed to replace. A detailed guideline was left to the profession to outline. The Swedish IVF clinics today, thus, recommend that only one embryo shall be transferred in the first two cycles in women under the age of 38 years. With this recommendation, almost 70% of the transfers performed in Sweden between 2003 and 2008 utilized only one embryo, and according to the latest Swedish IVF statistical report presenting delivery data between 2000 and 2015, the SET rate is 80% in fresh cycles (Fig. 60.1). During the same period, the overall delivery rate per transfer has remained fairly stable. For frozen/thawed cycles, the SET rate is 96% for 2015 (Fig. 60.2). The MBR has dropped to around 5%. Data from our own clinic also show that the overall pregnancy results are not affected by increasing the proportion of SET below 10% in 1998 to 86% in 2010 (Fig. 60.3). It is also interesting to notice that in women 40 years or younger, the birth rate remained stable, while a dramatic decrease in MBR occurred [27]. Comparing the Swedish

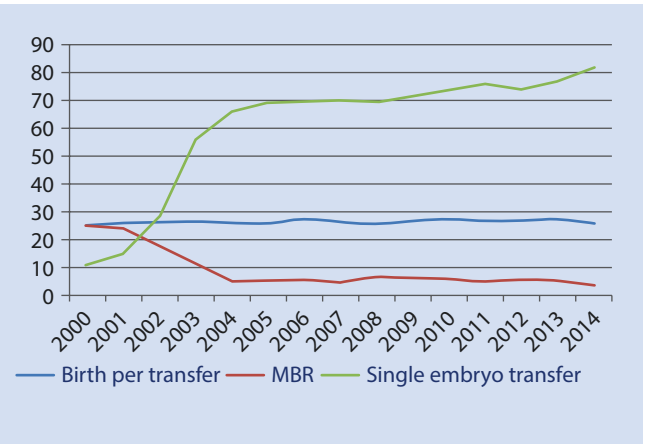

Fig. 60.1 Birth per transfer (standard IVF + ICSI), multiple birth rate (MBR), and single embryo transfer in Sweden in 2000–2015

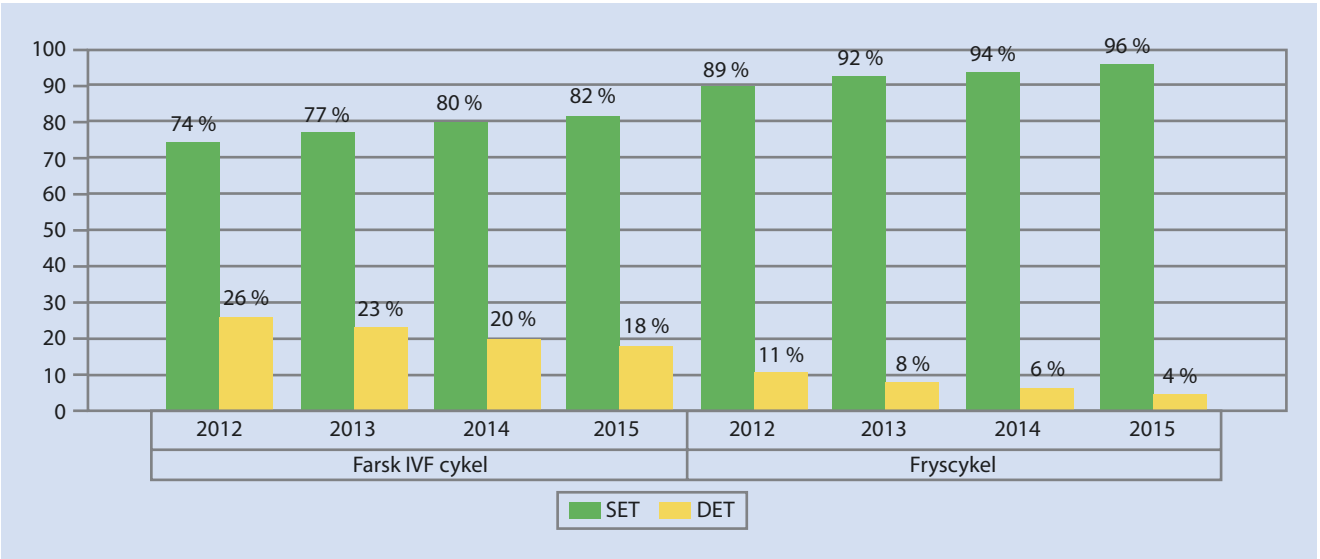

Fig. 60.2 SET and DET rate of fresh and frozen/thawed cycles in Sweden 2012–2015

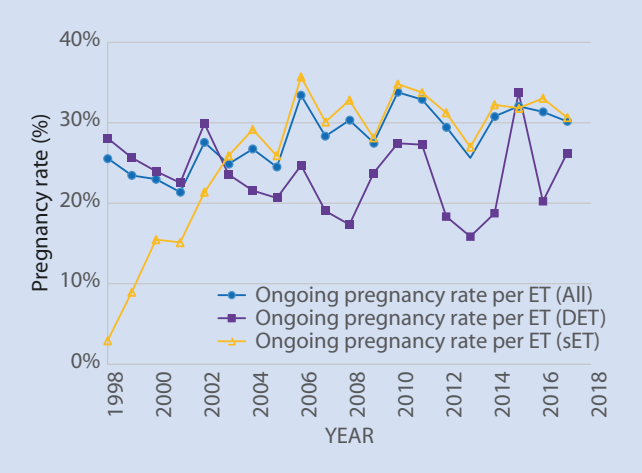

Fig. 60.3 Ongoing pregnancy rate after SET and DET at Fertilitetscentrum, Gothenburg, Sweden, during the period 1998–2017

results with the USA shows a continuous increase in delivery rate to 35%; however, the MBR is still around 20% (3).

The significant health consequences of such high MBR are obvious, and the cost for the American society is very high [2, 7].

If Sweden had continued to transfer two embryos in the majority of patients, one could have expected an increase in the delivery rate similar to the USA. However, considering the unchanged delivery rate at an acceptable level and the dramatic decrease in the MBR with decreased risks for the IVF children, SET seems preferable, both from the patient's and the society's point of view.

Result from Sweden, with an overall SET frequency of almost 70% resulting in a multiple birth of less than 6% without reducing the overall birth rate, as well as published cohort studies, indicates how important it is to choose the correct embryo when implementing SET. This is because SET often is performed when a good quality embryo is available from a cohort of embryos. DET is, therefore, only used on patients who have a worse embryo quality, are older, and/or have many previous failed cycles. By using SET on patients that run a high risk of a multiple pregnancy, you, therefore, reduce this risk significantly. Methods for embryo selection have improved during the last decade or so using mainly morphological markers to increase the power of the embryo selection. Although improved embryo selection has been pivotal in maintaining a high pregnancy rate despite introducing SET, improved embryo culture media, blastocyst culture, and general improvement within the IVF clinics have also played a big part.

A big factor that is affecting the decision to use SET or DET is if a clinic has a well-established and successful cryopreservation program. With the introduction of vitrification in particular and overall improvements in general, the importance of the embryos that are cryopreserved has increased dramatically over the years. According to the Swedish registry, the proportion of frozen embryo transfers (FET) increased from being only 50% of all fresh cycles in 2005 to almost equal in 2014. The results have also increased dramatically almost surpassing the fresh results in 2015. Implementing a successful SET program is therefore very much reliant on being able to successfully cryopreserve viable surplus embryos and an important argument both for the couple and regulatory bodies.

60.5 Conclusion

Successful implementation of SET requires that everybody involved in the IVF treatment perform at their best, and some authors claim that the degree of SET performed at a particular center is the best measure for performance of that center [28]. Although there are pros and cons with SET, it is likely that its use will increase in IVF as major benefits can be achieved both for the child and mother but also for the society as a whole.

Review Questions

1. Why should SET be performed?
2. Who is the ideal SET patient?
3. Are there clinical situations when DET should be performed?

Learning Objectives

1. List the variables which could affect the success of the embryo transfer.
2. What are the different methods of embryo loading?
3. What is the role of mock transfer in IVF-ET?
4. Which is the optimal site for placement of the embryos and why?
5. What is a difficult embryo transfer and how would you overcome it?

61.1 Introduction

The procedure of embryo transfer (ET) is the crucial last step of a long arduous journey of the IVF process. What seems to be easy and simple is the most crucial event in the sequence of events that encompass an assisted reproductive technology (ART) cycle. The goal of a successful embryo transfer is to place the embryos in an atraumatic manner to an area of maximum implantation potential (MIP) to maximize the chance of a pregnancy. The idea is to avoid damage to the embryos as well as the endometrium and to avoid too much of manipulation that can stimulate uterine contractions and result in expulsion of the embryos from the uterine cavity. These may be the potential reasons of a failed transfer in spite of transferring top-quality embryos into a receptive endometrium. Hence, over the last decade, a lot of interest has been diverted to the embryo transfer procedure as an important determinant of IVF success. This chapter is an endeavour to review the technique and optimize the various aspects of embryo transfer to help maximize the IVF success.

61.2 Technique of Embryo Transfer

In general, the procedure begins with the patient being advised to fill their bladder to a comfortable status. A comfortably full bladder is one which is full enough to allow excellent visualization of the endometrium on ultrasound (US) and the straightening of the uterocervical (UC) angle without causing any discomfort to the patient. Its role is enhanced in straightening the uterocervical angle specially in an acutely anteverted uterus. This potentially minimizes the chances of cervical trauma and uterine contractions which are common if a tenaculum is used to grasp the cervix in order to straighten the uterocervical angle [1, 2].

Analgesia or anaesthesia is not necessary in most cases of transcervical ET. The procedure is performed under sterile conditions; the patient is placed in a dorsal lithotomy position with legs supported on a stirrup and draped with sterile towels. The cervix is visualized by placing a Cusco's speculum and cleaned with cotton swab. Some clinicians soak the cotton swab in saline solution or culture medium. Cleaning the cervix and vagina aims to clear the excess mucus of the cervix and possibly reduces bacterial contamination to some extent. Vaginal antiseptics are not recommended at ET due to the possibility of potential embryotoxicity. It is appropriate to remove excess cervical mucus as embryos may stick inadvertently to the mucus and get dragged out during removal of the inner catheter following transfer. Cervical mucus can be removed with a sterile cotton ball soaked in normal saline or culture medium. Additionally, cervical mucus can be aspirated using a sterile tuberculin syringe.

There are various methods of embryo transfer techniques, which are usually done under ultrasound guidance. Some clinicians use the direct embryo transfer technique (preload), where the catheter, already loaded with embryo/s, is passed through the cervix into the uterus. In the afterload technique, an empty catheter is passed to the level of the lower uterine segment under ultrasound guidance to a point where the inner catheter enters the endometrial cavity, typically about 5 cm. The inner sheath is slowly removed, leaving the outer sheath just at the internal os. A second inner sheath is loaded by the embryologist, who then assists the transfer in threading the inner sheath into the catheter. The clinician then advances the inner catheter into the uterus to deposit the embryo/s.

The tip of the ET catheter is traditionally placed 1.5–2 cm below the fundus and the embryos ejected as slowly as possible under US guidance, and the inner catheter is rotated and drawn out as gently as possible maintaining pressure on the plunger. Rapid withdrawal may create a negative pressure and result in the expulsion of embryos following the catheter. The inner catheter is passed back to the embryologist to check for retained embryos. However, pregnancy rates (PRs) were not compromised when the retained embryos were discovered and immediately retransferred into the uterine cavity [3].

Gentle manipulation during embryo transfer should be the rule as stimulation of the cervix causes the release of oxytocin, thus increasing uterine contractions. Holding the cervix with a vulsellum should be avoided unless as a last resort. Even while introducing the vaginal speculum, one should avoid pushing the cervix unnecessarily. Lesny et al. (1998) demonstrated that touching the uterine fundus can initiate waves of uterine contractions from the fundus to the cervix that may expel out embryos. As a general rule, embryo transfer should be a simple and painless procedure. The mere presence of the transfer catheter might be one of the factors that can trigger uterine contractions [4]. Some clinicians wait for a while before transferring the embryos, and some wait before withdrawal giving time to the uterus to stabilize. Martinez et al. in a prospective randomized study found no differences in pregnancy rates between removal of the catheter immediately after embryo deposit and after a 30 s wait [5].

Although there is no consensus on the optimal embryo transfer technique, there is evidence that certain methods in ET are associated with improved outcome after IVF. An abundance of literature suggests that the overall "ease" of the ET procedure is strongly correlated with the pregnancy outcome [1]. Although the degree of difficulty or ease of transfer is subjective, a study conducted by Candido et al. suggested that the degree of difficulty in embryo transfer after IVF/ICSI was an independent factor for predicting pregnancy and that an easy or intermediate transfer resulted in a 1.7-fold better pregnancy rates than a difficult one [6].

61.2.1 Degree of Difficulty of Transfer

- Easy – Smooth, without any instrumentation, the catheter was clean of blood.
- Intermediate – Primary catheter met with some resistance, leading to the use of a tenaculum and/or use of outer sheath following which embryo transfer was smooth without any blood contamination.
- Difficult – Any one of the conditions where greater resistance was met, the procedure was time consuming, caused discomfort to the patient, there was a need to change to a harder catheter, involve additional instrumentation such as uterine sounding or cervical dilatation or there was blood in any part of the catheter.

One mechanism by which a difficult or traumatic transfer can hinder implantation is by inducing uterine contractions caused by fundal contact or cervical manipulation which releases oxytocin and prostaglandins. The presence of blood on the catheter is also associated with decreased pregnancy rates and a higher incidence of retained embryos [7]. In a recent study, Mohammad E. Ghanem et al. (2016) concluded that cervical traction and blood on the outer sheath do not compromise clinical pregnancy rate or implantation rate [8].

61.3 Preparing the Patient

Appropriate assessment of the uterine cavity by ultrasonography (USG) prior to IVF cycle helps in the detection of polyps and fibroids causing cavity distortion. Many studies have favoured the hysteroscopic removal of polyps due to higher pregnancy rates that follow the procedure. A polypectomy done closer to ET, the interval being as short as 2–16 days, showed high pregnancy rates possibly due to endometrial damage induced by the procedure followed by a massive inflammatory response and the secretion of cytokines that play a vital role in implantation [9].

61.3.1 Ultrasound Measurement of the Uterocervical Angle Before Embryo Transfer

The uterocervical angle gives us an idea about the direction and length of the uterine cavity and is measured by ultrasonography. It is measured from the external os to the fundus of the uterus. A midplane longitudinal section is obtained, and the angle between a line joining the external cervical os and the internal cervical os and a line joining the internal cervical os and the uterine fundus is the uterocervical angle.

HN Sallam et al. in a prospective controlled study measured the uterocervical angle by a transabdominal USG and concluded that moulding the transfer catheter according to the UC angle significantly increased implantation and clinical pregnancy rates compared to the "clinical feel method" and reduced the incidence of difficult and bloody transfers. Patients with larger angles greater than 60° had significantly lower pregnancy rates compared with those with no angle. It was necessary to measure the angle immediately before the transfer as it was found during preliminary studies that the uterocervical angle changes with the state of the bladder. It is suggested that the patients with a uterocervical angle more than 60° should have a very full bladder for easy negotiation of the ET catheter [10].

A mock transfer or trial transfer prior to ET prepares the clinician for any difficulty in entering the uterine cavity during the actual embryo transfer especially in situations such as large degree of anteflexion/anteversion or retroflexion/retroversion, pinpoint external os, fibroids, previous surgeries causing stenosis of the cervical canal and uterine cavity distortions.

A trial or mock transfer can be done at any point before the actual transfer, but the two most common times are before ovarian stimulation and immediately before the actual ET. A catheter is advanced to the uterine fundus to measure the full length and direction of the uterine cavity and cervical canal, and notes are made regarding the direction and curve of the catheter and type of catheter used. The mock ET can be done blindly or under USG guidance if difficulty is encountered. If the trial reveals a too stenotic cervix to permit passage of a catheter, a cervical dilatation can be planned well in advance before ET in the form of mechanical dilatation, use of osmotic dilators or operative hysteroscopic shaving. Dilatation at the start of stimulation allows sufficient time for the endometrium to recover from any trauma, inflammation or bacterial contamination before ET. Lower pregnancy rates are associated with cervical dilatation done within 5 days of transfer. Dilatation done several weeks before ET appears to improve PRs. While mock ET may possibly provide useful information to plan future ET procedure, a mock transfer remote from the actual ET is done under different circumstances and may not be reflective of actual conditions encountered on the day of ET.

The "afterload technique" is a trial transfer done at the time of ET in which an empty Wallace catheter is passed to the level of the lower uterine segment under ultrasound guidance to a point where the inner catheter enters the endometrial cavity, typically about 5 cm. The inner sheath is slowly removed, leaving the outer sheath just beyond the internal os. Then a second inner sheath is loaded by the embryologist and handed over to the clinician who threads the inner sheath into the outer sheath and completes the transfer.

Indeed, there are multiple benefits to the afterload technique. Since the uterus often changes position during stimulation, a previous mock transfer may not be relevant on the day of ET. It allows the transferring physician to take the time needed to slowly and gently pass a catheter through the endocervix while the embryos remain in the incubator, thus facilitating an atraumatic transfer while limiting the time the embryos are exposed to room environment. In addition, the embryos will not pass through the initial inner sheath that is placed through the cervix. In theory, this would decrease

mucus contamination of the catheter, which has been proposed to adversely affect implantation either by contamination of the cavity or by causing retention or displacement of the embryos. The clinical pregnancy rate in the group with ET using the afterload technique was higher than in the direct ET group (52.4% vs. 34.9%) [11].

61.4 Preparing/Loading the Catheter

A lot of attention has been given to the embryo loading technique in the recent years in order to improve the ART outcome. Embryo loading is a stage of embryo transfer that is performed by a clinical embryologist and is one of the key steps which influences the success of the ART procedure. Although it seems simple and easy, it is one of the most delicate steps in embryo transfer. The embryo is drawn from the culture medium into the catheter, and the loaded catheter is then handed over to the clinician for ET.

In general, there are two distinct catheter loading techniques: the air-fluid method and the fluid-only method. The most commonly reported method has been found to be medium-air-embryo-air-medium [12].

A soft catheter is used, and the ET catheter is flushed with Hams F10 using a 1 ml syringe prior to the loading. Embryos are loaded in approximately 30 μl of medium that is flanked by small air bubbles. Air bubbles can help with ultrasound visualization of the ET catheter and proper placement of the embryo(s) [2]. The total volume of medium injected during transfer is 30 μl with the embryos in the most distal 10 μl.

The embryo catheter loading technique involves several clinically relevant variables: the choice of syringe, the type of catheter, the type and volume of transfer medium, the presence of air bubble, catheter loading speed and embryo placement in the catheter. However, the volume of medium that is transferred and the presence of an air bubble are particularly important and also the most controversial. Christianson et al. performed a worldwide web-based survey of 265 IVF centres in 71 countries [12]. The most commonly reported methods of embryo loading were medium-air-embryo-air-medium (42%) followed by medium in the catheter with embryo at end (20%) and medium-air-embryo (15%). In 68% of centres, the final volume of the catheter was up to 0.3 ml with only 19% using 0.3–0.5 ml and 1% using 0.5–0.7 ml. Almost all centres (97%) prefer a catheter with the orifice on its top. The majority of the centres (82%) wash the catheter prior to loading the embryos.

Some clinicians are of the opinion that the presence of an air bubble in the ET catheter can be useful for identifying the embryos and the medium during ultrasound-guided ET (UG-ET) [13]. In addition, the use of air bubbles to flank the embryos from both sides can protect the embryos from the cervical mucus and accidental discharge before entering the endometrial cavity [14]. However, another school of thought believes that even a small amount of air in the uterus is a nonphysiological factor that has a deleterious effect on the embryos and implantation [15]. It was found that the presence of air increased the likelihood of the embryo moving up towards the syringe, thus increasing the risk of embryos being retained within the catheter.

A systematic review and meta-analysis conducted by Abou-Setta AM has found no difference in pregnancy rates with or without air bubble in the ET catheter during transfer [16].

Halvaei et al. compared embryo catheter loading techniques involving loading directly from the culture microdrop versus loading from the transfer dish and did not find any significant difference in terms of pregnancy rates between these two methods [17]. In group A, the embryos were drawn directly into the ET catheter from the culture microdrop under the oil. In group B, the embryos were transferred from the culture microdrop into G2 medium in a centre well dish and then drawn into the ET catheter in order to wash off the oil. The rationale for drawing the embryos directly from the culture drop is growth factors that are released from the embryos during culture. The periimplantation embryos may produce some beneficial factors for stimulating development of both self and adjacent embryos. Factors like PAF, IGF1 and IGF2, LIF and EGF can be useful for embryo survival and development as well as implantation success. But the disadvantage of this method is contamination of the catheter tip with oil that layers the culture drop, which could be detrimental to embryo implantation. Although the catheter tip is washed in the transfer medium prior to ET, some amount of microdroplets may still remain on the catheter tip.

61.5 Placement of Embryo

Proper placement of the catheter tip and ejection of embryos is another important variable affecting the ET outcome but lacks a uniform universal guideline regarding the ideal location of placement of embryos. Traditionally, the tip of the catheter has been placed 5–10 mm from the uterine fundus. However, several recent studies have suggested that transfer further away from the fundus was more ideal. A transfer depth of 15–20 mm from the fundus may optimize implantation by avoiding the lower cavity where implantation is compromised and, at the same time, avoiding problems like endometrial trauma, uterine contractions and ectopic pregnancy associated with upper cavity transfers. Coroleu et al. in a prospective randomized controlled study found that depositing the embryos >15 mm from the fundus had a higher PR (60% vs. 39.3%) compared to within 10 mm distance from the fundus [18]. Embryos deposited less than 5 mm from the fundus have a lower pregnancy rate and higher ectopic pregnancy rate.

Pope et al. determined the transfer distance from the fundus (TDF) and found that the pregnancy rates were higher when the catheter was anywhere from 5 mm to 27 mm from the fundus instead of being right at the fundus [19]. TDF was calculated by subtracting the depth of catheter insertion (DCI) from the cavity depth (CD) measured by ultrasound.

Lambers et al. assessed the position of the air bubble flashes at the time of ET and found that the air bubbles in the fundal half of the endometrial cavity were associated with higher pregnancy rates compared to the ones in the lower half of the cavity (43% vs. 24.4%) [20].

In a recent study, the location of air bubble flashes at the end of 60 min after ET was evaluated, and it was found that the implantation and pregnancy rates among patients with air bubble flashes located <15 mm from the fundus were significantly higher than those with embryo flashes located >15 mm from the fundus [21].

Some investigators have suggested that the desired location should take the length of the uterine cavity into account rather than a fixed reference point such as transfer distance from the fundus. A randomized controlled trial (RCT) conducted by Franco JG in 2004 showed similar implantation rates and clinical PRs in the upper and lower uterus but significantly higher rates in the mid-cavity. Mario Cavagna et al. studied the implantation sites after embryo transfer into a standard central area of the uterine cavity, and they found that the chances of implantation were maximum in the mid-cavity. Most data in literature support ET in the midportion to the lower midportion of the uterus, avoiding high transfers in the uterus [22, 23].

Another concern with ET is the possibility of expelled embryos. Mansour et al. using methylene blue demonstrated the dye was visualized at the external os of the cervix in 42% of cases. Embryos can move back into the cervix owing to capillary action whereby fluid injected actually trailed the catheter as it was withdrawn [24].

Mansour et al. described another study in which the blades of the speculum were collapsed on the lower uterine segment after ET while the catheter was still left in place, to minimize the fluid to be expelled out through the cervix.

Madani et al. (2010) studied the effect of pushing 0.2 ml of air into the catheter immediately following ET to prevent embryo expulsion. By pushing air gently, they have tried to generate a positive air pressure in order to stop embryos from backtracking with the catheter removal on the creation of a force of waves by uterine contractions and thus reduce the rate of embryo expulsion [25].

Use of Embryo Glue which is a useful and available embryo transfer medium with high concentration of hyaluronic acid was reported to be associated with higher implantation rates in recurrent implantation failures [26]. Hyaluronic acid also known as implantation-enhancing molecule [27] improves the chances of implantation by generating a viscous solution that increases cell-to-cell adhesion and cell-to-matrix adhesion and thereby prevents embryo expulsion. In a systematic Cochrane review [27], hyaluronic acid was found to increase the chances of pregnancy but also increased the chances of multiple pregnancies, which is a less positive result. RCTs specifically looking at its use during single embryo transfer and at cleavage stage and blastocyst embryos are warranted to draw any definitive conclusion (Table 61.1).

Table 61.1 Key elements for a successful ET

Goal	Protocol
Easy, atraumatic transfer without blood or mucus	Trial transfer, US, soft catheter
Proper placement guidance	Inject embryos slowly 1.5 cm from the fundus, US
Minimize embryo stress	Minimize transfer time, control temp./PH
Negotiate a difficult/stenotic Cx	Precycle laminaria, malleable stylet, ultrasound
Optimize implantation, minimize contractions	Day 5, FET, avoid trauma to Cx or fundus

Schoolcraft [2]

61.6 Variables Influencing the Success of Embryo Transfer

The success of ET depends not only on embryo quality and endometrial receptivity but also on the technique of embryo transfer. Several variables play a role in the success of a transfer. Literature strongly suggests that an easy atraumatic transfer, type of catheter used and use of ultrasound guidance can significantly improve implantation and pregnancy rates. Limited evidence also supports trial transfers, experience of the physician, removal of cervical mucus and deposition of embryos in the mid-cavity in the minimum possible amount of time.

61.6.1 Uterine Contraction in Embryo Transfer

Immediate or delayed expulsion of embryos after transferring them into the uterine cavity has always been of concern in assisted reproduction, and one of the most important causes of this is uterine contraction during embryo transfer, especially difficult embryo transfers. Uterine contractions can be present before, during or after embryo transfer and are usually triggered by instrumentation of the cervix, trauma to the endocervix and endometrium or the tip of the transfer catheter touching the uterine fundus. Even alteration in the normal contraction pattern may cause expulsion of the embryos from the uterine cavity [28]. Fanchini et al. investigated the possible consequences of uterine contractions just before ET as visualized by ultrasound on IVF-ET outcome. Approximately, 30% of patients who undergo ET experience uterine contractions. The higher the frequency of uterine contractions, the lower the chance of implantation and clinical and ongoing pregnancy rates. Patients with uterine peristalsis <3 waves/min had a higher chance of pregnancy compared with those more than 3 waves/min (uterine contractions >5/min have been significantly associated with worst IVF outcomes) [29, 30].

Holding the cervix with a tenaculum was found to stimulate uterine junctional zone contractions affecting implantation of the transferred embryos, the mechanism being the release of oxytocin and prostaglandins. When the tenaculum was used, it was temporarily associated with an elevation in oxytocin levels which remained elevated throughout the embryo transfer procedure, and in the absence of tenaculum, no increase in oxytocin levels was observed [31, 32]. Therefore, holding the cervix by a vulsellum or any other instrumentation should be completely avoided except in difficult cases. Even while introducing the vaginal speculum, care should be taken to avoid unnecessary pushing of the cervix [33].

The use of soft catheters should be the first choice in order to avoid injury of the endocervix or endometrium. When using the outer sheath, it is important to keep it just proximal to the internal os. Touching the fundus starts strong random waves of contraction in the fundal area which can expel embryos. Sometimes, the mere presence of the ET catheter might be one of the factors that can trigger uterine contractions [34]. Ultrasound-guided ET has the advantage of visualizing the catheter placement in the endometrial cavity minimizing the chance of touching the fundus. A comfortably full bladder in USG-guided ET helps in the correction of acute anteflexion of the uterus, and the use of a tenaculum can be avoided. Some authors have suggested that it is preferable to wait for the release of embryos till the contractions pass off or to wait before the withdrawal of the catheter after transfer so that the uterus can stabilize [35].

The role of adjuvants that prevent uterine contractions has been considered to improve ET outcome. Tocolytics, prostaglandin synthetase inhibitors and vaginal progesterone as uterine relaxants have been suggested. Other than vaginal progesterone, no other drug has been proven to be useful in preventing uterine contractions. Progesterone administration on the day of oocyte retrieval induces a decrease in uterine contraction frequency on the day of ET. During the luteal phase of ovarian stimulation, uterine contractility decreases progressively and reaches a near quiescent status 7 days after hCG administration, that is, at the time of blastocyst transfer [36]. It is possible that such a uterine relaxation assists blastocyst implantation. Moraloglu et al. concluded that oxytocin antagonist atosiban given intravenously 30 mins prior to ET increased the implantation rate and pregnancy rate and decreased the miscarriage rate. The rationale behind it is that higher concentration of circulating oestradiol due to controlled ovarian hyperstimulation (OHS) may be a causative factor for increased uterine contractions by promoting the oxytocin effect in non-pregnant uterus through the oxytocin receptor gene expression in the myometrium [37]. In a recent study by Kim et al., it was observed that the oxytocin antagonist on the day of ET improves the implantation rate but not the clinical pregnancy rate or miscarriage rate [38]. However, in a study by Lan UT et al., atosiban has been shown to improve implantation and pregnancy rates in patients with recurrent implantation failure [39]. As a general rule, embryo transfer should be a gentle and painless procedure, avoiding any manipulation that may trigger uterine contractions so as to improve the ET outcome.

61.6.2 USG-Guided ET

The clinical touch technique of embryo transfer has been gradually replaced by USG-guided embryo transfer since it is a blind procedure and the chances of catheter indenting or becoming embedded in the endometrium reduce the chance of implantation. Clinicians must rely on tactile assessment, and inadvertent contact of the catheter with the fundus may lead to uterine contractions and expulsion of embryos. Since first described by Strickler et al. in 1985, numerous studies have been published evaluating the effect of USG-guided ET on pregnancy rates. A 2010 Cochrane review of 17 RCTs comparing ultrasound versus clinical touch concluded that ultrasound did increase the ongoing clinical PRs over clinical touch [40].

USG-guided ET is routinely used by most clinicians as it gives us an opportunity to visualize the ET catheter, the exact location of placement of embryos and the process of ejection of the embryos into the uterine cavity in the form of air bubble flashes. Ultrasound guidance is especially helpful in cases of the uterus distorted by fibroids or previous caesarean section scar defects or a severely anteflexed uterus. Direct visualization of the catheter at the cervico-uterine angle allows the physician to place an appropriate curve on the catheter and negotiate in a severely anteflexed uterus. A full bladder required for abdominal ultrasound also helps to straighten the cervico-uterine angle and facilitate entry of the catheter. Touching the fundus can easily be avoided with ultrasound, and one can be certain that the catheter is beyond the internal os in cases of an elongated cervical canal. Patients also seem to take great comfort and satisfaction in visualizing this final step of an often long and tedious process in the form of air bubble flashes. USG guidance has been associated with fewer ectopic pregnancies in some studies [41]. The role of USG has been extended to the use of 3D/4D or vaginal ultrasound during embryo transfer with promising initial results.

Some authors have suggested the use of ultrasound guided-ET (UG-ET) using transvaginal (TV) ultrasound over transabdominal (TA) UG-ET approach with encouraging results. TV UG-ET was originally reported by Hurley et al. followed by few more studies suggesting the advantage of TV UG-ET over TA UG-ET [42]. TA UG-ET typically requires a full bladder carrying potential for cramping, which could impact on outcomes. In addition, TA UG-ET also necessitates assistance to help with the ultrasound or placement of the embryo catheter. In contrast, TV UG-ET does not require the assistance of a sonographer, avoids discomfort of a full bladder, gives greater resolution of the uterocervical angle and can more clearly delineate the catheter tip than TA UG-ET but needs the use of a Kitazato long ET catheter [42].

However, TA UG-ET is the most widely used approach as the procedure is less complex compared to TV UG-ET with associated practical difficulty in doing a speculum and TV scan together. A recent RCT compared TA and TV UG-ET demonstrating no differences in overall pregnancy, clinical pregnancy, live birth and implantation rates between both groups [43]. Another study conducted by Bodri et al. yielded similar success rates when they compared TV UG-ET to TA UG-ET but with the advantage of increased patient comfort due to the absence of bladder distension [44].

The severely anteflexed uterus seemed better served with a TA UG-ET as the full bladder tended to straighten the cervico-uterine angle. Conversely, the retroflexed uterus appeared to be better served with a TV UG-ET. Lastly, a pre-transfer ultrasound on the day of the ET (much like a mock ET) served as a guide to decide the optimal ultrasound approach, particularly with hyperstimulated ovaries that may alter the cervico-uterine angle following oocyte retrieval.

Gergely et al. in 2005 proposed a novel method that used 3D/4D USG in the precise placement of embryos at the *maximum implantation potential (MIP) point*. The shape of the uterus is like an inverted triangle with the cervix and vagina at the apex and the fallopian tube openings at either end of the base. The MIP point is the intersection of two straight lines drawn downwards to the midline from the openings of the fallopian tubes. This point is important because in this part the uterine endometrium has the richest blood supply and this is the area where the implantation of naturally fertilized ovum occurs. Embryo transfer at the MIP point increased the implantation and pregnancy rates and reduced the requirement of transferring multiple embryos, thus reducing the chance of multiple pregnancy and chance of ectopic pregnancy. The MIP point varied from patient to patient depending on the size and shape of the uterus [45].

Lanlan et al. (2009) compared 2D ultrasonography with 3D sonography in embryo transfer and concluded that 3D sonography had a definite advantage over 2D in terms of uterine cavity depth measurement and catheter placement, thus improving implantation rates and clinical pregnancy rates. 3D ultrasound has enabled accurate, non-invasive diagnosis of uterine anomalies and more accurate estimation of the catheter tip position in the uterine cavity specially in those with abnormal uterine cavity (arcuate, bicornuate and sub-septate uterus) [46].

61.6.3 Choice of Catheters

Soft catheters are preferred over rigid ones as they are less likely to traumatize the cervix and endometrium and to invoke any uterine contractions. The commonly used soft catheters (e.g. Wallace) have a softer inner cannula and a stiffer outer sheath. In two meta-analyses of RCTs, the use of soft catheters was associated with a higher PR than firm catheters [47, 48]. Alternatively, the outer sheath from this trial catheter can be left in place, either routinely or with difficult cases, while the soft inner catheter is loaded with the embryos and advanced through the sheath to the correct placement. This method, sometimes referred to as the afterload technique, may also decrease mucus contamination of the catheter. Occasionally, resistance to pass the soft inner cannula into the uterus usually at the level of internal os is encountered, and in these cases the stiffer outer sheath is advanced in the cervical canal to negotiate the resistance with the inner cannula which can now be advanced into the uterine cavity. A malleable stylet device can be used with some soft catheters to negotiate a difficult internal os. It was demonstrated that the use of this device compared with a soft catheter alone did not decrease clinical pregnancy or implantation rates. The inner stylet is then removed, and the softer cannula with embryos loaded in it is fed through the outer sheath to advance into the uterine cavity for transfer. When using the malleable stylet, it is important to leave the outer sheath just proximal to the internal os. Keeping it in this location before inserting the inner soft catheter was found to significantly improve clinical pregnancy rates. In some cases, insertion of the catheter is difficult owing to cervical stenosis. Different approaches have been undertaken to alleviate this issue, including cervical dilation at the time of retrieval. However, this was found to lower subsequent pregnancy rates. Dilation has also been accomplished several weeks before ET and was found to improve outcomes.

61.6.4 Time from Loading to Embryo Transfer

The time interval from loading the ET catheter to depositing the embryos in the uterus should be minimum as possible as embryos are vulnerable to exposure to environmental temperature, light or other agents in the catheter. A longer time interval of more than 120 s carries a poor prognosis [49]. This may be related to how long the embryos are "outside the incubator" as well for the difficulty of ET. However, a study conducted by Ciray HN et al. showed no adverse effect of the duration of the procedure where good-quality embryos were transferred and duration of the procedure lasted up to 7.5 min [50].

61.6.5 ET Speed

A study of fluid dynamics during embryo transfer conducted by Cezary Grygoruk et al. found that an increase in injection speed during embryo transfer increased the shear stress, dynamic stress and velocity differences acting on the embryo. The narrowing of the ET catheter by 20% amplified the transferred fluid velocity by 78%. An embryo positioned in proximity to the catheter wall was exposed to considerably higher shear stress, dynamic pressure and velocity difference than an embryo in the centre of the catheter lumen. Hence, transfer of an embryo should be conducted gently and with minimum injection speed. Any narrowing of the catheter lumen should

be eliminated, and the embryo should be kept far from the catheter wall during injection of the transferred load [51].

There is some evidence that local pressure fluctuations during ET may cause cell damage and influence embryo viability. The percentage of embryos that were shrunken and/or collapsed and undergone apoptosis was higher in the rapid injection group. That is reason enough to propose that ET should be performed as slowly as possible with minimum ejection speed to avoid exposing the embryo to steep pressure gradient. Additionally, rapid injection may possibly promote ectopic pregnancies [52].

61.6.6 Volume and Type of Media

Commercially available media are made up of various concentrations of ions, amino acids and carbohydrates, but still there is lack of evidence of a superior transfer medium over the other. Protein concentration and viscosity have not been demonstrated to impact pregnancy outcomes. Addition of fibrin sealants and a glycosaminoglycan, hyaluronic acid, to the transfer medium has been evaluated in order to see whether it improves the IVF outcome. A fibrin sealant added to the medium was studied in two RCTs. One of them showed no significant improvement in PR, and the other showed a benefit in older patients [53]. A recent Cochrane study reviewed the role of adherence compounds in embryo transfer media and found no evidence that fibrin sealants increase pregnancy rates. For hyaluronic acid, evidence of a positive treatment effect was identified in six trials that reported higher live birth rates [27].

Another matter of controversy is the volume of medium of the ET catheter. A very small volume of medium (<10 μl) along with air bubbles had a negative effect on the implantation and pregnancy rate [54]. Therefore, a volume of 10–30 μl has been proposed since high fluid volume may predispose to ectopic pregnancy. Also, a large volume of transfer medium >60 μl can increase the chance of dislocation of transferred embryos from the uterus into the cervix. On the other hand, Montag et al. compared 40–50 μl and 15–20 μl and found that high fluid volume increased both implantation and pregnancy rates [55]. However, a recent study by Marjan Omidi et al. did not show any significant differences in the pregnancy and implantation rates between 35–40 μl and 15–20 μl transfer volume [13].

61.6.7 Contamination of ET Catheter Tip with Blood or Mucus

Cleaning the cervix with normal saline and removing cervical mucus are necessary or else it may plug the ET catheter causing difficulty in delivering the embryos especially with such a small volume of culture media to inject with the embryos. It may so happen that cervical mucus introduced into the uterine cavity may surround embryos and dislodge them from their location dragging them out during the withdrawal of the catheter. If mucus is pushed higher into the uterine cavity while introducing the catheter, it may interfere with implantation. Studies have shown that embryos were more likely to be retained when the embryo transfer catheter was contaminated with mucus or blood. In a preliminary study, blood or mucus on the tip was associated with a significantly lower pregnancy outcome [56]. Contamination of the catheter with blood may be a marker for difficult ET and has also been linked to poor ET outcomes. Goudas et al. retrospectively demonstrated a clinical pregnancy rate of 50% with no blood, and this rate fell by half when a small amount of blood was present at the catheter tip. Pregnancy rates fell down to 10% when there was significant amount of blood [57].

61.6.8 Role of Rest After ET

Embryo transfer is the crucial last step in assisted reproductive treatment. To achieve optimum outcome, both the clinician and the patient will do everything conceivable to improve the chances of success. This includes use of various hormonal preparations, many nonhormonal medicines, etc. The patients also try to follow medical direction to optimize the chances of success, including use of some non-medical advice. Bed rest after embryo transfer is one such issue, which has traditionally been viewed by patients as an important part of their effort to increase the chances of implantation. This is contrary to the reasonable body of evidence showing no role of prolonged bed rest after ET as far as implantation rate is concerned.

During initial days of ART, it was believed that prolonged bed rest after embryo transfer will help avoid expulsion of the embryo. There has been a plethora of advice regarding the kind of bed rest ranging from prone position for 4 h to complete bed rest for 24 h. There has been an occasional clinic advising bed rest until the pregnancy test. A postal survey of 80 practitioners from 40 units regarding attitudes towards the factors affecting embryo transfer practice in the UK by Balen et al. showed that prolonged bed rest after ET is the least important factor to influence the outcome [58].

The available evidence shows that bed rest has minimal role in the success of IVF treatment. The study by Giuseppe Botta and Gedis Grudzinskas (1997) comparing 24-h bed rest versus 20-min rest has not shown any statistically significant difference in IVF-ET outcome. A total of 182 patients were studied and matched for all the other variables affecting the outcome. There has not been any difference in pregnancy rate, miscarriage rate and multiple pregnancy rate in both groups [59].

Another single-centre prospective study on 406 patients by Bar-Hava et al. (2005) comparing immediate ambulation with bed rest for 1 h shows no difference in pregnancy rate [60]. Woolcott R et al. investigated in a small prospective study in 1998 on 93 patients undergoing 101 consecutive

embryo transfers to assess whether standing upright immediately after the procedure affected the movement of embryo-associated air bubble as an indirect way of judging potential movement of embryo.

Transvaginal ultrasound-guided embryo transfer was done with a repeat USG in standing position immediately post-transfer. There was no movement of air bubble in 94.1% (95/101), in 4.0% (4/101) only <1 cm movement and 1–5 cm movement in 2.0% (2/101) of transfers. No movement of air bubble is noted out of the uterine cavity into the cervix or fallopian tube. The authors concluded that standing shortly after embryo transfer does not have a significant role to play in final embryo position [61]. In fact, a recent study by Sharayu Gaikwad et al. (2013) on 240 patients undergoing first-time embryo transfer with ovum donation in a prospective, randomized, parallel assignment, controlled trial has shown statistically significant higher live-born infant in the no rest group than the group resting for 10 min [62].

A systematic review and meta-analysis of four RCTs including 757 women showed no improvement in pregnancy and live birth rates but reduced implantation rate with bed rest. The findings are concordant with previously published literature suggesting that bed rest is not beneficial following ET. Rather, it might negatively affect the outcome of IVF/ICSI cycles via probable stress/anxiety mechanisms [63]. Mert Küçük (2013) also concluded that there is insufficient evidence to support bed rest after ET; instead, accumulated data indicate restriction of physical activity may actually be detrimental and associated with worse outcome [64].

61.6.9 Role of Antibiotics After ET

Use of antibiotics has been proposed by some to improve the chances of success following embryo transfer, as it is believed that the presence of infection at the time of ET would reduce the possibility of implantation. However, a recent randomized controlled trial of prophylactic antibiotics before embryo transfer by Brook N et al. [65] on 350 patients showed no such association as far as clinical outcome is concerned. There was, however, a significantly lower chance of growth of bacteria in the ET catheter specimen after the use of antibiotics (49.4 vs. 62.3%, RR = 0.79, 95% CI = 0.64–0.97, $p = 0.03$). The study showed no difference in clinical pregnancy rates between the two groups (36.0 vs. 35.5%, $p = 0.83$) though it revealed a significant ($p = 0.03$) association between the level of bacterial contamination and clinical pregnancy rates. Clinical pregnancy rate was 47.2% when the catheter tip was sterile; in contrast, CPR gradually diminished from 40% to 15.8% with increasing level of growth of Gram-positive bacteria, and it was 18.2% when the catheter tip had grown Gram-negative bacteria. The likely explanation for this association is that bacterial contamination reduces the implantation potential of the embryo as well as its effect on the endometrium. The authors of this study did not recommend routine use of prophylactic antibiotics before ET.

61.7 Troubleshooting During Embryo Transfer

61.7.1 Difficult ET

Difficult embryo transfer is seen in 5–7% of patients having assisted reproduction treatment, and in about 1%, it might be extremely difficult to perform ET transcervically even by experienced practitioners. There is no universally accepted definition of difficult ET. A recent study defined very difficult embryo transfer as one which was being labelled so by an experienced embryo transfer practitioner (who had performed at least 100 embryo transfers per year for 2 years) and that took a longer time than usual and required two or more of any of the following manoeuvres: use of the tenaculum and/or change of the embryo transfer catheter and/or use of a stylet and/or reloading of the embryos or cancelling the procedure or cancellation of fresh embryo transfer and opting for frozen embryo transfer after cervical dilatation and hysteroscopy [66]. A recent study of 7714 ETs evaluating difficult ETs suggested objective classification of ET difficulty into four types: type 1, smooth or direct ET without additional manoeuvres; type 2, afterloading with an outer catheter sheath; type 3, afterloading with a Wallace stylet; and type 4, subsequent use of the tenaculum and/or poor ultrasound visualization [67].

To have a successful IVF procedure, doing an atraumatic ET is of utmost importance. The entry of the ET catheter inside the uterine cavity may prove difficult in the presence of associated factors such as cervical polyps, cervical fibroids, pinpoint external os and cervical deformation/stenosis either due to congenital anomalies or those acquired from a previous surgery. Easy or intermediate transfers have been shown to have a 1.7-fold higher pregnancy rate than difficult transfers (95% confidence interval 1.3–2.2) in a comparative study of 4807 ETs [68]. A meta-analysis performed in 2013 showed a lower clinical pregnancy rate for a non-easy transfer demonstrating a considerable harm (RR = 0.67; 95% CI = 0.51–0.87; $p = 0.003$). The authors concluded that there is a low-quality evidence to suggest that a difficult embryo transfer reduces the chance of achieving a clinical pregnancy. Unfortunately, none of the studies evaluated live birth rate [69].

It has been suggested trial transfer, or mock transfer, helps to evaluate how the ET is going to be and makes an appropriate procedure plan. It is ideally performed in the month before the actual IVF cycle. It helps one assess the ease/difficulty in the passage of a transfer catheter via the cervical canal into the uterus, the cervico-uterine length and the position of the uterus (anteverted or retroverted) and thus can guide the clinician during the process of actual ET. Any abnormalities found can then be treated accordingly. For example, a cervical stenosis can be successfully overcome by doing a cervical dilatation prior to starting ovarian stimulation [32]. However, there are studies questioning the benefit of a trial transfer claiming that it might not be reflective of an easy or difficult actual ET since the uterine position at actual ET might be different from that at the mock ET due to enlarged ovaries from ovarian stimulation [70]. There is no

overwhelming evidence suggesting that performing a trial transfer prevents a difficult embryo transfer. Conversely, Mansour et al. in their RCT of 335 women concluded that trial transfer conducted in the cycle preceding the actual IVF-ET cycle significantly improved the clinical pregnancy rate from 13.1% to 22.8%, thus avoiding unexpected difficult ET [71]. It is generally considered a good practice by most of the clinics to do a trial transfer prior to IVF-ET.

Conscious sedation has been used as an alternative method during difficult ET [72]. Further studies are required to confirm the efficacy of sedation in women with difficult ET.

61.7.2 Endometrial Cavity Fluid in IVF

In an IVF cycle, 2–3% of women have presence of fluid in the endometrial cavity on the day of oocyte retrieval. Excessive amount of fluid in the endometrial cavity (≥3.5 mm in anteroposterior diameter in the sagittal plane) on the day of oocyte retrieval was found to have a negative impact on the outcome of IVF-ET [73]. In 25% of cases, this fluid collection is found to be due to coexisting hydrosalpinx, while in others, it could be due to other tubal pathologies, subclinical endometrial infection or abnormal endometrial development.

A recent meta-analysis of six studies evaluating 5928 ART cycles showed that the pregnancy rate was significantly lower in the group with ECF than in the group without ECF (OR = 0.74, 95% CI = 0.55–0.98) [74]. In view of the suboptimal cycle outcome, deferring the fresh embryo transfer, elective cryopreservation of all the embryos followed by their replacement in a frozen thaw cycle is considered to be a better option when fluid is present in the endometrial cavity. An alternative option explored for women with excessive ECF is aspiration of the ECF before embryo transfer. Griffiths and colleagues reported a case series of five women in which they removed 5–6 mL of ECF with an embryo transfer catheter immediately before embryo transfer leading to pregnancies in all of them [75]. A much larger prospective matched control study of 132 women undergoing IVF found similar implantation rates in women who underwent ECF removal compared to controls [76]. Few other studies failed to reproduce these positive results. Hence, at the moment, ECF aspiration as a modality of treatment for patients with ECF should be reserved in couples who do not want to postpone embryo transfer.

61.7.3 Cervical Mucus at the External Os

Despite significant research, it is not yet clear whether cervical mucus should be removed or not prior to ET. On one hand, it is thought to help in easy insertion of the ET catheter providing a slippery coating as a natural lubricant over the cervical canal, while on the other hand, it seems to have certain detrimental effects.

Cervical mucus may clog the tip of the transfer catheter, thereby causing difficulty in pushing the embryos into the endometrial cavity. Mansour and colleagues did an interesting study by doing intrauterine instillation of methylene blue dye as a surrogate for culture media in a mock embryo transfer model [77]. In this study, the patients underwent mock ET before and after cervical mucus aspiration. Their results demonstrated that the dye extrusion rate at the external os was higher when the cervical mucus was not aspirated compared to when it was aspirated (57% and 23%, respectively).

The tip of the catheter might get contaminated by the microorganisms present in the cervical mucus. The positive culture rate of the cervical mucus and catheter tip was 70.9% and 49.1%, respectively, in a study by Egbase and colleagues. The clinical pregnancy rates for catheter tip-negative women were higher when compared to catheter tip-positive ones (57.1% and 29.6%, respectively) [78]. Careful cleaning of the cervix prior to embryo transfer is therefore considered as a norm rather than exception.

There is increased incidence of retained or expulsion of embryos because the embryos stick to the cervical mucus which dislodge them from their original placement. Nabi and colleagues found that the chance of embryo retention is nearly six times more likely when the embryo transfer catheter is contaminated with mucus (3.3 vs. 17.8%) [3].

While there are reported detrimental effects of excessive cervical mucus as above, there are concerns that the procedures of removing cervical mucus can possibly stimulate uterine contractions or cervical bleeding. Studies have evaluated two ways to tackle the cervical mucus – either an aspiration of cervical mucus using a syringe and culture media or to remove it manually using wither cytobrush or a cotton swab. In a prospective controlled trial of 286 women, Eskandar and colleagues evaluated the effect of cervical mucus aspiration prior to ET on the clinical pregnancy rate [79]. The mucus-aspirated group showed a significantly higher CPR (63/143) than the control group who did not have cervical mucus aspiration (38/143) (OR = 2.18, 95% CI = 1.32–3.58). This was seen despite the fact that there were a higher proportion of easy transfers in the latter (OR = 3.00, 95% CI = 1.05–8.55).

The effect of removal of cervical mucus by a cytobrush prior to embryo transfer was studied in a single-blind randomized controlled trial of 317 couples assessing live birth rate as the primary outcome. Live birth was not significantly different between the two groups (24% vs. 21% in study and control, respectively). They concluded that it was unlikely that pretransfer cervical mucus removal has a significant effect on live birth rate [80].

The biggest study till date was by Moini and colleagues who evaluated 530 women undergoing fresh embryo transfer following IVF. The intervention group had cervical mucus removed using a sterile cotton swab, while the control group had routine ET without removing the mucus. The intervention group had significantly higher clinical pregnancy rate, implantation rate and live birth rate compared to the control group. The logistic regression analysis gave an odds ratio of 2.3 (95% CI = 1.55–3.4) for pregnancy in the intervention group as compared with the control group [81]. As of today, cervical mucus removal should be a part of standard practice before embryo transfer.

61.7.4 Retained Embryos in the Catheter

Retained embryo following an initial transfer attempt is a fairly uncommon event, but certainly is the one capable of creating anxious moments for the clinicians, embryologists and patients. Most of the studies quote an incidence of <3%; however, there are few who quote up to 10%. The reported but yet not conclusively proven risk factors of retained embryos at ET include:

1. Higher number of embryos transferred
2. Cleavage-stage ET
3. Clinician's experience
4. Transfer technique
5. Difficult ET
6. Contamination of the ET catheter with mucus or blood

The timing of the appearance of the problem of retained embryo precludes performing an RCT. Hence, the available evidence largely comprises of retrospective analysis. Various such studies have shown that the pregnancy rate is not compromised if retained embryos are immediately recognized and retransferred into the uterine cavity [3]. It is unlikely that any evidence to the contrary is possible in the near future.

61.7.5 Fresh ET vs. Frozen ET

A recently published systematic review of national and regional ART registry data of seven regions, including a total of 7,079,145 ART cycles, assessing the changes in clinical practice between 2004 and 2013 showed significant overall increase in the utilization of freeze thaw embryo transfer cycles [82].

The objective of elective freeze-all policy is to place the embryos in a more favourable intrauterine environment, without facing the possible adverse effects of OHSS and supraphysiologic hormonal levels over the endometrial receptivity [83]. This has been made possible by having significant advancement in the field of cryopreservation, importantly vitrification, leading to excellent post-thaw survival rate in excess of 90%.

There has been plenty of research comparing fresh vs. frozen embryo transfer in recent years. The evidence is divided with availability of studies showing similar outcome in both the groups [84, 85] or a higher pregnancy rate in the frozen ET group [86, 87]. A recent Cochrane review with four studies and 1892 couples found no superiority of fresh ET over frozen ET with moderate- to low-quality evidence [88].

61.7.6 Effect of Controlled Ovarian Stimulation (COS) on Endometrial Receptivity

Supraphysiologic levels of oestradiol and subtle increase in progesterone level during COS could lead to morphologic and biochemical alterations in the endometrium, hampering the receptivity. This leads to embryo-endometrium asynchrony leading to reduced pregnancy rates, which can be completely avoided by opting for frozen ET due to precise control of endometrial development. A recently conducted meta-analysis of three RCTs including 633 cycles showed an increase of 32% in the ongoing pregnancy rate when elective frozen embryo transfer was performed compared to fresh transfer (RR = 1.32, 95% CI = 1.10–1.59). Elective freeze-all policy with subsequent FET virtually eliminates the risk of late-onset OHSS, which tends to constitute most cases of moderate to severe OHSS during IVF. OHSS is an iatrogenic and potentially lethal complication encountered of COS in IVF. Since the major trigger for OHSS is hCG, substituting it with an agonist trigger has led to drastic reduction in the incidence of OHSS, thus improving the safety aspect of IVF. This approach together with elective freeze-all policy supports the concept of "OHSS-free clinic".

61.7.7 ET in the Presence of Uterine Anomalies

Uterine anomalies are not uncommonly reported as more and more 3D ultrasound scans are performed routinely nowadays. In a large prospective study, 13.3% of infertile females were found to have uterine anomalies with 88% being constituted by arcuate uterus [89] which is now considered as a normal variant. The pregnancy rate was not different between controls, women with arcuate uterus and women with major uterine anomalies, but the miscarriage rate was higher in the latter.

Although there is a lack of RCT evaluating the reproductive outcome of uterine anomalies undergoing IVF, controlled studies have reported increased risk of miscarriages and reduced live birth rates in women diagnosed to have uterine anomalies. Uterine anomalies are evaluated actively in women undergoing IVF since many of them would choose correction prior to ET. 3D transvaginal ultrasound is an excellent modality and is considered as gold standard for the evaluation of uterine anomalies [90].

Observational studies have suggested a beneficial effect of septal resection on IVF-ET success rate compared to those with non-resected septum [91]. In conditions like bicornuate uterus with one underdeveloped horn, cervical anatomical abnormalities, etc., the ET procedure might require necessary modifications for improving pregnancy rate like depositing the embryos in the well-developed horn in a bicornuate uterus to have a better outcome. The scenario becomes a little more complicated in the presence of cervical and vaginal septum as these need a proper speculum examination to be diagnosed and are better treated well before ET.

61.7.8 Transmyometrial ET

Transmyometrial ET (TMET), also known as the "Towako" method, has been first reported in 1993 by Kato and colleagues. This method is an effective alternative if transcervical ET is proved to be difficult due to cervical scarring or stenosis due to previous cervical surgeries. While attempts of pretreatment cervical dilatation and mock ET are done if difficult

transcervical ET is anticipated, practitioners may be faced with the difficulty in negotiating the cervical canal on the scheduled ET day with the embryos ready to transfer. Transmyometrial ET is the effective method then, if the unit has the appropriate equipment and expertise.

The equipment needed for transmyometrial ET apart from the ones required for routine ET include a vaginal ultrasound probe and a Towako ET catheter set containing a 18–19-gauge needle of 32.5 cm length and a 2.0 French catheter of 32.5 cm length.

Transvaginal-transmyometrial transfer is performed under sedation and ultrasound scan guidance. A vaginal probe is inserted, and the bevelled needle with its stylet is passed under ultrasound guidance through the anterior vaginal fornix and the myometrium of the anterior wall of the uterus. If the uterus is retroverted, the needle is passed through the posterior vaginal fornix and the posterior wall of the uterus. The needle is advanced through the myometrium to the junction with the endometrium without puncture of the latter. The stylet is then removed, and the preloaded transfer catheter is passed through the needle. After release of the embryos, the catheter is checked for any retained embryos.

The possible complications associated with the procedure include pain, junctional zone contractions with associated expulsion of embryos, haemorrhage and infection.

It has yet not become popular among reproductive medicine specialists and is seen by many as a very traumatic way to put the embryos back. The fears are pertaining to possible trauma to the endometrium and myometrium by the needle giving rise to complications including haemorrhage. Another fear is of inducing junctional zone contractions, though one study comparing TMET with very difficult transcervical ET showed that both were equally provocative in terms of junctional zone contractions.

The largest study done to date comparing these two groups showed a non-significant increase in live births in the TMET group (26.1% vs. 16.4%) and a significantly lower miscarriage rate in the TMET group (20% vs. 34%) [66]. The unquestioned need of TMET arises in case of gross anatomical defects like cervico-vaginal agenesis besides the impossible transcervical transfer due to cervical stenosis. Otherwise, there is no evidence showing the superiority of TMET over difficult transcervical ET.

61.8 Evidence-Based Recommendations for ET

- Use of ultrasound guidance for embryo transfer (Grade A)
- Removal of cervical mucus prior to ET (Grade B)
- Use of soft ET catheters (Grade A)
- Placing of the ET catheter tip in the upper or middle area of the uterine cavity, greater than 1 cm from the uterine fundus (Grade B)
- Immediate ambulation once the embryo transfer procedure is completed (Grade A)
- Immediate retransfer in case of retained embryos (Grade B)

61.9 Interventions with No Evidence of Benefit

- Acupuncture (Grade B)
- Analgesics, massage, general anaesthesia, whole systems traditional Chinese medicine (Grade C)
- Prophylactic antibiotics prior to and on the day of ET (Grade B)
- Immediate withdrawal of the embryo transfer catheter after embryo expulsion (Grade B)

61.10 Interventions Which Need Further Evidence Before Becoming a Standard of Care

- Trial transfers prior to ET
- Slow injection of embryos vs. fast injection (Grade C)

Review Questions

1. List the variables which could affect the success of embryo transfer.
2. What are the different methods of embryo loading?
3. What is the role of mock transfer in IVF-ET?
4. Which is the optimal site for placement of embryos and why?
5. What is a difficult embryo transfer and how would you overcome it?

G-CSF and GM-CSF: Clinical Applications in Reproductive Medicine

Wolfgang Würfel

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_62

Learning Objectives

- Describe the colony-stimulating factors (CSFs) 2 (granulocyte-macrophage colony-stimulating factor, GM-CSF) and 3 (granulocyte colony-stimulating factor, G-CSF), the nature of their receptor interactions, and the location of these functional systems in the organism.
- Provide an overview of the physiological functions performed and supported by both CSFs, particularly with respect to reproduction.
- Describe and discuss the current state of data concerning administration of CSFs to patients with repeated implantation failure (RIF) or recurrent spontaneous abortions (RSAs).
- List issues that are still open in this respect and areas where information is still required.
- Describe potential risks of use of CSFs in reproductive medicine and during pregnancy.

Key Points

- Members of the family of colony-stimulating factors, such as granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF), can be found throughout all stages of reproduction from the follicle and endometrium to the trophoblast, together with their specific receptors.
- As growth factors, G-CSF and GM-CSF have a direct positive influence on reproductive processes, such as oocyte maturation and growth of preimplantation embryos or trophoblasts, but also influence those processes indirectly by activating immunocompetent cells.
- So far, we know that when added to culture medium, GM-CSF is able to increase implantation rates in ART treatment, as is G-CSF, in the form of either intrauterine instillations or systemic administration.
- For patients experiencing recurrent spontaneous abortions (RSAs), systemic administration of G-CSF in the first trimester of pregnancy increases birth rates. Approval of G-CSF as a drug is currently undergoing examination at phase II study level.
- Administration of GM-CSF and G-CSF during ART treatments or pregnancy does not cause chromosomal aberrations in newborns; no teratogenic effects or increases in malformation rates are known.
- At the dosages and duration of administration described here, no increased risk of malignant diseases is expected.
- Questions still unanswered include issues such as when G-CSF is more beneficial than GM-CSF and vice versa, correct indications of their use, required dosages, and necessary duration of treatment.

62.1 Introduction

In human pregnancy, implantation establishes a close connection at cellular level between the mother-to-be and the embryo or fetus or – to be more precise – between the trophoblast and placenta. This connection is so close that it may even trigger the formation of fusion cells such as Langhans giant cells [1]. In pregnancy, the connection causes an intensive exchange between the two individuals, involving nutrients but also hormones, cytokines, growth factors, and cells. While these cells may already be differentiated, in many cases they are stem cells. As a result of this cell transfer, which generally takes place from the embryo/fetus to the mother-to-be, the mother-to-be becomes a chimera or, given the relatively low volumes of embryofetal cells, a "microchimera," from which the term "microchimerism" (MC) has been derived to describe the general phenomenon [2]. MC is a complex subject that is still not well understood today [3], primarily because it has two sides; the transferred stem cells appear to be capable of activating repair processes [4], yet development of autoimmune disorders may result [5]. Stem cells, which are the focus here, play a role both in MC and in placentation itself, that is, trophoblast invasion and development (cytotrophoblasts and syncytiotrophoblasts). The quality of implantation in turn determines the quality of support to the embryo/fetus and thus the further progress of pregnancy. This draws our attention to the regulatory processes that play a part here, that is, the growth factors and cytokines that control cellular growth. In recent years, members of the colony-stimulating factor (CSF) family have increasingly been shown to play a major role here [6, 7]. Five different CSFs have been identified to date, the most important of which are G-CSF (granulocyte colony-stimulating factor) and GM-CSF (granulocyte-macrophage colony-stimulating factor). They will therefore be examined in more detail.

62.2 History

In the mid-1960s, Metcalf, Sachs, and their assistants were the first to identify colony-stimulating factors for hematopoietic progenitor cells, based on cell culture assays [8]. The first factor to be isolated was G-CSF, which was shown to differentiate myelomonocytic leukemia cells in mice [9]. GM-CSF was purified in 1984 and shown to stimulate neutrophil granulocytes [10]. cDNA in mice was identified in the same year [11]. Identification of human G-CSF followed as the next step in 1985 [12, 13]. Very soon, it became evident that G-CSF and GM-CSF were two different cytokines [14, 15]. Human cDNA was likewise described in 1985 [16], while mapping of the G-CSF gene and cDNA was performed in 1986 [17].

62.3 G-CSF and GM-CSF and Their Receptors

62.3.1 Structure of G-CSF and Its Receptor

The single gene of G-CSF (CSF-3) is located on chromosome 17 (35.43–35.43) [18]. This gene has five exons with a length of approximately 2.3 kb; splicing variants are encoded in tandem at the 5′ terminus of the second intron [19]. Human glycoprotein consists of 174 amino acids and has a molecular weight of 19.6 kDa.

G-CSF acts via specific high-affinity receptors. Basically, it was thought that there were four different receptors. However, there is one encoded receptor, also known as cluster of differentiation (CD) 114. The CSFR gene is located on chromosome 1 (36.47–36.48) [20]; its molecular weight is approximately 19.06 kDa.

The G-CSF receptor belongs to the cytokine receptor superfamily and performs its functions by means of tyrosine phosphorylation and activation of members of the Janus protein kinase (Jak) family. Additionally, an activation pathway of the signal transducers and activators of transcription (STAT) family is described.

62.3.2 Structure of GM-CSF and Its Receptor

Although G-CSF and GM-CSF are extremely similar in some respects, the gene for GM-CSF (CSF-2) is located on a different chromosome, namely, chromosome 5 (132.07–132.08). Although DNA codes for 144 amino acids, the active form of GM-CSF consists of only 127 amino acids. Its molecular weight is thus no longer 23 kDa, but 16.3 kDa [21].

The GM-CSF receptor is a heterodimer consisting of one α- and one β-chain [22]. The α-chain is designated CSF2RA (CDw 116) and is coded for the pseudoautosomal region of the X and Y chromosomes (Xp 22.32). The β-chain (CSFRB) is located on chromosome 22 (12.2–13.1) [23].

The GM-CSF receptor is likewise part of the type I cytokine receptor superfamily. Like the G-CSF receptor, it performs its functions via members of the Jak or STAT family [22].

62.3.3 Tissue Distribution of the G-CSF Receptor and the GM-CSF Receptor

G-CSF and GM-CSF receptors can be detected in many myeloproliferative tissues and their cells, for example, in monocytic cells like T-cells, natural killer (NK) cells, macrophages [24, 25], and even platelets [26].

The following description will be limited to an examination of the receptors in connection with reproductive functions.

The GM-CSF receptor is found in bovine ovarian follicles and granulosa cells [27] and can be identified in human corpora lutea throughout the luteal phase [28]. However, expression of the subunits appears to vary, at least in mice [29]. Expression in the endometrium is at its highest during the mid-secretory phase of the endometrium [30]; after menopause, expression drastically declines [31].

G-CSF receptor expression increases during maturation of the preovulatory follicle [32]; expression is also proven in the second part of the cycle, that is, luteinized human granulosa cells [33]. In human endometrial cells, G-CSF receptor expression exists throughout the entire cycle [34]; expression is under the positive influence of estrogens [35].

The GM-CSF receptor can be identified in both bovine and human testicular tissue, where its activation results in improved sperm motility [36].

The G-CSF receptor is expressed on the trophoblast [37] and in the placenta [38]. The highest G-CSF receptor expression can be seen in the first trimester. It declines over the second trimester and rises again in the third trimester [39]. The G-CSF receptor is easily identified in the human extravillous trophoblast during the first trimester [40] as well as in other trophoblast cells [30].

In the human fetus, G-CSF and GM-CSF receptors are present in nearly all tissue types, for example, hematopoietic and neural stem cells [41, 42] and cells of the kidneys and the gastrointestinal tract [43, 44], and in various areas of the brain and central nervous system [45]. They can first be identified 8–16 weeks after conception [41]. Adults also show both receptors in virtually all types of body tissue.

62.3.4 Cellular Synthesis of G-CSF and GM-CSF

G-CSF and GM-CSF are synthesized by NK cells, particularly uterine NK (uNK) cells (CD 56^{bright}) [46, 47]. Further immunocompetent cells with synthesis of both colony-stimulating factors include macrophages/monocytes [48], T-cells [49], and dendritic cells [50].

G-CSF and GM-CSF are synthesized by granulosa cells and luteal cells [33, 51], increasing particularly during the preovulatory phase [32]. This synthesis can be activated by estrogens [35] and progesterone and, interestingly, by components of seminal fluid [52].

G-CSF is synthesized in decidual cells [53] and in the chorionic villous trophoblast [54], but not in the cytotrophoblast. The synthesis rate for both cell types is significantly higher in the first trimester than at term. Both trophoblast and decidual syntheses have been shown for GM-CSF [30], although it should be remembered that all these tissue types are highly permeated by immunocompetent cells, chiefly large granular leucocytes (LGL) (CD 56 ^{bright}), and may potentially secrete G-CSF and GM-CSF.

G-CSF and GM-CSF can be identified in amniotic fluid [55, 56]. Their concentration appears to increase in

pathological pregnancies, primarily with inflammatory complications such as amniotic infection syndrome (AIS) [57], concomitant with increasing receptor expression in the placenta [58].

62.4 Physiological Significance of G-CSF and of GM-CSF

G-CSF is considered to be a major cofactor during the ovulation process in humans [58].

GM-CSF promotes follicular development (in rats) [59] and cumulus cell expansion in cattle [60].

Thickening of the endometrium in rats is induced by G-CSF [61]. In diabetic rats (experimental diabetes mellitus), intraperitoneal injection of G-CSF significantly reduced degeneration of ovarian follicles and the decline of AMH (anti-Müllerian hormone) [62].

A higher percentage of hatching blastocysts in mice can be seen under the influence of G-CSF and GM-CSF [63]. In 2005, GM-CSF was shown to have the same effect on human blastocysts, with positive influence on both generation rate and growth [64]. GM-CSF promotes glucose uptake and results in enhanced proliferation and/or viability of blastomeres in murine blastocysts [65]. G-CSF-deficient mice are viable and able to have offspring, but have lower fertility rate and a significant higher rate of spontaneous abortions [66]. G-CSF works in an anti-abortive manner in mice [67].

Both GM-CSF and CSF-1 are capable of accelerating differentiation of the human trophoblast. This is accompanied by an increase in the synthesis rate of human placental lactogen (hPL) and human chorionic gonadotropin (hCG) [68].

G-CSF is able to pass the placenta barrier in rats [69]. This has also been demonstrated in mice, where increased concentration in the fetus can be seen only 30 min after a single dose of 50 ug/kg rh-G-CSF (with peak concentration after 2 h) [70]. The ability of GM-CSF to pass the placenta barrier has also been proved [71].

Chorial cells start proliferating under the influence of G-CSF [53]. During pregnancy, concentrations are higher than in nonpregnant women [72], although this is not undisputed [70].

G-CSF and GM-CSF are able to enhance concentrations of regulatory T-cells [73] and to activate dendritic cells [74]. G-CSF is also able to reduce toxicity of NK cells [75].

G-CSF and GM-CSF lead to increased migration and proliferation of endothelial cells [76].

In summary, it can be established that both G-CSF and GM-CSF (together with CSF-1, i.e., macrophage colony-stimulating factor (M-CSF)) and their receptors are located in many different areas of the reproductive tract and are expressed in many different stages of the reproductive process, in some cases with sustained effects [77]. Absence of these factors or their reduced expression leads to lower fertility per se, not only in animal testing, and to an increase in pregnancy pathologies [64, 78].

62.5 Applications in Diagnosis

ART treatments such as IVF or ICSI appear to show a positive correlation between concentrations of G-CSF in follicular fluid and the probability of implantation or subsequent pregnancy [79–85]. The publications of this working group indicate that this only applies to G-CSF, with concentrations >30 pg/ml offering the highest probability of subsequent implantation of the embryo (class I) and concentrations of <18.4 pg/ml (class III) the lowest; while concentrations did not necessarily correlate to embryo morphology, the highest implantation rates were shown by embryos with excellent morphology and extremely high follicular G-CSF concentration. Interestingly, this correlation clearly also applies in the case of patients with pronounced ovarian insufficiency (AMH < 0.1 ng/ml).

A testing system for these concentrations is available commercially under the name of Diafert™.

The approach is extremely interesting with respect to improving the accuracy of estimated individual prognosis [86], but also of prognosis with respect to individual oocytes; admittedly, however, application of the system in practice in follicular puncture is extremely complex.

62.6 Clinical Applications

Today, recombinant (genetically engineered) substances are commonplace in treatment of humans. In the case of GM-CSF, these may be molgramostim or sargramostim, the latter produced from yeast cells. Filgrastim is a recombinant human G-CSF analog from *E. coli*, while lenograstim is produced from CHO cells and is still glycosylated in position 133, that is, somewhat more physiological. PEGylated forms are approved as lipegfilgrastim and pegfilgrastim.

However, it should be noted that many countries currently only allow h-CSF analogs, but not h-GM-CSF analogs.

62.6.1 G-CSF and Oocyte Maturation

A positive effect on ovulation induction is also noted; a single dose of rh-G-CSF (lenograstim, 100 mg) 48 h before administration of hCG results in a significant reduction of LUF (luteinized unruptured follicle) syndrome in CC (clomifene citrate) cycles [87], which may enable approximately 90% of all LUF syndromes to be avoided [88].

62.6.2 G-CSF for Thin Endometrium

In 2011, Gleicher et al. [89] first reported on intrauterine instillations in four patients with thin endometrium as part of an ART program. After G-CSF instillation, all four patients showed increased endometrial volume, and all four underwent embryo transfer (ET) resulting in pregnancy. A subsequent noncontrolled cohort study confirmed the initial

positive impression of G-CSF instillation [90]. Two further studies showed a positive effect on endometrial growth (unresponsive thin endometrium) and increased pregnancy rate [91, 92]. Tests with rats furnished proof that this phenomenon is actually based on the increased regeneration and proliferation of endometrial cells [93].

In contrast, after G-CSF instillation in patients with thin endometrium, Eftekar et al. [94] noted higher implantation and pregnancy rates but no increase in endometrial thickness.

Of course, instillation appears to provide no benefits for "normal" ART patients with well-developed endometrium, neither increasing endometrial thickness nor boosting pregnancy rates [95, 96]. (We have ourselves observed sustained endometrial growth through systemic administration of rh-G-GSF (lenograstim, 13 m) every second or third day during the follicular or stimulation phase.)

With respect to GM-CSF, no data on intrauterine instillations with ART patients have yet been published.

In summary, intrauterine G-CSF instillations are clearly able to improve implantation rates after embryo transfer for patients with implantation problems and poorly developed endometrium; however, they are ineffective in patients with normal endometrium. Similar results are anticipated from GM-CSF.

However, endometrial thickness is not a very reliable parameter. It would be more important to know the type of cells which make up the endometrium in patients with good and poor implantation outcomes; key roles are likely to be played by uterine NK cells, but also peripheral cells. This information would enable more precision in establishing indications.

There is also uncertainty over applicable dosages, particularly in correlation with endometrial findings.

62.6.3 G-CSF and GM-CSF in Culture Media of ART Cycles

As described here, GM-CSF results in an increased blastocyst generation rate and accelerated growth, shown in tests including GM-CSF-deficient knockout mice [97]. The effect was also shown in human preimplantation embryos where 2 ng/ml of rh-GM-CSF was added to the culture medium for ART treatment [98]. Furthermore, GM-CSF appears to be capable of preventing inner cell mass apoptosis [99]. A randomized double-blind placebo-controlled multicenter study [100] showed that supplementation of culture medium by adding rh-GM-CSF significantly raises pregnancy and birth rates; out of 1149 embryo transfers recorded, the implantation rate rose significantly from 20% to 23.5%, and the birth rate rose from 24.1% to 28.9%. Patients with a previous history of one or more abortions benefited particularly from GM-CSF.

The culture medium is now commercially available under the name EmbryoGen™. It is approved for medical histories involving a minimum of one spontaneous abortion. Under the name of BlastGen™, the medium is now available for 5-day cultures in addition to 3 days.

A culture medium with added 0.5 ng rh-G-CSF/ml is also a patent applied for [101].

62.6.4 Systemic Application of h-GM-CSF and/or h-G-CSF in Patients with Repetitive Implantation Failures (RIFs) in an ART Program

There is now no doubt that some patients show implantation problems. Plentiful evidence is available from ART treatments, in cases where pregnancy does not result despite multiple embryo transfers under highly promising conditions (e.g., young age of patient, excellent embryo morphology, blastocysts where applicable).

As early as 2000, we reported [102] on our experiences with a single dose of GM-CSF (300 ug molgramostim) or G-CSF (34 m filgrastim) at the time of embryo transfer. Results are shown in ◘ Table 62.1. While filgrastim was very well tolerated, some cases showed undesirable side effects after administration of human-derived GM-CSF, such as high blood pressure and chest tightness.

◘ **Table 62.1** Results of the pilot study for RIF patients [102]

	Molgramostim 300 ug	No medication	Filgrastim 34 m	No medication
Number of patients	107	107	69	69
Number of embryo transfers (day 2)	107	106	69	69
Clinical pregnancies	46	21	35	13
Pregnancy rate/embryo transfer (clinical pregnancies)	42.9%	19.8%	50.7%	19.8%
Abortions (abortion rate)	9 (19.5%)	2 (19.0%)	7 (29%)	2 (15.4%)

Definition of RIF: More than four treatment cycles with at least eight embryos of good morphology transferred. ET was performed on day 2. The age of all groups was between 37 and 38

Patients in a randomized controlled double-blind study (RCT) from 2016 likewise received 300 ug G-CSF as a single shot at the time of ET [103]. The study showed an increase in (clinical) pregnancy rate from 14.3% to 37.5%. The same procedure was reported by Davari-tanha [104], who noted a significant rise in the implantation rate, albeit without affecting the rate of spontaneous abortion.

In 2010, we reported on continuous application of lenograstim (13 m every third day after embryo transfer) to RIF patients [105]. To obtain a more precise purely clinical indication of RIF, we identified any deficiency in activating killer immunoglobulin-like receptors (KIRs) in advance [106, 107]. Application after embryo transfer was restricted to cases with this deficiency, combined with a predefined RIF constellation. Compared with the average pregnancy rates of our ART program, rates with G-CSF rose significantly, with a pregnancy rate of 42% per ET on day 2 and 73.8% on day 5. An ongoing observational study (>800 embryo transfers) showed lower figures but continued to record significant higher results with administration of G-CSF, particularly for embryo transfers on day 5. Gil-Herrera [108] pursued the same strategy with a small group of patients and reported high pregnancy rates, low spontaneous abortion rates, and excellent tolerance of SC injections.

In 2012, Scarpellini and Sbracia [109] published a randomized controlled study of 109 RIF patients. ET was performed on day 2 after ET patients had been given a daily dose of 60 mg rh-G-CSF. In cases of positive pregnancy tests, this regimen was continued for a further 40 days. The treatment group showed a (clinical) pregnancy rate of 43.1% per ET, compared to 21.6% in the placebo group (saline injections), resulting in a highly significant difference ($P < 0.001$).

In summary, it can be assumed that G-CSF, in the form of both single shot and continuous administration, is capable of improving implantation and pregnancy rates in RIF patients [110–112]. However, with the exception of the clinical definition of RIF, there are still no clear-cut diagnostic criteria for identifying patients that would benefit from G-CSF. If these criteria existed, patients could be identified at primary level without needing to go through a series of unsuccessful treatments.

A plausible initial approach in this direction involves identification of KI receptors in correlation with the HLA groups of both partners. There are doubtless constellations in which embryo-maternal communication is predictably disrupted [106, 107], so that a central growth factor like G-CSF (or GM-CSF) can stabilize pregnancy.

A further open question is the issue of dosages, although these are similar throughout all available studies. No study designed to identify dosage has been conducted to date.

No further published data are available with respect to GM-CSF. This may be because virtually no specialty pharmaceuticals are available; however, a patent application for this indication is pending with the European Patent Office (EPO) [113].

62.6.5 G-CSF in Patients with Recurrent Spontaneous Abortions (RSAs)

Data from the Severe Chronic Neutropenia International Registry (SCNIR) gave the first hints that CSFs may be able to lower the abortion rate. For example, Boxer et al. reported in 2010 [114] that patients suffering from neutropenia and receiving G-CSF during pregnancy showed significantly fewer abortions, namely, 5%, compared to 32% in patients who did not receive G-CSF. At the same time, premature births and infant mortality were observed to decline.

In 2009, Scarpellini and Sbracia [115] reported the results of a randomized placebo-controlled study of RSA patients. The main results are depicted in ◘ Table 62.2.

The birth rate in the treatment group was significantly higher compared to the placebo group. The abortion rate and the obstetric outcome for both groups were similar; no malformations were reported. Striking results are the significantly increased hCG levels in the G-CSF group, which is approximately 30% higher than in the control group (9th week of gestation).

Santjohanser et al. in 2011 [116] reported on RSA patients in an ART program (◘ Table 62.3). The report showed that the G-CSF group experienced higher pregnancy rates per embryo transfer and lower spontaneous abortion rate in subsequent pregnancies. This difference was also noted in comparison to the third patient group, which received drugs such as heparin,

◘ **Table 62.2** Main results of the study by Scarpellini and Sbracia [115] in patients with recurrent spontaneous abortion (RSAs) receiving G-CSF vs. placebo

	Rh-G-CSF	Placebo	*P*-value
Patients	35	33	
Age (years) (start of pregnancy)	34.9 ± 2.9	33.8 ± 2.9	
BMI (start of pregnancy)	27.4 ± 1.9	33.8 ± 1.8	
Smokers (>10 cigarettes/day)	1	2

Clinical abortions (%)	7 (30.4%)	4 (50%)	6 (50%)

cortisone, ASS, and/or immunoglobulins, that is, substances that are, or should be, designed to improve the pregnancy rate per ET and decrease spontaneous abortion rates.

In 2015, we published our data [117] available to date concerning treatment of RSA (and RIF) patients who received doses of 2 × 13 m rh-G-CSF per week up to complete autonomy of the trophoblast/placenta, that is, up to the 12th week of pregnancy. The data captured over 600 pregnancies. Data on the progress of pregnancy were available in 88% (RIF) and 91.8% (RSA) of cases, respectively. The baby take-home rate per pregnancy begun was 72.4% and 78.1%, respectively; around 86% of births were after the 37th week of pregnancy. In cases of repeated abortion, we always tried to conduct genetic analysis of the abortion material. Where this was possible, genetic abnormality rates of 67.4% and 60.9%, respectively, were found. Medication was without documented undesirable side effects in all cases; accompanying nausea (morning sickness) was virtually universal. Strikingly, all patients in our care showed high levels of hCG, progesterone, and estradiol. Sonograms performed between the 8th and 11th week of pregnancy on RIF patients with known embryo transfer dates often showed preemptive biometric data. No increase was seen in documented malformations compared to the normal population; in fact, the percentage trend was actually lower than the average.

Now, in early 2017, we have data from over 900 pregnancies; figures and observations have shown no major changes.

These studies and observations show without a doubt that "G-CSF deficiency syndrome" or "CSF deficiency syndrome," that is, "CSF-DS," must exist. However, this is based less on an absolute deficiency in CSFs (which would cause serious illness in patients) than on reduced release of these substances during pregnancy and in utero in particular, in other words, a communication problem.

We assume that uNK cells, in particular with their killer immunoglobulin-like receptors (KIRs), are in close dialog with the trophoblast, that is, the conceptus [118, 119]; if this dialog is interrupted, disruption to implantation and growth of the embryo results. This is the case, for example, where activating KI receptors are absent and the partners' HLA groups correspond to a large extent, particularly the HLA-C groups that are so important for communication (or have only weak effects: HLA-C groups 2) [106, 107, 120]. Systemic administration of G-CSF is then likely to be useful in compensating for this relative deficit and stabilizing the pregnancy. The positive effect on growth (particularly of the trophoblast) can easily be seen in the increased hCG values. Accelerated growth of the trophoblast automatically leads to increased transfer of embryo cells to the maternal organism, which neatly explains the virtually universal nausea experienced in pregnancy (microchimerism; see above).

No data are available for systemic administration of GM-CSF to RSA patients. This is surprising, given that EmbryoGen™/BlastGen™ culture media are approved for cases of previous spontaneous abortion after ART treatment. It would thus be only logical to support the embryo not only up to the time of transfer but also beyond it, that is, during and after implantation.

The effects of G-CSF and GM-CSF on embryo growth, implantation, and pregnancy as described above would naturally suggest their use in treating further types of pregnancy pathologies. Patients have already been granted for administration of G-CSF in the treatment of preeclampsia [121] and for prevention of premature birth [122].

Nora Therapeutics, the holder of these patients, is currently driving G-CSF approval to avoid RSA (phase II study). Scarpellini and Sbracia have already patented (with the EPO) a procedure – as already mentioned – for administration of GM-CSF for the same indication [113].

62.7 Risks

62.7.1 G-CSF and GM-CSF Before and During Pregnancy

Where EmbryoGen™/BlastGen™ are used, embryos are "bathed" in a culture medium with added 2 ng/ml rh-GM-CSF for several days, 24 h a day. Agerholm et al. showed as early as 2010 [123] that this procedure neither positively nor negatively modifies the chromosomal constitution of preimplantation embryos.

SCNIR holds relatively extensive data on the administration of G-CSF during pregnancy. No higher morbidity or mortality was observed [124, 125]. Boxer et al. [114] observed fewer severe maternal and neonatal complications and no significant increase in the rate of malformations. This is also the view of the European branch of SCNIR, so that women with chronic neutropenia are no longer advised to avoid G-CSF treatment in pregnancy. This is confirmed by several case reports of women who gave birth to healthy babies after having received G-CSF injections [126, 127].

In addition, there are numerous reports of pregnant women who have received G-CSF, either to support chemotherapy [128] or to mobilize autologous stem cells during chemotherapy [129–132]. No teratogenic effects or malformations were seen.

With regard to peripheral blood stem cell (PBMC) harvesting during pregnancy, and therefore during administration of G-CSF, on the basis of currently available information, a review [133] came to the conclusion that treatment using G-CSF is safe in pregnancy and that healthy pregnant women can donate PBSC and bone marrow after receiving G-CSF.

As described above, according to our information, administration of G-CSF in pregnancy does not result in increased risk of malformation in live births, in fact, rather the opposite. A tendency toward higher birth weights has been noticed.

62.7.2 Risk of Induction of Malignant Cells

Chemotherapy, that is, the treatment of malignomas, is the "classical" indication for G-CSF/GM-CSF. Current guidelines see no enhanced risk of lymphoproliferative disorders, tumor progression, or induction of a second malignoma (e.g., guidelines of EORTC and ASCO [134]; of ESMO [135]; of DGGG and DKG, 2012, for breast cancer [136]; and of DKG, 2013, for Hodgkin's lymphoma) [137]. Additionally, G-CSF has been proved not to increase the percentage of circulating tumor cells (CTC) [138, 139].

Healthy bone marrow donors receiving filgrastim for a short period are not at increased risk of developing myeloid leukemia and/or myelodysplasia (observation period: 3–6 years) [140], similarly stated by the National Marrow Donor Program Registry [141].

However, in some patients, continuous high-dosage administration over several years may result in development of myelodysplasia syndrome (MDS) or acute myeloid leukemia (AML). The risk is estimated by SCNIR at 9% in 13 years [142] and by Rosenberg at 2.3% after 10 years [143].

62.8 Summary

Historically, representatives of the family of colony-stimulating factors (CSFs), such as granulocyte colony-stimulating factor (G-CSF) or granulocyte-macrophage colony-stimulating factor (GM-CSF), were long assumed to be cytokines for regulating myeloproliferative processes, as their names imply. It is now known that they are, in fact, ubiquitously occurring and ubiquitously acting growth factors which are shown to exist at practically all levels of reproduction, together with their specific receptors. For example, they play a role in regulating oocyte maturation and in spermiogenesis, as well as in the ovulation process; they are present in the endometrium, accelerate the generation and growth of preimplantation embryos, and support the implantation process and trophoblast growth. Accordingly, they are already in clinical use. Concentration of these substances in the follicles correlates with later implantation rates of the resulting fertilized oocytes, which can be used in diagnosis. Addition of GM-CSF to the culture medium used in ART treatment increases the percentage of blastocyst formation and growth, as well as subsequent pregnancy and growth rates. The same clearly applies to G-CSF, be it used as intrauterine instillations or systemic administration. Patients with repetitive implantation failure (RIF) or a history of abortion appear to benefit from the treatment. The same evidently applies to patients with spontaneous conception but with recurrent spontaneous abortions (RSAs). In these cases, systemic administration of G-CSF likewise results in a significantly higher birth rate. However, indications for the specific use of G-CSF or GM-CSF are as yet unclear. HLA typing of both partners in combination with determination of KIR genes is likely to be useful in this respect. Further open questions concern dosage levels for systemic administration and the duration of administration. Available recombinant specialty pharmaceuticals are well tolerated, with no indication of teratogenic effects, chromosomal changes, or even increased malformation rates among live births. In addition, at the dosages and duration of administration used here, induction of malignancies is not anticipated. It may be assumed that CSFs will continue to be used in other indications in the future, such as prevention of premature birth or preeclampsia.

Summary Bullet Points

- GM-CSF and G-CSF play an important role in reproductive functions, not only in regulation of myeloproliferative processes.
- In diagnostic terms, determination of G-CSF in follicular fluid is already used to predict later likelihood of pregnancy in ART treatment.
- Addition of GM-CSF to the culture medium used in ART treatment improves implantation and birth rates,

particularly for patients with repeated implantation failure (RIF) or history of abortion.
- Intrauterine instillation or systemic administration of G-CSF is evidently also able to increase implantation and birth rates resulting from ART treatment.
- Systemic administration of G-CSF to patients with recurrent spontaneous abortions (RSAs) increases the birth rate.
- No teratogenic effects or increased malformation rate is known to result from administration of GM-CSF or G-CSF; at the dosages described, induction of malignancies is not anticipated.
- Indications for the specific use of G-CSF or GM-CSF are as yet unclear, as are more precise indications and which dosage levels and duration are the most favorable in systemic administration.

Review Questions

1. Is the role of G-CSF and GM-CSF limited to regulation of myeloproliferative processes?
2. Does the concentration of G-CSF in follicular fluid have any predictive significance?
3. Can the presence of GM-CSF in the culture medium increase pregnancy rates in ART programs?
4. What are the effects of intrauterine instillation of G-CSF in an ART program?
5. Can systemic administration of G-CSF increase birth rates among patients with recurrent spontaneous abortions?
6. Does the administration of G-CSF or GM-CSF involve risks, for example, of malformation or malignoma?
7. What are the indications for use of G-CSF and GM-CSF?

The Freeze-All Cycle: A New Paradigm Shift in ART

Bruce S. Shapiro, Forest C. Garner, and Martha Aguirre

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_63

Learning Objectives

- The history of in vitro fertilization (IVF) paradigm shifts and how embryo/oocyte cryopreservation and the freeze-all strategy fit into that history
- The evidence regarding success rates of the freeze-all strategy in selected patient populations
- The evidence regarding maternal and perinatal risks relevant to fresh or frozen embryo transfer
- Pertinent new research areas

63.1 The Classic IVF Paradigm

63.1.1 A Brief History of IVF Technology

It is well known that the first live birth of an infant following in vitro fertilization (IVF) was reported by Steptoe and Edwards in 1978 [1]. That first live birth followed a fresh autologous embryo transfer in a patient with tubal factor infertility. However, that was neither their first embryo transfer nor their first reported pregnancy. Their first reported pregnancy was announced 2 years before the famed live birth [2]. That pregnancy was ectopic, a result that they attributed to the untoward effects of controlled ovarian stimulation (COS). In 1977, before the first live birth from IVF, Edwards and Steptoe discussed the advantages of avoiding the negative effects of uterine COS exposure by freezing all embryos for subsequent frozen-thawed embryo transfers (FETs) of single embryos. In that discussion, they attributed previous failures to an inability to control "the endocrine conditions necessary for implantation" and attributed implantation failures to "abnormal endocrine conditions arising in patients treated with HMG and HCG" [3].

Since then, the technology has improved greatly, and the indications for IVF are now numerous. Despite the early reservations regarding the effects of COS on the uterine environment, the fresh autologous cycle remained the dominant type of IVF cycle for more than three decades. However, recent technological improvements in cryopreservation techniques along with a series of findings proving untoward effects of COS on endometrial receptivity, maternal risk, and perinatal risk have challenged the fresh cycle's dominance in favor of a freeze-all strategy. In a freeze-all cycle, all embryos or oocytes are cryopreserved for thaw and transfer in a subsequent cycle without uterine COS exposure.

In the classic fresh autologous cycle, the patient receives injections of exogenous gonadotropins, typically recombinant follicle-stimulating hormone (rFSH) and/or urinary-derived human menopausal gonadotropin (hMG), so that her ovaries may develop multiple follicles that will yield multiple mature oocytes. As the follicles mature, rising follicular production of estradiol and, later, progesterone can modify hypothalamic behavior, so that hypothalamic gonadotropin-releasing hormone (GnRH) can cause pituitary release of a surge of luteinizing hormone (LH). A premature LH surge can greatly reduce the chance of success, often requiring the patient to repeat a cycle of COS. Therefore, from the late 1980s, prolonged daily administration of GnRH agonist was used to desensitize the pituitary to GnRH and therefore prevent premature LH surges. By that time, cleavage-stage embryo transfer was the norm, typically on day 3 of embryo development, and embryos were morphologically selected based on cell count, symmetry, and fragmentation.

The use of the agonist for pituitary downregulation limited the options for final oocyte maturation to human chorionic gonadotropin (hCG), resulting in a significant frequency of ovarian hyperstimulation syndrome (OHSS) in patients with high ovarian response to gonadotropin stimulation.

Unrecognized at the time, exposure to COS with exogenous gonadotropins resulted in advanced endometrial development and impaired endometrial receptivity via embryo-endometrium asynchrony, reducing the ability of the transferred embryos to implant and also negatively affecting the health of resulting offspring [4]. The low implantation rates in the 1990s, often <20%, compelled clinicians to compensate by transferring many embryos into each patient's uterus, risking multiple pregnancy with corresponding additional risks to the health of offspring.

Routine extended culture to the blastocyst stage was adopted by some centers in the late 1990s and has steadily become more common. Extended culture eliminates from consideration those embryos that cannot form blastocysts. Also, blastocyst morphology is more complex than cleavage-stage morphology, allowing more advanced grading of embryo quality and therefore potentially better embryo selection. Implantation rates are therefore greater with blastocyst transfer than with cleavage-stage transfer, supporting the transfer of fewer embryos and wider use of elective single-embryo transfer (eSET).

The classic IVF cycle changed slightly but significantly at the end of the twentieth century, when GnRH antagonists were approved by the US Food and Drug Administration (USFDA). The use of a GnRH antagonist allowed the agonist to be reserved for possible use as an ovulatory trigger, causing final oocyte maturation by inducing a surge of pituitary LH. Agonist trigger virtually eliminated the risk of clinically significant OHSS [5], although published case reports prove that rare cases of clinically significant OHSS remain possible. The daily GnRH antagonist injections were usually initiated late enough in the cycle to allow estrogen receptor modulators or aromatase inhibitors to be used early in the cycle to stimulate hypothalamic GnRH release, so that pituitary FSH could augment exogenous FSH for several days.

The classic IVF paradigm remained essentially static since the end of the twentieth century. As this is written, some centers in the United States still routinely use agonist downregulation, hCG trigger, and fresh transfer of multiple cleavage-stage embryos, practices associated with reduced implantation rates and increased health risks to patients and offspring when compared to modern practice.

63.1.2 The Fresh Embryo Transfer

Live birth rates following fresh transfer increased steadily until approximately 2008 [6], after which there was little or no improvement (Fig. 63.1). With FET, the corresponding improvement was more rapid and continued until at least 2014, the latest data available (Fig. 63.2), so that live birth rates per transfer with FET exceeded those with fresh transfer in each age group excepting only the youngest (<35 years) age group.

Implantation rates with fresh transfer continued to increase in recent years (Fig. 63.3), but the corresponding increases in implantation rates following FET (Fig. 63.4) were more rapid, and implantation rates with FET now exceed those of fresh transfer in every age group.

Zooming in on one age group for illustration (Fig. 63.5), in patients aged 38–40, national average live birth rates following fresh transfer were 26.5% in 2004, increased to 28.2% in 2008, and then remained essentially constant, with a value of 28.0% in 2014. The risk ratio (RR) for live birth was 1.06 when comparing 2014 to 2004. The corresponding birth rates for FET were 23.1%, 26.1%, and 38.3%, for a RR of 1.66 over the same period. As of 2014, the latest data

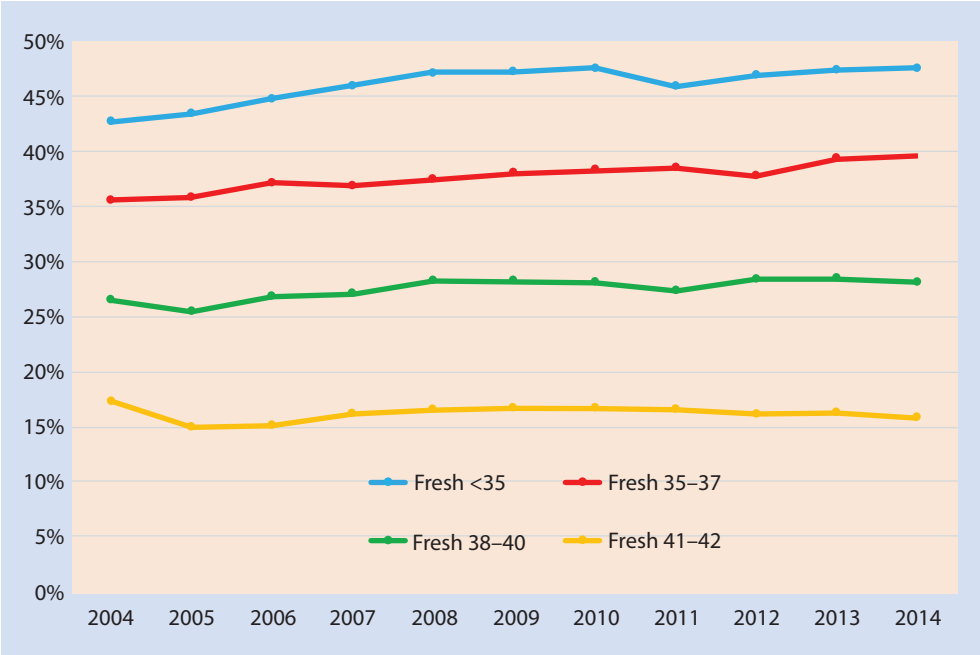

Fig. 63.1 Trends in national average live birth rate per fresh autologous transfer from reporting year 2004 thru reporting year 2014 as reported by the CDC, broken out by age group. Note moderate increasing trends prior to 2008, with little or no improvement thereafter

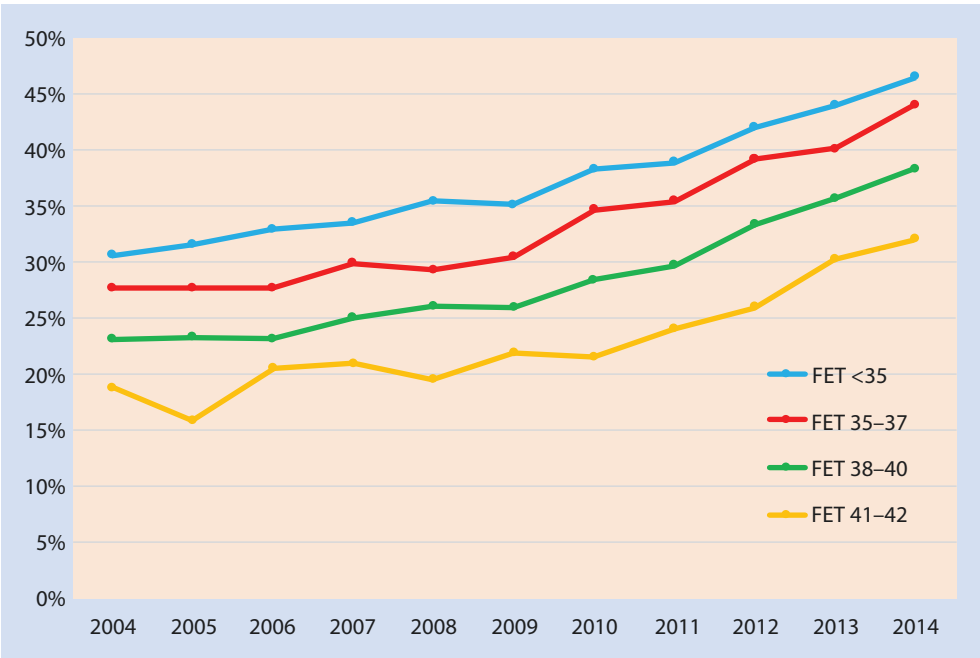

Fig. 63.2 Trends in national average live birth rate per autologous FET from reporting year 2004 thru reporting year 2014 as reported by the CDC, broken out by age group. Note generally increasing trends throughout the period. Compare to Fig. 63.1

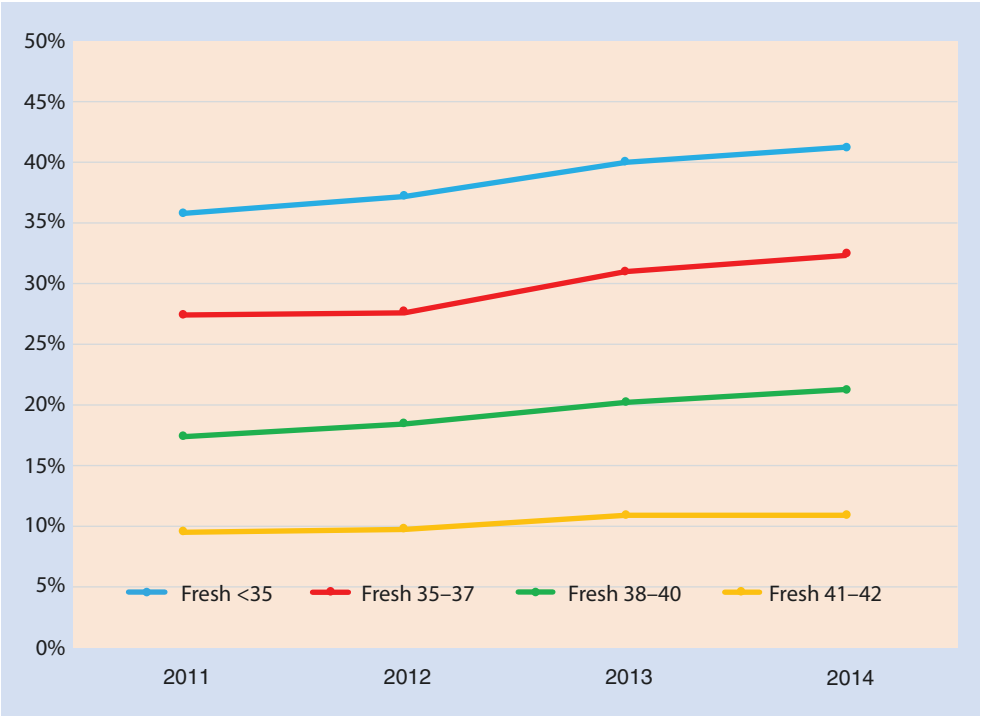

Fig. 63.3 Trends in national average implantation rate per transferred embryo in fresh autologous transfers from reporting year 2011 thru reporting year 2014 as reported by the CDC, broken out by age group. Note moderate increasing trends throughout the period

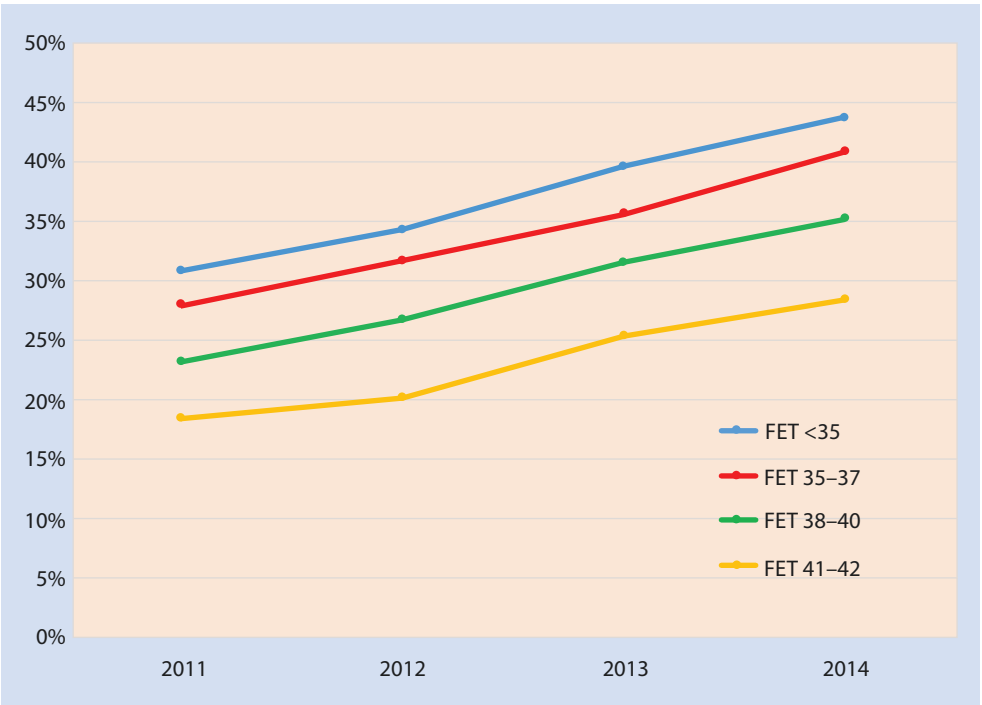

Fig. 63.4 Trends in national average implantation rate per transferred embryo in autologous FET from reporting year 2011 thru reporting year 2014 as reported by the CDC, broken out by age group. Note increasing trends throughout the period. This time period was selected because the CDC started reporting implantation rates for FET in 2011. Compare to Fig. 63.3

available, the birth rate following FET exceeded that of fresh transfer by a risk ratio of 1.37. The Centers for Disease Control and Prevention (CDC) published implantation rates for FET starting in 2011, and Fig. 63.5 also shows that implantation rates following FET increased more steeply than those following fresh transfer in 2011–2014.

The increasing success rates with FET probably reflect improving cryopreservation techniques, increasing use of freeze-all cycles so that more primary (best-of-cohort, rather than supernumerary) embryos are used in FET, and, in the older age groups, perhaps increasing use of preimplantation genetic screening (PGS) of embryos.

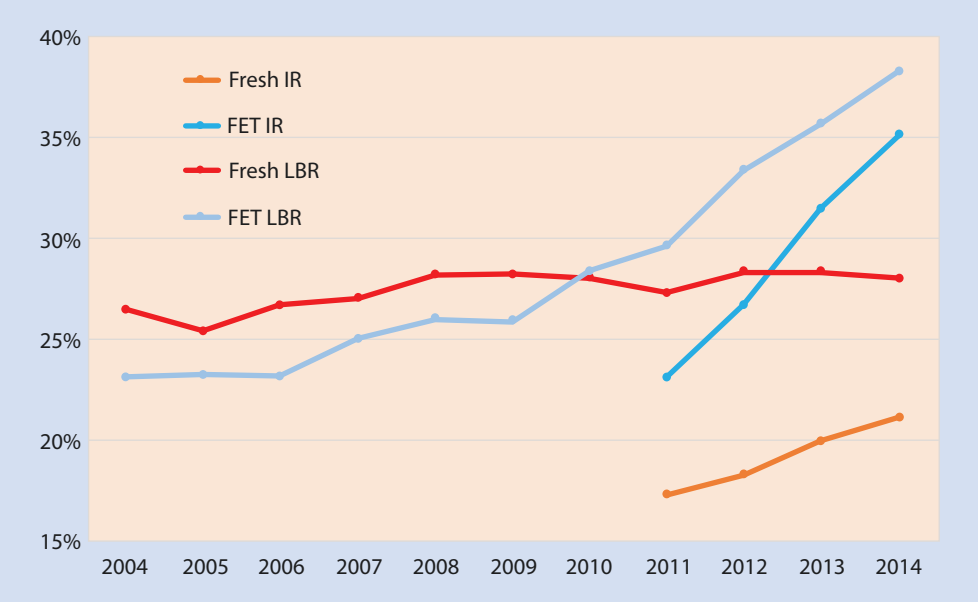

Fig. 63.5 Trends in national average live birth rate (LBR) and implantation rate (IR) per transferred embryo in autologous transfers from 2004 thru 2014 as reported by the CDC for patients aged 38–40, broken out by cycle type. Note the more rapidly increasing trends for FET than for fresh transfers in this period. The domain for IR is 2011–2014 because the CDC started reporting implantation rates for FET in 2011

63.1.3 A Brief History of Oocyte and Embryo Cryopreservation

The first scientific discussions of sperm cryopreservation date back at least to the nineteenth century, while the first low-temperature preservation of rabbit oocytes was published in 1948. Mouse embryos were successfully frozen in 1972.

The first human pregnancy with a frozen embryo was reported in 1983 [7]. That pregnancy was achieved in just 1 of 15 patients undergoing transfer of thawed cleavage-stage embryos. The embryo in that cycle was thawed 13 h before transfer to "allow recovery of cell function and a reassessment of cryoinjury" prior to transfer. Unfortunately, the ongoing pregnancy terminated at 24 weeks due to septic infection secondary to premature rupture of membranes.

The first live birth following FET was reported in 1984 [8]. Monozygotic dichorionic twins were born following the transfer of one intact thawed eight-cell embryo. The authors justified the development of FET methods, "The question of suboptimal uterine receptivity as a result of hormonal pretreatment has received little attention." Equally visionary, the first observation of greater success with frozen embryos than with fresh embryos in 1987 led to the conclusion that "…a normal pregnancy rate may result if the embryos originating from an unsuccessful IVF-ET cycle are transferred in a favourable uterus" [9].

Early cryopreservation protocols used conventional slow freezing of cleavage-stage embryos, with glycerol, dimethyl sulfoxide, propanediol, and/or sucrose frequently used as cryoprotectants to prevent intracellular ice crystal formation. By 2000, blastocyst cryopreservation was becoming routine due to much greater subsequent implantation rates than were realized with thawed cleavage-stage embryos [10].

Today, the predominant methods used are oocyte vitrification and blastocyst vitrification, while cryopreservation at other stages and conventional slow freezing are used less often. The ongoing rapid increases in success rates due to improving cryopreservation techniques have resulted in increasing popularity of the freeze-all cycle.

63.2 Indications for a Freeze-All Cycle

There are now numerous indications for the freeze-all cycle, and some of them will be described here.

63.2.1 Embryo-Endometrium Asynchrony

Because many human oocytes and embryos are nonviable, it is routine to collect many oocytes in order to increase the probability of obtaining one or more viable embryos through IVF. COS with exogenous gonadotropins is routinely used for this purpose. By developing numerous follicles, COS allows the collection of many mature oocytes and the subsequent creation of multiple embryos.

However, COS is associated with supraphysiologic serum levels of estradiol and with both early and supraphysiologic progesterone increase. These supraphysiologic elevations are found in nearly all COS cycles resulting in oocyte collection and result from the numerous large follicles that develop. Estradiol promotes endometrial development, and progesterone initiates endometrial maturation in preparation for the implantation of a hatched blastocyst, suggesting the potential for abnormal endometrial development under endocrine conditions altered by COS.

Studies have revealed that the human endometrium is histologically advanced after COS exposure, typically by about 2 days [11, 12]. This is significant because histologic maturity lasts no more than 2 days [11]. In other words, COS

typically displaces the period of histologic advancement and the putative implantation window by approximately the full duration of that window. Progesterone and its endometrial receptor appear to be in the causal pathway of this advancement. The degree of histological advancement correlates with pre-trigger progesterone levels [11, 13]. The endometrial progesterone receptor is downregulated about 2 days earlier in COS cycles [14]. Premature progesterone elevation correlates with advanced echogenicity [15] and implantation failure in fresh transfer [16, 17] but not if the embryos are cryopreserved and transferred in a subsequent cycle [18].

This evidence suggests that COS might create a bias toward implantation of rapidly developing embryos. This is precisely what has been reported clinically [19–24], and it seems no coincidence that embryo scoring algorithms developed over decades of fresh autologous transfer favor transfer of the most developed embryos. Furthermore, it has also been shown that slowly developing embryos, specifically day 6 blastocysts, have greater implantation rates after freezing and thawing than in fresh transfers [19, 21]. Because freezing and thawing are unlikely to transform nonviable embryos into viable embryos, the most plausible explanation seems to be that COS reduces endometrial receptivity for slowly developing embryos by advancing endometrial maturation and therefore inducing an asynchrony between the embryo and the endometrium.

Randomized trials have reported superior implantation and pregnancy rates in FET cycles when compared to fresh transfers following COS exposure [25–28], although in one trial, that difference was not significant [28]. A retrospective matched-pair comparison of fresh and FET cycles, matched on patient age, embryo morphology, and day of blastulation (day 5 or day 6), also found superior success rates with FET and that the benefit was much greater for (slowly developing) day 6 blastocysts than for their faster day 5 counterparts [24].

Performing a fresh transfer in cases of embryo-endometrium asynchrony following uterine COS exposure risks wasting the best embryos, perhaps the patient's only embryos, in a non-receptive uterine environment. Therefore, it is often better to freeze the entire embryo cohort for later use than to transfer fresh embryos. However, embryo cryopreservation risks loss of embryos through cryodamage. The choice of whether to transfer fresh or to freeze all embryos or oocytes must balance these two effects while considering the efficacy of the laboratory methods and personnel. Current vitrification techniques are associated with very low risk of embryo loss.

Multiple studies have shown that premature progesterone elevation corresponds with increased risk of implantation failure [16, 17, 22, 29]. Premature progesterone elevation further advances endometrial development and further exacerbates the embryo-endometrium asynchrony induced by COS exposure. However, premature progesterone elevation can also correspond with larger follicles and superior oocyte and embryo cohorts, partly mitigating the asynchrony effect. The solution is to cryopreserve embryos in cycles with premature progesterone elevation. This solution has been shown to significantly increase implantation and pregnancy rates [18].

Slow embryo development, such as with blastocysts that fully expand on day 6 instead of day 5, has an effect that is similar to premature progesterone elevation [22]. The two effects together are substantially worse than either effect alone [22, 29]. Embryo cryopreservation followed by FET has been shown to increase implantation and pregnancy rates of slow-growing embryos [24]. Because cryopreservation is not believed to improve the embryos themselves, the putative cause of this effect is superior synchrony between the embryo and endometrium in FET cycles.

Some may believe that the issues discerned by the comparisons of day 5 and day 6 blastocysts are not relevant in cleavage-stage embryo transfer. Transfer of cleavage-stage embryos cannot negate the effects of delayed blastulation. While transfer on day 3 blinds the clinician to the day of blastulation, the embryos still must blastulate and hatch before implantation is possible. Day 3 transfer cannot restore synchrony for slowly developing embryos and therefore cannot change their fates. Pregnancy and birth rates with cleavage-stage transfer can be comparable to those of day 5 blastocyst transfer only if extra cleavage-stage embryos are transferred to compensate for their unknown blastulation potential and unclear synchrony. The transfer of extra embryos increases the risk of multiple pregnancy, simultaneously increasing numerous maternal and perinatal risks. As synchronous single-blastocyst transfer becomes the norm, the transfer of multiple cleavage-stage embryos to compensate for their lower implantation potential grows obsolete.

63.2.2 Normal Responders

One randomized trial has compared fresh transfer and FET success rates in normal responders [25], defined as having 8–15 antral follicles observed on ultrasound. Patients were also required to be 18–40 years of age, to have cycle day 3 FSH <10.0 IU/L, and to be undergoing their first IVF cycle. That study employed conventional slow freezing of entire cohorts of bipronuclear oocytes, followed by thaw of entire cohorts and extended culture to the blastocyst stage. Patients in both study arms had two blastocysts transferred when available, and genetic testing of embryos was not allowed. These methods were chosen so that each study arm would have best-of-cohort blastocysts transferred and so that post-thaw extended culture could eliminate from consideration any embryos that were too damaged by slow freezing to resume development.

In that study of normal responders, the FET arm had significantly greater success rates than did the fresh transfer arm. These measures included the implantation rate (70.8% vs. 38.9%), the clinical pregnancy rate per transfer (84.0% vs. 54.7%), and the ongoing pregnancy rate per transfer at 10-week gestation (78.0% vs. 50.9%). Because the main outcome measure (clinical pregnancy) met the stopping criterion at this interim test point, the study was halted early, after 103 patients were completed. The researchers concluded that

the results "strongly suggested" impaired endometrial receptivity following COS exposure.

The high implantation rates in that study indicate the FET method is ideal for single-blastocyst transfers.

63.2.3 PCO Patients and High Responders

Another randomized trial compared fresh transfer to FET in a population of patients 20–34 years of age meeting the Rotterdam criteria for polycystic ovary (PCO) syndrome [26]. This study employed cleavage-stage embryo transfer and cleavage-stage vitrification.

The 1508 randomized patients included 746 randomized to freeze-all and 762 randomized to fresh transfer. Of those, 49.3% and 42.0% achieved live birth, respectively (RR 1.17, 95% CI 1.05–1.31). The authors concluded that PCO patients undergoing freeze-all have a greater chance of live birth than those undergoing fresh transfer. They also noted reduced OHSS risk in FET, but also greater risk of preeclampsia.

Another randomized trial compared fresh transfer and FET in high responders [28]. This study found clinical pregnancy rates per transfer of 79.6% with FET and 65.4% with fresh transfer. The RR for clinical pregnancy was therefore 1.22, which was similar to that of the larger study in PCO patients [26]. However, in this smaller study, those observed differences were not statistically significant.

63.2.4 Prior Implantation Failure with Fresh Embryos

In 1987, Testart retrospectively studied 63 fresh transfers and 77 FETs and reported lower pregnancy rates following fresh transfers of primary embryos (10.5%) than in transfers of frozen-thawed supernumerary embryos (27.1%) following failed fresh transfers and concluded that "uterine inadequacy" in some patients following COS could be addressed through FET into a "favorable uterus" [9].

Another retrospective study compared fresh cycles with freeze-all cycles in a population of patients with prior implantation failure following at least one fresh blastocyst transfer. In this study, 163 patients opted for another fresh cycle, while 106 opted for freeze-all followed by FET. Patients opting for freeze-all followed by attempted FET had 46.2% live birth rate per retrieval, while those opting for another fresh cycle had only 21.5% live birth rate per retrieval. The authors concluded that patients with prior implantation failure with fresh embryo transfer had a significantly greater chance of live birth with freeze-all than with another fresh cycle [30].

63.2.5 Advanced Age

A retrospective analysis examined fresh autologous transfer and found the risk of having at least one indicator of embryo-endometrial asynchrony, including elevated preovulatory progesterone and/or delayed (day 6) blastulation, increased with increasing patient age [31]. Specifically, this risk increased from 50.0% in patients <35 years of age to 68.1% in patients ≥35 years old.

Live birth rates decreased when asynchrony was indicated, such that 62.9% of synchronous transfers in patients <35 resulted in live birth, but only 27.9% of patients had live birth when day 6 blastocysts were transferred after elevated progesterone was observed. In patients ≥35, those rates were 38.9% and 18.1%, respectively.

The age-related negative effects of COS on success rates following fresh transfer may explain why the national average success rates in FET (Figs. 63.2 and 63.4) have been consistently less disperse across age groups than those in fresh transfer (Figs. 63.1 and 63.3).

63.2.6 Risk of Ovarian Hyperstimulation Syndrome

Ovarian hyperstimulation syndrome (OHSS) can occur when numerous corpora lutea, such as seen in high responders or PCO patients, have prolonged stimulation by human chorionic gonadotropin (hCG). hCG from an ovulatory trigger injection can induce early-onset OHSS, while hCG produced by implanting embryos in early pregnancy can result in late-onset OHSS.

There are several published methods to reduce the risk of early-onset OHSS. The most effective of these, other than outright cycle cancellation, is to trigger with a GnRH agonist instead of hCG [5]. The agonist induces an immediate surge of pituitary LH, which matures the oocytes much as hCG would. However, LH has a much shorter half-life than hCG. The rapid decline in LH levels typically results in rapid and irreversible luteolysis, such that any developing signs of OHSS following agonist trigger rapidly fade shortly after oocyte collection, in marked contrast with the sustained and worsening OHSS symptoms that can follow hCG trigger.

There are limitations to the use of agonist trigger. First, the agonist is only able to induce an LH surge if daily agonist is not used for pituitary downregulation. Second, OHSS remains possible, although at a greatly reduced rate when compared to hCG trigger. Lastly, the success rates with fresh transfer are reportedly compromised following agonist trigger [32]. The reduced success rates following fresh transfer make the use of agonist trigger an indication for freeze-all cycles [33, 34].

Reducing the risk of late-onset OHSS, especially after an hCG trigger in a high responder, generally requires freezing all embryos for later use in another cycle.

A randomized trial in PCO patients found the overall risk of OHSS was reduced (1.3% vs. 7.1%, respectively; RR = 0.19, 95% CI 0.10–0.37) if all embryos were frozen in lieu of fresh transfer following ovulatory hCG trigger [26].

Elevated OHSS risk is therefore an indication for freeze-all, regardless of whether hCG or GnRH agonist is used for the ovulatory trigger.

63.2.7 Preimplantation Genetic Screening

PGS is increasingly used to select the most viable embryos for transfer. With PGS, a biopsy of one or more cells is taken from each embryo and is then analyzed for chromosome copy number. Embryos with the normal number of chromosomes are eligible for transfer. Success rates with trophectoderm biopsy of blastocysts are reportedly improved over transfer of untested embryos [35].

However, the genetic testing is typically performed by a specialized laboratory distinct from the clinic itself. The embryos must be shipped to that laboratory, and the results become available at least 1 day later. Holding an expanded blastocyst in growth media for 1 or more extra days, to the fully hatched stage and beyond, might exceed the embryo's implantation window. It is therefore common to freeze all embryos in cycles employing PGS.

A randomized trial compared fresh and freeze-all cycles in 179 patients using next-generation sequencing for PGS. The fresh group had day 5 blastocysts biopsied, cultured overnight, and transferred on the morning of day 6. The freeze-all group had day 5 and day 6 blastocysts biopsied before vitrification. The fresh group had significantly lower live birth rates than did the freeze-all group, on a per transfer basis (59% vs. 77%) or per intent to treat (40% vs. 62%) [27]. Similar conclusions were already reached with retrospective analysis [36] and literature review [37].

63.2.8 Oocyte Banking

Cryopreservation of oocyte cohorts is increasingly common. One purpose is for women who wish to preserve their fertility, such as before oncotherapies or as they approach advanced age. Chemotherapy and radiotherapy are established threats to ovarian function. Cryopreserving oocytes is one option for preserving the chance of pregnancy with autologous oocytes.

Another purpose of oocyte cryopreservation is for donor egg banks. Donor egg banks provide a less costly means for patients to obtain donor eggs when compared to traditional fresh oocyte donation cycles in which the donor and recipient have synchronized cycles.

63.3 Risks in Fresh Transfer and FET

63.3.1 Maternal Risks

Fresh embryo transfer is associated with altered maternal risks when compared to FET.

A randomized trial showed that fresh transfer following hCG trigger in PCO patients increased OHSS risk when compared to freeze-all [26]. This makes physiologic sense, as a fresh transfer allows hCG produced by implanting embryos to stimulate the corpora lutea, which can induce late-onset OHSS or sustain early-onset OHSS. Freezing all embryos for use in a later cycle precludes those possibilities, as the follicles will luteolyze after clearance of the hCG trigger.

Fresh transfer following COS exposure is also associated with increased risk of ectopic pregnancy when compared to FET [38–40]. One physiologic explanation for this is that the elevated levels of estradiol and progesterone associated with COS alter uterine contractility and tubal ciliary motions, facilitating embryo displacement. Another explanation is that impaired endometrial receptivity following COS exposure leaves unimplanted embryos available to potentially implant elsewhere, such as the tubes. These mechanisms could be cooperant.

Fresh transfer may alter other maternal risks. Increased risks of placenta previa, placental abruption, and antepartum hemorrhage were associated with fresh transfer in meta-analyses [41], while one randomized trial reported reduced risk of preeclampsia with fresh transfer [26]. However, FET has been associated with increased use of caesarian delivery.

Overall, the current literature suggests FET has reduced maternal risks when compared to fresh autologous transfer.

63.3.2 Perinatal Risks

Fresh autologous embryo transfer following COS exposure is also associated with altered risks to the fetus and offspring, when compared to FET.

Increased risks of preterm birth, low birthweight, being small for gestational age, and perinatal mortality have been associated with fresh transfer in meta-analyses [41]. However, reduced risk of macrosomia has also been associated with fresh transfer [42].

Randomized trials have reported 162–166 g lower mean birthweight with fresh transfer when compared to FET [26, 43]. This birthweight difference probably explains the greater risk of low birthweight, the reduced risk of macrosomia, and the reduced use of caesarian deliveries that have been associated with fresh transfer when compared to FET. A large retrospective study of singleton birthweights in Australia [44] found singleton birthweights were reduced by 156–167 g in fresh transfer when compared to natural conception or FET. Natural conception and FET did not differ significantly in singleton birthweight.

Other large retrospective comparisons of singleton birthweights found that birthweights were similar following fresh and frozen-thawed embryo transfers in oocyte donation cycles in which neither group had uterine exposure to COS [45, 46], contradicting an embryonic effect of cryopreservation on birthweight.

Therefore, the existing evidence points to a uterine effect of COS exposure on birthweight. This is further supported by the association between COS and abnormal placentation seen in a rodent model [47].

It has long been known that low birthweight is more prevalent among singleton births following IVF than in the general population of singleton births [48]. It is also known

that birthweights in the general population are already less than the birthweight corresponding with minimal infant mortality [49]. This suboptimal state of the general population might be because a high proportion (37–51%) of births in the general population follow unintended pregnancies and because the incidence of low birthweight is increased by unintended pregnancy [50–52].

All IVF pregnancies are intended; therefore, the ideal reference group includes only births following intended pregnancies, where the incidence of low birthweight is reduced. The use of a reference group with greater birthweights would clarify that birthweights following fresh transfer are reduced and low birthweight incidence is increased to even greater degrees than previously estimated. Therefore, it seems likely that the ~165 g greater mean birthweight following FET is an improvement over that of fresh transfer, despite the increased risk of macrosomia and the increased use of caesarian delivery with FET. However, this hypothesis awaits proper study to compare the frequency, cost, and health effects of relevant risks.

Increased epigenetic DNA methylation has been associated with fresh autologous transfer, but not FET, when compared to natural conceptions [53].

63.4 The Changing Paradigm of Assisted Reproduction Through the Freeze-All Strategy

63.4.1 The Ongoing Paradigm Shift

The proportion of freeze-all (banking) cycles reported by the Centers for Disease Control and Prevention has recently increased (Fig. 63.6), as has the number of transfers that use frozen embryos. The number of fresh transfers has decreased.

No medical organization has openly endorsed or encouraged this paradigm shift. The shift can only be attributed to clinicians and patients mutually recognizing the advantages of freeze-all and FET in the medical literature and/or at their own centers as cryopreservation techniques continue to improve.

63.4.2 Optimizing the Freeze-All Cycle

To date, COS protocols for freeze-all cycles have been largely the same, those developed and routinely used for fresh transfer cycles. Every randomized trial comparing fresh and freeze-all cycles has used the same COS protocol for the fresh transfer arm as for the freeze-all arm. These protocols evolved over the decades of fresh autologous transfers and are therefore optimized for fresh transfer cycles. Such protocols are designed to obtain a useful cohort of viable oocytes and embryos for fresh transfer without impairing endometrial receptivity. These are conflicting goals, given the advanced endometrial receptive phase associated with COS, and therefore both goals are typically compromised.

The traditional COS protocol includes an ovulatory trigger once two to three lead follicles reach 17–18 mm, leaving many developing follicles somewhere <17 mm in size at the time of trigger. However, it has been shown that larger follicles, those larger than 18 mm, are more likely to yield mature oocytes, fertilized oocytes, and day 3 embryos with the least fragmentation and that oocyte maturity and fertilization potential increased steadily with greater follicle size [54]. This suggests a trigger based on lead follicle size of 17 or 18 mm compromises the oocyte cohort.

It has further been shown that extending stimulation so that more oocytes are collected does not increase success rates in fresh transfers, putatively because preovulatory

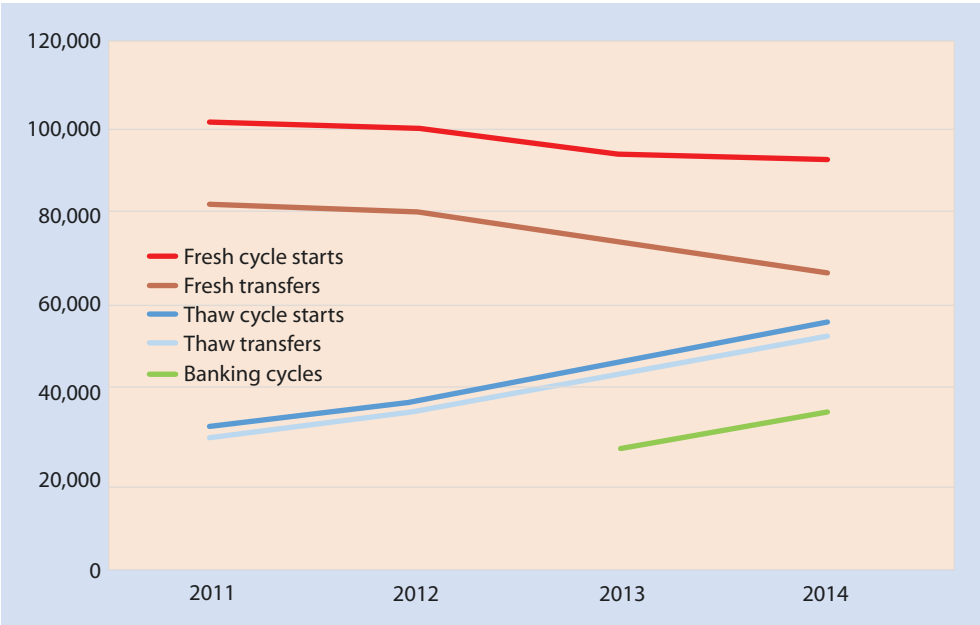

Fig. 63.6 Trends in national numbers of reported autologous cycles from 2011 thru 2014. Note the decreasing numbers of reported fresh cycle starts and fresh transfers and simultaneously increasing numbers of thaw cycles, thaw transfers (FETs), and banking cycles. The domain for the trend in banking cycles is limited to 2013–2014 because the CDC started reporting this statistic in 2013 and 2014 is the latest data available as this is written

progesterone levels increase and impede endometrial receptivity [55]. This is not an issue in freeze-all cycles, and the COS protocol can be adjusted to optimize the oocyte cohort without regard to endometrial receptivity. This has yet to be tried in any randomized trial, however.

Furthermore, the cost of COS can be reduced in freeze-all cycles. For example, GnRH agonists and antagonists are routinely used to prevent premature LH surges. However, much cheaper oral progestogens have been shown to work as well at preventing LH surges, presumably by controlling hypothalamic GnRH secretion [56]. Such use of progestogens is incompatible with fresh autologous transfer because endometrial receptivity would be impaired. However, for freeze-all cycles, the lack of endometrial receptivity is irrelevant. Therefore, the COS protocol for freeze-all cycles can take advantage of the reduced cost and simpler administration of oral progestogens when compared to GnRH agonists and antagonists. The use of progestogens to control the hypothalamus retains the option of using GnRH agonist as the ovulatory trigger in patients at risk of OHSS.

However, a COS protocol optimized for the freeze-all strategy might be suboptimal for fresh transfer cycles and might even preclude implantation following fresh transfer. Therefore, the use of such optimized protocols may require routine freeze-all cycles.

63.4.3 Impact of Freeze-All Strategies on Laboratory Operations

IVF laboratory techniques have changed dramatically in the last four decades. These changes include more controlled and complex embryo culture media providing the basis for in vitro blastocyst culture. PGS, when used as an embryo selection criterion, and improved cryopreservation technique by vitrification further allow increased pregnancy rates per transfer and per cohort.

These techniques require skilled professionals, training, detailed operating procedures, appropriate laboratory facilities and equipment, controlled laboratory conditions, and quality control.

Embryo cryopreservation techniques themselves have evolved. In the 1990s, pre-embryos were frozen in media containing DMSO as cryoprotectant using the slow freeze and slow thaw method using the controlled-rate freezing unit. In those cases, thawing a single vial for a frozen embryo transfer could take hours. Initial results were encouraging, but pregnancy rates were still low, especially by modern standards. Gradually, the use of propanediol and glycerol as cryoprotectants combined with non-permeating sugars like sucrose became standard [10]. For many years, conventional slow freezing techniques provided reasonable survival and success rates. With controlled-rate freezers, many embryos from different patients could be frozen simultaneously during a period of 3–4 h. Different freezing curves and cryoprotectants were tried for various embryo stages. The freezing curves basically avoided the formation of intracellular ice, while the embryos were subject to a dehydration process. The embryos were thawed by a rapid thaw in air, followed by a water bath, and then taken through different solutions of decreasing concentrations of the cryoprotectant. By about 1995, embryo thaw and transfer became an easy task for well-trained personnel.

The embryology workload increased with PGS combined with vitrification in the modern laboratory. Modern trophectoderm biopsy requires the highest level of training and typically also requires blastocyst vitrification.

Vitrification now yields survival rates near 100% and very high pregnancy rates. Several commercial vitrification solutions are commercially available.

The technique of cryopreservation has an interesting relationship with laboratory workload. One embryo can be vitrified in <10 min. Freezing one or a few embryos from one cohort is typically much faster with vitrification than with conventional slow freezing. However, vitrification requires constant attention from the embryologist(s), while a controlled-rate freezer does not. Conventional slow freezing becomes easier than vitrification when large numbers of embryos are frozen from multiple patients each day, such as with routine cryopreservation of all cohorts at the bipronuclear stage at a center with many oocyte retrievals daily.

A busy freeze-all program can require multiple dedicated embryologists. Also, vitrification devices are at least ten times as expensive as those for slow freezing, and the commercial vitrification solutions are also relatively costly. Freezing one embryo per device, as required after blastocyst biopsy and in centers where eSET is the standard of care, increases the number of devices required and the space required per patient in the liquid nitrogen storage tanks.

In addition, the freeze-all program also impacts laboratory dynamics. Embryo thaws may need to be performed early in the morning if hours of observed re-expansion are required to confirm survival. The success of a modern freeze-all laboratory is measured by rates of blastocyst formation, post-thaw survival, thawed blastocyst utilization, implantation (fetal hearts per transferred embryo), sustained implantation (live birth per transferred embryo), and perinatal outcomes. Traditional live birth rates and pregnancy rates are less useful if multiple embryos are transferred, as the success rate can be manipulated by transferring multiple embryos to compensate for poor technique.

63.4.4 Freeze-All and PGS as Synergistic Pathways to Elective Single-Embryo Transfer in All Patients

Successful IVF requires the transfer of a viable embryo into a synchronously receptive uterine environment. The greater implantation rates with FET in randomized trials suggest embryo-endometrium synchrony is improved in artificially prepared cycles when compared to COS cycles.

Trophectoderm biopsy and PGS support the selection of embryos that are most likely to implant [35]. However, PGS results typically require a day or more to arrive, and this delay often compels the freezing of all embryos. PGS, freeze-all, and FET are therefore often used together.

Increasing implantation rates make eSET practical and more acceptable and desirable to patients. As implantation rates increase beyond 50%, the pregnancy rate is less affected by the number of embryos transferred. Theoretically, at 100% implantation rate, all transfers would result in pregnancy regardless of the number of embryos transferred, removing any motivation for multiple-embryo transfer for patients desiring one child at a time.

Multiple-embryo transfer greatly increases the risk of multiple pregnancy. The increased risks associated with multiple pregnancy are well known and include maternal death, premature birth, low birthweight, perinatal death, blindness, deafness, and cerebral palsy, among others. The financial costs to society and parents are significant. If the multiple pregnancies resulting from IVF had been singletons, the estimated cost savings for insurance claims alone would have been approximately four times the total cost of IVF services in 2004–2009 [57]. There are additional costs not covered in that analysis, such as increased child-care costs or when multiple birth compels the purchase of a larger vehicle, a larger home, or a parent to forego a career in order to care for multiple infants.

Therefore, any reasonable and safe method that improves the implantation rate and therefore encourages eSET should be applied and should be endorsed by medical organizations.

63.4.5 Cost-Effectiveness of the Freeze-All Strategy

At first, it may seem the freeze-all strategy would be more expensive than a fresh transfer strategy, given the added costs associated with cryopreservation. However, the cost per cycle is not the most relevant statistic, as patients seek fertility treatment to have children, not cycles. The cost per pregnancy or per live birth would be much more meaningful statistics for comparing cost-effectiveness.

To date, there have been two published comparisons of the cost-effectiveness of the freeze-all strategy and the fresh transfer strategy. Both studies found the freeze-all strategy to be more cost-effective than the fresh transfer strategy.

One study of 530 cycles reported the cost per ongoing pregnancy was about 18% greater with a fresh transfer strategy when compared to freeze-all [58]. The other study of 252 cycles reported the cost per live birth was 17% greater with a fresh transfer strategy than with freeze-all [59]. Further research should also consider costs associated with maternal risks (e.g., OHSS, ectopic pregnancy, preeclampsia) and perinatal risks (e.g., prematurity, low birthweight, macrosomia). Current evidence suggests most of these risks are more prevalent with fresh transfer, and therefore their consideration might make the fresh transfer strategy appear even less cost-effective.

Further cost benefits should be realized as the increasingly greater implantation rates of FET encourage increased use of elective single-embryo transfer (eSET), reducing the elevated risk of multiple pregnancy that has long been associated with IVF. The implantation rate with transfer of vitrified-warmed blastocysts is reportedly as high as 70% in a group of patients 18–40 years of age with at least normal ovarian reserve, even without PGS [60]. This rate is ample to support eSET.

63.4.6 New Opportunities

The freeze-all strategy creates new opportunities and treatment paradigms.

One example is the opportunity to bank multiple cohorts of oocytes or embryos before attempting transfer. This might be advantageous, for example, in an older patient who produces few oocytes and is opting for PGS or PGD. In older patients, a single oocyte cohort has only a modest chance of yielding a morphologically and genetically acceptable blastocyst. By banking multiple cohorts, the derived blastocysts can be tested in one group in order to take advantage of package pricing for PGS while also increasing the chance of having at least one euploid blastocyst to transfer. This option is impossible under the classic fresh transfer paradigm.

A similar example arises for women desiring multiple children. A woman of advanced age is unlikely to produce multiple viable blastocysts from one retrieval. If she achieved pregnancy and live birth in the fresh transfer paradigm, it would typically be years before she returned to try again. Her ovarian reserve could decrease significantly in that interval, making subsequent births problematic. Alternatively, under a freeze-all paradigm, she could repeatedly bank embryos until the number and quality of stored embryos indicated a high probability of achieving her goals and then proceed with a series of thaws, single-embryo transfers, and births until her goals are achieved.

63.4.7 Summary and Needed Research

Current evidence indicates generally improved success rates, reduced costs, and reduced maternal and perinatal risks with the freeze-all strategy when compared to fresh transfer.

Randomized trials comparing success rates are still needed in some populations, including low responders. Future research should consider cumulative live birth rates per oocyte retrieval.

Further research should investigate the greater flexibility of COS protocols when no fresh transfer is planned, as originally discussed by Edwards and Steptoe in 1977 [3]. This allows oocyte and embryo cohort optimization unrestricted

by endometrial receptivity concerns. Maternal and perinatal risks must be minimized, such as through GnRH agonist trigger [33, 34]. Patient costs must also be minimized. Societal costs of the entire process should be minimized, such as through routine elective single-embryo transfer [57]. New research of the cost-effectiveness of the freeze-all strategy should consider costs associated with maternal and perinatal risks.

Future investigation of birthweight effects should transition from comparing birthweight distributions following fresh transfer, FET, or the general population of all pregnancies to instead comparing ideal birthweight distributions based on minimized overall risk [49]. If a control group of natural conceptions is to be used, it should be restricted to intended pregnancies [50–52].

Review Questions

1. To date, randomized trials have compared success rates following fresh transfer and freeze-all strategies in all of the following populations except:
   A. Low responders
   B. Normal responders
   C. High responders
   D. PCO patients
   E. Patients opting for PGS

2. Based on current evidence, which of the following risks is/are reduced by the freeze-all strategy and FET when compared to fresh transfer?
   A. OHSS
   B. Ectopic pregnancy
   C. Low birthweight
   D. Perinatal mortality
   E. All of the above

3. Based on current evidence, which of the following risks is/are increased in singleton pregnancies following FET when compared to fresh transfer?
   A. Placenta previa
   B. Placental abruption
   C. Macrosomia
   D. Prematurity
   E. All of the above

Answers to Review Questions

Management and Regulation in the ART Laboratory

Contents

IVF Data Management: From Clipboards to Smart Apps

Jacques Cohen, Stephen Fiser, and Giles Tomkin

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_64

Learning Objectives

- To evaluate different facets of data management in clinical medicine and assisted reproduction in particular
- To examine shortcomings of current electronic medical recordkeeping systems for clinical medicine and assisted reproduction and approaches how to address them
- To discuss the sparsity of cloud-based applications in assisted reproduction
- To present the first QC app for laboratories and compare its structure to generic utility apps

64.1 Introduction

There is a tremendous amount of data handling and paperwork in clinical medicine [1]. When only paper is used, the task of organizing, controlling, and safekeeping patient records is demanding and subject to varying degrees of error. Transcription inaccuracies are very common, even when prescribing drugs [2]. A significant body of evidence points to such medical paperwork errors as a leading cause of iatrogenic death and injury [3, 4]. The inaccuracy of information technology is also blamed for other adverse clinical events. This is largely due to the absence of "interoperability," rather than a shortage of time spent by professionals on collection and recording of information. The Healthcare Information and Management Systems Society (HiMSS) defines interoperability in healthcare as "the ability of different information technology systems and software applications to communicate, exchange data, and use the information that has been exchanged" (► http://www.himss.org/library/interoperability-standards/what-is?).

The outdated and inefficient paper-based bureaucracy simply does not allow interconnectivity or interoperability.

It is estimated that doctors and other healthcare professionals spend close to 50% of their time shuffling through paper charts, forms, messages, and reports [5]. Improved scrutiny and oversight through nongovernmental and governmental inspections and audits are clearly increasing this burden. This is especially true in assisted reproduction where laboratory staff may spend even more time on paperwork than other team members. It is estimated that only 50% of IVF clinics have implemented an electronic medical record (EMR) system, although this figure is difficult to confirm since no studies have been published on the topic.

64.2 Complexity of ART and Streams of Paperwork

Assisted reproduction is the only medical intervention that is designed to treat not just individuals but couples or multiple participants, including, for instance, gamete donors and gestational carriers. To make matters even more complicated, these multiple individuals have associated with their gametes and embryos, the development of which must be monitored and recorded meticulously during several days in the laboratory. The monitoring of procedures, observations, and dispositions generates staggering amounts of information and paperwork for each patient, embryo, and procedure. Yet, order can be established in what may look to the unfamiliar like an impossible system integrating patients, gametes, embryos, lab procedures, assays, surgery, counseling, and more. Patients often undergo multiple attempts, but what may be considered standard treatment in one clinic or country can be considered illegal or unconventional in another locale. Generally speaking, there are three streams of data, more or less integrated, each with a potential software solution: (1) the EMR, which is a system for tracking patient information and providing clinical care; (2) an "enterprise software" system which is a set of tools that satisfies the needs of an organization like a hospital, laboratory, or clinic; and (3) the quality management (QM) system which generates data sets requiring customized forms and special standard operating procedures. Whereas electronic data management systems exist for the first two sources of data, QM remains largely confined to forms, paperwork, and clipboards.

64.3 The EMR System

64.3.1 General Characteristics

The first data stream involves patient procedures and attempts to achieve pregnancy. This includes monitoring follicular development in the female partner, the administration of drugs, and the surgical procedures. Later, individual gametes and embryos are tracked, although in many labs, embryos are grown in groups so that individual identity within the cohort is lost. This flow of information can be captured with a tailored EMR, often referred to as an electronic health record (EHR). An EMR is an ordered collection of patient health information data in a digital format. It becomes increasingly complex when records are shared across different healthcare settings. Sometimes, this can take the form of an entire country's healthcare records (e.g., national registries exist in Sweden, France, Belgium, the Netherlands, and other countries). Records are shared through network-connected information systems. EMRs may include a range of patient parameter data, including personal data and demographics, medical history, medication and allergies, vaccination status, laboratory test results, radiology images, vital signs, and billing information. EMRs for assisted reproduction have the added complexity of tracking two or more individuals throughout their treatment and following their eggs, sperm, and resulting embryos individually or in groups. The beginning of procedure and data input activity is usually straightforward, but because gametes and embryos can be cryopreserved and later thawed across multiple attempts, which may be combined for various reasons, the end of treatment is often unclear and assignment of final embryo dispositions can be delayed. Also, gametes and embryos, donated or shared, can be imported or exported from and to other clinics within or between countries.

At a minimum, an ART EMR should be able to monitor key performance indicators (KPIs). For instance, clinic management teams should be able to assess periodic fluctuations in egg maturity, fertilization rates, embryo development, blastocyst formation, implantation, miscarriage, and live birth rates. Preferably, the data should be sortable by attempt, age, staff, etiology, and procedure type. Existing EMR systems generally do not have automatic error detection capabilities and cannot flag incorrect or missing data; some systems even lack any detailed reporting features. These deficiencies are especially perplexing because subscription fees to assisted reproduction EMR systems are quite high, naturally increasing total treatment cost to the patient. Laboratory instrumentation tracking and possible correlation with outcomes are absent in most EMRs. ART, oddly enough, has not yet embraced improvements in data handling through cloud-based applications (apps) but more on that later.

64.3.2 Safety and Privacy

Safety of data storage and privacy of data are clearly paramount. However, some clinics are still using single copies of paper medical charts in unsecured cabinets. Some EMRs have no privacy settings such as those defined by the Health Insurance Portability and Accountability Act (HIPAA) of 1996 in the USA and a law of the same name in the UK since 1998 under the Data Protection Act of 1998. Similar laws exist in Canada, the Personal Information Protection and Electronic Documents Act (PIPEDA or PIPA), and Australia with the early Privacy Act of 1988 amended in 2012 to cover Internet-based data handling.

64.3.3 EMR Objectives and Limitations

EMR systems should be designed to collect and store all relevant data and to capture the status of a patient's ART attempts across time. They should obviate the need to track down and search a patient's paper records for information, particularly if the data are properly validated and accuracy is established, perhaps through multilevel filtering and interactive reporting. EMRs should reduce data duplication, keep the patient file up to date, and decrease the risk of information loss. A major advantage of EMRs is that digital data, even when encrypted, are searchable and analyzable and may be copied at any time. This is achieved by reporting and filtering features, which should always be integral parts of the EMR. However, unfortunately, this ideal scenario is often not actual, and users may complain about either the lack of reporting features or their impracticality. Due to digital sorting and searching, EMRs can be very effective when extracting medical data for the examination of possible trends and fluctuations in outcomes over time. An EMR without search features and clever reporting is narrow and not much more useful than a written record system. EMR user satisfaction levels are mostly anecdotal; no systematic survey had been done until 2013 or published by individual EMR providers, but general attitudes and complaints regarding the use of EMRs have at last been detailed and studied after the American Medical Association (AMA) commissioned the Rand Corporation with a large investigation, the results of which were published in 2013 [6]. The study focused particularly on physician and nurse satisfaction with EMRs. More than 100 physicians in different disciplines were interviewed and surveyed extensively. The study demonstrated that most health experts were aware of the potential benefits of electronic tracking of patients such as remote medical record access; however, at least ten major complaints were identified in the Rand study. The most common areas of concern involved the differences in practice and clinical care between clinics and physicians. EMRs are often delivered "as is" meaning that end user-specific needs – for instance, having to do with workflow – can only be accommodated by clinic-specific customization, a process which is both time-consuming and expensive as it requires new coding or recoding. Other complaints concerned the complexity of systems and the fact that this complexity interfered with face-to-face care and that there was insufficient external health information exchange and information overload such as frequent alerts. Importantly, physicians felt that the systems did not improve over time. The more complex the EMR, the greater the dissatisfaction expressed. The situation described in the Rand study is reminiscent of that in assisted reproduction. Complaints about EMRs used in IVF are plentiful, yet the subject has not been "formally" studied. Some IVF groups still avoid using an EMR or switch between EMR providers hoping that this would solve their problems. ART EMRs are often based on outdated computer languages, data input, and local network systems. Dynamic reporting appears unattainable. To address these issues, flexibility or allowance for "dynamic input" is key when designing new generations of EMRs for ART.

64.4 Enterprise Software

The second stream of IVF information includes organizational and administrative data, such as that of any large organization or enterprise. Enterprise software satisfies the needs of the organization rather than the individual users. Such organizations include businesses, manufacturing plants, schools, charities, governments, universities, and clinics. Services provided by enterprise software are typically business-oriented tools such as online purchasing and payment processing, automated billing, security, IT management, client services, project, collaboration and human resource management, manufacturing, occupational health and safety, application integration, and forms automation. Many of these aspects are needed in the IVF environment; however, rarely are any such enterprise software systems developed for independent IVF clinics. A possible drawback is the cost and the need to train and test staff. Enterprise software is often available as a suite of customizable programs. The complexity of these tools, indeed the system as a whole,

demands expertise and specialized knowledge, which often come at prohibitive costs. A potential solution in IVF is the incorporation of some practice management tools into the EMR.

64.5 Laboratory and Program Quality Management

The third information stream in ART is the quality management (QM) program for andrology, embryology, and chemistry laboratories. Organized and electronic recordkeeping is mostly lacking in this area. Quality control (QC) of laboratory instruments and activities most commonly involves multiple forms which are completed on a daily basis by hand, or, less often, directly into a "makeshift" Excel sheet and very rarely compiled in a way that allows effective and timely analysis and reporting. QC data review typically occurs on a periodic basis, and the paperwork is only partially tracked and audited during annual laboratory inspections. Rarely do labs scrutinize the data to gain insight into instrument performance, unless some catastrophic event occurs. This is partly because the format of data collection makes such an effort unreasonably time-consuming, mostly uninformative, and difficult. Fluctuations in instrument performance may therefore be overlooked. Filing handwritten forms in cabinets or binders (usually for a finite minimum period as defined by law) is an outdated system, which basically means that large amounts of important data are being discarded.

64.6 New Opportunities: Big Data and Cloud-Based Applications

According to IBM, the world population is now creating 2.5 quintillion bytes of data on a daily basis. That means that 90% of the world's data has been created within the past 2 years [7]. This has placed an incredible demand on technologies designed to store and analyze data. On the bright side, the new technologies in combination with the explosion of mobile devices have created a unique opportunity to improve the state of affairs in the laboratory. Instead of transcribing information on forms attached to a clipboard and entering the data into an outdated system at a later point in time (or usually not), laboratory staff should be able to enter or dictate the data on a phone or tablet while they work – mostly eliminating errors that occur due to a messy multistep process – and generate a searchable, permanent, and immediately useful electronic record.

Rightly or wrongly, there are no international uniform requirements for the setup and maintenance of laboratories and equipment. This means that any existing software such as Excel or statistical packages will be suitable for some situations, but not for others, which in turn means the reports generated by these varied programs will be too different for comparison. Thus, each clinic will follow its own standards.

64.7 An Example of a QC App

We have recently released an app (Reflections™ by IVFqc) that allows customization of quality control for any laboratory instrument and associated parameters. The app is accessible from all Internet-connected devices (computer, tablet, or smartphone of any make) and not only does away with the clipboard but also allows for real-time fluctuation tracking and detailed reporting. The app can be applied to QC programs in any type of laboratory and is malleable to almost all laboratory systems. It has a so-called generic JSON API, which means that it allows connection to other software and hardware with relative ease. Some early adopters of the Reflections™ app are laboratory directors who run multiple laboratories and can now conveniently and efficiently track each of their laboratory's QC activities from their phone, switching from lab to lab with just a few clicks. The standard of security is based on HIPAA, as well as two-factor authentication and encryption. The app's second version is slated for release by the end of 2019 and will have an "action package" such as the ability to send useful notifications and reminders to users within a team. It will also allow for tracking instrument performance within a set range. In this way, a subtle drift upward, for instance, of temperature within the established range of temperature in an incubator, can be spotted before it becomes problematic. Such shifts can provide early warning of failure of many kinds of instruments. In addition, the app will be able to follow Westgard multi-rules to assist in determining the impact of fluctuations using a set of standards over time [8, 9].

Reflections™ finds utility in many different types of laboratories. The application has a sign-up and a sign-in section, including secure dual login, similar to banks. Once logged in, users can add one or more new labs and add members with specific assigned access levels. When a new lab is added, new instrument types (or groups) are defined by the user, followed by individual instruments within each group. For example, in the embryology laboratory, instrument groups could include different types of incubators, warmers, hoods, dewars, refrigerators, etc., and each group can include individual makes and models with different QC requirements. Within each instrument, parameters can be created and their acceptable normal ranges added. For example, for incubators, CO_2 and O_2 levels, pH, VOC, temperature, and humidity, display and measured, may be added, with specific acceptable ranges for each of these parameters determined, which can be modified at any time if needed without affecting the data already collected. When the instrument groups and instruments are in place, users can create one or more data logging plans, which can be set for desired intervals including daily, weekly, monthly, etc. These too can be edited later as desired. Data entry can be performed using any smartphone, tablet, notebook, or regular computer with Internet access, though handheld devices are preferable for their portability. Data review can take place at anytime from anywhere, which is particularly useful

for entities with multiple laboratories dispersed in different rooms, buildings, cities, or even countries. Directors and supervisors can check for task completeness and review data via their browser on any Internet-connected device including their cell phones. Summary reports can be generated and viewed by staff members with permitted access. These can be downloaded as PDF for printed records and emailed to overseers as required; alternatively, electronic signatures may be obtained. Fluctuation and detail reporting shows all entries made for instruments within any instrument type, so that instrument's recorded data can be seen for any time period as a graph, giving staff the opportunity to see early indications of instrument or system malfunction. Incident reporting allows for staff to enter important occurrences that merit further attention, reasonably divided into varying levels. This allows direct and effective follow-up according to urgency.

As far as the authors are aware, as of spring 2019, no other general applications are extant with such features. None of the existing utility apps offer the total flexibility that is allowed by Reflections™. None offer the useful reporting functions that allow accurate real-time instrument monitoring. There are applications suitable for certain business entities that have some similar features, but they have limited flexibility and often are enormously expensive to purchase and maintain. Reflections™ can be used by a range of business entities that require quality control and management, from ART laboratories to diagnostic laboratories, even zoos, chemistry labs, agricultural facilities, and wineries. Reflections™ provides a serious step toward the important but elusive goal of paperless quality management while improving service to patients and lowering cost.

Review Points

1. There are enormous advantages to electronic recordkeeping in ART. Though limitations related to clinical and laboratory practice variation among users exist, requiring customization at high cost, new and innovative ways of coding could overcome these limitations.
2. Only one of the three areas (EMR, enterprise, and QM) of ART clinic data handling has been addressed by commercially available electronic practice management products.
3. A first app for QC tracking of instruments has been recently introduced, but the field is in great need of a recordkeeping overhaul.

Regulation of the ART Laboratory

Doris J. Baker

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_65

Learning Objectives

- Describe methods of oversight for reproductive laboratories.
- Differentiate certification and accreditation.
- Describe major procedures performed in ART laboratories.
- Give reasons and cite examples for regulation of ART laboratory procedures differing among states.
- List concerns regarding ART laboratory procedures, and explain how the expertise of the embryologist might be responsible for these issues.
- Describe the current status of the clinical embryologist.
- List general criteria for certification for an embryologist and for an embryology laboratory director.
- Discuss future plans for recognition of the embryologist as a healthcare professional.

Assisted reproductive technology (ART) laboratories, also referred to as embryology laboratories, are a fundamental component of reproductive medical practices. Procedures performed in these facilities focus on the treatment of infertility but may also include processes for fertility preservation, sex selection, preimplantation genetic screening, and interventions for the prevention of genetic diseases. Professional organizations provide data on the status of ART worldwide [1–11]. The most recent triennial (2010–2013) account from the World Collaborative Report on Assisted Reproductive Technology's International Committee for Monitoring Assisted Reproductive Technology (ICMART) presented data between 58 and 61 countries from a total of nearly 2500 ART clinics [1]. Aggregate country data for the years 2008, 2009, and 2010 estimated that 4,461,309 ART cycles were initiated resulting in 1,144,858 live births. The number of oocyte aspirations increased by 6.4% between 2008 and 2010. Although ART application remained relatively constant for the time period (436 cycles/million in 2008 and 744 cycles/million population in 2010), there was a wide range among countries (8–4775 cycles/million population) worldwide. The most recent surveillance estimates that there are between 3706 and 3895 ART centers, an increase over the range of 3528–3877 previously reported in 2010 [2, 3]. The International Federation of Fertility Societies (IFFS) also monitors ART practices [4]. The latest IFFS Surveillance was reported in 2013 providing a view of ART applications, as they existed worldwide in the fall of 2012. This surveillance conveyed that countries with the highest number of ART facilities (≥200) were Brazil, China, India, Italy, Japan, and the United States and those with the lowest total (≤5) were Iceland, Ivory Coast, Latvia, the Philippines, Senegal, Slovenia, Togo, and Uruguay.

65.1 ART Interventions/Services

As with the usage of ART for treatments, the types of ART services that are performed in the various embryology settings differ greatly with variation among countries, within nations, and among national practices [1, 4]. The commonality is that ART services involve handling reproductive tissues in vitro for the purposes of establishing a pregnancy. Establishment of pregnancy may be limited to the use of participating couples' mature gametes although these gametes may be manipulated to improve rates of success. Spermatozoa may be injected into retrieved oocytes (intracytoplasmic sperm injection or ICSI), and in some laboratories, immature oocytes may be matured in vitro [12–14]. Third-party reproduction typically involves donated gametes and/or embryos to establish pregnancy [15–17]. In a limited number of cases, donor cytoplasm has been transferred to a recipient's oocyte [18]. Multiple-party reproduction may include gestational carriers or surrogates when the intended mother is unable to establish a pregnancy or cannot carry a gestation to term [19]. Posthumous insemination using postmortem spermatozoa also may be performed in ART laboratories [20].

Preimplantation genetic screening and diagnosis (PGS, PGD) may be performed on polar bodies or embryos for the prevention of disease with replacement of healthy embryos only [21–23]. Sex selection is performed for prevention of genetic disease. For example, in the case of a woman carrying the gene for an X-linked disorder that would result in disease in any male offspring, only non-affected female embryos would be transferred. This technique also may be used for sex selection based on preference of one sex over another for family planning [24]. In the forefront of practices for prevention of genetic diseases are mitochondrial replacement techniques (MRT) to prevent maternal transmission of mitochondrial disease from the affected woman to her offspring. The new techniques involve transferring either the nucleus from the intended mother's oocyte or both oocyte and spermatozoon pronuclei from a couple's recently fertilized oocyte into an enucleated donor oocyte containing healthy mitochondria. Offspring resulting from these procedures would have DNA from three different individuals [25–33].

65.2 Regulation and International Practices

The scope of ART procedures performed typically depends on regulation of the practice and the technology and expertise available at the facility. Regulation may be influenced by religion, culture, history, and politics (Box 65.1). Oversight of ART may be via statute, directive, licensing, guidelines, certification, and accreditation, or the ART laboratory and embryologists may function without benefit of any type of scrutiny [4]. A *regulation* is an authoritative rule dealing with

details or procedures that is issued by an executive authority or regulatory agency of a government, whereas a *statute* or *law* is enacted by legislature [34, 35]. For example, in the United States the Food and Drug Administration (FDA) has regulatory authority over cryopreserved reproductive tissues, and the Human Fertilisation and Embryology Authority (HFEA) regulates ART facilities via statute, the HFE Act 2008 [36, 37]. A *directive* is an official or authoritative instruction such as the EU Tissue and Cells Directive [38, 39]. A *license* is a permit from an authority [40]. The HFEA has responsibility for licensing all clinics and establishments in the UK that carry out IVF and human embryo research [36]. A *guideline* is a principle put forward to set standards or determine a course of action [41]. Guidelines for ART are typically set by a professional society but may be established by a government agency. In the United States, the American Society for Reproductive Medicine (ASRM) provides guidelines for embryology and andrology laboratories [42]. Although guidelines are typically voluntary, there are exceptions. Singapore voluntarily reports to the Director of Medical Services of the Ministry of Health, and in India, the state accrediting authority has the power to levy a fine for any violation and may even close a clinic for failure to comply with established guidelines [6, 43]. *Certification* is used for verifying that personnel have adequate credentials to practice certain disciplines, as well as for verifying that products meet certain requirements. Some form of external review, education, assessment, or audit often, but not always, provides this confirmation [44]. *Accreditation* is a specific organization's peer review process of a certification process [45]. In the United States, the Clinical Laboratory Improvement Amendments (CLIA) of 1988 regulations for clinical laboratories apply to andrology tests, and a voluntary peer review by the College of American Pathologists (CAP) accredits ART laboratories via their Reproductive Laboratory Accreditation Program [46, 47].

The 2013 IFFS Surveillance conveyed that regulation of ART varied among the 60 countries reporting with 31% having only legislation to regulate, 21% having only guidelines, and 37% having both legislation and guidelines. Nine percent of those responding to the survey had neither legislation nor guidelines. There was a licensing body to regulate ART in 74% of countries. Various methods for implementation were reported for countries with legislation: 16% had on-site inspections, 6% submitted a periodic report, and 29% had both inspection on-site and periodic reports. Two percent of respondents listed other methods, and 24% stated that no type of surveillance was undertaken [4].

Box 65.1 Glossary of Terms in Licensing and Regulation of the ART Laboratory

Accreditation—process that gives official authorization of approval by providing credentials that vouch for conforming to a standard
American Association of Bioanalysis—evaluates, through the certification process, individuals who wish to enter, continue, or advance in the clinical laboratory profession
American Board of Bioanalysis (ABB) Certification—based on an individual's education, experience, and knowledge of the laboratory field in which certification is granted
American College of Embryology (ACE)—professional organization for the advancement of the practice of clinical embryology
American Society for Reproductive Medicine (ASRM)—professional organization devoted to advancing knowledge and expertise in reproductive medicine and biology
Assisted hatching (AH)—in vitro procedure in which the zona pellucida of an embryo is thinned or perforated by chemical, mechanical, or laser methods to assist separation of the blastocyst
Assisted oocyte activation—a technique that simulates effect of spermatozoa penetration into an oocyte, inducing oocyte activation; used in combination with ICSI to improve fertilization outcome; typically recommended for cases when classic IVF has failed. Methods of activation include calcium ionophores, electrical stimulus, and ethanol
Assisted reproductive technology (ART)—all treatments or procedures that include the in vitro handling of both human oocytes and sperm, or embryos, for the purpose of establishing a pregnancy, including, but not limited to, in vitro fertilization (IVF) and embryo transfer, gamete intrafallopian transfer, zygote intrafallopian transfer, tubal embryo transfer, gamete and embryo cryopreservation, oocyte and embryo donation, and gestational surrogacy; does not include artificial insemination with either partner or donor sperm
Association of Clinical Embryologists (ACE)—professional body of and for embryologists in the United Kingdom, founded in 1993 to promote high standards of practice in clinical embryology and to support the professional interests of embryologists working in the United Kingdom
Board certified—having completed the process of board certification in a specialty field
Board examination—qualifying examination for a specialty field
Body of knowledge—represents the complete set of concepts, terms, and activities that make up a professional domain, as defined by the relevant professional organization and professional association

Cellular and tissue-based products (CGTPs)—established by Part 1271 by the FDA to establish good tissue practices to prevent introduction, transmission, and spread of communicable disease; refers to human cells or tissue intended for implantation, transplantation, infusion, or transfer into a human recipient which is regulated as a human cell, tissue, and cellular and tissue-based product or HCT/P; includes reproductive tissues

Centers for Disease Control and Prevention (CDC)—one of the major operating components of the Department of Health and Human Services (DHHS) whose mission is to collaborate to create the expertise, information, and tools that people and communities need to protect their health—through health promotion; prevention of disease, injury, and disability; and preparedness for new health threats

Centers for Medicare and Medicaid Services (CMS)—federal agency within the US Department of Health and Human Services (DHHS) that administers the Medicare program and works in partnership with state governments to administer Medicaid, the State Children's Health Insurance Program (SCHIP), and health insurance portability standards. In addition to these programs, the CMS has other responsibilities, including the administrative simplification standards from the Health Insurance Portability and Accountability Act of 1996 (HIPAA), quality standards in long-term care facilities through its survey and certification process, and clinical laboratory quality standards under the Clinical Laboratory Improvement Amendments

Certification—process through which an organization grants recognition to an individual, organization, process, service, or product that meets certain established criteria

Chimera—coexistence of more than one cell line in an individual, due to the fusion of originally separate zygotes

Clinical laboratory—any facility that does laboratory testing on specimens derived from humans to give information for the diagnosis, prevention, or treatment of disease or impairment and for the assessment of health

Clinical Laboratory Improvement Amendments (CLIA)—passed by Congress in 1988 to establish quality standards for all laboratory testing to ensure the accuracy, reliability, and timeliness of patient test results regardless of where the test was performed; financially managed by the CMS. The FDA is responsible for test categorization

College of American Pathologists (CAP)—medical society serving physician members and the laboratory community throughout the world; accredits laboratories; does accreditation of laboratories under deemed authority by CMS

Consanguinity—relationship by blood or by a common ancestor

Cryopreservation—freezing or vitrification and storage of gametes, zygotes, embryos, or gonadal tissue

Cytoplasmic transfer—ART procedure where the cytoplasm from a donor oocyte is injected into a recipient oocyte that has compromised mitochondria. A resulting embryo would have two sources of DNA: nuclear and mitochondrial from the recipient and mitochondrial DNA from the donor

Directive—order or instruction, especially one issued by a central authority

Directive 2004/23/EC—EU Tissues and Cells Directive adopted by the European Parliament, April 2004, that sets standards of quality and safety for the donation, procurement, testing, processing, preservation, storage, and distribution of human tissues and cells

Embryo—state of an organism's development that begins after the primitive streak develops and that persists until major organs are formed. In the human, the embryonic stage begins approximately 14 days postfertilization and encompasses the period when organs and organ systems are being formed or product of the division of the zygote to the end of the embryonic state, 8 weeks after fertilization (does not include parthenotes—generated through parthenogenesis—nor products of somatic cell nuclear transfer (SCNT)

Embryo donation—transfer of an embryo resulting from gametes (spermatozoa and oocytes) that did not originate from the recipient and her partner

Embryo/fetus reduction—procedure to reduce the number of viable embryos or fetuses in a multiple pregnancy

Embryologist—professional with specialized training in embryology; scientist having training and skills to handle oocytes, spermatozoa, and preembryos in the embryology laboratory

Embryology Laboratory Director (ELD)—certification by the American Board of Bioanalysis. Minimum requirements include a B.S. degree, having personally performed at least 60 ART procedures in humans under current standards of care, passing ABB's examination for ELD, and having directed an embryology laboratory prior to July 20, 1999

European Society of Human Reproduction and Embryology (ESHRE)—European professional organization with the main aim or promoting interest in, and understanding of, reproductive biology and medicine through facilitating research and subsequent dissemination of research findings in human reproduction and embryology to the general public, scientists, clinicians, and patient associations. It also works to inform politicians and policymakers throughout Europe and offers embryology certification

Ethics—a theory or a system of moral values

European Parliament of the Council—European Union's main decision-making body

Food and Drug Administration (FDA)—federal regulatory agency in the DHHS responsible for ensuring the safety of an array of consumer products. It has large scope, and it plays a critical role in a number of industries

Gamete intrafallopian transfer (GIFT)—ART procedure. Both sperm and oocyte are transferred to the fallopian tubes

Gestational carrier (*gestational surrogate*)—woman who carries a pregnancy with an agreement that she will give the offspring to the intended parent(s). Gametes can originate from the intended parent(s) and/or a third party (or parties)

Guideline—principle put forward to set standards or determine a course of action; typically does not carry the force of law

Health and Human Services (HHS)—department that is the US government's principal agency for protecting the health of the Americans and providing essential human services, especially for those who are least able to help themselves

High-order multiples—pregnancy or delivery with three or more fetuses or neonates

Human cells, tissues, and cellular and tissue-based products (HCT/Ps)—Center for Biologics Evaluation and Research (CBER), an FDA branch regulating HCT/Ps, including reproductive tissues, to prevent introduction, transmission, and spread of communicable disease by donor testing and following established good tissue practices under 21 CFR Parts 1270 and 1271, compliance effective May 2005

Human Fertilisation and Embryology Authority (HFEA)—UK's independent regulator that oversees the use of gametes and embryos in fertility treatment and research

Infertility—disease of the reproductive system defined by the failure to achieve a clinical pregnancy after 12 months or more of regular unprotected sexual intercourse

International Committee for Monitoring Assisted Reproductive Technology (ICMART)—independent, international, nonprofit organization that has taken a leading role in the development, collection, and dissemination of worldwide data on assisted reproductive technology (ART); International Federation of Fertility Societies (IFFS)

Intracytoplasmic sperm injection (ICSI)—procedure in which a single spermatozoon is injected into the oocyte cytoplasm

In vitro *fertilization* (IVF)—an ART procedure that involves extracorporeal fertilization

Law—body of rules of conduct established and enforced by an authority of legislation

Legal—meeting the requirements under law

Licensing body—competent authority able to grant permission to exercise a certain privilege that, without such authorization, would constitute an illegal act

Mandate—directive, order

Mitochondrial replacement techniques (MRT)—creating an embryo with nuclear DNA (nDNA) from the intended mother and mtDNA from a woman with a nonpathogenic mtDNA through modification of either an oocyte or zygote (fertilized oocyte) to prevent transmission of mtDNA disease from mother to child; two techniques: (1) maternal spindle transfer (MST), which involves manipulation of oocytes, and (2) pronuclear transfer (PNT), which involves manipulation of zygotes

National Health System (NHS)—comprehensive publically funded government healthcare system service in Britain covering virtually the entire population

Nuclear transfer—in ART, the introduction of the nucleus from the oocyte of an older patient into the enucleated oocyte of a young oocyte donor for the purpose of fertilization

Ovarian hyperstimulation syndrome (OHSS)—an exaggerated systemic response to ovarian stimulation characterized by a wide spectrum of clinical and laboratory manifestations; classified as mild, moderate, or severe according to the degree of abdominal distension, ovarian enlargement, and respiratory, hemodynamic, and metabolic complications. Severe OHSS is defined to occur when hospitalization is indicated

Oversight—supervision, control, overseeing, managing, administration

Preembryo—conceptus during early cleavage stages of development until approximately 14 days postfertilization

Preimplantation genetic diagnosis (PGD)—analysis of polar bodies, blastomeres, or trophectoderm from oocytes, zygotes, or embryos for detection of specific genetic, structural, and/or chromosomal alterations

Preimplantation genetic screening (PGS)—analysis of polar bodies, blastomeres, or trophectoderm from oocytes, zygotes, or embryos for detection of aneuploidy, mutation, and/or DNA rearrangement

Professional organization—a nonprofit organization seeking to further a particular profession, the interests of individuals engaged in that profession, and the public interest

Pronuclei—the haploid nucleus of a sperm or oocyte before fusion of the nuclei at fertilization

Public Law 102–493 (*Fertility Clinic Success Rate and Certification Act of 1992*)—requires assisted reproductive technology programs to report annually to the secretary of HHS, through the Centers for Disease Control and Prevention to report pregnancy success rates and report each embryo laboratory used by the program and whether it is certified and mandates development of model program for certification of embryo laboratories to be carried out by the individual states
Regulation—rule or order prescribed for management or government
Reproductive cloning—technology used to generate an animal that has the same nuclear DNA as another currently or previously existing animal, in a process called "somatic cell nuclear transfer" (SCNT)
Sanction—(n) mechanism of social control for enforcing a society's standards
Somatic cell nuclear transfer (SCNT)—transfers genetic material from the nucleus of a donor adult cell to an enucleated oocyte. The reconstructed oocyte containing the DNA from a donor cell must be treated with chemicals or electric current in order to stimulate cell division; once the cloned embryo reaches a suitable stage, it is transferred to the uterus of a female host where it continues to develop until birth
Standard—basis for comparison; a reference against which other things can be evaluated
Statute—a law enacted by a legislature
Therapeutic cloning—production of human embryos for use in research. The goal of this process is not to create cloned human beings but rather to harvest stem cells that can be used to study human development and to treat disease; stem cells are extracted from the inner cell mass of the blastocyst
Third-party reproduction—the use of oocytes, sperm, or embryos that have been donated by a third person (donor) to enable an infertile individual or couple, the intended recipient, to become parents
Total delivery rate with at least one live birth—estimated total number of deliveries with at least one live born baby resulting from the initiated or aspirated ART cycle including all fresh cycles and all frozen-thawed ART cycles. The rate is used when all of the embryos (fresh and/or frozen-thawed) have been used from one ART cycle. Delivery of singleton, twin, or other multiple pregnancy is registered as one delivery
Traditional surrogacy—treatment in which a woman is inseminated with sperm for the purpose of conceiving for an intended recipient. The surrogate has genetic and biological link to pregnancy she might carry
Values—important and enduring beliefs or ideals shared by the members of a culture about what is good or desirable and what is not
Vitrification—an ultrarapid cryopreservation method that prevents ice formation within the suspension, which is converted to a glass-like solid
Zygote—one-cell stage that follows breakdown of the pronuclear membrane and precedes the first cleavage or a diploid cell resulting from the fertilization of an oocyte by a spermatozoon, which subsequently divides to form an embryo
Zygote intrafallopian transfer (ZIFT)—procedure in which zygotes are transferred into the fallopian tube

65

65.3 International Practices

Several IFFS 2013 survey questions addressed both the clinical practice and the role of the laboratory. The following tests, procedures, and services are lab associated.

65.3.1 IVF

The most basic ART procedure is in vitro fertilization and embryo transfer that resulted in the first in vitro birth in the United Kingdom in 1978 [48]. IVF is now performed in developed countries internationally. The procedure was unconstitutional in the country of Costa Rica until 2016 [49]. The lifting of the restriction ended the last full IVF ban in the world. Spin-offs from the IVF procedure such as gamete intrafallopian transfer (GIFT) and zygote intrafallopian transfer (ZIFT) are still practiced although GIFT appears to be limited to niche populations that may reflect religious dogma opposed to fertilization outside the body or to regulation [6, 50]. Embryo culture may be restricted to the cleavage stage or extended to the blastocyst stage of development [51].

65.3.2 Cryopreservation Procedures

Cryopreservation is routine in most settings but freezing may be limited to cleavage-stage embryos and partner semen to have available for backup in case of problems at the time spermatozoa are needed for insemination or may be expanded to include cryopreservation of zygotes, blastocysts, oocytes, donor spermatozoa, and ovarian and testicular tissues [52–55]. Cryopreservation procedures are dependent on the level of laboratory technology and on regulation. Newer technology, such as the technically simpler and rapid-to-perform vitrification procedures, has been responsible for the expan-

sion of cryopreservation in ART laboratories [56]. Moving cryopreservation of oocytes from the investigational status to an acceptable clinical procedure has also resulted in expansion of these services [4]. Regulation regarding preservation of embryos and gametes continues to be refined. Embryo cryopreservation is allowed by statute or guidelines in 83 countries. Venezuela is the only country to prohibit freezing fertilized oocytes, and Italy permits embryo freezing only in specific cases. Oocyte cryopreservation is permitted in 42 countries, and cryopreservation of germinal tissue is allowed in 70 countries but is not allowed in Ivory Coast and Senegal. There are often restrictions regarding cryopreservation of gametes, embryos, and reproductive tissues. For example, in Switzerland only zygotes may be cryopreserved. Fertility preservation is for cancer patients only in Australia, Hong Kong, Ireland, and Turkey, and in Spain it is limited to cases of high ovarian hyperstimulation syndrome (OHHS) risk [4].

65.3.3 Oocyte Maturation

Oocytes may be matured in vitro. In vitro maturation (IVM) is an evolving procedure that involves culturing immature oocytes to maturity in vitro to perform IVF. The procedure has the advantages of not requiring gonadotropin stimulation, making it less costly than traditional IVF, and eliminating the risks associated with patients at risk for ovarian hyperstimulation associated with pharmacologic gonadotropins. Oocytes can be retrieved at any time during the cycle, making the procedure ideal for young patients undergoing oncotherapy [4, 14]. ICSI is typically required for inseminating in vitro matured oocytes. The IFFS 2013 reported that 29 of 43 countries with statutes, laws, and guidelines permitted IVM, but two, Denmark and Senegal, prohibited the procedure. The practice was restricted by statute in 5 countries and by guidelines in 12. Nine countries reported using IVM as a routine part of their cryopreservation program [4].

65.3.4 Third-Party Reproduction

Gamete and embryo donation may be influenced not only by technology but also by history, culture, and predominant religion(s) in a state. The IFFS 2013 addressed this practice. Sperm donation is not allowed for non-IVF in 22% of the countries surveyed and is prohibited in the Arab nations of Egypt, Libya, Senegal, Tunisia, Saudi Arabia, and Turkey. Oocyte donation is not permitted in Austria, Italy, Norway, and Switzerland and is allowed only in special cases in Slovenia. Embryo donation is approved in 53% of countries responding to the 2013 IFFS survey but prohibited in many including Israel, Austria, Denmark, Iceland, Italy, Norway, Slovenia, Sweden, Switzerland, China, Egypt, Libya, Saudi Arabia, Senegal, Tunisia, and Turkey. Donation of germinal tissue is banned in 43% of reporting states [4].

Third-party reproduction may extend beyond gamete, embryo, and reproductive tissue donation to include gestational carriers and surrogates [19]. The term gestational carrier or gestational surrogate refers to an arrangement in which the gametes are of the genetic couple contracting the surrogacy arrangement with the surrogate host being unrelated to any offspring that might be born from the arrangement. This differs from a partial surrogacy where the surrogate is the genetic mother. The IFFS 2013 survey addressed gestational surrogacy only. Of the 62 responding countries, only 19 or 31% sanctioned the arrangement, and only 9 reported actually using gestational surrogates. States allowing the agreement had precise requisites regarding the contractual provisions [4].

65.3.5 Micromanipulation Procedures

65.3.5.1 Intracytoplasmic Transfer

Micromanipulation procedures, designed to increase the success of an IVF cycle, include ICSI and assisted hatching (AH) [12, 13, 57]. Although ICSI is indicated for male factor infertility, it is reportedly used routinely in ART units in several countries including Brazil, Australia, Ireland, Finland, Libya, the United States, South Africa, and Slovenia. The procedure is not prohibited in any state, and only Venezuela reports using the technology for specific cases only [4].

65.3.5.2 Assisted Hatching

Assisted hatching is a mechanical or chemical disruption of the zona pellucida to improve pregnancy rates. It may be performed on embryos with a thick zona pellucida, on those that have been frozen and thawed, and for women who are over 38 years of age or who have had repeated implantation failures. The technique also may be used to breach the zona pellucida prior to preimplantation genetic screening [4, 21, 22]. Assisted hatching is accepted in 58 of the reporting states. It is banned in Ivory Coast and Senegal and is used with restrictions in several countries [4].

65.3.5.3 Cytoplasmic Transfer

Cytoplasmic transfer involves the transfer of ooplasm from oocytes of young donors to the oocytes of older women to introduce healthy mitochondria believed to rescue an embryo from developmental block at the two-cell stage, referred to as the two-cell block [58, 59]. The procedure results in offspring with two different strains of mitochondrial DNA. Cytoplasmic transfer is permitted in Argentina, Greece, India, Kazakhstan, and the United Kingdom. It is not allowed in 25 countries, and law in Austria strictly prohibits the procedure. The FDA regulates the procedure in the United States. The use of the procedure requires an approval letter from the agency. To date, the FDA has not approved any applications. The procedure may be used for research purposes only in France [4, 26].

65.3.5.4 Mitochondrial Donation

In the forefront of micromanipulation procedures is mitochondrial donation, more technically accurately referred to as nuclear genome transfer, techniques designed to allow a small number of women with a rare kind of severe mitochondrial disease to have a healthy and mostly genetically related child. The techniques involve transferring the nucleus of an affected woman's oocyte, or the nucleus of a fertilized embryo, into a donor's enucleated oocyte or embryo, with the healthy mitochondria remaining. In this process, the nuclear DNA is inherited from the intended mother and father and mitochondrial DNA from the donor oocyte provider, resulting in offspring with DNA from three different individuals [25–33]. Great Britain was the first country to legalize mitochondrial transfer in 2015 [30]. In the United States, an FDA advisory panel says mitochondrial therapy research is ethical if limited to male embryos [33]. The agency is now considering mitochondrial replacement [25].

65.3.5.5 Genetic Screening and Diagnosis

Preimplantation genetic diagnosis (PGD) is more accurately referred to as preimplantation genetic screening (PGS) for determination of genetic disease. The procedure typically involves removing one or two blastomeres from an eight-cell embryo on day 3 of development for genetic analysis although screening can be performed using polar bodies and trophectoderm cells [22]. Only unaffected embryos are transferred. Of 40 countries with statutes, laws, and guidelines, 38 allow PGD. Two countries, the Philippines and Switzerland, do not allow the testing. In eight of these countries, PGD is restricted to specific hereditary disorders [4].

65.3.5.6 Sex Selection

Sex selection is applicable for family balancing or to prevent transmission of sex-linked, inherited genetic diseases. Selection may be by sperm sorting using flow cytometry to separate X- or Y-enriched semen for insemination, IVF following preimplantation genetic screening with selection of desired sex for transfer, or by other methods. Other methods consist of sperm separation on a gradient, timing of sexual intercourse, and termination of pregnancy with an unwanted sex. Sperm sorting selects for males with 75% success rates and for females with 85% success rates. IVF following PGS has a success rate of 99% [4]. IFFS 2013 shared that very few countries perform sex selection by either the sorting methods or IVF following embryo biopsy for determination of sex [4, 23]. The procedures are allowed in only 9 countries and are not allowed in 29. They were not mentioned by law in 5 but were reported as being practiced by one or both methods in 20 countries [4].

65.3.5.7 Posthumous Reproduction

To date, posthumous insemination has been performed using a man's cryopreserved spermatozoa or posthumous sperm retrieval [20]. The IFFS 2013 Surveillance queried respondents about this practice and learned that is was not permitted in most (43%) states [4].

65.3.6 Research

65.3.6.1 Research on the Preembryo

Research on the preembryo is controversial and based on religious principles and status of the conceptus. Of 54 responding to the IFFS question, 22 noted that experimentation is acceptable, 29 stated that it is unacceptable, and 3 did not know. Third-party approval was a requirement, and there was an established maximum age restriction, typically 14 days, beyond which experimentation was proscribed. The ruling tends to be in line with culture and religious dogma regarding when life begins [4].

65.3.6.2 Cloning

Therapeutic cloning involves harvesting stem cells from the human embryonic inner cell mass with the intent of having the cells undergo differentiation to be used for therapeutic purposes [60, 61]. Therapeutic cloning is used in 8 of the 46 countries that have laws, statutes, and guidelines and is not used in 38 countries. Research on embryonic stem cells is permitted in 14 of these countries [4].

Reproductive cloning or somatic cell nuclear transfer (SCNT) is a technique for cloning that involves removing the nucleus from a healthy oocyte and transferring DNA from the somatic cell of an animal to be copied. Following in vitro development, an early-stage embryo is implanted into a surrogate womb. The young animal, the clone, has the same genetic makeup as the animal that donated the somatic cell [60, 61]. Reproductive cloning in humans is prohibited in all countries except China, where there are no reports of the procedure being practiced [4].

65.4 Concerns Regarding ART Laboratory Practices

There are many concerns regarding ART practices, several of which are directly related to the laboratory and the embryologist. Embryologists with varying degrees of education and training preform the very advanced and technical ART procedures. ART procedures are associated with increased birth defects [62–85]. Whether the cause is procedural or due to the underlying infertility, or in some cases advanced parental age, confounds the problem. If procedural, there are also multiple factors to consider including culture media/conditions and the skill of the embryologist. Some ART-related birth defects and newborn health issues are due to higher order multiple births [63, 64, 66]. These births with their increased healthcare costs concern society as a whole [64, 80]. Although the clinician and the parents make the decision regarding the number of embryos to transfer, the quality of the embryos for transfer is directly related to the skill of the embryologist. The embryologist's capability determines whether the laboratory is successful with culture to the blastocyst stage, in vitro maturation of oocytes, cryopreservation of reproductive tissues, and successful embryo biopsy for

genetic screening. The skill of the technologist is crucial for performing micromanipulation procedures. ICSI does not allow for natural selection of spermatozoa and skips several stages in fertilization, including oocyte binding and penetration. The procedure is associated with several categories of birth defects, including epigenetic changes. It is not clear if the defects are due to the causal fertility problem, culture conditions, or the skillfulness of the embryologist [69]. Another micromanipulation, assisted hatching, can damage the embryo, making it unacceptable for uterine transfer [4, 21, 22]. Chimerism has resulted from IVF using ICSI and assisted hatching of the resulting embryo [78, 79, 82, 85]. Mitochondrial transfer may result in mitochondrial-nuclear mismatch and carryover of mutated mtDNA, affecting tissues of the child born from these techniques, and that would be passed on to the future generations [26].

Laboratory error is another adverse consequence of ART. Gametes have been switched, embryos have been damaged or lost, and embryos have been transferred to the wrong recipient [86–94]. Although these errors are rare, the results are devastating [87]. The greatest chance for error occurs in cryopreservation procedures due to the multiple steps involved in labeling, freezing, storage, and thawing gametes and embryos. The chance of error may increase if donor gametes and/or embryos are included in the procedures. Outcomes of medical negligence claims for 1 carrier for practices over a 10-year period (2005–2015) for 10 practices in 9 states for a total of 184,015 total IVF cycles were reported. There were 176 incidences resulting in 30 claims, of which 22 resulted in indemnity disbursements. Misdiagnosis or errors in diagnosis and lost oocytes or embryos continue to be the most frequent causes of claims [95].

Embryo biopsy, which demands much skill, is performed for the purpose of preimplantation genetic screening [96]. Improperly performed procedures may impact the developmental potential of the embryo. Nuclear transfer for prevention of mitochondrial genetic disease requires that the embryologist not transfer maternal DNA to the enucleated donor oocyte. Genetic material can be lost during transfer, or small amounts of mtDNA from the unhealthy oocyte may be transferred [26].

The embryologist must possess attributes in addition to advanced technical skills, including a commitment to medical ethics. Confidentiality is paramount in the ART setting, which may include patients wishing to maintain secrecy regarding situations such as their infertility or third-party reproduction.

65.5 Status of Embryology Profession and the Embryologist

Although ART has been an expanding discipline for more than 40 years, the field of embryology is not widely recognized, and the embryologists performing the numerous, highly complex, multidisciplinary procedures in ART facilities are not acknowledged professionally. International regulations and practices document this lack of recognition. Only 3 of 27 European healthcare systems recognize clinical embryology as an official profession [97]. In the United States, embryology laboratories, and embryologists, are specifically excluded from regulation that oversees clinical laboratories, and the Australian Health Practitioner Regulation Society Health Agency that enforces the Practitioner National Law (2009) regulates 14 health professions and has 39 protected titles; embryology is not among them [46, 98]. This lack of acknowledgment may reflect the fact that the field of clinical embryology is not cohesive in terms of (1) terminology describing the discipline and the embryologist, (2) regulation of the laboratory practice, (3) required education and training for embryologists, (4) certification, and (5) requirements for continuing professional development for these clinical professionals.

65.5.1 Terminology

Defining the embryology laboratory and the embryologist poses challenges. First, labeling the clinical embryology facility as a "laboratory" is problematic. For example, in the United States, CLIA defines a laboratory as a place "for examination of materials derived from the body (such as fluids, tissues or cells) for the purpose of providing information on diagnosis, prognosis, prevention, or treatment of disease" [99]. Because embryos are not derived from the human body, this definition does not match with standard clinical laboratory procedures. Efforts to include embryology laboratories under CLIA have failed because of the definition of facilities and testing that are under the CLIA mandate [100].

There is also absence of consistency regarding the status of the embryologist as determined by professional interest groups, legislation, and certifying groups. The lack of coherence prompted the Alpha Expert Panel Consensus Meeting in 2014, an international task force charged with arriving at a consensus on the professional status of the clinical embryologist [101]. To approach this question, the work group sent a questionnaire to 40 national and international societies for clinical embryology. Based on the 26 responses from groups representing 58 countries located in Africa, the Americas, Asia (including India), Europe, the Middle East, and Oceania, it was concluded that there was not an international agreement on the role of embryologists.

65.5.2 Regulation

Since laboratories are not always included in ART surveillance, the 2013 IFFS survey addressed laboratory surveillance separately and found that results were similar to data for clinical surveillance. The majority (77%) had some type of laboratory surveillance. Twenty-two percent had on-site inspections only, 8% periodic reports only, and 31% both on-site inspections and periodic reports. Sixteen percent reported that laboratory surveillance was by other methods.

Most (69%) centers were accredited, and 65% had laboratory certification. Voluntary accreditation via a national reproductive professional society was reported as a common method of laboratory assessment. Fifty-seven percent of reporting centers stated that specific penalties were in place for violations [4]. The Alpha survey reported that 19 of 27 respondents favored regulation with some noting that regulation was in progress [101].

65.5.3 Education and Training

Acceptable education and training for clinical embryologists vary according to state. Although some have minimal requirements for embryologists, most legislation and accrediting bodies rely on the embryology laboratory director to determine education qualifications and training for reporting embryologists. Expectations for laboratory director include an earned doctorate in science although a master of science is acceptable in some countries. Most employers require only a bachelor's degree for embryologists entering the field [97]. A BSc/MLT was reported as the minimum requirement for embryologists for countries with regulations or published guidelines [101]. Certification programs do, however, have education requirements.

Typically, senior-level colleagues train new embryologists. Accrediting agencies typically require documentation of education and training, and these records are compulsory for application for embryology certification.

Lack of curricular-based programs in the field may contribute to the varying educational requirements for embryologists. There are a limited number of programs awarding M.S. and Ph.D. degrees in clinical embryology. These programs are located primarily in Europe [102]. The value of degree programs in clinical embryology continues to be challenged. Several programs have opened and closed in several countries over the decades. An established program in the United States, which had graduated several successful embryologists from certificate and master's programs over an 11-year period and which had opened a basic sciences Ph.D. with clinical rotations in andrology and embryology, was closed to support more traditional medical programs [103, 104].

The Association of Clinical Embryologists (ACE) Training Committee that administered and awarded a Certificate in Clinical Embryology stopped accepting applications as of December 31, 2015 [105]. Qualifications for the certificate were based on a minimum of BSc degree, current employment as a clinical scientist, supervision by an "in-house" HCPC-registered clinical scientist, completion of a log book documenting candidate's ability to perform various procedures in assisted reproduction, and a final examination. The course was expected to take approximately 2 years to complete.

Education programs that are ongoing are not consistent in terms of didactic curriculum and required clinical training and/or experience. Established programs for educating and training other health professionals follow a model that dictates certain courses and clinical experiences. For example, in order to be accredited as a medical laboratory science program in the United States, the curriculum must include a minimum number of credits in both lectures and student laboratories for all applicable discipline areas (clinical chemistry, hematology, immunology, microbiology, management) followed by clinical practica in all areas. The degree is awarded following completion of coursework and clinical practica [106].

65.5.4 Certification

Certification is not required in most states. The Alpha survey found that only 5 of 27 respondents required this credential. An education survey of centers in Australia and New Zealand conducted by the Fertility Society of Australia in 2010 addressed certification. They reported that although 60% of respondents wanted certification, 10% did not, and 30% were not sure [101].

Eligibility for embryology certification is based on education credentials, documentation of successful performance of clinical embryology procedures, and passing applicable examinations. This method of credentialing is not in line with required education and certification for other clinical laboratory personnel. In the United States, medical laboratory scientists (also referred to as medical technologists and clinical laboratory scientists) must complete a degree specific for the field and pass a national qualifying examination prior to entry into the field. As opposed to work experience being a requirement for certification, laboratory practice is a requisite for specialty certification in a specific clinical laboratory discipline, such as hematology or clinical chemistry [107].

The European Society for Human Reproduction and Embryology (ESHRE) provides the only internationally recognized certification [108]. Certification as a clinical embryologist requires a BSc in natural sciences and a minimum of 3 years hands-on experience with human gametes and embryos in a clinical ART laboratory, documented in a submitted logbook, and successful completion of a certifying examination. To qualify as a senior clinical embryologist, the individual must hold an MSc or Ph.D. in natural sciences and be able to document a minimum of 6 years' experience.

In the United States, the only embryology certification that is recognized by the embryology laboratory accrediting agencies (College of American Pathologists or CAP and the Joint Commission) and state licensing boards that certifies individuals in embryology is offered by the American Board of Bioanalysis (ABB) [109–111]. To be certified as an embryology laboratory scientist, an individual must document 30 ART laboratory procedures in humans and 1 year of acceptable full-time experience in the discipline of embryology, meet minimum education requirements, and pass examinations in basic laboratory knowledge and embryology. Minimum education accepted is 24 h semester hours of

courses in science or medical laboratory technology. Although an embryologist directing a laboratory prior to 1999 may grandfather as a director with minimum education requirements, individuals becoming directors after 1999 must meet stringent requirements. They must have an earned doctorate degree with chemical, physical, biological, or clinical laboratory science as a major and have completed a minimum of 32 semester hours in these sciences and have a minimum of 4 years of clinical laboratory training or experience within the 10 years immediately prior to the application date on human specimens, or both, including at least 2 years of experience within the 10 years immediately prior to the application date directing or supervising high-complexity testing in a clinical setting. In addition to these general requirements for laboratory director, the individual must have experience including 60 personally performed, completed assisted reproductive procedures and pass the ABB examination in general knowledge and at least 1 of the following disciplines or specialties: andrology, chemistry (including urinalysis, endocrinology, and toxicology), diagnostic immunology, embryology, hematology (including flow cytometry), microbiology (includes bacteriology, parasitology, virology, and mycology), molecular diagnostics, or public health microbiology.

65.5.5 Continuing Professional Development (CPD)

Continuing professional development (CPD) refers to continuing education to maintain knowledge and skills, following initial training. CPD is typically a regulatory requirement or guidance. For example, the European Union Tissues and Cells Directive (2004/23/EC—Article 18) states that "The centre should establish documented procedures for staff management that ensure all staff have initial basic training and updated training as required, on-going competence assessment, continuing education and professional development, and appropriate access to meetings and communications" [112]. However, there is a lack of this expectation internationally. Only three countries in the Alpha survey reported mandatory, regulated CPD, and two others had voluntary, regulated systems in place. One had a requirement for CPD, but no regulation in place, while four were planning to have national CPD systems [101].

Certifying bodies, including those for embryology, require CPD for maintenance of certification. ESHRE offers the opportunity to revalidate certificates through the Continuous Embryology Education Credit (CEEC) system [113]. Credits must relate to the field of embryology and assisted conception. Attendance at scientific meetings, publications, contributions to meetings, and courses will all be taken into consideration for the award of credits. Senior clinical embryologists will need ten credits over a 3-year block, and clinical embryologists must have six credits, obtained over a 3-year period, in order to apply for renewal of their certificate. The AAB also requires continuing education for renewal [114]. Certificants must document at least 2.4 CEUs (24 contact hours) each biennium. Acceptable credits are stricter than those of ESHRE. For example, all publications are not acknowledged.

65.6 Future

The range of disciplines associated with the multidisciplinary field of ART continues to evolve. New procedures are accompanied by the potential for genetic, social, and legal issues. For example, cryopreservation of oocytes and reproductive tissues opens the door for posthumous reproduction beyond the use of spermatozoa, along with issues regarding custody of gametes and tissues [4, 52–55]. Mitochondrial transfer with associated genetic implications is legal in Great Britain and is being reviewed in other countries. Polar body genome transfer and maternal spindle transfer are on the horizon [26]. Assisted oocyte activation is undertaken in some ART facilities [115]. Cloning, though not practiced, is legal in China [4]. It is anticipated that these advances coupled with malpractice claims and harsher violations will result in updates or increases in regulations. The 2013 IFFS reported that legislation had been updated in 43% of countries surveyed since the 2009 report and that 77% considered the new regulations an improvement [4].

Recognition of the field of embryology and the professional status of the embryologist is expected. As the field advances, the embryologist will assume greater responsibilities. The importance of the embryologist's credentials is highlighted by Great Britain's requirement for mitochondrial transfer. As part of the license to perform the procedure, *the competence of the embryologist must provide a CV with references that support their experience and knowledge and documentation of competence in performing micromanipulation on oocytes or embryos* [116]. The demand for education for embryologists is being realized. Professional societies and individual practices continue to offer numerous hands-on courses in specific techniques.

A newly opened Ph.D. program in reproductive clinical science focuses on education of embryologists already practicing in the field [117]. It is an online program that has been designed "for adult learners and working professionals who are in the workforce, while they are enrolled in this program."

Although a limited number of degree programs are available, they are not part of an overarching system that confers consistency and continuity to the academic programs. Degree programs in clinical embryology are not consistent in terms of coursework and clinical experience. This is not in line with other professional programs that have set requirements for courses and clinical practica prior to taking a certification/license examination [107]. This was addressed by the consensus work group resulting in Alpha's plans to develop an educational program for clinical embryologists. The planned program "will provide the material to meet the consensus requirements for knowledge development, as well as competency-based training, and continuing professional

development, to meet the current and future needs of Clinical Embryologists worldwide" [101]. This important first step will give them parity with other healthcare professionals. This is a critical step in positioning embryology to function as an independent profession and having embryologists recognized as a healthcare profession. Once achieved, these professionals will be able to establish guidelines, develop criteria for education and continuing education, and, most importantly, be able to influence policy regarding their practice.

Review Questions

1. Based on the most recent reports, how many live births have been produced using ART procedures?
2. Distinguish between regulation, statute, directive, and license.
3. Define laboratory certification and accreditation.
4. List at least five countries in which a specific ART procedure is forbidden. Associate this ban/restriction with the underlying reason(s).
5. List three methods for sex selection.
6. Describe assisted oocyte activation.
7. What are the major concerns regarding cytoplasmic and mitochondrial donation?
8. How do therapeutic and reproductive cloning differ? In what country is reproductive cloning legal?
9. What are the most common errors in the ART laboratory? How might these errors be minimized?
10. What tends to be the minimal education requirement for a clinical embryology director? An entry-level embryologist or embryology assistant?
11. What qualifications do the certifying bodies ESHRE and ABB require for embryology certification?

Legislation in the UK

Rachel Cutting

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_66

Learning Objectives

- To provide an overview of the history of legislation of ART in the UK
- To explain the structure and functions of the HFEA
- To describe the legislatory framework that centres must work within
- To discuss how centres are assessed for compliance and describe the process of licensing of centres by the HFEA

66.1 History of Legislation in the UK

66.1.1 The Warnock Committee

Although the birth of Louise Brown in 1978 was a major breakthrough in the treatment of the infertile couple [1], it raised many ethical concerns with both professionals and the general public. In response, a committee was established in 1982 in the UK to inquire into the technologies of in vitro fertilisation (IVF) and embryology and to form the principles of future regulation. Chaired by Mary Warnock, the terms of reference were to 'consider recent and potential developments in medicine and science related to human fertilisation and embryology; to consider what policies and safeguards should be applied, including consideration of the social, ethical and legal implications of these developments; and to make recommendations' [2]. The findings, which considered all processes involved in IVF, donor insemination and surrogacy, were published in the Warnock Report in 1984. The report concluded that the human embryo should be protected by law by giving it a special status outside the human body; however, research of human embryos could be permitted under certain circumstances. Other recommendations included the provision of counselling and ensuring patients give informed consent prior to treatment commencing. A key proposal was to establish an authority to regulate both research and treatment [2]. The first step to meeting the 60-plus recommendations in the report was for the Medical Research Council and the Royal College of Obstetricians and Gynaecologists to establish an interim licensing authority to provide a framework for inspection.

66.1.2 Founding the HFEA and the HFE Act 1990

Following the Warnock Report, the government undertook an extensive public consultation. The findings led to the publication of a government white paper, 'Human Fertilisation and Embryology: A Framework for Legislation', in 1987. The act drafted following this paper received royal assent on 1 November 1990 and paved the way for the establishment of the Human Fertilisation and Embryology Authority (HFEA) in 1991. This executive, nondepartmental public body was the first statutory body in the world and had the remit under the legislation to regulate IVF clinics through the licensing of:

- The creation of human embryos outside the body and their use in treatment and research
- The use of donated gametes and embryos
- The storage of gametes and embryos

The HFEA is comprised of a chair and members. The members who are appointed via the Appointments Commission are from diverse backgrounds and have the scope to determine policies and review treatment and research licence applications. Several committees support the process by providing advice on specific aspects, for example, the Audit and Governance Committee oversees corporate governance, risk, audit arrangements and financial matters and the Scientific and Clinical Advances Committee reviews and provides recommendations on recent developments. The HFEA is also obliged to provide information to the public, particularly those having treatment and donating gametes or embryos or those who are donor conceived. For this process to work efficiently, the HFEA maintains a formal register of information which records all treatments and donor information. The information held on this register can be used for research purposes depending on the type of consent provided by the patient.

66.1.3 Changes in Legislation 1991–2016

Although the 1990 legislation remained in force until the amended act in 2008, there have been various changes to the UK regulations over the years. This included allowing the storage periods for embryos to be extended in certain circumstances in 1996 and extending the purposes for which embryos could be used in research to include 'increasing knowledge about the development of embryos, increasing knowledge about serious disease and enabling any such knowledge to be applied in developing treatments for serious disease' in 2001.

A major change which impacted greatly on centres was the removal of anonymity from gamete and embryo donation which came into force in April 2005. This change permitted donor-conceived children access to the identity of their sperm, egg or embryo donor upon reaching the age of 18. This change raised concerns regarding the impact of this on donor recruitment, but although initially studies showed an overall trend in a decrease in recruitment, other studies have reported that over a longer time period, they were able to meet demand for recipient cycles [3]. At this time, payment for donation was not permitted, so in 2010 the HFEA started to review the legal and ethical issues surrounding payment and undertook a public consultation to formulate a new policy which came into force on 1 April 2012 [4]. This policy allows centres to compensate egg donors £750 per cycle and sperm donors £35 per centre visit with the flexibility for a donor to claim more if higher expenses are incurred, and receipts are produced as evidence.

In 2004, new EU regulations regarding common safety and quality standards were introduced to enable easier movement of tissues between members of the EU. UK centres had until 2007 to comply with the introduction of Directive

2004/23/EC [5] and the Commission Directives 2006/17/EC [6] and 2006/86/EC [7]. The HFEA was nominated as the competent body to assess centre compliance. The directives encompassed donation, procurement, testing, processing, preservation, storage and distribution of human tissue and cells.

Technology advances rapidly in assisted reproduction technology (ART), and in 2004, it became apparent that scientific developments and changes in public attitude necessitated a review of the 1990 Act. After public consultation and a review by the House of Commons Science and Technology Committee, the government published the white paper [8]. Following this, the draft bill was published in 2007, and after scrutiny the new bill received royal assent in November 2008.

The HFE Act 2008 [9] is divided into three parts:

1. Amendments to the Human Fertilisation and Embryology Act 1990
2. Parenthood
3. Miscellaneous and general

The main new elements of the 2008 Act [9] are:

- Ensuring that the creation and use of all human embryos outside the body – whatever the process used in their creation – are subject to regulation
- A ban on selecting the sex of offspring for social reasons
- Removal of the previous requirement within 'welfare of the child' of the child's 'need for a father'
- Allowing for the recognition of both partners in a same-sex relationship as legal parents of children conceived through the use of donated sperm, eggs or embryos
- Enabling people in same-sex relationships and unmarried couples to apply for an order allowing for them to be treated as the parents of a child born using a surrogate
- Changing restrictions on the use of data collected by the HFEA to make it easier to conduct research using this information
- Provisions clarifying the scope of legitimate embryo research activities, including regulation of 'human admixed embryos' (embryos combining both human and animal material)

Statutory storage limits for gametes and embryos increased within the new act from 5 to 10 years. It also became possible to extend the storage of gametes and embryos up to a maximum of 55 years provided that at each 10-year checkpoint, the centre obtains a written opinion from a registered medical practitioner that the person to be treated (or one of the people who provided the eggs or sperm) is or is likely to become prematurely infertile.

66.2 Code of Practice

Section 25 of the 1990 Act requires the HFEA to maintain a code of practice to provide guidance to centres in order for them to comply with the regulatory requirements when providing licensable activities. The first edition was published in 1991; the latest edition, the ninth edition, was published in January 2019. The code comprises of 33 guidance notes, each one describing the mandatory requirements, the HFEA interpretation of the mandatory requirements, best practice guidance and other relevant legislation, professional guidelines and information [10]. This comprehensive document is well used by centres and forms the basis of any procedures and processes which are carried out in a licensed centre. The 33 guidance notes are as follows:

1. Person responsible
2. Staff
3. Counselling and patient support
4. Information to be provided prior to consent
5. Consent to treatment, storage, donation, training and disclosure of information
6. Legal parenthood
7. Multiple births
8. Welfare of the child
9. Preimplantation genetic screening (PGS)
10. Embryo testing and sex selection
11. Donor recruitment, assessment and screening
12. Egg sharing arrangements
13. Payments for donors
14. Surrogacy
15. Procuring, processing and transporting gametes and embryos
16. Imports and exports
17. Storage of gametes and embryos
18. Witnessing and assuring patient and donor identification
19. Traceability
20. Donor-assisted conception
21. Intra-cytoplasmic sperm injection (ICSI)
22. Research and training
23. The quality management system
24. Third-party agreements
25. Premises, practices and facilities
26. Equipment and materials
27. Adverse incidents
28. Complaints
29. Treating people fairly
30. Confidentiality and privacy
31. Record-keeping and document control
32. Obligations and reporting requirements of centres
33. Mitochondrial donation

Centres use the Code of Practice to check their own compliance and for reference for many different clinical situations. In recent years, there has been much focus towards witnessing and minimising multiple births. The implications of inadvertent mixing of gametes or embryos resulting in the birth of a child with the 'wrong' genetic parents are catastrophic. It is therefore a mandatory requirement that centres have robust contemporaneous witnessing procedures and documentation in place to double check both the identity of patients and their samples throughout the treatment pathway. Electronic witnessing can be used, but a full risk

assessment must be conducted, and certain conditions such as double manual witnessing must occur when gametes are inseminated at embryo transfer or when samples are put into or removed from storage.

An expert report published in 2006 [11], which highlighted that multiple pregnancy was the biggest risk to the health of the mother and child during ART, led to the HFEA producing a policy and integrating the requirement for a multiple birth minimisation plan into the Code of Practice. The policy adopted a stepwise approach with the target being reduced over a period of 4 years. Centres are currently obliged to ensure their multiple birth rates do not exceed 10% and to perform regular audits to evaluate the effectiveness of their policies. Although after a legal challenge the licence condition (T123) had be to be removed, the HFEA remains committed to reducing multiple birth rates, and centres who do not meet the target are invited to attend a management review at the HFEA to discuss the issues.

The most recent Code of Practice focusses on the leadership role of the person responsible and introduces the concept of a patient support policy which ensures centres provide emotional support to patients before, during and after treatment.

66.2.1 Licensing and Inspection of UK Centres

In order to carry out assisted reproduction techniques in the UK, centres must be inspected by the HFEA to assess compliance against the HFE Act 1990 (as amended). The compliance cycle is 4 years with an inspection within every 2 years. An initial or renewal inspection has a planned agenda and is usually conducted with between two and four inspectors over 1–3 days depending on the size of the unit. Prior to the inspection, centres are asked to complete a self-assessment questionnaire which is analysed by a risk tool alongside other general performance measures. The focus of inspection is always on the quality and safety of patient care and protection of the embryo. Inspectors will directly observe practice, interview patients and check records. An interim inspection is often unannounced and will be focussed around specific themes. More frequent targeted inspections may be carried out if specific concerns are raised. In 2013, the HFEA extended its remit to include the inspection of surgical procedures in England to prevent centres being inspected by the Care Quality Commission (CQC) as well as the HFEA. This helped to reduce regulatory burden on centres and to streamline the regulatory process.

Once an inspection is complete, a report is produced, and the licensing decision whether to grant a licence is made by the licensing committee. Clinics do hold the right to appeal through the Appeals Committee. The HFEA also continually monitors a centre's performance through a risk tool which focusses on six key areas: incorrect identification of gametes or embryos; cross infection of gametes, embryos or patients; consent failures; damage or loss of gametes or embryos; multiple pregnancy; or incorrect or incomplete information on donors. The system also analyses a centre's success rates, multiple pregnancy rates, submission of critical donor information, payment of fees and incident reporting. Reporting incidents is a statutory requirement. Incidents are defined by the HFEA as 'any event, circumstance, activity or action which has caused, or has been identified as potentially causing harm, or loss or damage to patients, their embryos and/or gametes, or to staff or a licenced centre, including serious adverse events and serious adverse reactions'. Once received, the HFEA will grade the severity of an incident and determine what further action is required.

If a centre is non-compliant and there is a risk to patients, donors, gametes or embryos, then a formal process commences through the executive licensing panel using the guidance from the compliance and enforcement policy. Ultimately, a licence can be revoked.

66.2.2 Recent Changes

Although in 2015 the UK parliament voted to permit the use of mitochondrial donation for the purpose of avoiding the inheritance of severe mitochondrial disease, the expert panel reporting to the HFEA recommended that the safety and efficacy of the technique required further evaluation. The further 2016 review [12] provided comprehensive evidence in order for the HFEA to determine whether the technique could be used in clinical practice. The report concluded that clinical treatment could proceed cautiously in restricted circumstances with further research being conducted. On 15 December 2016, the HFEA permitted the use of this technology.

Section 33 in the Code of Practice outlines the specific criteria which must be complied with for treatment to be undertaken. Individual cases of maternal spindle transfer (MST) or pronuclear transfer (PNT) have to be submitted to the HFEA's Statutory Approvals Committee for authorisation.

66.2.3 Other Accreditation Schemes

Many clinics seek to optimise their services and comply with the HFEA requirement to have a demonstrable quality management system by choosing to be ISO9001:2015 certified. Diagnostic andrology services must also be certified to ISO15189:2012 or equivalent. The professional bodies relating to reproductive medicine produce best practice guidelines and provide comprehensive training and validation programs. In the UK, embryologists are trained via the master's-level Scientist Training Program in order to attain state registration.

66.3 Conclusion

The HFEA provides a unique comprehensive regulatory mechanism for ART. The framework drives standards and ensures high-quality patient care. Although seen by some as

burdensome, the regulations provide protection to both patients and embryos, and they have served to reassure the patient that this sensitive and ethically challenging area of medical practice is performed ethically.

Review Questions

1. Following the Warnock Report, the HFE Act received royal assent on 1 November 1990 and paved the way for the establishment of the Human Fertilisation and Embryology Authority (HFEA) in 1991. The HFEA regulates IVF clinics through the licensing of?

2. What major change in legislation in 2005 had impacted on donor treatments, and what further change in 2012 was made to help encourage people to come forward to donate?

3. The HFEA licences centres through an inspection process; describe the inspection cycle.

4. What are the current statutory storage periods for gametes and embryos, and under what circumstances can the storage period be extended?

Regulation, Licensing, and Accreditation of the ART Laboratory in Europe

Julius Hreinsson and Borut Kovačič

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_67

Learning Objectives

This chapter aims at informing the reader of the following:

- Overarching regulatory framework in the field of assisted reproduction in the European Union with special emphasis on the EU Tissues and Cells Directive (EUTCD)
- Relevant European institutions in this respect
- Important differences in national legislation among European countries
- Status of clinical embryology in Europe

67.1 Introduction

Legislation on ART varies considerably in Europe. Rules and regulations regarding procedures such as gamete donation, embryo cryopreservation, and other aspects of ART are not identical among the European countries. Details regarding specific requirements for laboratories vary as well; examples of this are the requirement of ISO 15189 accreditation of ART laboratories in some countries and ISO 9001 certification in several other countries. We will first discuss relevant European institutions in health care which influence the practice of ART and standards relevant in Europe. After that, we will focus on common requirements with reference to the EU Tissues and Cells Directive (EUTCD) [1], and at the end of the chapter, we will discuss the great variation in national legislation among the European countries.

Although some laboratories in some European countries may currently be operating without fulfilling the specifics in the EUTC Directive, they will in the coming years be expected to do so. This chapter is not planned to give guidelines as to how to perform the various ART procedures in the clinic or laboratory. For this purpose, other documents have been published, for example, De los Santos et al. [2].

The terms regulation and licensing may be considered relatively unequivocal. The term accreditation on the other hand occasionally gives rise to potential misinterpretations in the context of medical laboratories. It may be understood to mean recognized conformity to the international ISO 15189 standard on the one hand, or it may refer to the evaluation of competence by a designated authority without necessarily adhering to any particular ISO standard. In this chapter, we are referring to the second interpretation unless otherwise specified.

The most commonly applied international standards in the IVF laboratory are the ISO quality control standards, published by the International Organization for Standardization (ISO) (► www.iso.org). The two most commonly applied ISO standards are ISO 9001 for certification of quality management systems and ISO 15189 for accreditation of medical laboratories. Many laboratories also apply the ISO 14001 standard for environmental management system. In addition to the ISO standards, standards for good medical/laboratory practice (GMP/GLP) are also in use.

Common to these standards are stringent rules on document control as well as a requirement for a thorough description of all methods and procedures in use in the operation at hand. There are certain differences between the standards, where ISO 9001 places emphasis on process analysis and continuous improvement. ISO 15189 on the other hand focuses more on laboratory competence and the competence of personnel active in the laboratory. Both these standards are applicable to the IVF laboratory, and implementing them will greatly improve the quality in the laboratory. One great advantage of the ISO 9001 standard is that it can be applied to the laboratory and clinic alike which simplifies the implementation of the quality control routines and emphasizes the cooperation between the laboratory and the clinic.

67.2 European Institutions in Health Care

Even though every European country has its governmental institutions, taking care of its health-care system, there are also European institutions involved in creating health-care politics. The Council of Europe, founded in 1949 located in Strasbourg (France), is one of them and now consists of 47 member states. Its main task is promoting intergovernmental cooperation among all European countries to improve the quality of life for all Europeans not only in the areas of public health but also of human rights, democracy, rules of law, and culture.

Rapid progress of medicine makes it necessary for the fields of human rights, religion, and law to adjust to it. The same level of public health development is not expected due to economical, social, religious, and political differences among European countries. However, the main role of the Council of Europe is to harmonize European health-care systems and their ethical issues related to the rapid advances in biological and medicinal research and to provide minimal standards for all national health-care systems. Transplantational medicine with its rapid development is a good example of how necessary the coordination among the European countries is. Human tissues and cells are being used in an increasing variety of new ways, and today the transplantation therapy and assisted reproduction techniques are already routine methods used in daily practice. However, using human tissues and cells also raises questions of safety, quality, efficacy, and ethical dilemmas.

67.2.1 European Committee on Organ Transplantation

In 1987, the Council of Europe Committee of Experts on the Organizational Aspects of Cooperation in Organ Transplantation was created and later formed the secretariat responsible for activities related to organs, tissues, and cells. This secretariat was transferred to the European Directorate for the Quality of Medicines and Health Care (EDQM) of the Council of Europe.

67.2.2 European Directorate for the Quality of Medicines and Health Care

Today, the EDQM consists of internationally recognized experts from the Council of Europe member states, observer countries, the European Commission, representatives from the Committee on Bioethics of the Council of Europe, the WHO, and different nongovernmental organizations. The EDQM is a key European organization involved in harmonization, coordination, standardization, regulation, and quality control of medicines, blood transfusion, organ transplantation, pharmaceuticals, pharmaceutical care, consumer health, cosmetics, and food packaging. It promotes the noncommercialization of organ, tissue, and cell donation and develops ethical, quality, and safety standards.

The EDQM/Council of Europe has established several recommendations in the field of transplantation covering the ethical, social, scientific, and training aspects. Whereas agreements and conventions are binding of the states to ratify them, recommendations and resolutions are statements to governments that propose actions to be followed.

Article 168 of the Treaty on the Functioning of the European Union, which is the article about public health in the European Union (EU), gives the EU a mandate to establish high-quality and safety standards for substances of human origin, such as blood, organs, tissues, and cells with the aim to provide the common approach to the regulation of human tissues and cells across Europe [3]. As a result of this mandate, the European Parliament and the Council issued the Directive 2004/23/EC, the first of the EU Tissue and Cells Directives [1], followed 2 years later with two new directives, the Commission Directive 2006/17/EC [1.B] and the Commission Directive 2006/86/EC [1.C].

The EDQM/Council of Europe also issues guidelines. One of these is the second edition (the third edition is in preparation) of the guide to the quality and safety of tissues and cells for human application [4], including also a special chapter about ART. These guidelines help in understanding the EU Tissue and Cells Directives in detail. They are mostly written very generally with the aim to cover all fields of medicine that use live human tissues and cells for treatments.

67.3 The EU Tissue Directive and ART

The tissue directive was conceived to provide a regulatory framework for the foreseen rapid development of regenerative medicine. It was immediately obvious that other areas of medicine, such as transplantation medicine and assisted reproduction, were conceptually related and therefore needed to be covered by any regulatory initiatives. However, stem cell culture, organ transplantation, and assisted reproduction present very different challenges and have requirements that may be in conflict if a too rigid legislation is applied. The EU consulted with experts in the respective areas, and the technical directives, which guide the implementation of the tissues directive, are a result of the efforts to bring the different perspectives together. However, more work needs to be done to adapt the overall objectives of the directive to the practicalities of assisted reproduction. This chapter describes the current interpretation of the tissues directive for implementation in assisted reproduction.

67.3.1 Laboratory Personnel

Strong but not specific requirements for competence of personnel, both formal and practical, are put forward by the EU directive. The clinical disciplines such as medicine and nursing already have formally recognized education and training systems. The relevant authorities in each country issue formal license to practice, and separate licensing often does not follow formal training in ART. In spite of this, formal training programs for gynecologists are available (ESHRE/EBCOG). Formal training programs for embryologists however are not easily available in most European countries. Usually, some form of biomedical or medical-technical education is required as a basic education for the embryologist, but the complicated micromanipulative nature and richness of detail in the work as well as its academic nature places high demands on the embryologist.

In response to this, the European Society of Human Reproduction and Embryology (ESHRE) has established a certification program for clinical embryologists where an academic level of competence is established. Practical training still has to be performed at the clinics. This certification program forms an excellent basis for acknowledgement of the embryologist's competence in years to come.

In the EU directive, many of the details regarding which level of competence should be attained by the various categories of personnel are left for the individual clinics to decide. The clinic in question has to document in its quality system, and enforce in practice, how sufficient competence of personnel is regulated with reference to the activities performed. The following requirements are put forward by the directive:

- Evidence of training and competence testing must be documented. Personnel must be assessed regularly for competence, and professional development must be ensured.
- Sufficient numbers of personnel at the clinics must be ensured.
- Knowledge of the legal framework and ethical aspects must be established.
- The clinical disciplines have established licensing systems in all countries, but each laboratory must ensure the competence of embryologists employed at the clinic/lab.
- Laboratory and clinical directors must have documented academical and practical experience for several years.
- Access to the laboratory of a senior medical consultant is mandatory under the EU directive.
- No formal requirement with regard to level and area of education is put forward by the directive.

67.3.2 Authorities and Enforcement

For members of the European Union, there is a requirement to register and accredit or license all establishments involved in the procurement, processing, or storing of human cells and tissue for pharmaceutical or therapeutic purposes. These requirements are specified in the EU Commission Directives and their annexes, which thus provide a regulatory framework. Each country then applies this framework onto its own institutions and confers the authority to license and accredit and to perform inspections of tissue establishments. The designated national body may decide to use existing industry standards (e.g., the ISO 9000 series) as components of the regulatory system and may, thus, outsource part of the regulatory oversight. However, the ultimate responsibility rests with the designated national body.

The scope of the directives is very broad, and, as a consequence, the technical solutions or standards required for compliance are not specified in detail for every area, but guidance is found in the annexes. In some areas, the annexes are very specific, but most detailed requirements are instead specified by the designated national body. A consultative forum, constituted by representatives from all the specialties, may be used to support this body in determining the specific technical requirements. The European Society of Human Reproduction and Embryology (ESHRE) has also been active in this respect. Each tissue establishment must have a responsible person, who must be suitably qualified and who is responsible to the authority for ensuring that the establishment is compliant with the directives.

After verifying that a tissue establishment complies with the directives, the authority shall issue a license for the tissue establishment for specified activities. In order for the tissue establishment to retain the license, it must be subject to inspections of the laboratory and clinic, to be undertaken at regular intervals (not longer than 2 years). Annual reports of the clinical and laboratory activities must be submitted to the authority. The inspections should evaluate all processes and documentation pertaining to the directives, and the authority must be granted access to premises and documents as required. The findings of the inspections shall be available to the commission and to other member countries.

Adverse events must be reported, and the authority may decide to inspect the establishment after such events. Also, substantial changes in operation of the clinic/lab must be reported and approved as well as any change of key personnel at the clinic/lab. If a tissue establishment fails to comply with the directive, its license may be withdrawn by the authority. However, if it can be shown that compliance on a particular technical point is detrimental to the tissue, the compliance requirement may be waived for this particular situation.

The European Commission has published an operations manual for the competent authorities regarding inspection of the tissue establishments [5]. This manual describes, for example, the requirements for the inspectors, who should have a relevant university education and previous work experience in this or related fields.

In most European countries, the authorities verifying the implementation of EUTCDs and their performance are pharmaceutical specialists. Specialists from clinical embryology are rarely a part of inspection authority. The inspection process includes checking of all segments described in EUTCD and should be performed minimally every 2 years. Every ART center should designate a responsible person ensuring that human tissues and cells intended for human applications are handled, stored, and distributed in accordance with EUTCD and with the laws in force in the member state. This person must inform the authority in cases of adverse events and reactions that could harm the biological material and could have or have had health consequences for people involved in the treatment with cells or tissues. Although the responsible person for EUTCD is usually the medical doctor, the head of the IVF laboratory is an indispensable participator in the inspection because most of the EUTCD details in the field of ART are related to the work of the IVF laboratory.

The inspectors have to prepare the report about all evaluations and verifications and list the inconsistencies observed during verification. The inconsistencies are classified as critical, bigger, and smaller recommendations. For critical inconsistencies, a very limited time is given to the tissue establishment for their elimination, and an extra inspector's visit can be expected in such cases. The tissue establishment has to provide a timetable and a list of future activities to the authority for the elimination of inconsistencies. Their elimination and prevention or corrective actions are usually an embryologist's obligation.

With the introduction of EUTCD, the inspections, and the legislative obligations to report huge amount of data from everyday clinical and laboratory work to different authorities and registers, reproductive medicine became one of the most regulated and controlled branches of medicine.

67.3.3 Andrology Laboratories

Andrology laboratories that perform semen analyses only are usually under the rules and standards available for general medical diagnostic laboratories. Although the legislation for andrology laboratories is not as strict as for therapeutic laboratories, they have to follow specific standards, mostly provided by the WHO. The last edition of WHO laboratory manual for the examination and processing of human semen from 2010 has a larger part of the manual devoted to the standardization of semen analyses with the aim to minimize the intra- and interobserver variability in sperm assessments. Many international institutions provide their assistance in verification of individual objectivity and accuracy in semen analyses by comparing the individual measurements of semen samples with the measurements of the same samples in reference laboratories.

Andrology laboratories perform a kind of cytologic analysis. That is why they are sometimes under the patronate of cytologists/pathologists as it is the case in the UK.

The andrology laboratories which perform sperm preparation techniques for ART have to work under the same conditions as IVF laboratories, fulfilling all requirements described in EUTCDs.

67.4 Facilities

67.4.1 General Aspects

The high demands on air quality in terms of particle counts and presence of microorganisms made by the EU directive were one of the areas that caused the most concern among ART professionals. Performing IVF under clean room conditions (class A) is certainly very difficult to achieve in practice and may be detrimental to oocytes and embryos because of cooling effects of the high rates of airflow required to maintain such conditions [6]. The final version of the EU directive which, with annexes 1.A–1.D, is in force allows for exceptions under certain circumstances, namely, when a validated microbial inactivation or validated terminal sterilization process is applied, where it is demonstrated that exposure in a grade A environment has a detrimental effect on the tissue or cell concerned, where it is demonstrated that the mode and route of application of the tissue or cell to the recipient imply a significantly lower risk of transmitting bacterial or fungal infection to the recipient than with cell and tissue transplantation, or where it is not technically possible to carry out the required process in a grade A environment. European countries have, in general, adopted exceptions 2–4 for ART, and in these cases, a lower standard of air quality may be applied: class D, according to EU GMP criteria, Annex 1. Particle counts and microbial counts are specified with a maximum allowed level of 3,520,000 particles larger than 0.5 μm, 29,000 particles larger than 5 μm, and 100 colony-forming units (CFUs) collected on sedimentation plates under a period of 4 h. For further details, see relevant GMP criteria.

This standard of air quality specifies particle counts of laboratories "at rest" only and applies to all facilities where oocytes, embryos, and/or sperm are procured, processed, stored, and used for assisted reproduction. Although this level is not very difficult to reach in a room with minimum activity when measurement takes place, the directive also dictates that each ART clinic/lab must show that the conditions under which the operations are performed are sufficient in terms of the above parameters. It must be demonstrated and documented that the chosen environment achieves the quality and safety required taking into account the intended purpose, mode of application, and immune status of the recipient—that is, the burden of proof lies on the clinic/lab to show that it is operating under safe conditions. Documented hygiene routines must be in place, and the planning of the facilities must be adapted to the procedures.

Other aspects of air quality such as the presence or maximum allowed levels of volatile organic compounds (VOCs) are not specified by the directive although this may well be significant in the context of ART. This can however be regulated at the national level and should be considered in the quality system in each ART clinic. General aspects of laboratory standard such as restricted access, entrance log, definition of levels of access for personnel, alarm for unauthorized access, alarms for low O_2 in liquid N_2 storage areas, and alarms for low levels in CO_2 tanks and liquid N_2 storage tanks are not specified in the EU directive but are inferred and should be considered in the quality system of the ART laboratory (see discussion on equipment below).

The standard of facilities and air quality specified in the EU directive is at a reasonably attainable level for a modern clinical laboratory. The exceptions mentioned above for ART cannot however be considered to apply for more advanced forms of clinical applications such as processing and storage of ovarian biopsies for later retransplantation to the patient. Laboratories offering such treatments may need to consider applying higher laboratory standards. In ◘ Table 67.1, the minimum obligatory standards for laboratory quality for the ART clinic and laboratory are specified. Note that no specifications regarding, for example, volatile organic compounds are given, even though data is available regarding the importance of carefully controlling these substances (for a review, see [7]).

◘ **Table 67.1** Laboratory standard for ART

	Obligatory specifications	Parameters for each clinic/lab to specify
Particle counts	3,520,000/ m^3 > 0.5 μm	
	29,000/ m^3 > 5 μm	
Microorganisms	100 CFU	
Access		Restricted
Access log		To be considered
Alarm for unauthorized access		To be considered
Changing facilities		To be considered
Alarm for low O_2		To be considered
Number of air changes per unit of time and positive pressure		To be considered
Direct sunlight		Avoided
VOCs		To be considered
Hygienic routines		To be considered

Minimum obligatory standards for the ART laboratory according to EU regulations

67.4.2 ART Facilities

ART clinics must have designated and suitable facilities for their operations.

Rooms for oocyte pickup and embryo transfer, laboratory facilities for culture, processing, storage, cryopreservation, etc., must fulfill at least class D (ISO class 8) air quality, although local higher standards may be applied. In practice, this is in most cases taken to mean:

- Restricted access
- Changing room be close to the laboratory/operation room
- HEPA-filtrated ventilation
- Positive pressure from lab/operation to surroundings
- Conditions be specified with regard to the above points:
  - Particle count and microbial count
  - Rules for access be documented
  - Hygienic standards be established
  - Laminar airflow hoods be used for cell culture work

67.5 Methods and Quality

67.5.1 Equipment and Materials

One purpose of the tissue directive is to minimize the risk of adverse effects on the tissue by handling, processing, or storing. Therefore, it is a basic requirement that all equipment and materials are fit for purpose. If possible, all materials and equipment used must conform to the requirements of Council Directive 93/42/EEC of June 14, 1993, concerning medical devices and Directive 98/79/EC of the European Parliament and of the Council. This should preferably be evidenced by the equipment and materials being CE marked.

The tissue establishment shall identify equipment and materials that are critical to the safety and the function of the tissues. The suppliers of these materials and equipment must be evaluated and assessed regularly for compliance by the tissue establishment. It is furthermore required to validate the function of the equipment and materials and document the results of the validation. Also, the establishment must have documented plan for maintenance and replacement. There must be documentary evidence of maintenance occurring and that the equipment remains in conformity with the directives. Measuring equipment should be calibrated against a traceable standard, where available.

In order to ensure that the equipment and materials function as required, there must be instructions for their use and documentary evidence that staff have the competence to use the equipment and materials correctly. The tissue establishment must document which individual (critical) equipment and which batch of materials have been used for each sample of tissue. The function of critical equipment must be continuously monitored and all data logged. An alarm system must be fitted, so that corrective action can be taken quickly in response to malfunction. Backup equipment must be available for critical systems.

It is important that the environment is maintained in a way that allows the equipment to function properly. This includes reliability of utilities, such as electricity and gas supplies, as well as control of temperature, humidity, and other physical variables that may affect the function of the equipment. Also, storage facilities for materials must conform to the requirements of the materials so that their properties do not change during storage. For example, culture media should be stored under the conditions specified by the manufacturer. There must be documentary evidence of measures to control the environment.

67.5.2 Traceability and Documentation

Tissue specimens must be appropriately labeled, so they are identifiable with regard to what they are and from whom they were taken. The fate of the specimens must also be recorded. When the tissue is collected, moved, used, or discarded, this must be recorded also, and consent for these actions must be documented and archived. In order to ensure that the information is accurate, there must be regular audits of the tissue specimens.

It is, moreover, a requirement that the methods of handling, processing, and storage of the tissues are documented in detail and retrievable when the tissue is to be used. For example, the documentation of embryo freezing must contain a detailed description of the freezing protocol as well as information on which medium was used. Thus, it is not sufficient to just state that "embryos were cryopreserved by slow freezing with propanediol." The exact protocol used at that time must be available, as must information on the specific type of medium used. This information ensures that appropriate methodology and media are used for thawing. Furthermore, if an adverse or otherwise significant outcome has been associated with a certain protocol, it is important to identify all tissues exposed to that protocol in order to inform affected practitioners and tissue recipients of these events.

All materials that come in contact with the tissues must be identifiable by product description and lot number. Again, if an adverse or otherwise significant outcome has been associated with a certain product or product lot, it is important to identify all tissues exposed to that protocol in order to inform involved practitioners and tissue recipients of these events. This is, of course, particularly relevant when biologically derived materials are used and there is a risk of disease transmission through these materials, for example, gonadotropins or human serum albumin for culture media. Thus, tissue culture plastics, liquid handling consumables, ET catheters, aspiration needles, culture and handling media, etc., must all be traceable.

It is a duty of the tissue establishment to ascertain that, when receiving/dispatching tissues, the dispatching/receiving establishments adhere to the standards set out in this directive. Special regulations apply for the export and import of tissues to and from other countries (see below).

As mentioned above, the tissue establishment must have a documented system for quality management. This system should contain all guiding documents, that is, instruction how to perform a procedure. The system should also contain all reporting documents, that is, forms. All documents should be reviewed regularly and reauthorized. This is to ensure that the documents are up to date and that there are documents covering all procedures and also to allow culling of documents no longer required. It is of great importance that only the latest version of any document is in use and therefore distribution must be controlled. Old versions of a document must be recalled when a new version is issued, and the use of nonauthorized documents should be discouraged. For reasons given above, old versions of documents must be archived. Document control is demanding, but there are software systems to assist the quality manager in this regard. Standards for quality management systems, for example, the ISO 9000 series, provide good guidance for document management.

For all documents issued, it must be clear who has authored it and when. Reporting documents must state who did what, when, and with what authority (position in tissue establishment, e.g., embryologist) and then be signed. All staff involved in a procedure should be identified. Records may not be changed without proper authority, and there must be an indelible log of all changes to records. Consent to procedures by patients and donors involved must be documented, and national standards apply for the process of consent taking. Raw data forms should be stored for 10 years. Information on donors and patient notes must be kept for a minimum of 30 years after the tissue was used.

Documents must be legible not only at the time they were created but also for the duration of the archiving period. Handwritten notes rarely meet this requirement. There should be mechanisms in place to ensure that the information contained is complete and accurate. This could be achieved by double witnessing and audits.

Access to the documents should be tightly controlled to prevent unauthorized changes and, above all, to prevent unauthorized access to confidential client information. This can be implemented by a combination of physical and software-based solutions. Regulatory authorities must be given access to documentation and records for inspection and control.

If the clinic ceases operations, all documents must be transferred to another tissue establishment. There must be a documented plan for this contingency.

67.5.3 Quality Management

A documented quality control system must be established in every ART laboratory. Establishing such a system is a complex task, and most laboratories find it useful to rely on some of the published standards, which define such systems and describe their function. The most commonly used of these standards are as follows:

- ISO 9001, commonly called certification standard, since competence testing of the procedures in question is not implicit in it. This standard is commonly used in many establishments and in the industry and has a strong focus on continuous quality improvement.
- ISO 15189, commonly used for establishing a high level of competence in medical laboratories.
- GLP/GMP standards, which are often used in the pharmaceutical industry.

Details on the differences between these standards are beyond the scope of this chapter and are not discussed further here.

The ART laboratory does not have an isolated existence. Some laboratories may operate in a highly independent manner, but most are integrated into the ART clinic. Therefore, irrespective of the standard applied in the ART laboratory, the clinic may decide to establish a corresponding quality control system by utilizing the ISO 9001 standard.

The first step taken toward establishing a quality control system is usually to systematically document all procedures (standard operating procedures, SOPS). Computerized solutions may be of great assistance in this respect. Other aspects of quality control are, for example, registering and process of nonconformities, internal and external revisions, and continuous improvements in processes and procedures. In Table 67.2, the requirements of the EU directive in this respect are specified and simplified as a comparison to the ISO 9001 standard.

67.5.4 Methodology

The methodology used for collecting, transporting, processing, and storing tissues must protect the critical characteristics of the tissues and cells. For gametes and embryos, this means preserving the ability to participate in fertilization and retaining the ability to develop normally. All procedures used

Table 67.2 Simplified comparison between the EU directive and the ISO 9001 quality management standard

	Directive 2004/23/EC	ISO 9001
Document all procedures and SOPs	X	X
Document control	X	X
Document checklists	X	X
Training manuals	X	X
Guidelines	X	X
Nonconformities	X	X
Internal/external audits	X	X
Process analysis		X

must be documented and validated prior to being used with a view to ensuring that this requirement is met. This validation can be made in-house or be based on published good-quality scientific studies. All procedures carried out at the tissue establishment should be monitored in order to ascertain that the outcomes meet acceptable standards and that performance is consistent, and regular audits must be performed. When possible, inter-establishment validations should be conducted. The validation procedures should be documented, as should all outcomes from the validations and monitoring activities. Any changes to any critical procedure must be followed by a revalidation of the procedure. A more detailed guidance on methodology for ART clinics can be found in good practice guidelines issued by international bodies like ESHRE. Procedures should be carried out only by staff with verified and documented competence. Staff should be regularly assessed for competence in performing procedures.

67.5.5 Coding

A single European coding system is now established for all tissue establishments [8]. Exception is made for partner donation, and a possibility for exception is also allowed for member states to give for tissues and cells other than reproductive cells for partner donation, when these are used and remain within the same center. Information on the coding system is available at the EU website (► https://webgate.ec.europa.eu/eucoding/), and the system came into force in April 2017. In addition to the code for the tissue establishment, an international code such as ISBT 128 for the tissue/cells in question may be used. The ISBT 128 system is currently used for blood, tissue, and organ identification (► http://iccbba.org/).

The implementation of a single European coding system will have major effects for ART clinics in years to come. Some form of bar-coded identification system (such as ISBT 128) will almost certainly be implemented, meaning further standardization of labeling and laboratory processes as well as increased demands on computerized labeling and documentation systems. Even though such labeling systems may not be obligatory for ART with partner donation, it will be difficult for any ART laboratory to avoid implementing them in the long run. This is partly not only because the old methods of labeling will soon be considered obsolete when the larger clinics implement the new systems but also because any use of donated gametes will demand laboratory competence in handling such systems even though the clinic in question may not have a donor sperm bank since many ART laboratories handle oocyte donation. It is relevant to note that most medical laboratories, such as blood banks and analytical laboratories, have such computerized systems in place today, and in this respect, the typical ART laboratory may be considered some years behind current development.

67.5.6 Cryostorage of Gametes, Embryos, and Gonadal Tissue

Cryostorage of cells and tissues is an important aspect of the EU directive as well as for ART laboratories. Maximum storage times must be specified according to the directive and an inventory system established. Procedures regarding all aspects of the storage system must be documented, and all laboratory tests must be completed before release of products.

Regarding details on storage, such as selection of a suitable carrier system for sperm, oocytes, or embryos, as well as selection of cryotanks, this is up to each laboratory to decide. Risk of cross-contamination must however be eliminated. Therefore, gas-phase storage and use of sealed containers have been extensively discussed in the context of ART as well as the relative risks associated with controlled-rate freezing vs. vitrification [9].

The current interpretation of the situation is that gas-phase storage in assisted reproduction is not considered mandatory for oocytes and embryos since this may compromise the cells because of the small volumes involved. Gas-phase storage for sperm samples may be recommended but is not considered mandatory since secure sealed containers are available. As a general rule, sealed containers are highly recommended wherever possible to ensure a controlled environment for the gametes/embryos irrespective of cryopreservation method. Audit of storage tanks and records must be performed each year, whereas time limits for storage vary according to local legislation.

67.5.7 Laboratory Tests

Tissue donation involves a risk of disease transmission, and for that reason, donors must be tested for certain communicable diseases. The situation in standard assisted reproduction, involving a couple in a stable relationship, is special in that the participating individuals are already exposed to this risk, so screening will not prevent horizontal transmission. However, vertical transmission to the offspring may be prevented by screening, and in cases with donation from a third party or gestational surrogacy, screening is essential. Genetic screening is also performed in certain risk groups that may be carriers or at risk of genetic conditions.

For standard assisted reproduction, couples undergoing treatment must be screened for viral infection, such as HIV 1 and 2, HTLV I & II and hepatitis B and C, as well as syphilis. Sperm donor should be screened for *Chlamydia* infection. Screening for rubella immunity and vaccination reduces the risk to the fetus of becoming infected and developing the congenital rubella syndrome, a common consequence of which is deafness. Depending on the local disease spectrum, the designated national body may determine that additional screening is needed. The interval for retesting in ART is currently implemented at 2 years in most, if not all, EU countries.

Donors need to be screened prior to donation, the donated tissues then need to be quarantined for 6 months, and the donors are retested before release. However, if the initial screening assays involve nucleic acid amplification techniques of the samples, quarantine and repeat screening are not required according to the EU directive. The laboratory tests must be performed by a competent laboratory that has been authorized by the designated national body. This requirement is often interpreted as a requirement for ISO accreditation of the assays in an ISO-certified laboratory.

For partner donation, a positive test result does not necessarily exclude treatment. Here, the situation is determined by the national authorities. However, in all other cases, a positive infection test results exclude the donor.

67.5.8 Import and Export

According to the EUTC Directive, the European Union is considered one area with free import and export between countries since the same regulations and minimum requirements apply within the EU. Restrictions apply however concerning import and export to and from countries outside the EU. Member states must take necessary measures to ensure that imports and exports of tissues and cells from and to third countries are undertaken by tissue establishments accredited, designated, authorized, or licensed for the purpose of those activities and that imported tissues and cells can be traced from the donor to the recipient and vice versa. Several member states have established registers of authorized tissue establishments in this respect.

67.5.9 Reporting

Volume of activities at the ART laboratory must be reported in some detail to the local authorities. This includes the number of oocytes and sperm samples collected, inventory status of cryostored samples, and number of samples destroyed. Local forms for this purpose may be established. In addition to this, all adverse events and serious adverse events in connection with ART activities must be reported to the local regulatory authorities. Exact definitions of what constitutes an adverse event or serious adverse event are not available in detail; however, some examples may be mentioned. All cases of identity mix-up are considered serious adverse events as well as any cases of transmission of infectious disease in this context. Inventory irregularities in cryostorage should be considered an adverse event, whereas reduced cell survival after thawing, which is difficult to avoid in many cases, should not be considered such an event. Accidental destruction of cells during processing must be considered an adverse event, whereas failed fertilization in many cases cannot be considered such an event. Ovarian hyperstimulation syndrome (OHSS) is usually not considered an adverse event in the context of the tissues and cells directive, whereas local health authorities may require incidence of OHSS to be reported. For details regarding these aspects, local authorities must be consulted.

67.6 Legal Aspects and Local Legislation

Although implementation of the EU directive on tissues and cells calls for coordination of regulatory demands on ART in Europe, local legislation varies considerably. Public financing is one such area as most European countries offer some public funding of treatment and a few offer full coverage for at least a number of treatments. Usually this funding is contingent on age limits and/or medical indications for treatment. Usage of ART varies greatly among European countries, where affordability is a driver of usage [10]. Other areas of variation include availability of treatment for single women or lesbian couples with donated sperm, donor anonymity, time limits for cryostorage of oocytes and embryos, and the use of genetic diagnosis and genetic screening for treatment purposes and embryo research – to name a few examples. For further information on the variation of legislation within Europe, see also Berg Brigham et al. [11].

67.7 Clinical Embryology in the EU

Clinical embryology is a young branch of laboratory medicine which covers a part of therapeutic procedures in the treatment of infertility. Staff working in ART laboratories closely collaborate with gynecologists during most steps of the treatment. Together, they represent the core of the reproductive medicine, young gynecological subspecialty.

Clinical embryology started with its development in research and improvised laboratories. Today, all ART methods must be performed in high-tech laboratories with sophisticated equipment ensuring the optimal and constant physicochemical conditions, appropriate for the beginning of human life, development of human embryos, and their culture in vitro until the blastocyst stage. With the introduction of micromanipulation techniques for mechanical fusion of gametes and for biopsies on embryos, it became evident that the personnel from IVF laboratories require special education and long-term training.

According to the estimation of ESHRE, around 1400 IVF clinics existed in Europe in 2012/2013. Around 70% of them were private and 30% were public. Half of all IVF clinics were ISO certified. In 2012/2013, there were around 7000 laboratory workers who performed 540,000 fresh IVF cycles and 160,000 frozen embryo replacements [12].

In around 80% of European countries, the IVF laboratories are operated by embryologists/scientists with MSc or PhD. Physicians are rarely the managers of IVF laboratories with the exception of France, Poland, Romania, and Russia where they predominate. The analysis of the educational structure of remaining personnel working in IVF laboratories showed that in the Northern and Western Europe, the prevalent profile was that of laboratory technicians without

or with BSc. Personnel with university education in natural sciences and MSc or PhD were in minority. The situation was opposite in the Southern and Eastern countries.

The title clinical embryologist had various interpretations within and among the European countries, but it was an officially recognized occupation in national health-care systems in only three countries. In other countries, the personnel had to be registered under another official occupation. Among all European countries, only the UK had clearly defined requirements for accessing the title clinical embryologist.

The survey showed that only 40% of the countries had at least some form of an official document that vaguely defined the requirements for managing IVF laboratories. In the remaining countries, no such document existed. Even more worrisome is the fact that organized postgraduate education or training for independent work in IVF laboratories was reported to be mandatory in only four European countries. In other countries, the only way for acquiring practical experience and knowledge was reported to be by transmitting the experiences of more trained to the less trained staff.

For now, there is no agreement on uniforming the European organized training in ART or the specialization of clinical embryology. Only few countries regulate this field on their own, mostly by certification of staff using national rules. The only international examination of theoretical knowledge from clinical embryology, which attracts the highest number of embryologists from all European and also non-European countries, is the ESHRE certification. The ESHRE certificate is not recognized as an official document in most of the countries. However, the certification of knowledge from clinical embryology is one of the minimal standards mentioned in the revised guidelines for IVF laboratories [12].

ESHRE is continuing in improving the embryologist certification program by also introducing the system for the evaluation of continuing professional development (ESHRE-CPD). ESHRE's further activities in improving the professional status of clinical embryology and clinical embryologists will be focused on European institutions, responsible for medical specializations and examinations.

Acknowledgment A previous version of this chapter was written in collaboration with the late Dr. Peter Sjöblom. We owe a debt of gratitude to him for his knowledge and his generous input from years of experience in the field of assisted reproduction.

Review Questions

1. Which of the ART laboratory processes should not be considered to be included in the exception of laboratory standard specified in the EUTC Directive?
2. What is the current interpretation on gas-phase vs. liquid-phase storage for reproductive cells?
3. Which laboratory tests should be performed for patients coming for treatment in the ART clinic?
4. Which of the ART processes are exempted from the unified EU coding system implemented in April 2017?

Regulation, Licensing, and Accreditation of the ART Laboratory in Brazil

Fabiola C. Bento and Sandro C. Esteves

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_68

Learning Objectives

This chapter aims at informing the reader of the following:

- Current ART regulation in Brazil
- Air quality requirements
- Quality management system (QMS) requirements
- ANDROFERT experience with QMS

68.1 Introduction

According to the International Federation of Fertility Societies (IFFS) latest surveillance report, there are approximately 5353 ART centers around the globe. Only 57.1% of the countries have to follow specific legislation regulating ART activities, while 24.3% have only national society guidelines without any formal legislation, and 18.6% have no regulatory structure in the form of legislation or guidelines [1].

In Brazil, the regulatory agency (ANVISA) issued regulations for reproductive cell and tissue banks, which include assisted reproductive technology (ART) centers, in 2006 [2]. This directive was later reviewed, in 2011, to include more details and explanations not very clear in the first resolution [3] and was again reviewed in 2016 to include specific testing instructions due to the Zika virus outbreak and microcephaly cases [4]. Besides the regulatory agency directive, ART centers must observe ethical standards established by the Medical Council (CFM 2121/2015) [5], a professional organization that doctors and clinics must comply with and whose objective is to guarantee the safety and efficacy of medical procedures and treatments involved in ART.

ART units providing assisted reproduction treatments involving in vitro manipulation of gametes and embryos that operate in Brazil are therefore obliged to comply with specific regulatory requirements, as defined by standards of quality and safety for the donation, obtaining, testing, processing, preservation, storage, and distribution of human tissues and cells (Table 68.1). To operate, ART units must have a license permit issued by the regulatory agency (ANVISA) and must renew it annually.

Table 68.1 Summary of regulatory requirements in Brazil

Requirements	RDC/Anvisa #72, 2016	CFM 2121/2015
Quality management system	X	
Infrastructure and equipment	X	
Air quality control	X	
Written consent for assisted reproduction treatments	X	X
Age limit for female patients		X
Requirements for patient selection and donor selection	X	
Sex selection prohibition		X
Limitation on number of embryos transferred according to age		X
Fetal reduction prohibition		X
Same sex and single parenting allowed		X
Rules for oocyte, semen, and embryo donation and anonymity	X	X
Rules for cryopreservation of oocytes, semen, and embryos	X	X
Preimplantational genetic diagnosis		X
Rules for gestational carriers, who must be family members		X
Rules for discarding embryos	X	X

68.2 Air Quality Requirements

A few regulatory agencies have issued directives that include specific requirements for air quality control in embryology laboratories. Fertility centers holding assisted reproduction technology (ART) units in countries where such regulations are in place should operate in conformance with these directives. The basis for mandating ambient air quality control is to safeguard public health preventing transmission of infectious diseases via transplanted tissues and cells, according to the premises of the precautionary principle. The precautionary principle is used when measures are needed in the face of a possible danger to human health where scientific data do not allow a complete evaluation of the risk.

The Brazilian directive dictates that laboratory air quality for particulates should be at least equivalent to ISO class 5 in the critical areas where tissues or cells are exposed to the environment during processing. One of the following methods is recommended to achieve such conditions: (i) biological safety cabinet class II type A, (ii) unidirectional laminar flow workstation, and (iii) cleanroom at least equivalent to ISO 5.

Laboratory background air, which includes indoor air in areas for carrying out less critical stages, should be pressurized and filtered for particulate matter when biological safety cabins and unidirectional laminar flows rather than cleanrooms are applied. Areas in which oocytes/reproductive tissues/sperm are surgically retrieved should be pressurized as well (Table 68.2) [6].

Table 68.2 Ambient air quality requirements for in vitro fertilization laboratories operating under regulatory directives in Brazil

Particle filtration	At least equivalent to ISO class 5 (NBR/ISO 14644-1) in the critical areas where tissues or cells are exposed to the environment during processing
Microbial contamination	Microbiological monitoring required, specifications not clearly defined
Volatile organic compound filtration	Ventilation systems should be equipped with filters imbedded with activated carbon

Adapted from Esteves and Bento [6]

68.3 Quality Management Requirements

Besides all technical requirements for operation, the Brazilian regulatory agency requires the establishment of a documented quality management system (QMS), which should include:

1. Elaboration and periodic review of standard operating procedures (SOPs)
2. Periodic personnel training
3. Periodic internal audits, to verify compliance with technical regulations
4. Procedures for detection, registration, correction, and prevention of errors and nonconformities
5. Compliance with biosafety regulations
6. A system to evaluate and control equipment and materials used

Many other demands also related to a quality management system are included in the regulation, such as:

1. Having a technical manual with:
    1. Administrative and technical organization
    2. Qualification and responsibilities of all professionals involved
    3. Conduct in case of nonconformities
    4. Biosafety norms
    5. Annual review
2. Having proper sample identification
3. Keeping at least two copies of all data (in other words, a backup system) and guaranteeing that data cannot be altered at any time
4. Having a maintenance plan for all equipment

68.4 ANDROFERT Quality Management System Experience

After making an extensive research, we at ANDROFERT decided to follow the International Organization for Standardization (ISO) 9001 quality management model [7], first because it included all basic aspects of the Brazilian directive and second because the ISO is recognized worldwide as the most complete quality management model.

We started by creating our "nonconformity and corrective action registration procedure" and allowing anyone from any area to record nonconformities, even if the nonconformity was not from this person's area. Specific training was given, and even though registering nonconformities was rather easy, responding to nonconformities was the greatest problem. Most people think only in immediate actions to solve whatever problem happens or think of solutions that do not address what caused the nonconformity in the first place. Analyzing the cause of the nonconformity was our main challenge but was of crucial importance to consolidate the idea of continuous improvement.

At the same time, we started a lengthy training program, focused on ethics, moral values, organizational values, etc., to emphasize the importance and responsibility of each one in the process of offering a quality service. The creation of the concept of "teamwork" was our primary goal.

Another concept that had to be established and fully accepted was that of "continuous improvement." It is not easy to be criticized if it is seen negatively. Therefore, it was important for all staff to learn to accept this criticism and mainly to see it positively, as a means to achieve our ultimate goal, which is offering a high-quality service. To avoid competition among colleagues and make people focus on our common goal, nonconformities were registered in the name of the area in which it had occurred rather than in the name of the person involved. In other words, we avoided the direct criticism of any individual team member and worked on the idea of teamwork directly. They had to respond to the nonconformity as a team. This teamwork led them to develop a closer bond with each other and also taught them that they depended on each other to have a good performance. Performance was not seen individually; therefore, it required some time for people to adapt to that, share responsibilities, distribute tasks, and really work together instead of simply sharing the same workspace. A deep change occurred.

As for our SOPs, in our laboratories, all procedures were already described and reviewed periodically. Besides that, we already controlled all equipment and had a maintenance plan in place. The maintenance periodicity was established and differentiated according to the use and importance of the equipment.

Regarding our clinical activities, almost all procedures were described too. We already had a description of most procedures performed by nurses and doctors. All those not described were then formalized and documented to guarantee uniformity.

Our administrative procedures had no descriptions at all. To start with, we decided to create different flowcharts showing the moment a patient calls to schedule appointments and tests, the moment a patient comes into our center for any procedure, and so on. From those, we were able to determine the activities performed by our administrative staff and

describe them. We identified and formalized all procedures performed within the center, trained all staff, and therefore were able to monitor whether or not they were being done correctly.

While developing and describing SOPs, we established our mission statement and came up with our quality policy, and later with our policy objectives, which determine what aspects of our quality system are evaluated and monitored.

As for our laboratory performance, we determined the indicators that were going to be monitored, such as fertilization rates and embryo development. We also determined how often they were going to be analyzed. This "quality control" was already in place before the establishment of the ISO system. We just had to improve it, setting meetings to analyze data in a more systematic way, recording all actions decided during these meetings, and adjusting parameters to better comply with worldwide performances and also to continuously improve our own.

With the establishment of a paper-free laboratory and development of our own electronic information system, this data can be monitored daily. Every patient's data that is added is automatically used in calculating indicators, so today we have results in real time, without having to calculate any rate or making any data survey.

68.5 Conclusion

Assisted reproductive technology units providing assisted reproduction treatments involving in vitro manipulation of gametes and embryos that operate in Brazil are obliged to comply with specific regulatory requirements for the donation, obtaining, testing, processing, preservation, storage, and distribution of human tissues and cells. To operate, ART units must have a license permit issued by the regulatory agency that must be renewed annually.

ART units operate under a regulatory directive that requires cleanroom standards to reproductive laboratories. The regulatory directive aims to safeguard public health in line with the precautionary principle, thus preventing transmission of infectious diseases via transplanted tissues and cells, but it does not specifically address how periodic testing and validation of these areas should be carried out.

ART units in Brazil must also have a quality management system; however, the regulation does not require a certification. Instead, it determines all items that should be included in the system implemented.

Review Questions

1. Do all countries have specific legislation regulating ART activities?
2. Why is air quality control mandatory in some countries? What is it based on?
3. What should be included in the QMS required from ART centers in Brazil?

Troubleshooting in IVF Laboratories

James Stanger

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_69

Learning Objectives

- To appreciate the complexity of the IVF system
- To identify the sources of risk and variability
- To create tools to manage the IVF system
- To develop and manage key performance indicators (KPIs)
- To develop a sound approach using KPI history to troubleshoot the performance of an IVF clinic

69.1 Complexity of IVF Systems

IVF is something that just should not happen. The key element in all life systems is reproduction, and, in mammals, it is both highly managed and through survival of the fittest, driven to succeed. Enormous evolutionary effort has been devoted to ensure reproduction occurs from delayed puberty and subtle endocrine controls, from complex systems for gamete production and maturation and from implantation and parturition. Reproduction is unimaginably complex. Social and environmental interactions add even more complexity. Yet within a very short period of time since IVF came into being, it has turned into a universal and transportable activity and industry. During its development, IVF researches have dismantled some control systems such as follicle development and ovulation, sperm selection and natural selection of gametes and replaced them with other control mechanisms in some way more complex than nature. GnRH antagonists, intracytoplasmic sperm injection (ICSI) and preimplantation genetic diagnosis are classic examples of the new norms.

IVF activity is more than just biology; in fact, biology of reproduction is almost a side issue. IVF clinics by and large do not attempt to achieve pregnancy in fertile healthy couples; rather it seeks to achieve pregnancy where nature has failed. Apart from social activities such as same sex or single women's conceptions, IVF is largely about trying to make the impossible possible. In many ways, IVF has been remarkably successful with pregnancy rates close to or above those seen following the honeymoon period for fertile couples (OK, maybe recent social changes have dented this somewhat but pre-contraception and universal marriage alliances saw conception rates of more than 20% per month and 80% in the first year). Rates of more than 50% per transfer are increasingly the normal expectations in the most fertile of an infertile population (under 35 years of female age and the first 2 treatment transfer cycles).

This has several consequences. Firstly, it puts pressure on all clinics to try and maintain such high goals as more and more low-probability clients request treatment. Secondly, it may produce a generation of scientists that may never have experienced poor outcomes and be poorly prepared to deal with them, and, thirdly, much of this success has been due to applying increasingly complex technology such as PGD, thereby increasing the possible likelihood of system failure.

69.2 Defining Expectations

The complexity of IVF systems may start with the most logical ones such as the laboratory process, but more importantly it is overlaid by individual clinic dynamic ones such as patient mix, staff mix (especially clinical activities since clinical personnel continue to this day to see themselves above variation), staff competency, treatment mixes, technology mixes (CSI, PGD, cryopreservation) and activity loads. The responsibility to manage this usually falls to a quality manager or if not designated and then usually to a scientific staff member. If the net activity of all these sources of variation is carefully managed, they approach a productivity that is relatively stable, as occurs in established larger (but not too large) clinics. In such periods, there may be little need to troubleshoot. The issue is when to troubleshoot and when not to. Changing systems because a medical director says things are declining is not necessarily desirable since when any change is instituted, then there must follow a period of review. In my view it is better to develop a system of management tools to provide clues if the system is failing or if the system is changing, is responding to changes and innovation or is just moving within its natural limits. These two perspectives (failing and changing) may both produce a decrease in productivity, but troubleshooting them is quite different.

Just because the pregnancy rate in a recent period is lower than previously or in comparison to other clinics (say in an annual accreditation review) does not mean the laboratory is the cause. Impetuous changes to systems may result in more variation than desirable.

Having made this statement, one is ready to concede that IVF systems are very complex, and lack of focus can easily result in significant decreases in productivity at a biological level, but if the system is stable and well managed and appropriately supervised, then biological-based failure (i.e. gamete or embryo loss of viability) is rare. In approaching troubleshooting in an IVF clinic, one should first establish one's own productivity. This can be measured in a myriad of ways, and the quality manager should utilise as many as possible to know if change is happening or not. More importantly, each clinic should recognise that the clinical and technological process is always undergoing change and needs to develop sets of data, based upon previous performances against which current practice is measured for evidence of problems, and these reference data sets are routinely reassessed and recalculated to provide a realistic tool for comparison, in other words a robust set of key performance indicators (KPIs).

69.3 IVF Clinics Are More Than the Laboratory

At the very basic level, every embryo will develop in vitro with some degree of trauma not experienced in vivo (except where in vivo environments are toxic or misaligned). In fact there is no real information on how a human embryo devel-

ops in vivo, so the above statement is purely conceptual. Experimental work with mammalian and specifically with human embryos has suggested embryos are resourceful in using whatever environment agents are available to develop, and it is presumed that many of these biochemical routes would unlikely ever be used in vivo. Other data suggest that where the environment is compromised, the embryo will commit more resources (energy reserves) in an effort to counter the issues, an action that may reduce their developmental capacity. A good example of this is pH [1].

In terms of troubleshooting IVF labs, the starting point is to appreciate that all oocytes (and presumably sperm) and preimplantation embryos are compromised by the very nature of IVF, and the role of the IVF lab is to minimise the degree of stress, and it is wrong to believe the culture environment is great. It is also worth remembering that the vast majority of embryos will never have the capacity to implant or result in a term delivery and a live baby. The simple fact of the matter is that while great strides have been made in ovarian stimulation and control, the vast majority of follicles do not produce a viable (baby) oocyte. From variation in maturity, size, vascularisation, etc., the complex process of oocyte development remains incomplete or compromised at the time of ovulation induction and oocyte recovery. About 13% of all oocytes may result in a live birth in any cohort, so IVF is about sorting out the "good" from the "less good" oocytes/embryos and that any tool that seeks to measure performance needs to keep in mind that the vast majority of oocytes/embryos will fail [4].

It is against this background that any trauma (loss of quality in the environment) will impact most on the poorer quality gametes and embryos. If one thinks back to the very earliest days of IVF when significant levels of contamination and suboptimal environmental conditions existed, some very healthy embryos still managed to survive and when transferred result in healthy babies and children. Granted not many but the point is that the best embryos will by and large tolerate considerable discomfort and maintain their viability. Even when for a while, embryo fragmentation was considered to be a normal state for human embryos (in the mid-1980s), the pregnancy rates were still about 10–15%.

One further point about trauma is that it starts with a preovulatory oocyte. Unlike cleaving embryos, oocytes are exceptionally vulnerable cells. Again using pH as an example, the mature oocyte has virtually no capacity to self-regulate their internal pH. This capacity increasingly develops after fertilisation and with cleavage such that only after compaction does the embryos really start to control its own internal pH [2]. So any troubleshooting should always start with the oocyte and move forward rather than the final embryo stages and move backward.

The sources of "trauma" would encompass inappropriate:

- Salt or energy concentrations
- Protein and environmental elements such as antioxidants
- Toxic oil
- Culture dishes
- Gas mixture
- Incubator temperature or CO2 concentrations
- Warming stages and other handling environments
- Needles, catheters and other handling tools
- Environmental issues (perfumes, deodorants, renovations, etc.)
- Staff and personnel

The thing with all these sources of trauma is that it can all be easily managed. Each source of stress should be defined and managed. Each clinic may well have a variable list of potential sources of trauma and as part of their quality management programme institute procedures to monitor and minimise variation in them. There may well be many more that a scientific director or quality manager could identify and outline a strategy to monitor. The point is that these are not dynamic but relatively stable and should not change without a conscious and approved decision by the senior team. I will get to staff later, but the golden rule is that all staff, via the quality manual, do not change them.

Each potential source of trauma should have a set of rules and periodic monitoring and recording that are routinely reviewed and certified to meet expectation. As part of a laboratory audit process, the senior quality manager should be able to confirm to the senior clinical management and to auditors and accreditation inspectors that each risk factor is identified, has a monitoring protocol attached to it, is monitored and recorded as per protocol and is reviewed as per protocol. There is an enormous effort (often boring and time-consuming) discharged on a daily basis to ensure these risks remain under control. But the point of all these is to recognise that the potential for all oocytes, sperm and embryos can never improve under IVF culture conditions, only deteriorate. Importantly, when a downturn in productivity occurs, often when a clinician remarks that there have been few pregnancies of late, the quality manager should be able to affirm and prove that the laboratory key parameters are under control.

Let's quickly run through the trauma risks listed above to illustrate how a quality manager may be able to affirm each risk is under control. Many of the views are personal views developed over 30 years on managing IVF laboratories, and it may well be that other scientists may have different views.

69.3.1 Salt or Energy Concentrations

When IVF was first developed, most researchers used media commonly available to routine tissue culture laboratories such as Ham's F10 or Earle's balanced salt solutions. As human IVF developed, so did the realisation that human embryos were not the same as cell lines developed of years to grow in culture and formulations based upon guesstimated tubal fluid concentrations evolved, and their descendants now dominate the IVF industry. They have by and large been

spectacularly successful and formed one of the first quantum leaps in productivity. No clinic can validly prepare their own media these days purely due to cost and the requirements for quality control (QC) and certification. This means that each clinic needs to make a decision which media to use. Often the decision is based on cost or supply issues rather than on whether they are best for embryos. The market place for media is huge, and selection of media is and will remain problematic. Who now knows what is best – I certainly don't and I guess no one else does. There has been a conflict in recent years on whether media should be sequential to reflect the changing needs and environments the embryo encounters before implantation or can a standardised universal media achieve the same result. Do media need to be changed every 2 days or can it provide a stable environment for the complete duration of embryo culture?

The IVF culture system is also undergoing huge changes in the evolution of blastocyst transfers, vitrification, embryo biopsy and analysis and time-lapse monitoring. So the ten golden rules for media are:

(a) Record the media type and batch numbers for every case.
(b) Don't change media or mix and match different media with a good reason. Every time an embryo moves from one type to another, some form of readjustment needs to occur. Every time this happens, more energy is used to adjust and compensate detracting from growth and development.
(c) If you are in the top 50% of clinics according to accreditation documented success rate, don't change.
(d) If you are in the lower 50% of clinics according to accreditation documented success rate, look to change to a media used by what you consider to be a peer clinic.
(e) Use a media that reflects to primary process, e.g. if 80% of transfers are on day 2, why would you change to media that is for day 5 biopsy cycles? If you plan to move from one process to another, make one change only. Staff will struggle with having to use different media in different situations.
(f) Use as few formulations as possible. Many media suppliers have a media formulation for every step of the process that may have a logical basis, but is it necessary? The fewer steps there are the better. Remember that if sperm are held in sperm processing media, then when added to an IVF insemination drop, they will alter the composition.
(g) Remember that with a large cryopreservation programme, embryos put in storage now may not be recovered for several years.
(h) Purchase media in the smallest volume possible that will last for a defined period to allow for *all* media of a set batch number to be replaced at the same time. It is impossible to manage each bottle of media through a QA system if each patient's embryos are exposed to a multiple mix of lot numbers and deliveries. It is my view that it is better to purchase lots of small bottles of the same media and cycle through them in a managed manner than purchasing one large bottle that is repeatedly accessed. This is false economy and guarantees each cohort of embryos will be exposed to a dog's breakfast of new and aged, pristine and exposed media.
(i) Recognise that some wastage is OK, and factor this into your costing rather than use every bottle to the very end. Recognise that every time a bottle of culture media is opened and used, its composition will change slightly and be exposed to contamination. Embryos grown in the first drops from a new bottle to that in the last drop will not be growing in the same media.
(j) From a quality management perspective, it is better to replace media as frequently as possible with new lot numbers rather than purchase large supplies of media to last a long time. In other words, buy media in the shortest delivery time frame possible. On delivery, maybe do a quick sperm survival check and replace all media with the new lot number. Move all the old media to the back of the storage area (refrigerated) and discard prior to the next delivery. The logic is that it is naïve that all media is OK since any one bottle may not meet quality control specifications of the manufacturer and the risk of some form of introduced toxicity is ever present. The best solution to this is to recycle media and their containers to avoid exposure to a large number of clients.

Finally, I have long been a supporter of single-use media containers, whereby a clinic purchased a number of packs of media to service the needs of one client. Each media container is used once and discarded along with unused containers. It will revolutionise quality management, dispense with multiple accessing of containers and allow the manufacturers more control over the supply chain.

69.3.2 Protein and Environmental Elements Such as Antioxidants

Proteins provide both buffering and osmotic buffering functions, a reserve of nutrients and a scavenger function. Early systems using serum were a system with little control. Most culture media supply their own protein source either as integral part of the culture media or as an addition prior to use. Some provide purified serum albumin or recombinant albumin, while others supply albumin as a serum substitute preparation containing albumin plus alpha and beta globulins. Early issues with the production of ammonia breakdown products involving amino acids and protein are largely irrelevant in the current climate.

As for culture media, it is problematic for a scientist to choose any protein source over another, but from a troubleshooting perspective, one may argue the fewer combinations and the shorter exposure times (from the time a bottle is opened), the better. In fact, choosing a media that is delivered with the protein already added makes problem-solving and quality control much easier. So unless there is a clear benefit

in mixing media and protein lot numbers, use a premixed media. It also means that any pretesting is testing the whole culture environment, not just a part of it.

69.3.3 Toxic Oil

This is the big elephant in the room. Mineral or paraffin oil has allowed IVF to be performed in culture dishes rather than test tubes and has been the mainstay of all developments in the culture story. However, no one should be under the impression that oil is non-toxic and is actively associated with pH, gas and osmotic control and modifying the culture environment. As with media and protein, from a QC perspective, using oil supplied by the same supplier of media is the best option for several reasons. The primary one is that the media manufacturer has tested their media and additives in the presence of their own oil and the QC results for each batch are specific for that combination only. There is no guarantee that mixing oil and media from different suppliers will provide the same QC and will also certainly render void any responsibility of the supplier. One point to be made here is that supplier QC testing may be accepted as proof of quality, but a wise scientist would still confirm suitability in their own lab and culture system. There are stories that occasional sub-batches of some products may still fail, and failure to check the quality of all components on arrival is inviting difficulty if one needs to troubleshoot in response to a period of poor performance.

69.3.4 Culture Dishes

All culture ware is polystyrene plasticware, and many now are specifically tested for suitability for human IVF. The old systems using generic Falcon plasticware are long gone, but the newer dishes also must be treated with some caution. Issues such as duration of outgassing or rinsing prior to use should be clearly defined in the clinic policy manual and enforced with a signed checklist button by the scientist who sets up the next day's culture dishes. From a QC perspective that allows easy troubleshooting, a wise clinic would limit the number of types of plasticware used to the minimum number of items and then purchase a supply for culture dishes for a prolonged use, testing them against the current batch number prior to use. There have been anecdotal stories of items failing testing once, only to pass on a repeat test. This leads to another aspect that just because one packet of culture media is OK does not mean every packet of culture media is equally non-toxic. Supplier QC can only check a small percentage of items, and if there are within batch variation, then this may not be detected before shipping. This is why outgassing and/or rinsing has some appeal. It also raises questions whether all a client's embryos should be exposed to dishes from the same packet. One can easily become paranoid with such issues and in trying to spread the risk creating more confusion than required. The point is that if one couple embryos fail to develop or degenerate, then there is always the possibility of suboptimal quality in one dish among thousands.

69.3.5 Gas Mixture

Individual gas cylinders or specific gas mixtures are prepared in an industrial environment and dispute all precautions including stipulating only medical-grade gases, and where possible from a limited pool of cylinders, gas supply is one area that is not easily controlled. All one can do is to record when each cylinder is replaced and which delivery batch the cylinder came from. For additional cost, many suppliers can also provide a certificate of gas mix. The best way to manage gas complications is to use one or more in-line gas filters. These filters are largely activated charcoal and do have a limited life so as part of the QC manual is a requirement to follow the manufacturers' recommendations and change regularly.

69.3.6 Incubator Temperature or CO_2 Concentrations

The introduction of benchtop incubators has altered the complications arising from the use of large volume incubators with their inherent slow recovery times from each door opening and variation in temperature with location inside the incubator. Using large volume incubators for embryo culture requires considerably more QC management with the use difficult to document. Benchtop incubators while addressing such issues of recovery times, etc., suffer from problems in the actual monitoring of temperatures that the embryos are exposed to. They are also vulnerable to draughts and heat sources but do have the advantage that the location of each embryo cohort can be documented.

69.3.7 Warming Stages and Other Handling Environments

IVF has increasingly used heating stages on microscopes to try and minimise heat loss from the culture drops during handling and embryo manipulations. While a thermocouple can be attached to the stage near where embryo resides, it can be difficult to be clear what temperature the embryos are experiencing when there is a hole for light transmission in the middle of the stage. Even those with a glass plate still have temperature gradient issues. Ambient temperatures above the culture dishes give rise to the risks of draughts, etc. From a QC issue, all one can do is to document the temperature at least daily and make real-time monitoring available to all staff using the stages. Fully enclosed work stations solve many of these problems, but their use has failed to become mainstream in many laboratories. The author is an active supporter of their use.

69.3.8 Needles, Catheters and Other Handling Tools

While these tools are a necessary part of IVF, it is important to appreciate that they are sterilised with either ethylene oxide or equivalent and their lot number needs to be recorded for each case. In many laboratories, there may be many lot numbers of catheters and needles mixed together, making tracking of lot numbers unnecessarily complicated.

69.3.9 Environmental Issues (Perfumes, Deodorants, Renovations, etc.)

The risks associated with environmental pollution have adverse outcomes on IVF via the high exposure to volatile organic compounds which are well documented; other sources of variability may come from renovations and new equipment and motors, and personal items such as deodorants are far more difficult to note and manage. The use of air filters and positive air flows can alleviate some risks (but can also be the source of contamination). The use of air quality test monitors is probably a good inclusion in the laboratory particularly if the reading is included in a documented and auditable manner. An air quality KPI would be a very useful QC tool.

69.3.10 Staff and Personnel

Lastly, staff must be considered a key source of variability that is difficult to document and audit. Most clinics will review the pregnancy rate per staff member – both medical and scientific – but trying to track the contribution of each staff member to the success of a treatment cycle is nigh on impossible. There are several actions that the quality manager/scientific director could adopt. One is to enrol staff in a number of online quality control programmes dealing with identification skills (such as ► QAPonline.net). This will provide a tool to allow each staff member's visual assessment skills to be monitored. Second is to ensure each staff member is aware of and is abiding to the policies and procedure as set out by the clinic.

69.4 Knowledge and Awareness Is Power

If you have developed a set of rules for running the IVF laboratory as suggested above, then any circumstance that may result in a decrease of performance will hopefully pass quickly and with little noticeable effect. The central dogma is that there are a number of potential sources of "things" that may diminish the viability of gametes and/or embryos, but if you adopt an attitude of rapid recycling, then any such event will not significantly impact on your pregnancy rate. If your attitude is to do no harm to your clinic clients, then the best approach is to recycle quickly and minimise the exposure of detrimental components to as few clients as possible. You will never be able to identify such components, and their brief presence may only appear as a low point in the variability associated with your activity, but for me that is better than trying to prove something is toxic.

However, constant monitoring of the system will enable you to develop a set of information that you can use to both inform and alert you to potential downturns. Knowledge and awareness is indeed power, and all scientists should pursue this with vigour. Most clinical and nursing staff are focused on individual client's performance, and any information that you can supply on a regular basis will provide them with current information that can give to their clients and allow them to reassure them of the systems you have in place for their client's protection.

Knowledge is also important to alert clinical staff to trends that may affect the clinic's performance such as age ratios or number of embryos transferred and deflect their accusations that the laboratory is to blame for all clinical downturns.

To effect this, the clinic's database is your best friend as long as it allows you to interrogate any relationship. Excel spreadsheets and limited use databases may provide some limited KPI interrogation, but the clinic's plan should be to move to an information system with query capabilities.

69.5 Creating Tools to Manage the Clinic

This may be the critical section of this chapter. I have called the tools to monitor performance and troubleshoot possible complications KPIs, or key performance indicators ([3]). In reality all KPIs are tools to measure one or more parameters of an operation. The problem with IVF clinics is that many of the variables are unable to be controlled – for instance, the distribution of younger and older clients. So the KPI does not monitor production but provide guides to possible reasons why performance has changed. *After discussing KPIs, it is important then to identify the benchmark values for each KPI. KPIs only make sense when compared to their historical averages.*

In general, KPI may be divided into four categories:

1. Input clinical indicators (number and type of clients and treatment cycles started).
   (a) Number of new referral per time period (month) by age, previous history, needs (infertile, same gender, ovum donation, etc.), clinician referrals, etc.
   (b) Number of new treatment cycles per time period (monthly, quarterly, annually) by age (male and female), IVF × ICSI × PGD, previous history (previous attempts, attempt number, etc.), stimulated cycles × FET × ovum donation × sperm donation, PCOS × normal FSH × poor responder/ovarian failure (low FSH or AMH), etc.
   (c) Type of stimulation and FSH dosage regimens per time period

2. Gamete and embryo indicators
   (a) Number of oocytes/recovery/patient/time period (partitioned by age, FSH dosage, history, etc.).
   (b) Number of oocytes injected via ICSI/recovered/patient/time period/clinician. *This is a major KPI because the % injected/collected is a measure of oocyte maturation rate. It is also the "true" oocyte number/recovery. Many doctors will aspirate every follicle visualised, while others will only aspirate follicles with a reasonable chance of oocyte recovery.*
   (c) Fertilisation rate (FR) – by IVF × ICSI, 2PN × abnormal PN formation × sperm origins. *Using the ICSI true oocyte number for the time period, one can calculate the true IVF fertilisation rate. Note however that the IVF rate is often higher than the ICSI rate due to immature oocytes maturing after insemination and delayed fertilisation, giving a false impression of IVF superiority. One also measures alternative KPIs such as % failed fertilisation × all cases × cases with an acceptable oocyte number. Comparing FR from males with normal semen profiles to abnormal profiles to donor sperm profiles may also be of value. Sub-KPI may include:*
      (i) *# cases with no fertilisation*
      (ii) *# cases with no fertilisation with six or more oocytes*
      (iii) *# cases with abnormal fertilisation*
      (iv) *% abnormal fertilisations/fertilised oocytes*
      (v) *% FR for women≤35 and/or 38 years of age and six oocytes*
      (vi) *% FR for donor oocytes ≤35 and/or 38 years of age*
      (vii) *% FR for donor sperm cases*
   (d) Embryo cleavage – By IVF X ICSI × combined by day 1 2PN embryos. Variety of options including # 4 cell (day 2), A grade 4 cells (day 2), # 8 cells (day 3), # 7–9 cells (day 3), # A grade 8 cells (day 3), # viable blastocysts (day 5), # 4AA+ (best) grade (day 5), # viable blastocysts and 4 AA+ (days 5 and 6). *Note there are a number of combinations depending on how the clinic approaches day of transfer. These are all guides of embryo quality, and it does not really matter which one(s) one uses. The important issue is continuity. Any sustained decrease in the % viable embryos/2PN day 1 embryos may indicate either a decrease in oocyte quality or a change in culture conditions. Since embryo quality is always related to pregnancy rate, any decrease in % embryo quality should trigger an action response. It may be worth raising this at quality and/or management meetings since it may have associated costs to resolve.*
   (e) Usable embryos – by IVF × ICSI × combined × day of transfer (% of 2PN day 1 embryos and as % of oocyte numbers). This approach uses the definition of embryo quality as one that is suitable to transfer or cryostore. It suffers from lack of definition but in some ways actually reflects clinical practice. *Note this KPI has value in being one KPI to cover all laboratory activity and by and large can accommodate changes in clinical practice,* e.g. *does the clinic transfer cryostore on days 2, 3 or 5? Some clinic may transfer in day 2/3 but culture all residual embryos to day 5 or 6 to minimise the number of embryos going to cryostorage. Further, a clinic may have varying practices for younger or older women, egg number,* etc.
3. Pregnancy – outcome-based KPI.
   (a) % + ve hCG cases/transfer/fresh, frozen, combined. Each clinic should set their own hCG concentration for pregnancy depending on whether hCG is given as a luteal support, but 50 IU/l may be considered the lowest reasonable value to indicate if implantation has occurred. This KPI is an evolving one being updated with each pregnancy test. Some clinics do not test for pregnancy merely waiting to see if the client reports a pregnancy. However, most clinics are keen to ensure that all pregnancies are diagnosed and followed until clinical confirmation. *If your clinic has a relatively robust protocol for pregnancy diagnosis, then this KPI can be used as the first early warning tool for possible future issues. It can be used in-house to identify early pregnancy demise since clinical diagnosis may take another 3–5 weeks. Comparing fresh and frozen pregnancy and miscarriage rates (even if they are different modes) or the ratios of the two can be used as a KPI tool to identify major systemic issues in stimulation and/or culture or to issues with cryopreservation and recovery. Additional KPI may include:*
      (i) *Proportion of hCG values on the first day of testing above and below an agreed concentration, say <20 to >100 (or <40 to >100, you can decide any value). An increased incidence of low hCG indicates delayed implantation (either luteal support or poor embryo quality).*
   (b) % clinical (or ongoing) pregnancies/transfer/fresh, frozen, combined, donor oocytes, donor sperm. This KPI is a more stable statistic that is difficult to respond to and troubleshoot for since any issues that may have influenced a decease most likely will have past. For example, if a batch of media or oil was suboptimal, then by the time the total clinical pregnancies have been complied, eight or more weekly changes may have occurred. Furthermore, since only about 25–40% of cases will result in a clinical pregnancy, then the pool of cases will mean diagnosis is even more complicated.
   (c) % productivity rate [PR]. This KPI seeks to combine all the activity of clinics (fresh transfers, frozen transfers, freeze-all cycles, donors, etc.) and express the number of clinical pregnancies/treatment cycle (stimulated). Many do not understand this KPI since few use it, but for me, it represents what the clinic is all about – making babies against the main

activity (egg recovery). How many babies do you get per cycle? Regardless of how you manage your clinic – transfers on days 2, 3 or 5, PGD/PGS, and pro-cryostorage of blastocyst culture – it does not matter. What matters to the client is when all the embryos from any cohort have been transferred and what are their chances of having a baby. *The % PR is largely independent of how the clinic may change its activities. If the % PR falls, then you have a problem. If it rises, then any changes may have been positive. It does not work very well for age divisions.*

4. One further point about using KPIs for troubleshooting is more is not necessarily better. Select a suitable number to track regularly (weekly), others monthly, quarterly or annually. Don't confuse and overwork yourself with an excessive KPI list. Choose a limited number to present to monthly department or clinical meetings to both inform the clinicians and other staff and to demonstrate you are managing the system.
5. Having a number of KPI is fine, but to troubleshoot, you need to develop a set of reference ranges to identify potential issues.

69.6 Proactive and Reactive Approaches

Using benchmark reference ranges to troubleshoot.

The best way to use KPI is to develop a set or reference ranges with sufficient power to identify a mean and standard variation that is robust enough to identify if any single value is within statistical variability or exceeding the normal variation and therefore provides a warning sign of trouble.

The benchmark ranges need to be stable over time but capable of review being reset when appropriate. The most simple reference range is the previous year's activity. This should provide sufficient data points to give an appropriate estimate of variability and therefore be able to identify if any data point in the current years activity may be expected by chance alone or unlikely to be due to just random movement. The way to do this is to express it and every other data point as standard deviation (SD) units from the mean. This is known as the Z-score. If the mean value is say 10 units with a SD of 2, then a data point of 8 will be (8–10)/2 or − 2/2 or − 1. This means that the value of 8 is 1SD unit below the mean.

For example, if a basic KPI is % fertilisation rate (over all cases), then for every treatment cycle, there will be one data point. If the reference range for the previous year was 65% ± 25%, then an individual case of 75% will be (75–65)/25 or 10/25 or 0.4. In other words a 5Fr of 75% is entirely predictable, and you can rest easy. On the other hand, a %FR of 10% would generate a Z-score of (10–65)/25 or − 55/25 or − 3. It sounds easy but what does it tell you?

In effect once you have developed a reference score for any parameter, then you are able to place an estimate (in standard deviation units) of the likelihood of the value representing a normal fluctuation or a deviation from the routine fluctuations. It may allow you to write in a report if an outcome may signify an unusual event. But more importantly if you apply the Z-score function to two or more parameters, then you are starting to develop a set of tools to make troubleshooting decisions based upon statistical likelihood rather than knee jerk responses to a poor outcome. You can do this because you have rendered all the different values in a case (% mature oocytes, fertilisation rate, cleavage rate, good embryo rate, etc.) down to a common parameter.

Furthermore, you can aggregate data from individual cases to weekly means, monthly means, quarterly means and annual means. If the number of cases in any one aggregate is low, then you can operate the values as a combination mean of say the current and two previous periods. This has the effect of dampening the variability but allows for a better mean.

Figure 69.1 summarises all the information about how to use a Z-score profile. The plot is called a Levey-Jennings plot and can be applied to any circumstance where you have developed a set of data from which to draw a mean and standard deviation and data points is always presented in standard deviation units from the mean. Its primary function is to examine consecutive data points (% fertilisation cases) or monthly means or any other format and seeks to predict if the data set reflects a system under normal operating control or whether the system in not operating under normal control. There are a set of rules called the Westgard rules that can be applied to detect operating failure or ransom variability [5, 6]. In other words, if one uses say % fertilisation as the key KPI, then Westgard rules may be a tool that you can use to anticipate any deviation or set of deviations within normal operating variability or a reflection of dysfunction requiring you to inform others and to act to correct the problem.

Figure 69.1 illustrates several key aspects to this tool. These are:

1. Each point on the graph is an individual client's result (in this case it is % fertilisation rate) – each expressed as a Z-score (standard deviation from the preset mean).
2. They are all centred around the mean of the preset values.
3. Some are more than the mean, and some are less than the mean, i.e. tools can determine if a value is an increase or a decrease.
4. In these cases, about half the values are above the mean and half are below the mean. This is good in that it tells you that the mean is about correct for the current data set and the system (your laboratory) is functioning normally.
5. The two blue areas (two light blue and two dark blue) can be defined a Z-score range where you may wish to consider action. This tool can then provide you with a set of values that may indicate abnormal activity – the light blue may act as a warning – "keep an eye on the system", while the blue area may indicate you need to act in some prescribed manner. These warning and action cut-offs can be set by you to any value you consider appropriate, but in these cases, they are 2 SD and 3 SD deviations from the mean.

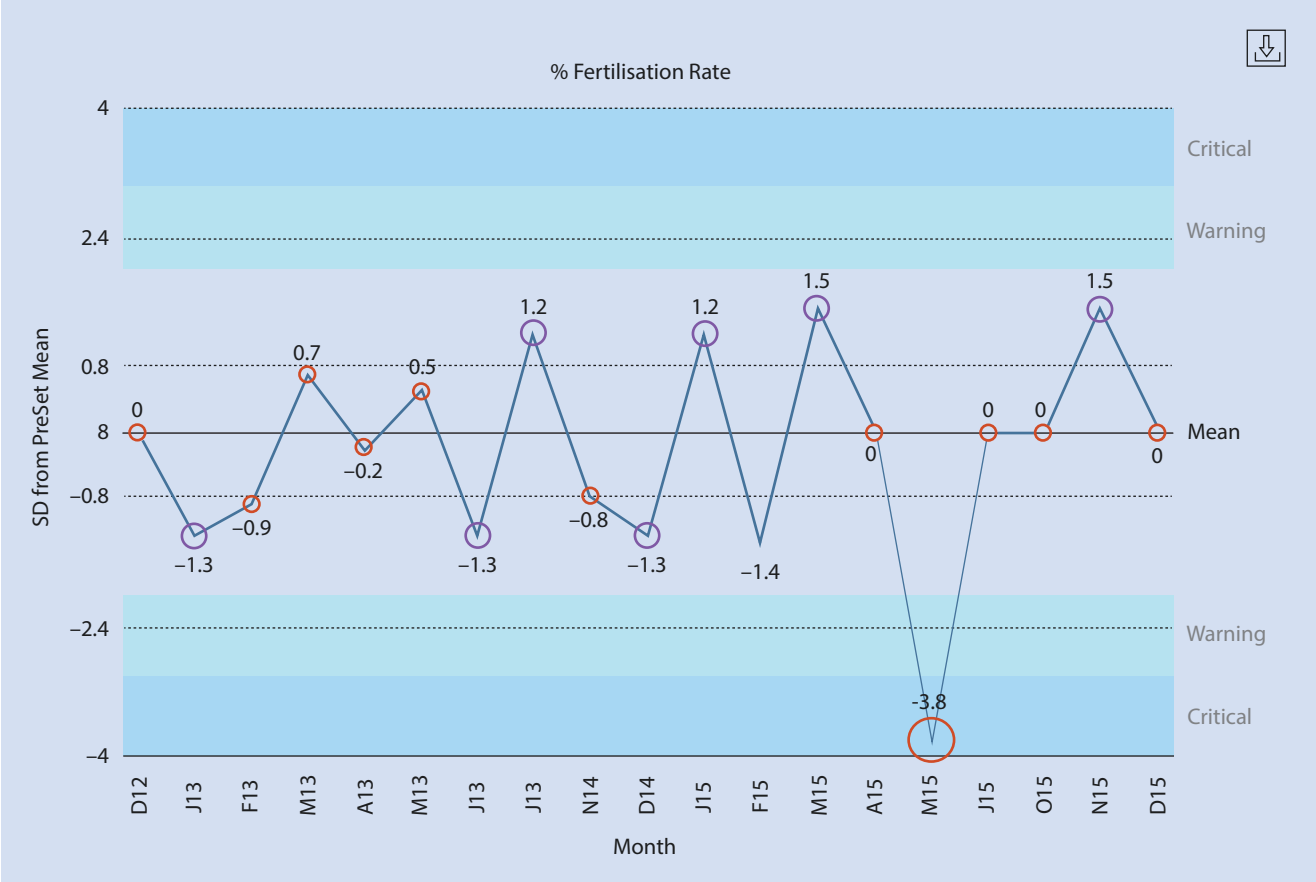

Fig. 69.1 An example of how to use the Z-score

6. Each value is represented by a dot of varying sizes. These dots indicate if the value is within 1 SD, 2SD or 3SD unit from the mean.
7. One value (M15) is more than 3SD units below the mean. The probability of his happening is less than 1/100 and may be interpreted as an abnormal event.
8. However from a troubleshooting perspective, it is a once-off event – more likely related to patient parameters than to a systemic laboratory event. *This underlies a critical difference to how Z-scores are used in an IVF setting compared to an industrial setting. In an IVF laboratory, there is always the chance an abnormal event (failed fertilisation) may be due to client medical factors (abnormal morphology, poor oocytes) than due to, for example, poor culture medium.*

69.7 Tools to Understand Sources of Variation and Risk

This last point is the hub of troubleshooting in an IVF laboratory. Does any individual outcome signify a change in laboratory quality or an individual client's dysfunction? How many bad outcomes do you need to record before you raise concerns and before you act? Remember that IVF is about treating clients with reproductive deficiencies and any failure may not be due to laboratory problems. Remember also that any issue (say poor media or oil) may well pass through the system before you can determine if the problem is persistent. They do require the data set to be normally distributed which some IVF KPI are not. In essence, 66% of all cases will lie within 1SD of the mean, 95% within ~2SD of the mean and less than 1% outside of 3SD from the mean. The rules basically look at how consecutive cases distribute themselves around the mean and look for combinations that are unlikely to occur by random chance. The rules were designed around biochemistry instrumentation and control testing, and their application to IVF is not the same where each data point (e.g. % fertilisation of patient X) is a mixture of many elements. The nett effect of this is that the standard deviations are usually quite wide, and therefore any deviation needs a significant one. The point of applying the Westgard rules is not to look at any one value but the trends in the distribution rolling forward with each case.

Notwithstanding these caveats, the Westgard rules (see ► www.westgard.com/mltirule.htm) are a useful stating point. In summary these include:

(a) 1_{3s} _ any case where one value is more than 3 SD from the mean [warning]

(b) 1_{2s} _ any case where two values are more than 3 SD from the mean [warning]

(c) $2_{2s\_}$ any situation where three values are more than 3 SD from the mean [action]
(d) R_{4s} – any situation where one value is <3SD from and the next is 3SD > mean [action]
(e) 4_{1s} – any situation where four values are more than 1SD from the mean on the same side of the control mean line [action]
(f) 8×, 10×,$12_{\times}$ – any situation where 8, 10 and 12 consecutive samples fall on one side of the mean regardless of SD from mean [action]
(g) $2of3_{2s}$ – any situation where two out of three KPIs exceed +2Sd or −2SD for any one month or any period) – multirule [action]
(h) 3_{1s} – any situation where three KPIs exceed +1Sd or -1SD on the same side of the control line for any one month or any period – multirule [action], e.g. % mature oocytes, %fertilisation rate, % utilisation rate
(i) $6_{\times,}9_{\times-}$ – any situation where between six and nine KPIs are on the same side of the control line for any one month or any period – if you have that many.
(j) 7_{T} – any period where a KPI SD from the mean incrementally changes over time in the same direction, e.g. from -2Sd to +2SD, each getting bigger.

Clearly one may go crazy trying to implement all these guidelines, but from a troubleshooting perspective, they are pointers to whether you need to look more closely at what is happening in the laboratory. A warning trigger may merely cause you to look at the last cases moving through the laboratory, while an action trigger may require you to look more closely at the cases, looking for changes in media, gases or equipment, and at staff (clinical and scientific). It will help enormously if the pre-emptive measures discussed above are implemented. For instance, I have always liked starting new media bottles each week (you can do it fortnightly if you are a big clinic) because you can look at the outcome of each case from Monday to Sunday. Have the log of when new plasticware or gases are introduced. Sometimes it is best just to talk to the staff or comments. There is where a permanent activity in the laboratory by all quality managers is a good thing since it keeps you in touch with the embryo quality.

Remember, IVF is both a robust technology and a fragile technology. There may well be many aspects that are suboptimal, but with a system that cycles lot numbers quickly through the laboratory, any adverse effect will be minimised. Most IVF equipment is pretested using the mouse embryo bioassay (MEB) which is good, but this is a very low-level quality tool. A set of plasticware may well pass the MEB but still possess some low-level toxicity. My strongest suggestion is to look at embryo quality, both rates and uniformity of cleavage and degree of fragmentation. While one may expect many embryos to be of less than perfect quality, there should be at least one or two embryos of A grade quality. If your staff are subject to routine quality assurance testing (as at ► www.QAPonline.net), then this is the best guide to laboratory quality.

Attempting to apply these rules in-house can be challenging, and some databases may provide for such analysis. There is one online, anonymous tool (► www.IVFbenchmark.com) that is available where the trends (monthly) are reviewed against the Westgard rules dynamically.

69.8 Communication Is the Key

If a set of KPIs that reflect the clinics activity are presented on a regular basis (monthly, quarterly), the QC manager is able to provide information to allow all senior staff to be aware of variations in activity and quality to ensure that any perception of a loss of performance is addressed. This has the effect of limiting unnecessary and time-consuming disruptions. Performance reports by medical and scientific staff are high on this list as most see this information personally. Using a Levey-Jennings approach to manage these KPIs will provide you with a case-by-case spyglass into the operation of the clinic and the laboratory and provide you with a response from clinic managers about quality and provide you with a rapid warning of change that may or may not warrant major action. Good luck.

Learning Objectives

- Learn the most common KPIs for the IVF laboratory and their values
- How to monitor the KPIs over time and how to interpret variations in them
- How to apply the above for troubleshooting in the IVF laboratory
- How to improve decision making in the IVF laboratory

70.1 Introduction

The concept of benchmarking or key performance indicators (KPIs) is well known in many operations in science, medicine, and business. It is not possible for a manager in any business operation to run her unit without monitoring, for example, EBITDA (earnings before interest, taxes, depreciation, and amortization). This principle is an integral part of any business management, and the laboratory KPIs must be considered in the same way. KPIs are also an important component of quality control systems such as the ISO accreditation standard ISO 15189 (▶ www.iso.org). The basic concept behind using KPIs is to collect information on the operation, and the information is then used as a basis for decision making. It cannot be sufficiently stressed that in order to achieve good-quality decision making, objective facts must be used as a basis for taking decisions. In this chapter the application of KPIs will be discussed, including how to select and apply them and also how to use them to achieve high-quality decision making in the IVF laboratory and thus to improve results.

This chapter aims at giving an introduction to the concept of KPIs and their use in the embryology laboratory as well as some aspects of decision-making processes. Focus is on the most important KPIs and their relevance for day-to-day activities. This chapter does not aim at listing all conceivable KPIs, and for a more thorough and detailed coverage, the reference list gives suggestions for further reading.

70.2 Key Performance Indicators (KPIs)

It is not possible to run a successful IVF unit without regularly checking the results of the work being performed. The first and most obvious parameter to monitor is the pregnancy rate for the clinic. This is of course important to know; it is usually the first thing a patient would wish to know, and it is the prime parameter of interest for clinicians – of course! The intended outcome of the activities is a healthy baby for the patient, and the rate of achieved pregnancies in the clinic per oocyte collection or embryo transfer is a surrogate marker for this goal.

The laboratory director, however, will soon realize that the clinics' pregnancy rate is not very useful for everyday decision making. Although interesting and important, the pregnancy rate has several disadvantages as an outcome parameter, including the following:

- The delay from the time of activity until results show up is approximately 3 weeks – at least.
- Results from several weeks or months must be collected to reach any statistical significance.
- Poor culture conditions may be partially masked by replacing several embryos at a time.
- Pregnancy rates from fresh transfers say nothing at all about embryos/oocytes which may have been eligible for cryopreservation.
- Pregnancy rates say little about other important aspects such as fertilization rates, canceled cycles, and other aspects relating to pre-transfer efficacy.
- The embryo transfer itself may – if improperly performed – ruin the results for a perfectly good embryo laboratory.
- Pregnancy rates do not allow any analysis of which processes in the laboratory may be suboptimal and how far they are from acceptable ranges.
- Accumulation of patients with poor prognosis during a period of time will lead to a drop in results without any faults in the laboratory.

Too often, decisions are made in IVF laboratories based on short-term changes in pregnancy rates without a proper analysis of the underlying reasons. This will most likely lead to poor-quality decision making and is not likely to lead to any long-term improvement.

If, on the other hand, the laboratory can ensure that all processes are functioning normally, then poor results need to be studied from the clinical perspective.

70.3 What Can Be Gained from Using KPIs

The main reason for measuring KPIs in the IVF laboratory is to ensure high performance and reproducibility in the daily processes. By correctly defining these parameters and ensuring that laboratory outcomes remain within acceptable levels, the probability of good results increases dramatically. Monitoring the laboratory activities by using KPIs will also increase the level of control of the laboratory activities, and proper use will aid in finding areas which need improvement. In fact, without KPIs, we are not accurately able to determine whether the program is on course.

70.4 Important KPIs for the Embryologist

Relevant and recommended levels of KPIs in assisted reproduction have previously been presented [1–3]. At the end of the day, the individual laboratory needs to define which parameters are relevant for its daily operations and which levels can be attained. Issues such as the patient population treated, embryo transfer policy, etc. need to be taken into consideration. At the same time, certain KPIs and their levels may be considered universal. Also, it is common to define

Table 70.1 The table specifies the most important KPIs for the embryologist/laboratory director to monitor

	KPI value (%)	Benchmark (%)	Frequency of monitoring
Oocyte recovery rate	80	90	Biannually
Oocyte maturity	75	85	Annually
Degenerated oocytes at recovery	3	1	Biannually
Sperm recovery rate	20	40	Biannually
Fertilization rate	60	70	Monthly
Polyspermy rate	5	3	Monthly
Poor fertilization rate IVF	10	5	Biannually
Failed fertilization after IVF	3	2	Biannually
ICSI damage rate	10	5	Monthly
Poor fertilization rate after ICSI	5	2	Monthly
Failed fertilization after ICSI	3	1	Monthly
Frequency of 1pn after ICSI	5	2	Biannually
Embryo cleavage rate	95	99	Monthly
Early cleavage rate	10	15	Biannually
Proportion of abnormal cleavage in time-lapse	10	5	Biannually
Blastocyst development rate days 5–6	40	60	Monthly
Good-quality embryo rate days 2–3	30	45	Biannually
Good-quality blastocyst rate days 5–6	25	40	Biannually
Embryo utilization rate	40	60	Biannually
Survival after cryopreservation/thawing	80	95	Biannually

The KPI value is the minimum acceptable level (or maximum acceptable level for "deviation" parameters such as failed fertilization). The benchmark value is the aspirational level to attain. Further details are given in the text

two levels, first the minimum acceptable level and second the aspirational level the laboratory strives to attain.

The minimum acceptable level is the point below which the process must be considered to have a problem which needs immediate attention. If the problem is not identified immediately and preventative measures taken, the process must be discontinued until the problem has been solved. The aspirational level on the other hand is often considered to be the "benchmark" of the process, i.e., the level at which the process is considered to be running optimally according to current best practice and knowledge.

The frequency of monitoring of the KPIs is important to define since it may not be meaningful to monitor all of the parameters at the same frequencies. Table 70.1 gives details on some 20 important KPIs for the embryologist, and although it should not be considered to be a definitive list, it contains most of the important parameters which the embryologist needs to pay attention to. Further details are explained below.

70.4.1 Oocyte Recovery Rate

Rate of identification of a cumulus-oocyte complex per aspirated follicle at oocyte collection.

70.4.2 Oocyte Maturity

Rate of mature (MII) oocytes per total number of oocytes collected.

70.4.3 Degenerated Oocytes at Recovery

Rate of damaged or degenerated oocytes per total number of oocytes collected.

70.4.4 Sperm Recovery Rate

Yield of motile sperm after preparation, i.e., the number of motile sperm cells obtained after preparation per total number of motile sperm in the sample.

70.4.5 Fertilization Rate

Rate of fertilized oocytes with two pronuclei (2 pn) per total number of inseminated oocytes.

70.4.6 Polyspermy Rate

Rate of oocytes with three or more pronuclei per total number of inseminated oocytes.

70.4.7 Poor Fertilization Rate After IVF

Proportion of treatment cycles in which <25% of inseminated oocytes were fertilized with 2 pn.

70.4.8 Failed Fertilization After IVF

Proportion of treatment cycles in which none of the inseminated oocytes were fertilized with 2 pn.

70.4.9 ICSI Damage Rate

Proportion of injected oocytes by ICSI which degenerate at any stage of manipulation, from denudation to microinjection until fertilization check.

70.4.10 Poor Fertilization Rate After ICSI

Same definition as for IVF above.

70.4.11 Failed Fertilization After ICSI

Same definition as for IVF above.

70.4.12 Frequency of 1pn After ICSI

Proportion of microinjected oocytes displaying 1 pn at fertilization check.

70.4.13 Embryo Cleavage Rate

Proportion of zygotes (2 pn only) which cleave to become embryos.

70.4.14 Early Cleavage Rate

Proportion of zygotes which have cleaved at the time of early cleavage check.

70.4.15 Proportion of Abnormal Cleavage in Time-Lapse

Proportion of zygotes displaying 1–3 cleavages, 2–5 cleavages, or reverse cleavage, i.e., frequency of abnormal cleavage.

70.4.16 Blastocyst Development Rate Days 5–6

Proportion of zygotes which are at the blastocyst stage 5–6 days after insemination.

70.4.17 Good-Quality Embryo Rate Days 2–3

Proportion of embryos with good-quality morphology at evaluation according to the laboratory evaluation system.

70.4.18 Good-Quality Blastocyst Rate Days 5–6

Proportion of blastocysts with good-quality morphology at evaluation according to the laboratory evaluation system.

70.4.19 Embryo Utilization Rate

Proportion of embryos (cleaved zygotes) transferred or cryopreserved for the patient.

70.4.20 Survival After Cryopreservation/Thawing

Proportion of embryos utilizable after cryopreservation/thawing.

70.5 Interpretation of KPIs and Correlation with the Clinical Activities

By using the KPIs to measure the efficacy of the various processes in the IVF laboratory, it becomes possible to identify potential improvement and to aid in troubleshooting at various stages. There may be several interpretations for the problems which may arise in the IVF laboratory. Below we give two examples of how KPIs may be used to assist in diagnosing problems and troubleshooting.

70.5.1 Poor Results in ICSI Cycles

The potential reasons for poor or dropping ICSI results can be many. For example, this may be caused by improper selection of buffer media for injection, faulty calibration of the warming plate, etc. The possibilities are numerous. This may also be a purely technical/manipulative issue with the cause residing in individual operators. One way of approaching such a problem is to look at the individual KPIs and look for clues.

First, a look at the rate of degenerated oocytes during denudation or microinjection will show whether these processes are a problem.

The rate of 1pn oocytes after ICSI will show whether sperm immobilization is an issue.

The cleavage rate of oocytes after ICSI and good-quality embryo rates will show whether the culture media system is performing properly.

By studying the KPIs, we can isolate a likely cause of the problem. For example, if degeneration rates are low (<5%) and cleavage rates are high but good-quality blastocyst rates are low, then perhaps the long-term culture incubator needs to be recalibrated. And vice versa if oocytes degenerate at a high rate (>10%) but those oocytes which do fertilize cleave normally, then probably the denudation or injection processes need to be analyzed further. If all laboratory KPIs are normal or high, then possibly the issue is outside the laboratory.

The important issue here is to have reliable data on the performance of the laboratory on which to base decisions regarding further actions.

70.5.2 Treatment Cycles with No Fertilization

High rates of cycles (>5%) without 2pn fertilized oocytes may be caused by various suboptimal conditions or processes in the laboratory. The most obvious cause could be that the selection of patients for ICSI could be improved but other more subtle reasons can have an effect. For example, if the aspiration pressure at oocyte collection is high (>120 mm Hg), this may damage oocytes, especially oocytes from older patients, and increase risk for failed fertilization cycles. The rate of damaged oocytes at collection should then be very low (see Table 70.1).

Another possible cause in this instance is that the insemination concentration may be low. In this case, an overall low fertilization rate should also be observed.

70.6 Control Charts

Another way to use the KPIs is to monitor and document these over time and plot them against time in a chart, creating a so-called control chart (Fig. 70.1). This allows us to identify slow changes in the indicators and will give additional information regarding laboratory performance. If conditions in the laboratory are slowly changing for the worse or for the better, these charts will give important information on these tendencies and will allow preventative action to be taken in case of deteriorating results.

Sometimes it is not clear whether the laboratory or the clinic is performing suboptimally. In these cases, if laboratory benchmarks are at high levels and control charts show stable performance, then clinical factors should be studied if pregnancy rates are low. The opposite may also be the case, of course. Interlaboratory controls, as specified by the international accreditation standard ISO 15189, are of course highly valuable to calibrate the IVF laboratory against international operations in the same field.

Control charts will also allow diagnosis of potential issues with instruments, such as temperature variations in incubators. Incubators have a recovery heat impulse after the door to the incubator has been closed. If the impulse is not correctly calibrated in terms of time or effect, unnecessary temperature variation will be observed. Figure 70.2 shows an example of such a situation.

70.7 How to Deal with Patient Variation Regarding KPIs

It is well known that differences in the patient population between clinics are an important cause of variation in IVF results [4]. The most important prognostic factor for IVF success is still female age at the time of treatment, but other factors such as number of previous treatments, source of sperm, and numerous others will also have an impact. It is therefore important to consider specifically monitoring KPIs for certain groups of patients, for example, women <38 years of age. KPIs for specifically defined groups of patients should remain relatively stable, while the total population of patients presenting at the clinic may vary over time. The laboratory and embryological parameters are relatively stable over various patient groups, but it is not reasonable to expect the same results from patients over 40 years of age and those who are under 35 years, for example. Therefore, when making decisions regarding whether a certain KPI is above or below an acceptable level, it is important to double-check the results when, for example, only patients under a certain age are included in the data collection.

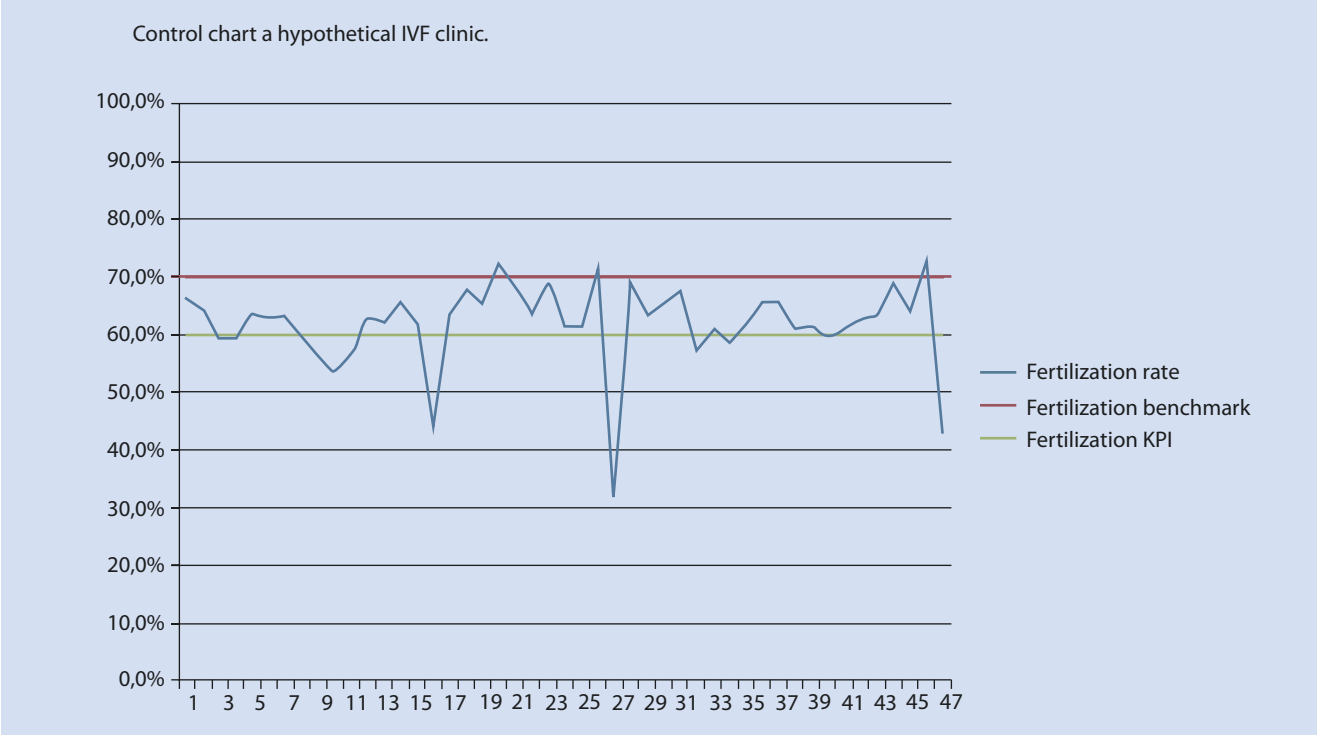

Fig. 70.1 Control chart from a hypothetical IVF clinic. Example of a control chart from a hypothetical but typical IVF clinic. The diagram shows the monitoring of fertilization rates per week during the year. The results are above the KPI most of the time, with sporadic dips in results but no obvious trend visible from the data. On the other hand, results in some weeks exceed the benchmark, often in close proximity to dips. The most logical explanation is that the laboratory has a sound culture system with acceptable fertilization rates but that, during some weeks, results are affected by patients with poor prognosis

70.8 Decision Making

In a situation with incomplete knowledge and a weak factual basis, decision making is difficult. A high workload, stress, and lack of time for reflection coupled with a hierarchical organization increase the risk of poor decision making. It is well known that in health care in general, poor decision making and a lack of communication are the underlying causes of mistakes, which all too often may lead to injury or have fatal consequences. International studies show that rates of medical injury range from 10% to 13% for hospitalized patients. Many of these problems are the result of cognitive mistakes but rarely because of technical or training mistakes or because of lack of knowledge [5]. Errors in medical diagnosis have been identified by several authors as an area where cognitive factors may be involved [6, 7]. From an organizational perspective, it is also clear that such a problem must be addressed in a systematic fashion and not just to be blamed on the individuals involved. Higher levels of security in health care are reliant on transparency of methods and secure systems allowing high-quality procedures. Involving the patients themselves in medical decisions is also considered helpful.

Table 70.2 gives an overview of the most common heuristics and biases along with a very short explanation of each one. Awareness of these issues has been established in safety culture industries such as aviation and nuclear power plants and recently in some areas of the medical literature. Focus has often been on the individual biases and errors, however, and a comprehensive theory on these issues is not prominent in all areas of the medical literature. Fortunately, however, some exceptions to this general rule can be found although they may not be very well known. Sadly, medicine is hardly to be considered a safety culture industry: if, for example, an airline company were to operate at a serious error rate of 9% per flight, then they would be out of business immediately!

Heuristics are useful in situations where decisions must be taken quickly and there is little time for reflection. It is crucial to realize that it is exactly in these situations when cognitive biases may have an effect, especially when many parameters must be evaluated simultaneously. Additionally, as medicine is a very complex system with a multitude of input parameters, it is easy to fall prey to biases such as feedback bias, where absence of feedback is taken for positive feedback. The reason may simply be lack of patient continuity or as in IVF where we never know if embryos which are deselected had the potential to lead to the establishment of a pregnancy. Another prominent opportunity for bias is confirmation bias where information on which decisions are based is selected according to the decision maker's opinions. A complete description of these biases and heuristics is beyond the scope of this chapter.

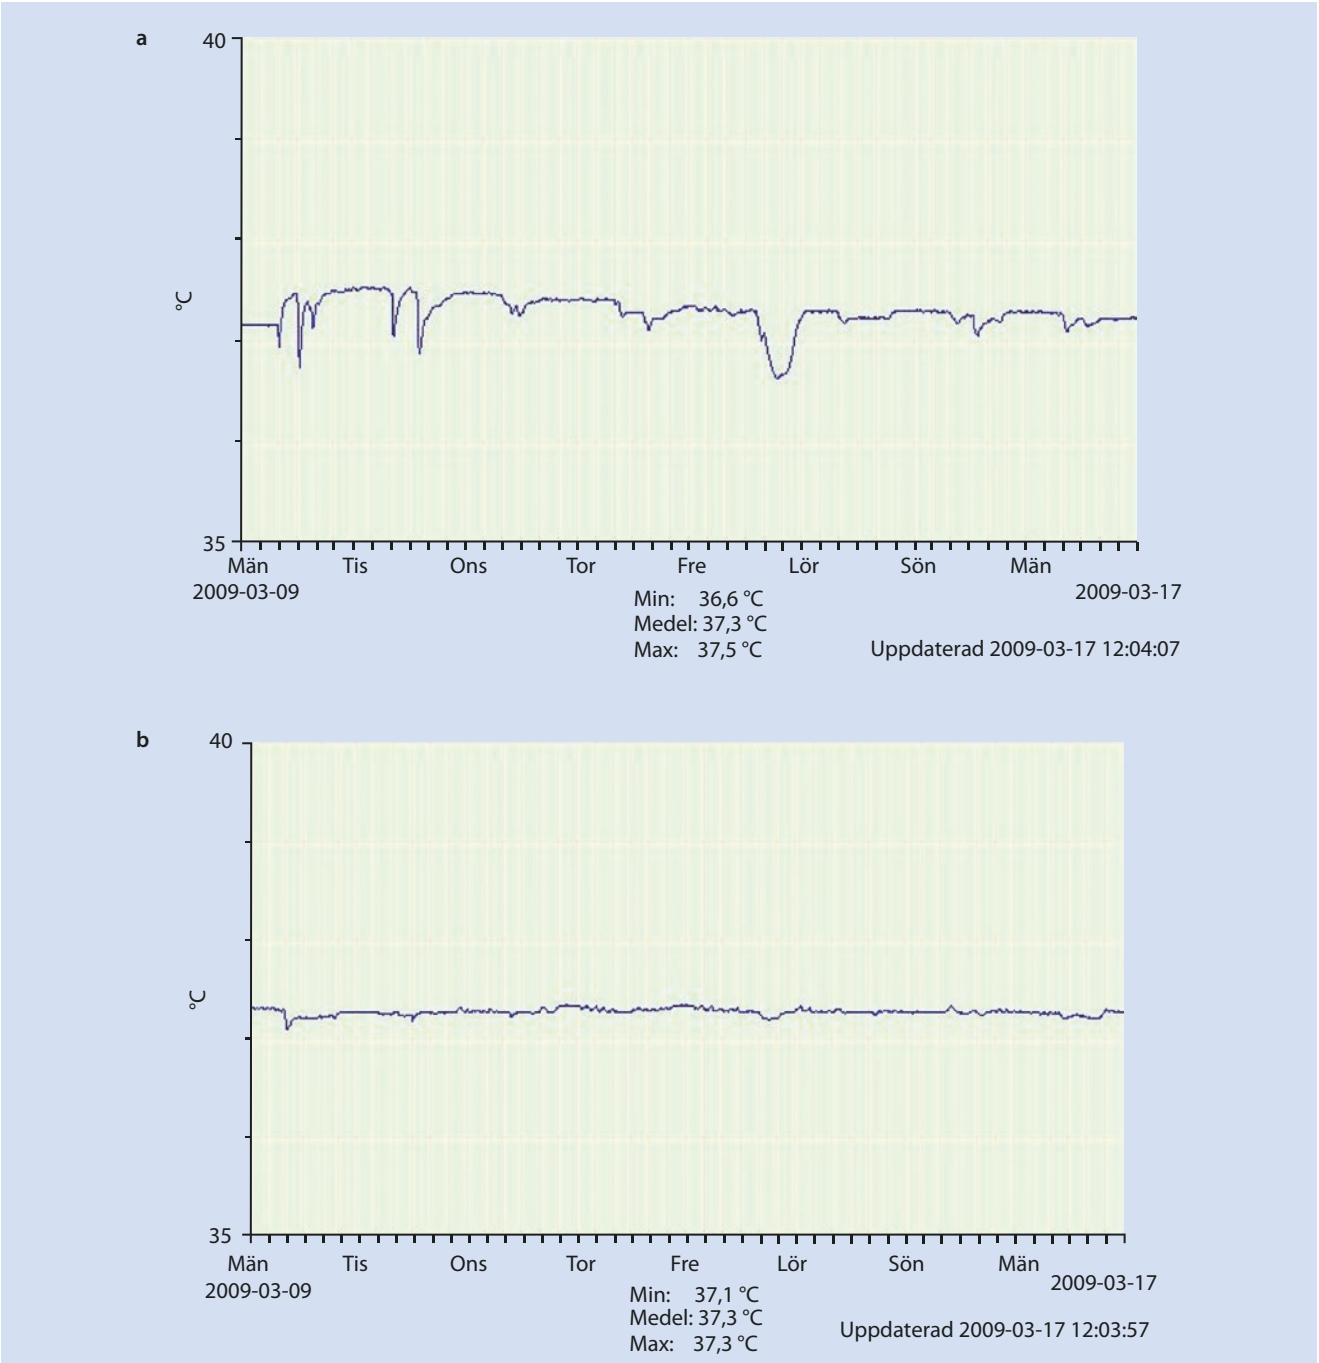

Fig. 70.2 Temperature monitoring in incubators. The charts show temperature monitoring in two incubators over a period of 8-day activity in an IVF laboratory. Incubator in 2.a has a poor regulation of the heat impulse after the incubator door has been closed

There are many ways to improve decision making. Knowledge of the abovementioned biases is the first step toward improvement. The use of information technology is a possible way to improve decisions in complex situations, for example, the use of algorithms and modern data processing techniques. Even the use of simple linear models may improve decision making in medicine. One interesting technique is to take an outsider's view on the situation or to externalize decisions in some way. However, the task of changing decision-making processes is a huge effort and one that is both very difficult and probably unappreciated since here we are working with thought processes which the individuals themselves usually are not aware of.

Poor decision making in the IVF laboratory is not likely to lead to direct harm to the patient but may decrease the probability of treatment success. Too often in the IVF laboratory, decisions are made on poor grounds, which almost inevitably leads to suboptimal results or failure to solve the problems at hand.

Table 70.2 An overview of heuristics, biases, and cognitive errors in decision making

Heuristics	Biases	Short explanation of each
Availability heuristic		Assessing frequency, probability, or cause by degree of availability from memory
	Ease of recall	Memories and recent experiences affect judgment
	Retrievability	Assuming available recollections are representative of a larger pool of samples
Representativeness heuristic		Stereotyping
	Insensitivity to base rates	Failure to plan for adverse outcomes
	Insensitivity to sample size	Draw conclusions from poorly powered studies
	Misconception of chance	Overestimate generalization of empirical findings
	Regression to the mean	Predict based on past data. Overinterpret statistical outliers
	Conjunction fallacy	Combination of descriptors is judged more probably than any one component
Positive hypothesis testing		Congruence heuristic. Assume a statement is true
	Confirmation trap	Evidence confirming own opinion are more highly evaluated than disconfirming evidence
	Anchoring	Initial evaluation is hard to adjust
	Conjunctive/disjunctive bias	Underestimating combined frequencies of independent events
	Overconfidence	Overestimating chance of success
	Omission bias	Tendency toward inaction for fear of causing harm
Affect heuristic		Emotional influence on decision making
Bounded awareness	Premature closure	Decision reached prematurely – Before all facts are examined
	Feedback bias	Misinterpretation of no feedback as positive feedback
Framing	Framing bias	Initial presentation affects subsequent thinking
	Status quo bias	Bias against action
Motivation and emotion	Positive illusions	Viewing the world in a more positive light than is objectively accurate
	Self-serving reasoning	Situation is perceived differently depending on the individuals' role
Escalation of commitment		Persisting on a previously determined course of action
	Sunk costs	Unwillingness to abandon a failing decision, coupled to ego
	Escalation paradigm	Analysis of forces affecting escalation of commitment

From: Refs. [5, 8]

70.8.1 Basis for Decisions

It is crucial to base decisions on facts. Everyone has opinions, and too often dominating individuals with strong views on the subject at hand may have a large influence on decision making. Facts can be collected in various ways. This chapter is on KPIs, and this is of course one way of collecting facts. Scientific literature and published data are extremely important in this respect. Informed strategic and tactical decisions for the laboratory must be made based on scientific and factual evidence.

One example of a situation in the IVF laboratory where published literature can be of assistance is the question whether it is beneficial to collapse blastocysts before vitrification. The individual laboratory may have limited time or resources to put into testing this issue completely, so the scientific literature needs to be used as a source of facts on which to base a decision on this issue. New and older publications show conclusively that improved cryosurvival is attained by collapsing blastocysts before vitrification [9, 10]. If the individual laboratory decides not to collapse blastocysts before vitrification, it is necessary to realize that this is then for other reasons than actual cryosurvival or hopes for better results.

70.8.2 Nontechnical Skills

Bias in decision making is an important reason for mistakes in health care as mentioned above. Many of these problems are the result of cognitive mistakes but rarely because of technical or training mistakes or because of lack of knowledge. Originally, attention was first turned to this type of problem in the aviation industry where several tragic accidents in the 1970s were traced to bias in decision making and which later led to the development of countermeasures in the form of training in nontechnical skills [11]. These skills are to a high degree utilizable in health care, especially in emergency situations, but also in situations of incomplete knowledge and complex and multiple data inputs. This is true for typical situations in the IVF laboratory; therefore a mention of nontechnical skills is relevant here.

According to Flin et al. [11], the most important nontechnical skills are the following:

- Situation awareness
- Decision making
- Communication
- Teamwork
- Leadership
- Managing stress
- Coping with fatigue

To some degree this applies to the situation in the IVF laboratory. It is, for example, important to realize which situations are most likely to lead to poor decision making, for example, during situations of stress or pressure in the laboratory. One of the most important issues here is to develop the ability to increase the quality of decisions by establishing routines for and facilitating shared decision making. This means simply to invite colleagues to discuss difficult issues from various points of view. Morphological evaluation and selection of embryos for transfer or cryopreservation are a typical issue where it can be very useful to improve the quality of decisions by shared decision making. Decisions on the issue of embryo selection may have several aspects separate from simply increasing the chance of pregnancy. There may be economical issues and medical situations to consider, one or two embryos to transfer, etc. One way to facilitate shared decision making in situations of limited decision-making time is to document routines for how to act in various circumstances and to use a systematic approach as far as is possible. This allows input from colleagues while facilitating quick and efficient work with the added value of opening up the possibility of process evaluation.

Developing a permissive atmosphere in the IVF laboratory is also important, and developing a situation where the IVF laboratory becomes an organization which facilitates learning and development must be the goal of management.

Table 70.3 Classification of an organization's ability to learn and improve its processes

Low ability	High ability
Difficulties or problems are hidden and considered signs of failure. Scapegoats are found	Problems are analyzed and discussed to keep the organization in a state of "continuous crisis"
Only attempts to change previously approved by the "center of power" are approved	Experimentation is encouraged
Excuses are found for failures	"Failures" are considered highly interesting and lead to new experiments
Rewards are given mainly with consideration to loyalty to management and tradition	Rewards are given to those who show new problems and solutions
Structure of power remains unchanged	Continuous displacement of power

70.9 The Learning Organization

The ability to change an organization is crucial to maintain long-term viability, and this is to a very great extent true of the IVF laboratory. New techniques are developed at a fast pace, competition is continuously increasing, and new demands from authorities and customers need to be considered. At the same time, opposition to change is a natural and normal reaction in any organization. The magnitude of opposition will depend on the nature of the proposed change, and sometimes opposition is part of shared decision making. Not all changes are beneficial, perhaps insight is limited, or timing may not be optimal for various reasons. It is necessary to be aware of three types of inertia as regards organizational changes: organizational inertia, insight inertia, and maneuvering inertia. It does not do much good if the organization realizes that changes need to be made but is incapable of implementing them [12].

The learning organization is distinguished by continuous development and improvements through learning. The learning is achieved through experience and feedback from others. It is important to create an environment characterized by tolerance and allow individuals to try new methods and approaches – to allow mistakes. This is not always easy in the strictly regulated environment of the IVF laboratory, but it is an important concept. Individual learning is then transformed to organizational learning through communication and quality systems.

A given organization may be considered to have low or high ability for learning, depending on how it reacts in different circumstances. See Table 71.3 (modified from Ref. [12]).

We need to remember that participation of those concerned is necessary to effectively change an organization because insight and information that a change is necessary are

important. Change is usually difficult in the beginning, but the processes become easier as time goes by – after the initial threshold is passed. The important issue is that the embryologist is a knowledge worker and it is crucial to approach work in the embryology laboratory in a professional way.

70.10 Conclusion

The IVF laboratory should be considered a learning organization, a center for the development of knowledge, not just a factory which provides routine services. In this way we will be able to allow the development and improvement of our daily work. One important step in this direction is to assure a professional attitude and processes in the laboratory. To assure this, proper decision-making processes must be applied. Decision making should be an inclusive process, especially in complex situations. Second opinions should be sought whenever necessary. Additionally, decisions must be based on facts – not hearsay or opinions. If we don't have the facts – we need to obtain them! Here, benchmarks give us a tool to evaluate our work and build on our own experience and that of others.

We should not accept lower standards than any other laboratory, and it is important not to put too much weight on pregnancy rates as an indicator of performance. Reality in the embryology laboratory is far too complex to rely on one quality control indicator as an adequate measure of the daily processes.

Review Questions

1. How would you interpret a low value for cleavage rates in the embryology laboratory? Give examples of possible explanations and how to use the KPIs to find the root of the problem.

2. The embryology laboratory has a high rate of degenerated oocytes after ICSI. What is a possible explanation for this and which steps can be taken to improve the situation?

3. What steps can be taken in everyday work to improve decision making in complex and stressful situations?

4. Is your place of work a learning organization? Why/why not?

Automation, Artificial Intelligence and Innovations in the Future of IVF

Alex C. Varghese and Charalampos S. Siristatidis

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_71

Learning Objectives

- To learn about the novel developments in automation and robotics related to IVF laboratories
- To understand the need of prediction models in the IVF setting
- To get familiarized with the development in IVF lab
- To understand the gaps related to the low rates in IVF
- To see how artificial intelligence works and how it can be implemented in the IVF setting

71.1 Introduction

The miracle technology in the medical field "in vitro fertilization (IVF)" which so far resulted in the birth of more than 5 million babies worldwide has gained momentum across the geographies as one of the best treatment options for infertility or childlessness [1]. A recent calculation on the demographic projection of the contribution of assisted reproductive technologies to world population growth indicates that an estimated 157 million people alive at the end of the century will owe their lives to assisted reproductive technologies (1.4% of global population) [2]. Even WHO has recently declared infertility as a disease. Compared to the scepticism by layman and even by medical professional in the early years of IVF, it has flourished well and now an established discipline in medical sciences. Almost all the countries worldwide have either fertility or advanced ART clinics to cater to its childless couples. IVF lab is unlike the other medical laboratories considered a workplace for human cell therapy, a very recent category of laboratories complying with the demands of regulatory authorities [3]. The assisted reproduction technologies (ART) labs provide resources for all steps of IVF treatment: gamete handling, IVF or micromanipulation, embryo culture, preparation for embryo transfer, and cryopreservation. Moreover, auxiliary laboratory resources are often integrated to the IVF lab, such as andrology, hormone analysis, quality control, and molecular genetics (PGD/PGS).

The early pioneers of in vitro fertilization who were trained in research or cell and tissue culture methods adopted the systems from similar field to cater to the needs of the embryo culture. Hence early days of IVF laboratories and methods were exact replicas of cell culture labs. As the research evolved on the optimization of culture conditions, newer embryo culture systems and procedures were introduced at a slower pace. "Slower pace" in development was typical across the IVF labs which may attribute to the scepticism or fear of introducing failures in outcomes in labs where they were getting consistent results as per the contemporary standards. Furthermore, as the demand for better equipment rose steadily, new companies emerged in order to supply the growing ART lab industry with adequately designed disposables and equipment. It is apt to conclude that the single most important factor for the worldwide increase in IVF success rate over the last two decades was the commercial availability of purpose-designed devices and equipment for the IVF lab.

Even though medical/tissue culture laboratories embraced advanced automation workflow systems, the IVF laboratories still lag behind in introducing new technologies. Unlike any other medical or pathological laboratories, IVF labs need an error-free system as it deals with creation of human embryos.

There is a tendency towards a fully automated performance of the modern IVF unit targeting the sum of its functional aspects, from the assessment of the subfertile couple to the embryological procedures and medical interventions. In this context, several technologies have been proposed, and, although they are not yet fully established as reliable approaches in the clinical management of infertility, the interest is growing fast. As an example, Meseguer et al. recently described the automation of the IVF process and more specifically in sperm selection, oocyte manipulation and selection of culture media and embryos to be transferred [4]. It is generally accepted that, apart from the developing embryological technologies, prediction of IVF outcome would be the second most important achievement in assisted reproduction, behind a successful IVF cycle resulting in live birth. Numerous methods have been proposed since 1986 in an attempt to develop a functional system; more recent statistical methods and other newer techniques have contributed in a significant way ([5–7]).

Serving this purpose, specific artificial networks (ANNs) have been introduced during the last 30 years, representing a technological combination of a "learning", self-adapting and predicting system. Their application encompasses a number of functions, such as the ability to associate symptoms and disease, a "learning" path by cumulatively integrating specific data and the ability to foresee the exact treatment outcome. So far, such ANN systems have been utilized in gynaecological oncology, where early detection of a disease is a prerequisite, in reproductive endocrinology and assessment of the infertile couple with contradicting results, in urogynaecology with successful prediction of the outcome of the surgical procedures applied and in the early identification and management of menopausal and osteoporotic women [5]. In that paper, authors acknowledged the limitations and pitfalls in prediction precision of such systems, which arise from the incomplete and faulty "training" of the system during data input and the reported instability of some of them as predictive models per se, due to the association of the type of the preselected data used and their usually retrospective nature [5].

71.2 Current Developments in IVF Lab

71.2.1 Time-Lapse Embryo Culture

The incubator is one of the most important pieces of equipment in the IVF lab, because stable and accurate culture conditions are crucial for embryo development and IVF success. For almost two decades, the water-jacketed or dry heat-type box incubators were the centrepiece of equipment in any

ART lab: variations include (1) CO_2-only type, (2) tri-gas models, (3) mini box incubators to reduce the gas usage, (4) passive and active humidification models, (5) TC or IR sensor based, (6) different modes of sterilization options, (7) internal air cleaning filters, etc. However one of the major drawbacks of these incubators were the changes in internal gas phase and thereby pH variations due to frequent door openings. To avoid this, many labs started investing in multiple incubators, and still when we search the Google images, one can see IVF labs with rows of box incubators set against the wall. Even some labs used to dedicate one incubator for each patient. These practices consequently increase the space requirement and workload for maintenance. Bench-top incubators (Cook, K-systems, ESCO, Astec and Planer) function according to the "waffle iron" principle by providing close contact heating both from the top and from below directly on the culture dishes. The bench-top incubators, which are a quite recent evolution in IVF incubator technology, have been shown to improve IVF results through their rapid recovery times after lid opening (ref). Many IVF labs are now replacing their old CO_2 incubators with bench-top incubators in order to improve culture performance and reduce space.

Recently a self-contained incubation system integrated with time-lapse imaging has been introduced into IVF labs. Conventional methods of embryo scoring in most ART centres rely on the use of the inverted microscope, which offers information based on morphological and developmental characteristics from the early cleavage till the blastocyst stage. However, this method has several limitations [8, 9]. Notably, transfer of top-grade and morphologically good embryos often fails to result in clinical pregnancy, while embryos with poor scores sometimes result in live births. Apart from morphological assessment, invasive and non-invasive methods of selection have been developed. Single-cell biopsy at the cleavage stage has been reported to not interfere with embryo progression to the blastocyst stage [10]. In this context, preimplantation genetic screening (PGS) has been used for embryo selection and aneuploidy screening; however, its effectiveness has been placed under scrutiny [11]. Non-invasive techniques, such as embryo oxygen consumption, testing of soluble HLA-G, amino acid turnover, proteomics and metabolomics, cumulus cell gene expression analysis and time-lapse imaging (TLI), have currently become more popular options for embryo selection after IVF [12].

The rationale behind the use of TLI is based on the improved assessment of the embryos and their early cellular divisions, enabling to determine the timing of specific morphological occurrences and permit comparison between them while also identifying anomalies in the blastomeres and the nuclei, which otherwise would not be detected. This information can lead to more objective selection of embryos for transfer and/or cryopreservation, and the improvement of the success rates for ART patients, and for those diagnosed with repeated implantation failures [13]. Moreover, the potential undesirable shock or stress due to sudden changes in environmental parameters, such as temperature and pH associated with the use of a microscope, is avoided [14].

The technology is easily assimilated into the ART laboratory and is used with any culture medium and environment. Images of the embryos are recorded at regular intervals without their removal from the culture environment, and images can be viewed instantly or merged to form a video showing complete development from the oocyte to blastocyst stage: their review can assist in identifying and selecting embryos with normal developmental profiles and in deselecting those with abnormal phenotypes [15, 16].

Reports on the modality have been numerous during the last 10 years or more. The target was to explore the dynamics of an embryo to implant successfully along with its various cleavage patterns and characteristics, by observing it at various stages of development [17–20]. Recent studies reported information on the association of various confounding factors on embryo kinetics and development. Interestingly, the sensitivity and specificity of the modality in terms of predicting the progression to the blastocyst stage was >90% by measuring parameters at day 2 after fertilization, before embryonic genome activation [21], while the bad prognosis of good-performing but unviable embryos reaches a specificity of 100% [22]; moreover, the area under the receiver operating characteristic curve has been reported to be 0.74 for live birth [23]. In addition, a recent cohort found better reproductive outcomes, whereas the results were more evident in women aged more than 40 years, although there was no effect of TLM on outcomes, when clinical/external factors were taken under consideration; notably, authors observed more "in range" cellular events in certain embryo cycles in women aged 35–40 compared to those >40 years, in non-smokers than in smokers, in the GnRH-agonist group as compared to the GnRH-antagonist as well as in the embryos resulted in pregnancy compared to those that did not, indicating the importance of the timing of cleavage events on embryo competence [20]. The technology is an effective and safe alternative for embryo incubation, and no adverse effects have been observed in obstetric and perinatal outcomes when a time-lapse incubator was used compared to a conventional one [24].

On the other hand, there are contradicting views on the benefit of embryo selection using a time-lapse algorithm or computer-automated time-lapse image analysis test [25, 26].

According to meta-analyses conducted during the last 15 years, data show that there is insufficient evidence of differences in live birth, miscarriage, stillbirth or clinical pregnancy to choose between TLM and conventional incubation, so that recommendations for a change of routine practice cannot be justified and that the technique for embryo selection should remain experimental and that couples should not be subject to a surcharge for having their embryos cultured in it [27–30]. All of them highlight the low quality and limitations of the included studies. Furthermore, in the most recent RCT, the use of a TLI hierarchical classification model of day 3 single embryo transfer had a significantly lower ongoing pregnancy rate compared with day 5 SET with

conventional selection [31]. One recent study even shows that the manual annotation was superior to the automated annotation provided by Eeva™ version 2.2, because manual annotation assigned a rating to a higher proportion of embryos and yielded a greater sensitivity for blastocyst prediction than automated annotation [25].

However, in a validation study of the addition of automatic annotations and a classification algorithm related to reproductive outcomes, where logistic regression analysis studying confounding factors was included, authors reported that the automated embryo diagnostic test provided extra information to the embryologist to select the best embryos; if at least one of the embryos was labeled as high, ongoing pregnancy rate was 2.567 times higher than a cycle where no high embryos were transferred [32].

In a retrospective study [33], having a cohort size of 14,793 patients and 23,762 cycles, the incidence of live birth ($n - 973$ deliveries) after embryo selection by objective morphokinetic algorithms was compared with conventional embryology selection parameters ($n - 6948$ deliveries). A 19% increase in the incidence of live birth was observed when morphokinetic data were used to select embryos for the patient cohort aged younger than 38 years (OR 1.19 with 95% CI 1.06–1.34) using their own eggs and an increase of 37% for oocyte recipients aged over 37 years (OR 1.370; 95% Cl 0.763–2.450). This is the largest study of the prospective use of time-lapse imaging algorithms in IVF reporting on live birth outcome, although the nature of purely a closed system versus standard incubation could not be assessed in this study.

Even though there are contradicting reports on the pregnancy outcome with TLI, the system undoubtedly provides a consistent microenvironment for preimplantation embryo development in the extended culture. This definitely avoids the exposure of embryos to outer environment which is the norm in the conventional incubation systems. The future holds promise for TLI as the systems might get automated and the objective embryo selection will become a reality. Such systems already hold promise for integration into the artificial neural networking.

71.2.2 Novel Optical Systems for Laboratory

Among the microscopy systems being used in IVF laboratories, the stereo zoom microscopes are the workhorse of lab, and the inverted microscope caters to the micromanipulator, conventional embryo monitoring and scoring. Differential interference contrast (DIC) is the most popular imaging technique used for visualizing the living cells like spermatozoa in assisted reproductive technologies. The interference image by DIC has a quasi-3D appearance, where regions of differing optical thicknesses possess edges that stand out as either brighter or darker than their surroundings. Hoffman modulation contrast (HMC) is a phase contrast method that produces a pseudo-3D image similar in appearance to that of DIC but does so by employing a different optical mechanism. Intracytoplasmic morphologically selected sperm injection (IMSI) makes use of the DIC method to receive high detail, high contrast images of sperm cells. The DIC image is captured using a 60x or 100x oil objective and subsequently enhanced through the use of a magnification changer, video zoom and digital camera and imaging system. More than 10 years after the development of IMSI, the indications of the IMSI technique and its ability to increase pregnancy and/or live birth rates (compared with conventional ICSI) are still subject to debate. Results from the recent Cochrane review of RCTs do not support the clinical use of IMSI, and there is no evidence of effect on live birth or miscarriage, and the evidence that IMSI improves clinical pregnancy is of very low quality [34].

Interferometric phase microscopy (holographic microscopy) may be the next stage of advancement for imaging in ART. Holographic imaging provides the prospect to obtain quantitative images where images may possess meaningful values at all of their points. Holographic imaging generates quantitative data regarding the thickness of the cell and provides the clinician with data regarding the 3D structure of the cell. The sperm acrosome and nucleus can easily be identified and measured as in labelled sperm, as the acrosome has a significantly lower optical path delay (OPD) due to its lesser thickness. Vacuoles can be located and measured due to their decreased refractive index [35].

While current imaging methods have been used for decades, with the introduction of simple and portable holographic modules, holographic imaging is now poised to bring the field of sperm selection to its next stage of development.

In recent years spectroscopy including Raman spectroscopy has emerged as one of the major tools for biomedical applications and has made significant progress in the field of clinical evaluation. This Raman spectroscopic technique does not require sample labelling, getting biochemical information directly from the inelastic light scattering induced by its molecular vibrations. The Raman frequency shifts are conventionally measured in wavelength, depending on the atomic mass or molecular bonds of specimens; all the chemical information involved is presented on a Raman spectrum that can be further interpreted and analysed using statistical, chemical and morphological methods. Raman spectroscopy is a relatively simple, non-invasive and nondestructive technique providing molecular-level information, allowing investigation of functional groups, bonding types and molecular conformations [36]. Raman spectroscopy can be easily combined with complementary optical approaches, such as holographic microscopy.

Raman spectroscopy has been demonstrated to successfully detect sperm DNA damage, mitochondrial status and fertilization potential [37].

Researchers are also studying confocal Raman spectroscopy (CRS) which can provide information about oocyte competency through measurement of changes in the macromolecular architecture during oocyte development and maturation. Non-invasive Raman imaging of Metaphases I and II (MI, MII) and germinal vesicle-stage living oocytes showed

changes in nuclear organization and cytoplasm macromolecular architecture during these development and maturation stages related to changes in chromosome condensation, mitochondria aggregation and lipid droplet numbers [38].

Raman microspectroscopy has also been used to investigate vitrification-induced structural damages in mature bovine oocytes [39] and to analyse the oxidative stress-induced damages in mouse oocytes [40]. This non-invasive imaging could represent a highly informative method of investigation to evaluate the oocyte quality in the future.

Morphological features are considered the gold standard in embryo selection in IVF. However, the method seems to be empirical and it does not specify the embryonic quality. Therefore, new evaluation techniques for embryonic quality are highly desired. Near-infrared (NIR) and Raman spectroscopy metabolic markers of spent culture media have been reported to have correlation with pregnancy outcomes [41, 42]. However, according to the Cochrane analysis of current trials in women undergoing ART, there is no evidence to show that metabolomic assessment of embryos before implantation has any meaningful effect on rates of live birth, ongoing pregnancy, miscarriage, multiple pregnancy, ectopic pregnancy or foetal abnormalities [43]. Raman microscopy offers a more direct method to assess the embryonic quality, based on the molecular compositions obtained from the embryo non-destructively, non-invasively and without labelling.

Raman spectroscopy can provide rich molecular information non-destructively and in situ, without labelling the cells. Even in complicated biological systems like embryos, information about biomolecules such as proteins, lipids and DNA can be separately extracted from a Raman spectrum, and their quantitative variations and structural changes can be investigated. Ishigaki M et al. [44] measured in situ the Raman spectra obtained for unfertilized, pronuclear, 2-celled, 4-celled and 8-celled developmental stages. The variations in proteins and lipids and the structural changes in proteins concomitant with embryo development and morphology were observed non-destructively. Embryos with low-grade morphological feature have high concentrations of lipids and hydroxyapatite, indicating that the bands attributable to these components can be distinctive factors for the assessment of embryo quality. However the authors warn that it is essential to carefully examine the invasiveness of laser irradiation in embryos. This technique may be a novel and feasible method for non-invasive embryo selection based on molecular and biochemical markers.

71.2.3 Microfluidics in Assisted Reproduction

Conventional embryo production requires in vitro manipulation of gametes and embryos innumerable times which induces stress on the preimplantation embryos via external culture systems and microenvironment. Microfluidic systems can be employed to handle/process gametes, mature oocytes and culture embryos and perform other basic procedures in a microenvironment that more closely mimics in vivo conditions. It has been hypothesized that microfluidic environment may look more like the in vivo environment which is just opposed to the static system in an embryo culture Petri dish. Culture systems that are static do not permit real-time changes in the culture media that surround the embryo as it develops unlike the in vivo environment in which embryos grow in physiological fluids with a constantly changing environment. This changing environment likely occurs because some metabolites necessary during one phase of preimplantation development may not be needed during other stages. Since the microfluidic systems employ a confined and dynamic growth environment for embryos at sub-micro/nanolitre volumes, the autocrine and paracrine factors released by embryos can support better development. As the system is closed, there is no worry of media evaporation and thereby any osmolarity changes.

Microfluidic systems or lab-on-a-chip can perform multiple functions and manipulations: (1) motile and normal sperm isolation, (2) fertilization, (3) cumulus cell removal, (4) embryo culture and (5) embryo selection via metabolomics and time-lapse imaging. Since microfluidic devices are mostly made from optically transparent materials, they offer the possibility of embryo morphokinetic analysis. A combination of time-lapse imaging and oxygen-consumption assays was used to identify embryo selection before transfer [45], confirming its analytical potential.

Microfluidic platforms have also been explored for its utility in vitrification process. For instance, using digital microfluidics, Pyne et al. [46] accurately timed the exposure of a single mouse embryo placed in a sub-microliter droplet to various equilibration/vitrification solutions. They have shown that the process could be entirely automated, with similar results compared with manual procedures [46].

ICSI-on-a-chip microfluidic systems that combine the laboratory steps of ART by providing gamete preparation, selection and ICSI while reducing the use of hand labour have been reported by Palermo's team [47]. The system included a cast PDMS microfluidic chip with embedded piezo-driven injection system and valves with etched electrodes and wiring. Normal and motile sperm cells were isolated by laminar flow system, and cumulus denudation was carried out chemically and mechanically within dynamically created chambers and alternating suction channels. Embedded electrodes facilitated the orientation of the oocyte to allow maturity assessment. ICSI was performed on the mature eggs using a piezo-actuator-driven needle following trapping and immobilization of the sperm cell via laser. Oocytes were then transferred into individual embryo assessment chambers where fertilization and long-term embryo culture was monitored.

Automation of the microfluidic platforms is particularly essential for standardization of the processes in the IVF labs. An automated interface has been developed to pilot the entire in vitro culture of embryos in six independent chambers, with controlled medium delivery, possible changes in the medium composition and in situ regulation

of the temperature and gas tension [48]. The future holds many hypothetical promises with such systems. The IVF treatment could be fully customized and personalized, depending on the patient's profile like age, oocyte quality and physiological needs of the embryo based on individual patient needs. The use of integrated and fully automated platforms to perform the whole IVF procedure in an objective way would lead to standardization of the treatment across laboratories and subsequently increasing the take-home baby rates [4]. It is true to say that even after three decades of development and research, we are yet to see the clinical application of microfluidic systems in human IVF. Collaboration between automation engineers and biomedical and IVF scientists can pave way to circumvent many challenges posed in microfluidic research. However, new technologies need thorough validation using animal models, followed by donated human embryos and, finally, through randomized clinical trials before its widespread application in human IVF.

71.2.4 Automation in Vitrification

Cryopreservation of oocytes and embryos has become an essential component of ART procedures with more and more clinics opting for "freeze-all" policies. The last decade has witnessed several new vitrification media and devices along with multitude of hands on workshops in many congresses. However, due to poor reproducibility and inconsistency across operators, the success and survival rates also vary significantly. The embryo vitrification typically employs high concentrations of cryoprotectants followed by cryopreservation with liquid nitrogen to produce extremely rapid cooling rates which need to be performed with higher skill and time-bound manner. The survival rate and pregnancy rate vary with operators. To address the need for standardization of vitrification across users and clinics as well as a reduction in labour intensity, automated systems for vitrification hold much promise in ART lab.

One such semiautomated system, Gavi®, is designed with a robotic liquid handling unit that dispenses the necessary vitrification solutions, removing the need to manually move embryos between fluids. The Gavi system was developed at Genea (Sydney, Australia) and Planet Innovation (Melbourne, Australia). The Gavi system performs automated equilibration for closed system vitrification of up to four embryos simultaneously. The system is comprised of the instrument (Gavi) which performs fluid exchange using a robotic liquid-handling unit with individual pipettes, has a heat-sealing unit and includes the liquid nitrogen bucket, the single-use "pod" closed system device containing a novel microfluidic "channel" that secures the embryo during fluid exchange and vitrification. After equilibration, the pod is then heat-sealed, so that it can be placed directly into LN2, without any risk of contamination to the enclosed embryo [49]. However, the warming procedure needs to be done manually by the embryologist.

Yu Sun and team from University of Toronto is developing a robotic vitrification (RoboVitri) and ultimately aim to standardize clinical vitrification from manual operation to fully automated robotic operation. Their robotic system is embedded with two contact detection methods to determine the relative Z positions of the vitrification micropipette, embryo/oocytes and vitrification straw. The system is integrated into an inverted microscopic stage. A 3D tracking algorithm is developed to visually observe the embryo loading and real-time monitoring of embryo volume changes during vitrification. Excess medium is automatically removed from around the vitrified embryo on the vitrification device to achieve a desired high cooling rate. Tests on mouse embryos demonstrate that the system is capable of performing vitrification with a throughput at least three times that of manual operation and achieved a high survival rate (88.9%) and development rate (93.8%) [50].

The capability of automated pick and place of single embryos enabled the robotic system to perform vitrification of multiple embryos in an optimally scheduled sequence. The system is claimed to pick and transfer embryos into equilibration solution by automated visual inspection and again transferring them from ES to vitrification solution. The system was able to process six embryos in 24 min. Only failure in RoboVitri arose when an embryo floated in the VS solution and happened to drift into blind regions of the multiwell plate.

Amir Arav has developed a fully automated device – SARAH – which claims to have (1) automatic stepwise exposure to equilibration and vitrification solutions, (2) automatic cooling into LN or LN slush, (3) automatic warming by exposure to warming solution and (4) automatic stepwise dilutions and washings. The device is claimed to vitrify/warm simultaneously up to 30 embryos/oocytes (mini straws) and up to 18 ovarian slices (maxi straws).

The automatic device to vitrify oocytes and embryos consists of a vertical robotic handle where a special straw holder, which can load up to six straws, is attached. This robotic arm moves in a vertical plane (up and down), at predetermined time intervals, and by so doing carries the biological samples contained in the straws between different solutions (vitrification and equilibration) arranged into nine cups placed in a temperature-controlled metal carousel plate. The final station on the carousel plate is the one containing LN where the straws are ultimately plunged and the entire cycle of vitrification is considered completed.

Prior to attaching the straws to the holder, the oocytes or embryos are first manually loaded into the straws, and then the straws are closed at one extremity by special capsules (50 μm pores) (Fertile Safe Ltd., Nes Ziona, Israel). After the holder is placed on the robotic handle and the protocol has been selected from the touchscreen, the process begins by touching the "ON" command. Once the entire preparatory steps are completed, the holder plunges the straws into a special insulated vessel containing LN or sterile liquid air. The special straw holder is then disconnected from the handle, and the straws can be either stored "as it is" or they can be

inserted into a 0.3 ml straw heat-sealed and then placed in LN tanks for long-term storage.

After the 100% VS and prior to immersion into LN, there is a step where the straws are inserted into a cup containing an absorbing paper to remove the VS and achieve the lowest volume possible.

The warming procedure consisted of first plunging the straws into 100% warming solution (WS) at 37 °C for 5 s and then immediately placing the straws in the vertical robotic arm of the SARAH device. In a reverse process than used for vitrification, for the rewarming the straws are automatically plunged into temperature-controlled 5 ml tubes containing warming solutions kept at room temperature, before arrival into the final holding medium station.

Arav A et al. [51] reported the preliminary successful results using the SARAH automated vitrification system with mice and bovine oocytes and embryos. Rewarmed 8-cell mice embryos had 95% (33/35) blastulation rate and 80% (28/35) hatched. Fresh control mice embryos had 100% (42/42) blastulation and 73% (21/42) hatching rates. Vitrified bovine oocytes had 100% survival (84/84), 73% (61/84) cleavage and 7% (6/84) blastocysts rates; fresh control had 83% (125/150) cleavage and 11% (17/150) blastocysts rates.

Samuel S. Kim et al. describe an automated device comprising a cryoprotectant holder, a cryoprotectant dispenser and a sample holder oriented to allow a sample to be in contact with cryoprotectant from the cryoprotectant dispenser. In this device, oocytes or embryos are kept in a sample holder (e.g. porous mesh) throughout the entire procedure, while the vitri/warming solutions are dispensed in and drained out of the device. The sample holder is a rotating sample holder that moves the sample from a position that allows introduction of the sample to a position that allows introduction of the cryoprotectant from the dispenser. The rotating sample holder further moves the sample from the position that allows introduction of the cryoprotectant to a position that allows sealing of the sample by the sample sealing device. The order, time and duration of administering the vitrification/warming solutions to the biological samples are said to be controlled via a control module.

In the very near future, we will witness different automated/robotic systems for cryopreservation getting into the day-to-day practice of embryologists. Many of them are still in prototype development or in the research/clinical trial phases. The major question posed by the inventors of automated devices is: How to equilibrate the embryos? This can be done by limited ways only. In manual human interventions, the embryos are moved from solutions to solutions by visual control. The same logic is applied by Sun et al. in their RoboVitri system where the system picks and drops the embryos in the desired area/solutions. In the second option, one has to park the embryo in a vessel and drop and drain the desired solutions in and out of the vessel. This is applied in the Gavi system. However, the optimal minimum volume of final vitrification solution around the embryos is in question. The third option is park the embryos in a device/vessel with porous embodiment. The desired fluids pass through the device/vessel while equilibrating the embryos with the necessary cryoprotectants.

The survival and quality of warmed embryos not only depend on the standardization of vitrification process but also on the warming procedure. Hence I'm of the opinion that the automation must look into both the process of vitrification and warming. Since there are many commercially available vitrification/warming media being used by laboratories, the system should cater to different brands. This may be achieved by software programming. Moreover the designs should integrate vitrification – warming and storage of the samples in the same system. The smart chip (Bluechiip, Australia) is a passive device based on microelectromechanical systems (MEMS) technology that contains no electronics and is either embedded or manufactured into cryogenic storage equipment such as vials, cassettes, straws, plates, racks and towers. Such sensors have the potential to get integrated into the automated storage vessels to track and retrieve cryosamples at desired time points.

71.2.5 IVF Workstations

IVF workstations have been evolved across the years from the simple horizontal/vertical laminar flow stations to dedicated flow hoods with warm benches and to isolator-type closed benches. IVF hoods provide the safe environment of all gamete/embryo manipulations. Even some versions contained dedicated area for integration of ICSI workstation. The ideas behind all these developments were to provide a physiological niche for gamete/embryo manipulation without much variation in physical parameters like pH, temperature, humidity, etc. Very recently a spurge of developments has been observed in many systems used in ART lab which fortunately have been done with collaboration with embryologist and inputs from scientists working in ART.

Comparison of conventional hood and enclosed chamber for all the IVF process reported that significantly more embryos developed to the blastocyst stage in the enclosed isolator-based system compared with conventional open-fronted laminar flow hoods [52].

Even though studies show the better physiological outcomes with enclosed workstations, they are yet to become popular among laboratories. Embryologists prefer to work with open workstations as it gives more convenience for movements. The open workstations are amenable to modifications which can yield an integrated work area cum incubation locus. This will also avoid embryologists running between workstations and incubators. These incubators integrated in hood can be either drawer type or time-lapse imaging incubators. A 6 feet workstation can also integrate on one side an advanced monitor only (no-ocular)-based inverted microscopy system with an incubation chamber on microscope stage for culture dish observation. This enclosed observation will help embryo scoring at physiological microenvironment. Moreover an integration of morphology scoring software in touchscreen monitor with standard

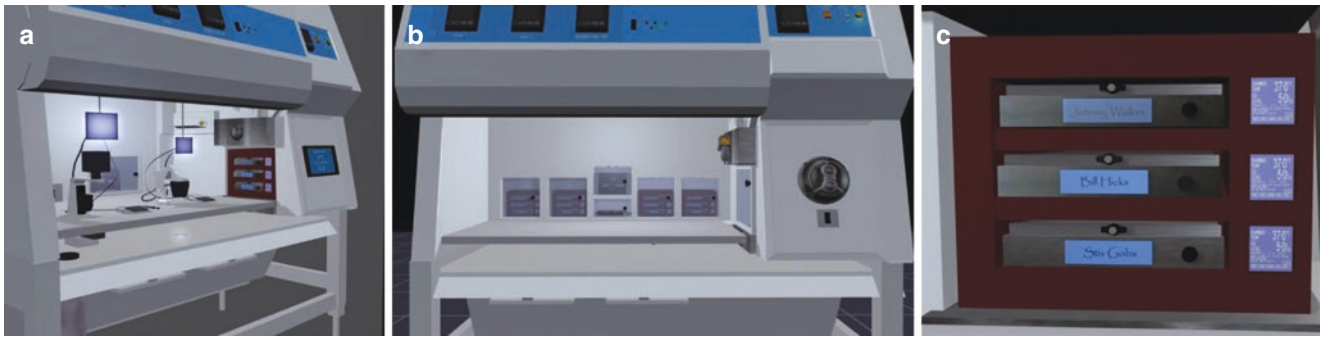

Fig. 71.1 A proposed model of an integrated open IVF workstation with ocular lens-digital microscopes **a** with image/data processing and multiple voice command drawer-type incubators **b**, **c**. The model also integrates electronic witnessing system along with a cloud-based QC app. (image provided by Alex C Varghese)

morphology patterns will make the process easy for embryologists (Fig. 71.1). Clinical embryology-specific microscopes need to be developed for this purpose. The size of culture media drop harbouring the oocytes/embryos is smaller with regard to the magnifications of inverted microscope objectives. This makes it difficult to locate/focus the embryos across the droplets. The operator needs to go back to lower magnification (5x) to see the droplet position and then shift to the higher objective to get a clear view of the embryos. This process during the embryo scoring also causes delay and thereby shifts in pH. Automation is feasible during the scanning of different droplets of media harbouring embryos. This along with an incubation chamber for the embryo scoring will make a portable and economically cheaper embryo scoring microscopy system.

Another area amenable to automation and ensured error-free process is a station to prepare and incubate the required number/type of dishes for each day/time as per the laboratory requirement. A prototype model is being developed (by the first author's team) with robotic fluid handling systems and software programming which may be helpful for busy laboratories and will ease the weekend duties of lab personal.

71.2.6 Artificial Intelligence

Subfertility is currently characterized as a disease with variable socioeconomic extends. Up to date, the IVF success rates remain relatively low, ranging from 4% to 40% based on various parameters, mainly patients' age. We estimate that this is due to an inaccurate cumulative assessment of couples' reproductive characteristics, the IVF cycle itself and the lack of incorporating indications from important biological aspects, such as molecular investigations and "omics". In this respect, improvement of IVF outcome would be a unique achievement in assisted reproduction and systems, such as computerized algorithms, hybrid architectures and ANNs are exceptional candidates in providing the fertility specialist with numerical estimates to promote personalization of healthcare and adaptation of the course of treatment according to the indications [6].

The rationale of implementing artificial intelligence in ART procedures, either clinical or embryological, is to enhance the probability of offering to infertile couples the best consultation/options for a successful outcome after IVF. Such a system can be scheduled to act as a routine information technology platform for the everyday IVF unit, either alone or in many of them. Its capability is mainly based on recalling and evaluating a vast amount of information, previously selected and usually in a retrospective, while rapid and automated, manner, which is used to provide an objective indication on the outcome of an artificial reproductive cycle. Among functions that its application involves, it is its ability to associate symptoms and disease, a "learning" path by cumulatively integrating specific data, and to foresee treatment outcome, the most important ones. Such systems have been utilized in a variety of clinical situations. Examples include in gynaecological oncology (where early detection of a disease is one of the ultimate goals), in reproductive endocrinology (where it is used for the assessment of an infertile couple with contradicting results), in urogynaecology (in successfully and early predicting both symptoms and outcome of surgical procedures), in the early identification and management of menopausal and osteoporotic women and in obstetrics in the intrapartum foetal monitoring [5, 6, 53–55].

On the other hand, an ANN has flaws, which are related to the objectivity of the network expert and medical staff responsible for the system "training" and the types of input parameters or the input of "true" or resolved cases during training. For this, careful interpretation of the dynamics of such system is of major essence. The obtained results should be in a harmonic balance with the clinical judgement and decision-making themselves, the latter to constitute the main part of clinical management that could not be substituted by any form of artificial intelligence, at least in its present form. In the same context, it is essential for obtaining the right output/result from the system, to evolve and readapt it, continuously; this can be achieved through incorporating new technologies and new feedback based on various IVF units experience that use it. This can be tested through a robust statistical evaluation of the degree of its predictive power in order to be adopted in an optimal way and establish its dynamics.

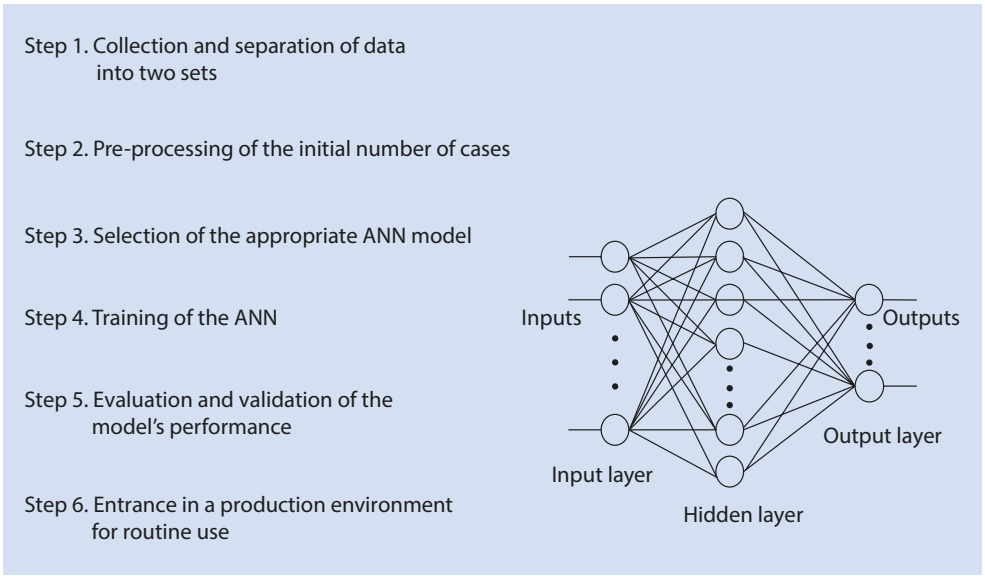

Fig. 71.2 Architecture of an ANN and steps of production

71.3 Description of an ANN

Historically, ANNs were first described in 1943 when McCulloch and Pitts popularized the concept of the artificial neuron: they reported that, by combining artificial neurons, mathematics and algorithms, they could create an artificial network similar to a biological one [56]. In 1949, Hebb introduced the concept of Hebbian or associative learning [57], where a learning mechanism could be applied in excited cells, to get information of their reaction. The idea of training came in 1962 from Frank Rosenblatt, who suggested that synaptic strengths had to be altered each time the network gave a wrong answer, while Werbos introduced the idea of propagating the errors back to former layers of the network ("back propagation of the error algorithm") [57]. Likewise, Hopfield et al. described that an asynchronous network could adjust and find a minimum, using the "least energy", so that problems requiring minimization of the network output could be solved, evolving a more biological reaction and identity [58].

The construction of an ANN is linked with the application of specialized algorithms addressing specific issues, varying from the investigation of couple's subfertility to those related to the organization and the performance of the IVF laboratory. The difference between these systems and the conventional computational ones is their ability to "learning through training". The function of an ANN resembles to "the capacity of the brain to learn and subsequently assimilate and recall this knowledge in anticipation of a future prospect; through supervised training, the characteristics of the structural components of the ANN are adapted and change in order to store the acquired knowledge" [6]; in this respect, the base of such a system is consisted of training algorithms that modify the characteristics of its components and the information flow through the network neurons [57].

The construction and the final function of an ANN consist of several steps/basic training principles [5, 6, 55] (Fig. 71.2):

1. The first step includes the collection and the separation of data into two sets, namely, the training and the test sets (at a 50/50 division), whereas percentages up to 80% for training sets have been reported [59]. The size of the data set depends on the nature of the question set a priori. Importantly, this size – usually – is changed upwards following evaluation of the primary results, so that if they are not satisfactory, new data are inserted in the initial data set, reprocessed, also clearing inconsistent entries and entries with missing data. Interestingly, an ANN trained by using all data cannot be considered as satisfactory for the addressed problem, because it cannot be guaranteed for usage on unknown data. For instance, ANN models can be trained to achieve very high performance on the training set, but eventually to exhibit poor performance in the test set (a problem known as "overtraining").
2. The second step includes the preprocessing of the initial number of cases and depends on the ANN type and the parameters selected. This is achieved by clearing any inconsistent values and by performing mathematical transformations suitable for the selected algorithm of the ANN model. The final goal is double: (a) to select the appropriate characteristics for the ANN training and to create the definitive input data set and (b) to separate these data into, at least, two sets, the training set and the test set, which are used to evaluate its training and performance, respectively [57, 59].
3. The third step is related to the selection of the appropriate ANN model and the definition of the characteristics of its components (neurons), while, according to the model, further individual characteristics are adjusted in advance.

4. The fourth step includes the training of the ANN, which is accomplished via the exposure of the training data set to the first network layer and by the fine-tuning of the system parameters. Importantly, a large number of cases with a previously known outcome are necessary for this purpose [59]. In specific, the training involves repeated steps of parameterization, evaluation of outcomes in the training set, extraction of performance metrics and validation on the test set (and/or the combined data set).
5. The final step comprises evaluation and validation of the model's performance, through the use either of the test set or the complete data set. Specificity and sensitivity are estimated, and ANN is tested if it is valid and has acceptable performance. The target in this step is the presence of an acceptable performance for the training set and the existence of no differences with the test set. This shows that the model parameters are fine-tuned. Further validity is checked by splitting the data several times via stratified random sampling, and the use of other models retraining through the same parameters found. In contrast, if it is not, all steps are re-evaluated from the beginning. Notably, a threshold of more than 75% for both positive and negative predictive values is considered to be a satisfactory result for the specific addressed problem.
6. A further step encompasses its entrance in a production environment for routine usage.

The ANN relies on the use and evolution of the particular set of algorithms that are implicated. The learning algorithms and the whole process are prone to pitfalls. Interestingly, most of them are encountered during the training stage [59]. The majority of them include the definition of the ANN dimensionality; the selection of the appropriate parameters; the inability of most ANNs to be trained again at any stage, when, for example, new data are at a later stage; the fact that most ANNs demonstrate poor performance at the test set, although it is excellent during the training set, because they are trapped to mathematical local minima; and the usual requirement of excessive computing power during the training stage [5, 6].

Current ANNs incorporate many and very popular algorithms, such as the back propagation algorithm-based networks; radial basis function-based networks; networks with recurrent architectures, such as Hopfield-type networks; systems with self-organization, such as the popular learning vector quantization network and the self-organizing feature map, both targeting clustering problems; and systems based on Hebbian learning, as referenced in two reviews of Siristatidis 2010 and 2011 [5, 6].

Technically, the justification/reasoning procedure is based on a mechanism that identifies the cases of the training set that have the greatest similarity to an unknown case; thus, the class of the unknown case is similar to the class of the cases used during training. Various types of ANNs have different characteristics, rendering their choice crucial before their use, for example, characteristics that are of great importance are its fast convergence; its resistance when getting trapped in data-related local minima, thus minimizing stability problems; and its generalization capability, which represents its performance on unknown data. Robustness of the ANN model is achieved with the random splitting of the data for several times, creating and training again new models using the same parameters, expecting that their performance on the new training and test sets are similar [57, 58].

Such models can be used in various combinations with the new web-based technology. As an example, a web-based multi-unit ANN model was proposed: the architecture involved the construction, evaluation, production and utilization of the model, for the everyday needs of the embryology lab; its main components included the server farm (consisting of the database server, the web engine and the application server), prediction models (with well-defined inputs and outputs available as web services), databases and, finally, the IVF unit, the lab and the patients [55]. Importantly, a further important key factor is the quality of the data inserted, for example, data of the metabolomic profile of the embryo and transcriptomics of the oocyte and endometrium.

A simple scenario of use could embody several poses (Fig. 71.3): the insertion of personal data into the system database, such as data from demographic and medical history of partners, clinical examination and previous IVF cycle and laboratory characteristics; call the artificial intelligence service supplied by the platform in order to evaluate the couple's probability for a successful outcome; response of the system with several alternative treatment scenarios; consultation of the physician by this service; clinical decision with the minimum risk of failure or complications; storage of all IVF cycle-related data in the database; the ANN supplied by the artificial intelligence service is used to evaluate the success rate and to provide risk details for the next step of the cycle; and all recorded results are again used for the training and test of the ANN model, thus enhancing its predictive potential [55].

Such models are expected to receive a wide acceptance as an innovative managerial tool in fertility centres worldwide and could possibly be established in routine clinical practice for the evaluation and management of infertile patients in the near future. The upper ambition is to end up to a personalized model used by the patient herself, improve the cost-effectiveness of an IVF cycle and provide a more targeted approach with more accurate predictions. This will eventually prevent the patient from potentially unnecessary costly tests or treatments, especially in cases with poor prognosis (e.g. advanced age, poor ovarian response) and provide more efficient resource exploitation. Additionally, the identification of a single best quality embryo for transfer promotes the reduction in multiple gestation rates and therefore potential complications, again reducing overall expenses for national health systems. The beneficial impact by alleviating the emotional state of the couple, through minimizing stress related to the IVF procedures and the anticipation for a positive outcome and the systematic adoption of intelligent systems with "omics" in IVF clinics could prevent extensive delays in family planning caused by multiple IVF attempts resulting in

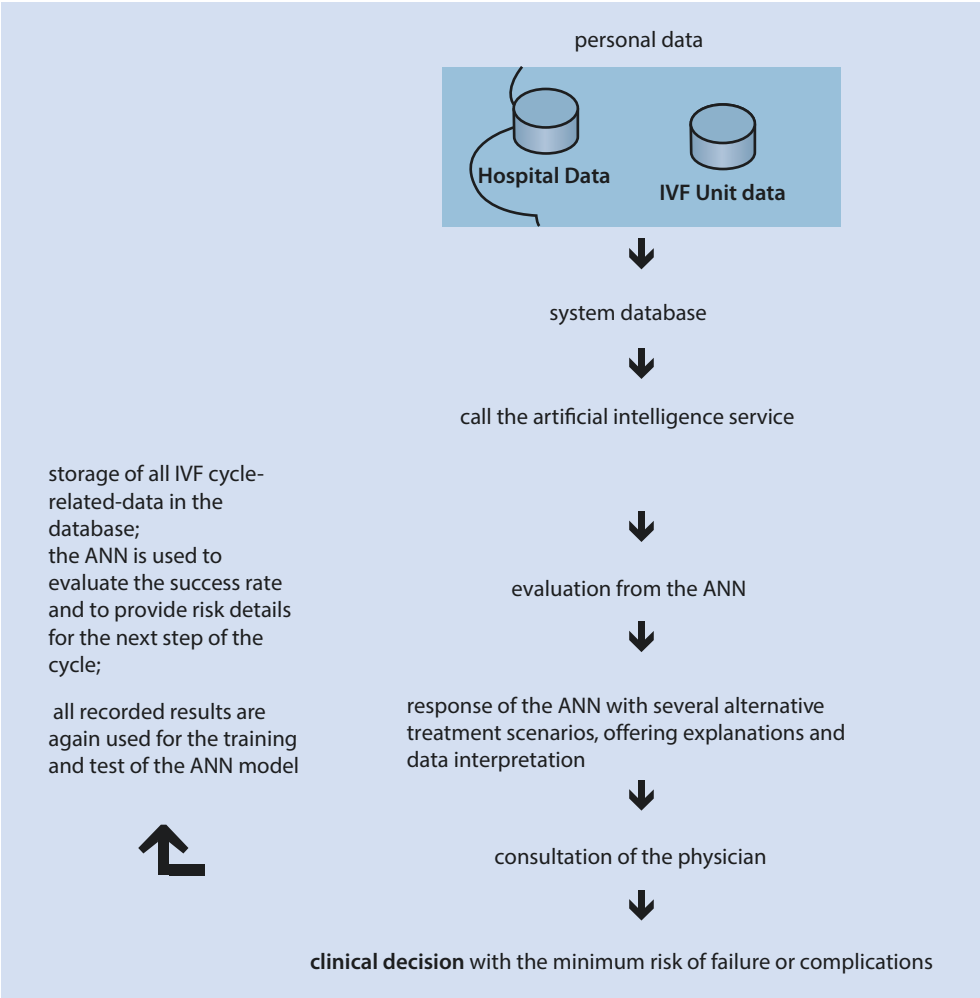

Fig. 71.3 The flow from personal data to clinical decision using an ANN

delayed parenthood and its accompanying consequences. From an ethical viewpoint, this intervention allows the minimization of cycles with poor prognosis, cycles with no embryo transfer and embryo biopsy due to failed IVF cycles (e.g. recurrent implantation failure) resulting from disregarding other potential indications leading to negative outcome.

71.4 A Typical Example on the Use of Artificial Intelligence in Embryo Selection (Life Whisperer: An Industry-Specific Use Case)

Life Whisperer uses computer vision and deep-learning artificial intelligence (AI) to assist the selection of healthy embryos in IVF and to ultimately improve outcomes for couples wanting to have children. An international clinical study involving 12 IVF centers across the USA, Australia, New Zealand and Malaysia has demonstrated that Life Whisperer's AI performs 30% better than highly skilled embryologists when identifying viable embryos from medical images – a critical pregnancy success factor for couples undergoing IVF.

Life Whisperer's embryo viability assessment model (Fig. 71.4) was created by developing a set of image recognition algorithms, which are then trained on a large data set of embryo images with matched outcomes. The output of this process is a classification model that can effectively assess and identify morphological features that constitute a viable embryo. Features detected by the model are of two kinds: targeted features previously established in the scientific literature (e.g. size, shape or texture) or more complex features and patterns that arise from performing deep learning on an extensive data set. The computer vision-AI approach can identify combinations of features in the images, some of which are impossible to see with the human eye and difficult to identify consistently using a manual approach.

Life Whisperer is delivered to IVF clinics globally via a scalable and easily accessible cloud/web-based app, which allows embryologists to drag and drop images of patient embryos immediately prior to implantation. The embryologist then receives an instant report as to the viability of each embryo. Embryologists can then use this report to support their decision on which embryo to implant. Life Whisperer's web-based approach does not require any costly hardware and thus can be delivered at a low cost to patients. This

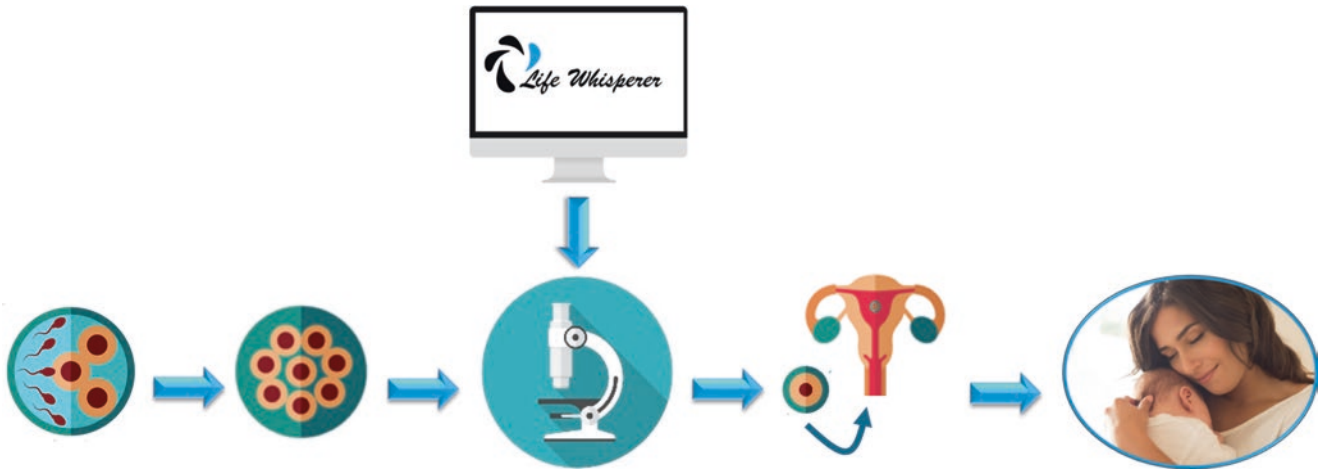

Fig. 71.4 Overview of the IVF process and the application of Life Whisperer web-based embryo viability assessment tool. (We acknowledge Life Whisperer Diagnostics Pty Ltd., Australia, for the figure and information about the Life Whisperer AI system)

approach also incurs limited change of process for the embryologists carrying out IVF.

The IVF process starts with an ovarian stimulation phase which stimulates egg production. Eggs are then retrieved from the patient and fertilized in vitro with sperm. Embryos develop over a period of up to 5 days, after which time they are expected to have formed a blastocyst suitable for transfer back into the patient. The selection of the best embryo at the point of transfer is critical to ensure a positive pregnancy outcome. Then an embryologist visually assesses the embryos using a microscope to make this selection. Many clinics already record images of the embryos at the point of selection. The embryologist then scores each embryo based on various metrics and their visual assessment down the microscope. The selected embryo is then transferred back to the patient.

71.5 Conclusion

The assisted reproduction technologies (ART) labs provide resources for all steps of IVF treatment: gamete handling, IVF or micromanipulation, embryo culture, preparation for embryo transfer and cryopreservation. There is a tendency towards a fully automated performance of the modern IVF unit targeting the sum of its functional aspects: from the assessment of the subfertile couple to the embryological procedures and medical interventions.

Time-lapse imaging, as a system of an improved automated way of observing the quality of embryos, provides a consistent microenvironment for preimplantation embryo development in the extended culture. This avoids the exposure of embryos to outer environment, which is the norm in the conventional incubation systems. The future holds promise for such automated systems, while the objective embryo selection will become a reality. Also, they can be integrated into the artificial neural networking.

Special imaging techniques are currently being used in the IVF laboratory, including micromanipulators, conventional embryo monitoring and scoring and differential interference contrast techniques, used for visualizing the living cells. Microfluidic systems have been employed to handle/process gametes, mature oocytes and culture embryos and perform other basic procedures in a microenvironment that more closely mimic in vivo conditions. From the freezing techniques, cryopreservation of oocytes and embryos through vitrification has become an essential component of ART procedures with more and more clinics opting for "freeze-all" policies. IVF workstations have been evolved across the years from the simple horizontal/vertical laminar flow stations to dedicated flow hoods with warm benches and to isolator-type closed benches. IVF hoods have been integrated to provide a safer environment of all gamete/embryo manipulations.

Improvement of IVF outcome would be a unique achievement in assisted reproduction; systems, such as computerized algorithms, hybrid architectures and networks based on artificial intelligence (ANNs) which are exceptional candidates in providing the fertility specialist with numerical estimates to promote personalization of healthcare and adaptation of the course of treatment according to the indications. The construction of an ANN is linked with the application of specialized algorithms addressing specific issues, varying from the investigation of couple's subfertility to those related to the organization and the performance of the IVF laboratory. The difference between these systems and the conventional computational ones is their ability to "learning through training". The function of an ANN resembles to "the capacity of the brain to learn and subsequently assimilate and recall this knowledge in anticipation of a future prospect; through supervised training, the characteristics of the structural components of the ANN are adapted and changed in order to store the acquired knowledge". Such models can be used in various combinations with the new web-based technology. They are expected to receive a wide acceptance as an innovative managerial tool in fertility centres worldwide and could possibly be established in routine clinical practice for

the evaluation and management of infertile patients in the near future. The upper ambition is to end up to a personalized model used by the patient herself, improve the cost-effectiveness of an IVF cycle and provide a more targeted approach with more accurate predictions. This will eventually prevent the patient from potentially unnecessary costly tests or treatments, especially in cases with poor prognosis, and provide more efficient resource exploitation.

Review Questions

1. Is the result of an IVF cycle today satisfactory?
2. Why has IVF not reached 100% in terms of positive outcomes?
3. Why do IVF labs need error-free systems?
4. Which are the scientific areas where ANN systems have been utilized?
5. What is the difference between time-lapse imaging and conventional methods for observing the embryos?
6. How is a more objective selection of embryos for transfer and/or cryopreservation linked with the improvement of the success rates for ART patients?
7. Which are the contradicting views on the benefit of embryo selection using a time-lapse algorithm or computer-automated time-lapse image analysis test?
8. Which are the applications of Novel Optical systems in a modern IVF laboratory?
9. What is the rationale of using microfluidic systems in the IVF laboratory?
10. What are the advantages of vitrification as a cryopreservation modality?
11. Why can automated vitrification be linked with the improvement of the success rates for ART patients?
12. What is the rationale of using IVF workstations?
13. Why are computerized algorithms, hybrid architectures and ANNs candidates in the improvement of the success rates for ART patients?
14. What are the steps/basic training principles for the construction and the final function of an ANN?
15. Give examples on how ANNs models can be used in various combinations with the new web-based technology.

Assisted Reproductive Technologies to Prevent Transmission of Mitochondrial DNA Disease

Louise Hyslop

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_72

Learning Objectives

- Reproductive options for women with mitochondrial DNA disease
- Advantages of vitrifying the patient rather than donor oocytes in preparation for the pronuclear transfer procedure
- Methodologies for minimizing carryover of mtDNA during PNT

Mitochondria are double membrane-bound cytoplasmic organelles located in the vast majority of cells of all eukaryotic organisms. Oocytes contain mainly spherical- to oval-shaped mitochondria, but during preimplantation embryo development, the morphology changes to a bean-like structure (see [1] for review of mitochondrial morphodynamics in human oocytes and embryos). Mitochondria have many functions, but the main role is in production of adenosine triphosphate (ATP) which is a source of chemical energy.

Mitochondria contain their own genome which is a circular DNA molecule (mtDNA) containing only 37 genes that encode 13 proteins, 22 transfer RNAs and 2 ribosomal RNAs. The mitochondrial gene-encoded proteins have a key role in energy production. Mitochondria are classified into haplogroups according to similarities or differences in the mtDNA sequence. mtDNA is maternally inherited with fertilized oocytes containing more than 200,000 copies. If all the copies of mtDNA have a mutation, this is known as homoplasy, whereas if the mutation is present in only some of the copies of mtDNA, this is known as heteroplasmy and the mutation load is the ratio of mutated to wild-type mtDNA. Pathogenic mtDNA mutations above a certain threshold of mutation load can cause a range of mitochondrial diseases. The severity of disease is determined by the mutation load with high risk of severe and life-threatening diseases with high mutation loads [2]. The transmission of mtDNA disease is unpredictable because women with a heteroplasmic mtDNA mutation can produce oocytes with varying mtDNA mutation loads.

72.1 Assisted Reproductive Options for Women with mtDNA Disease

72.1.1 PGD

PGD for mtDNA disease can reduce the risk of transmitting mtDNA disease and is an option available for women with a heteroplasmic mtDNA mutation. The mutation load of the biopsy sample is determined, and embryos with low mutation loads can be selected for transfer. Extensive analysis of a range of pathogenic mutations indicates the probability of developing mtDNA disease is low when the mutation load is less than 18% [2].

72.1.2 Oocyte Donation

Until the development of mitochondrial donation techniques, oocyte donation was the only option for women with a homoplasmic mutation or who only produce oocytes with a high mutation load.

72.1.3 Mitochondrial Donation

Mitochondrial donation has been developed for women with homoplasmic mutation or who consistently produce embryos with mutation levels above the threshold for mtDNA disease. The strategies involve transplantation of the nuclear DNA of either an oocyte or fertilized oocyte from an affected woman to that of a donor oocyte which has had its nuclear DNA removed.

1. Pronuclear transfer (PNT) – transplantation of the pronuclei in a fertilized oocyte from an affected woman to that of a donor-fertilized oocyte which has had its pronuclei removed (Fig. 72.1). Each pronucleus is transferred in a membrane intact karyoplast and fused with the enucleated zygote known as the cytoplast.
2. Maternal spindle transfer (MST) – transplantation of the spindle in an oocyte from an affected woman to that of a donor oocyte which has had its spindle removed (Fig. 72.2). The spindle is transferred in a membrane-intact karyoplast and fused with the enucleated oocyte known as the cytoplast.

These techniques could enable women to have a genetically related child with a greatly reduced risk of transmitting mtDNA disease. The risk is not eliminated since some mtDNA is carried over during the transplantation of the nuclear DNA.

72.2 Safety and Efficacy of Mitochondrial Donation

72.2.1 Carryover of mtDNA

The level of mtDNA carryover is low with both MST and PNT in studies with human oocytes and fertilized oocytes [3–5]. Various groups have derived embryonic stem cell lines from MST and PNT generated blastocysts to explore the fate of the carried over mtDNA after extended culture. The majority of human embryo stem cell lines had a similarly low level of karyoplast-derived mtDNA as the blastocysts from which the lines were derived. However there have been exceptions reported with an increased proportion of karyoplast-derived mtDNA in the ES cells and a wide variation between colonies compared to the blastocysts from which the cells were derived. It has been suggested that differences in mtDNA replication between haplotypes could explain why the carried over karyoplast-derived mtDNA is preferentially amplified in

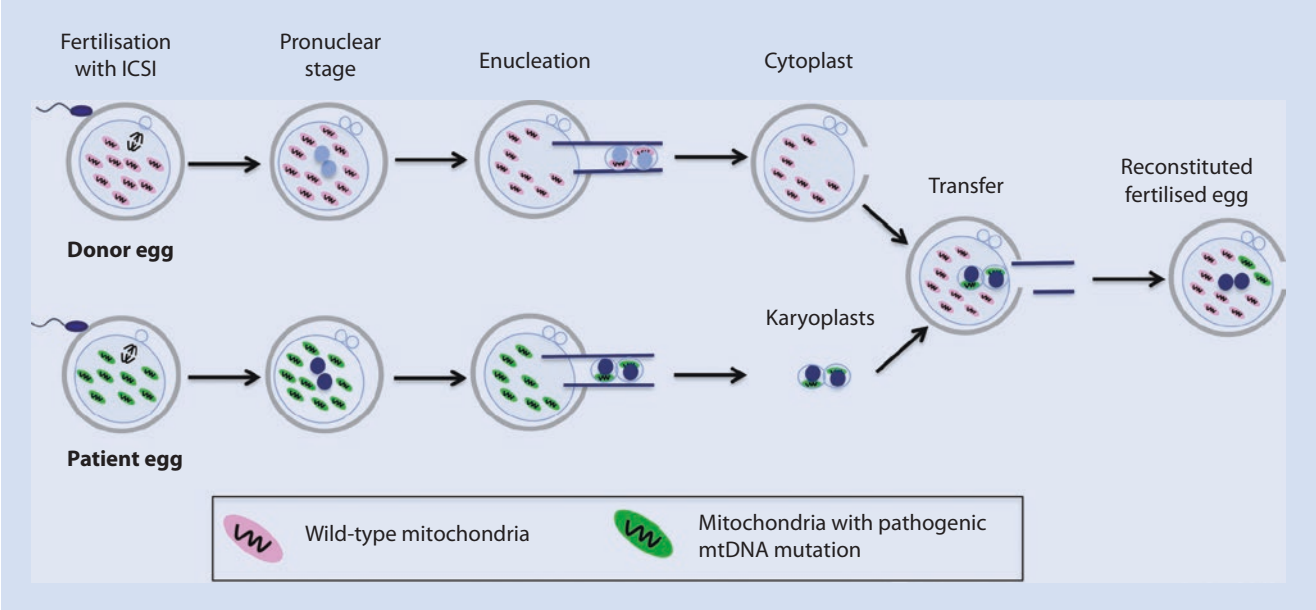

Fig. 72.1 Schematic of pronuclear transfer. Pronuclei are removed from the patient- and donor-fertilized oocytes within intact karyoplasts. The karyoplasts containing the patient's pronuclei are fused with the donor cytoplast. The reconstituted embryo contains mainly mitochondria from the donor-fertilized oocyte, but some carried over mitochondria contained in the patient's karyoplasts

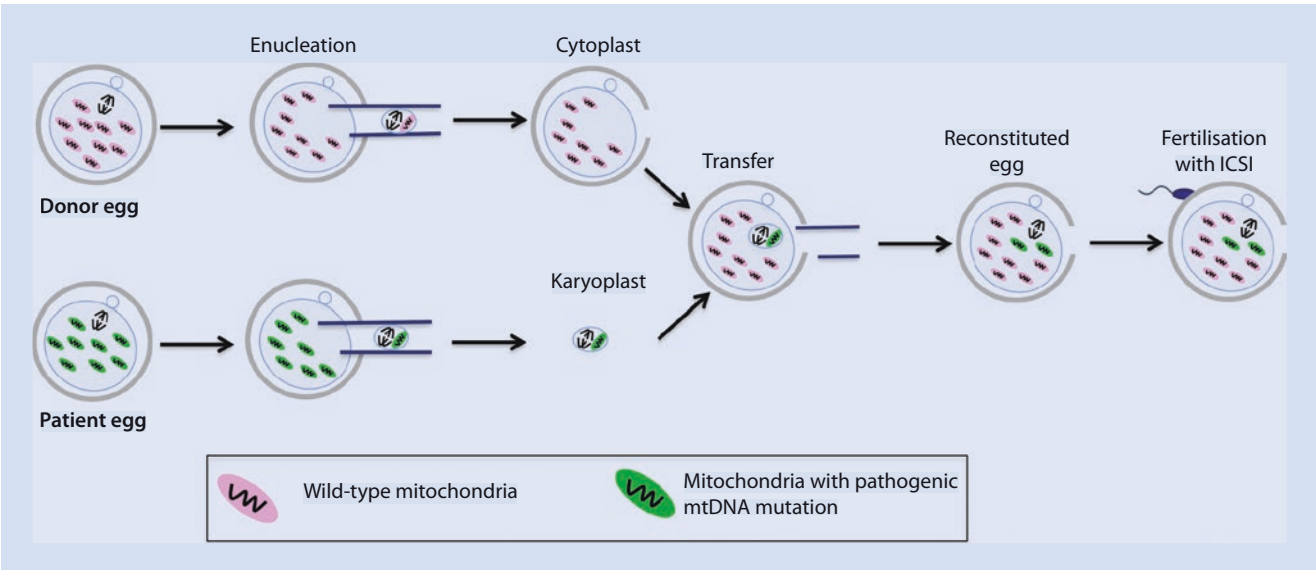

Fig. 72.2 Schematic of maternal spindle transfer. Spindles are removed from the patient and donor oocytes. The karyoplast containing the patient's spindle is fused with the donor cytoplast. The reconstituted oocyte contains mainly mitochondria from the donor oocyte, but some carried over mitochondria contained in the patient's karyoplast

the ES cells after prolonged culture. For this reason the haplogroups of the patient and egg donor should be recorded for the long-term follow-up of any children born as a result of treatment. Another possible reason for the upward drift is variation in sequences that interact with the mtDNA replication machinery. mtDNA replication is not fully understood, so further research is required to elucidate potential reasons for the upward drift. It should be noted that the relevance to what might happen in utero is unclear, so further research is required and long-term follow-up of births.

72.2.2 Embryo Development Post-procedure

Following MST the fertilization rate has been reported to be similar to controls, but there was a high incidence of abnormal fertilization with 25% of fertilized MST oocytes containing three pronuclei with a single polar body [5]. Studies are required to compare the blastocyst morphology and quality to unmanipulated controls in order to provide an indication of efficacy.

The blastocyst development rate of PNT zygotes was improved by performing the procedure shortly after appearance of the pronuclei rather than just prior to syngamy. Analysis of control and PNT blastocysts has revealed the PNT procedure had no detectable effect on gene expression and the incidence of aneuploidy.

72.2.3 Clinical Treatment

There are mixed views on the replacement of female embryos generated using mitochondrial replacement techniques. A report from the National Academies of Sciences, Engineering, and Medicine recommended only the transfer of male embryos to prevent carryover of mutated mtDNA to subsequent generations until there is clear evidence of safety and efficacy [6], whereas the expert panel convened by the HFEA to perform the fourth scientific review of the safety and efficacy of mitochondrial donation does not support the transfer of only male embryos [7]. Determining the embryo sex would require biopsy of the manipulated embryos for PGD which could further compromise embryo development and reduces the cohort of embryos from which to select the best quality for transfer.

At time of publication, a live birth had been reported following MST, and pregnancies were ongoing following PNT [8, 9]. MST was performed for a woman with a heteroplasmic mtDNA mutation. The mutation load of the embryo replaced was 5.7%, and the baby had a mutation load range of undetectable to 9.23% in different tissues at birth. PNT has been performed for couples that consistently produced poor-quality embryos rather than to reduce the risk of transmitting mtDNA disease. Therefore the carryover of mtDNA is not known for the embryos replaced following PNT.

72.3 Regulation of Mitochondrial Donation

In 2015 the UK was the first country to put legislation and a licencing framework in place to allow the use of mitochondrial donation. Centres in the UK can offer mitochondrial donation once a licence variation application has been assessed and approved by the HFEA's License Committee. Areas assessed include the process for following up children born as a result of the treatment and competence of the embryologist in performing the technique and minimizing carryover. Subsequently if mitochondrial donation is identified as a suitable treatment for a couple, the clinic must send a patient-specific application to the HFEA for assessment by the Statutory Approvals Committee. The evidence must demonstrate that without mitochondrial donation, there would be a significant risk that a child will have or develop serious mitochondrial disease. For example, a woman may have had PGD for mtDNA disease but consistently produced embryos with high mutation levels.

72.4 Pronuclear Transfer

72.4.1 Technical Aspects of Pronuclear Transfer

The key stages of the pronuclear transfer procedure include (a) creation of a hole in the zona to facilitate the insertion of the biopsy pipette, (b) pinching off each pronucleus with a minimal amount of cytoplasm to form a membrane-enclosed karyoplast and (c) fusion of the karyoplasts with an enucleated zygote (cytoplast).

72.4.2 Timing

Early pronuclear transfer soon after the appearance of the pronuclei maximizes the timeframe for the karyoplasts to fuse and pronuclei centralize prior to syngamy.

72.4.3 Laser-Assisted Opening of the Zona Pellucida and Enucleation

To facilitate the enucleation procedure, the zygotes are transferred to medium containing reversible microtubule and actin-depolymerizing drugs. Creating the hole in the zona pellucida should be performed as quickly as possible to minimize the exposure of the zygote to the inhibitors. The zygote is positioned with both pronuclei in focus and closer to the biopsy pipette than the holding pipette (Fig. 72.3). The size of the opening created in the zona pellucida should be just sufficient to allow easy insertion of the biopsy pipette and will assist with the pinching off of excess cytoplasm during the

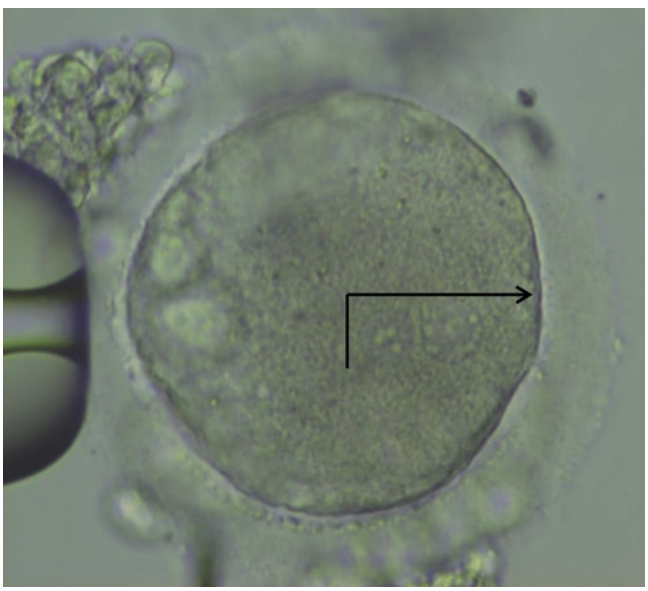

Fig. 72.3 Normally fertilized oocyte positioned prior to removal of the pronuclei. Both pronuclei are in focus and closer to the biopsy pipette that will be inserted at the 3 o'clock position than the holding pipette on the left-hand side

transfer. Too large an opening increases the risk of karyoplast expulsion prior to fusion.

The biopsy pipette is inserted and positioned to ensure there is minimal cytoplasm between the pronucleus to be aspirated and the biopsy pipette. The pronucleus is gently and slowly aspirated into the biopsy pipette. If too much cytoplasm is aspirated before the pronucleus, the biopsy pipette should be repositioned to minimize carryover. Once the pronucleus starts to enter the biopsy pipette, the pipette is slowly removed to facilitate separation. The karyoplast is expelled from the biopsy pipette and the procedure repeated for the second pronucleus.

72.4.4 Fusion

The most efficient method of fusion of the karyoplast and enucleated zygote membranes is with the fusion reagent hemagglutinating virus of Japan envelope (HVJ-E). Both karyoplasts are transferred in the biopsy pipette to a drop of the HVJ-E solution. It is critical that the karyoplasts are not expelled into the HVJ-E solution because the likelihood of lysis during replacement increases. Expel the karyoplasts until the leading karyoplast reaches the opening of the biopsy pipette. Aspirate the karyoplasts to ensure the leading karyoplast is moved away from the opening of the biopsy pipette and only a small amount of HVJ-E is aspirated into the tip of the pipette. Only the karyoplast closest to the opening of the pipette is exposed to the HVJ-E, but this is sufficient to achieve efficient fusion of both karyoplasts with the cytoplast. Transfer the biopsy pipette to the drop containing cytoplast. Using the holding pipette, immobilize the cytoplast with the hole in the zona positioned at 3 o'clock. Insert the biopsy pipette and slowly expel the karyoplasts beneath the zona pellucida (Fig. 72.4). Any excess cytoplasm in the karyoplast can be removed by pinching the karyoplast against the zona pellucida using the tip of the biopsy pipette. The risk of expulsion of a karyoplast prior to fusion is reduced if the karyoplasts are not deposited just underneath the hole in the zona pellucida. The risk is further minimized by the use of a large embryo manipulation pipette for washing the reconstituted zygote in embryo culture medium before transfer to the final dish for overnight culture.

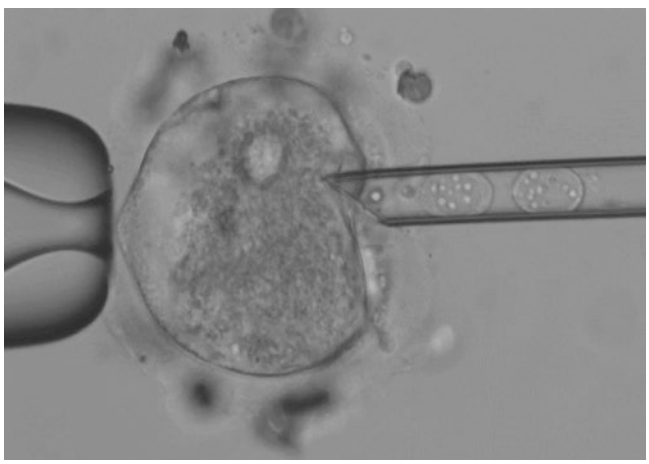

Fig. 72.4 Karyoplasts in the biopsy pipette prior to being deposited in the perivitelline space. The biopsy pipette has been inserted through the hole in the zona pellucida to allow the karyoplasts to be deposited

72.4.5 Training

During the training period, the trainee's competence in minimizing mtDNA carryover should be assessed alongside survival and onward development of the embryos. A realistic expectation is a new operator at the end of the training period will achieve approximately 90% survival and more than 95% fusion. The trainee should perform technical controls by removing and replacing the pronuclei in the same zygote (autologous transfer). It has been shown that the blastocyst development rate and blastocyst quality should not differ from unmanipulated controls [3]. In the UK, evidence of experience and competence is assessed by the HFEA. Only those assessed as competent are named on the clinics HFEA licence and are able to perform MST and/or PNT.

72.4.6 Practical Considerations for PNT

72.4.6.1 Synchronization of Patient and Donor Cycles

Synchronization of the patient and donor cycles for oocyte retrieval on the same day can be challenging. Vitrification of the patient rather than the donor oocytes has a number of advantages including:

- Banking of patient oocytes before they become susceptible to maternal age-related aneuploidy.
- To optimize usage of the patient oocytes, the number to be warmed can be based on the final follicle count of the donor. This would minimize the likelihood of not having enough donor-fertilized oocytes compared to the number of fertilized patient oocytes created for the procedure.
- Preclinical studies demonstrated that the carryover of mitochondria was lower if the cytoplast originated from the fresh rather than vitrified oocyte. Vitrification of the patient oocytes may minimize carryover.

72.4.6.2 Method of Insemination

ICSI synchronizes the PN appearance in a narrower timeframe than IVF insemination. This increases the likelihood of being able to perform the procedure with zygotes at a similar stage post appearance of the pronuclei.

72.4.6.3 Pronuclei Removal to Minimize Carryover

To minimize carryover, the pronuclei should be removed separately and not together in the same karyoplast. When early pronuclear transfer is performed, the pronuclei are rarely abutted so removal of both pronuclei in the same karyoplast will carry over cytoplasm between the pronuclei.

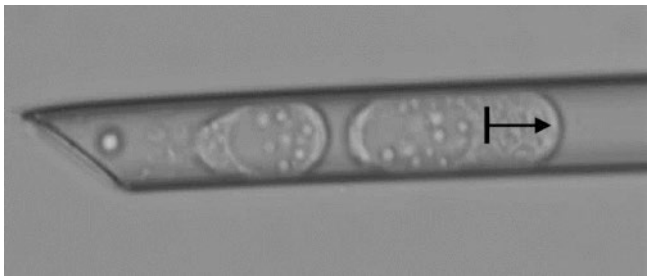

Fig. 72.5 Positioning of the excess cytoplasm in the biopsy pipette prior to transfer into the perivitelline space. Arrow indicates the excess cytoplasm to be pinched off during transfer of the karyoplasts

72.4.6.4 Transfer of Pronuclei to Reduce Carryover

If a karyoplast contains excess cytoplasm, the karyoplast should be aspirated into the pipette first by the excess cytoplasm before the pronucleus (Fig. 72.5). During the transfer the excess cytoplasm can be sheared with the tip of the biopsy pipette against the zona pellucida.

72.5 Maternal Spindle Transfer

72.5.1 Technical Aspects of Maternal Spindle Transfer

The key stages of the MST procedure are similar to PNT except the spindle is removed within a karyoplast. Polarization microscopy is required to visualize the meiotic spindle. HVJ-E is preferred to electrofusion for fusion of the cytoplast and karyoplast because of the higher rate of embryo viability and the lower rate of activation of the manipulated oocyte without fertilization [4, 10].

72.5.2 Timing

The timing of spindle recovery has been reported to be faster in vitrified oocytes compared to slow frozen [11, 12]. It is recommended that the optimal timing to visualize the maternal spindle should be determined within each centre for fresh and frozen oocytes.

72.5.3 Laser-Assisted Opening of the Zona Pellucida and Enucleation

For polarization microscopy, the oocyte manipulation dish needs to be a glass bottom dish. To facilitate the enucleation procedure, the oocytes are transferred to the manipulation dish with drops of medium containing a reversible actin-depolymerizing drug. Creating the hole in the zona pellucida should be performed as quickly as possible to minimize the exposure of the oocyte to the inhibitor. The oocyte is positioned with the spindle in focus and located between the 1 and 3 o'clock position. The size of the opening created in the zona pellucida should be just sufficient to allow easy insertion of the biopsy pipette and located next to the spindle.

The biopsy pipette is inserted and positioned to ensure there is minimal cytoplasm between the spindle to be aspirated and the biopsy pipette. The spindle is gently and slowly aspirated into the biopsy pipette with a minimal amount of cytoplasm. Once the spindle starts to enter the biopsy pipette, the pipette is slowly removed to facilitate separation. The karyoplast is expelled from the biopsy pipette and the procedure is repeated.

72.5.4 Fusion

The karyoplast containing the spindle is transferred in the biopsy pipette to a drop of the HVJ-E solution. It is critical that the karyoplast is not expelled into the HVJ-E solution because the likelihood of lysis during replacement increases. Expel the karyoplast until it reaches the opening of the biopsy pipette. Aspirate the karyoplast to ensure it has moved away from the opening of the biopsy pipette and only a small amount of HVJ-E is aspirated into the tip of the pipette. Transfer the biopsy pipette to the drop containing cytoplast. Using the holding pipette, immobilize the cytoplast with the hole in the zona for replacement of the karyoplast at 3 o'clock. Insert the biopsy pipette and slowly expel the karyoplast beneath the zona pellucida. The reconstituted oocyte is transferred to a culture dish to allow fusion of the karyoplast and cytoplast. After confirmation of fusion and spindle recovery, the oocyte should be fertilized by ICSI.

72.5.5 Training

During the training period, the trainee's competence in minimizing mtDNA carryover should be assessed alongside survival and normal fertilization rate of the reconstituted oocyte. A realistic expectation is a new operator at the end of the training period will achieve more than 90% fusion of the cytoplast and karyoplast containing the spindle.

72.5.6 Practical Considerations for MST

The issue of synchronizing the patient and donor cycles for egg collection on the same day have been described earlier in the chapter. The time difference between warming the oocytes and the fresh oocyte retrieval should be carefully considered based on local protocols.

72.6 Future Direction for Mitochondrial Donation Techniques

A current concern is the upward drift in the karyoplast-derived mtDNA in the minority of ES cell lines with prolonged culture. Methods have been refined to minimize the amount of cytoplasm transferred within the karyoplast so alternative techniques are being investigated to reduce further or eliminate the carryover of mtDNA. Polar body transfer is

one example of a methodology which could further reduce the carryover of mtDNA. Polar bodies contain a very low number of mitochondria and are ready-made karyoplasts for fusion with an enucleated donor oocyte. This methodology has shown promise when a study using human oocytes demonstrated that following polar body transfer the levels of aneuploidy were similar between control and polar body-derived blastocysts.

Review Questions

1. What are the current reproductive options for women with mtDNA disease?
2. Why is pronuclear transfer performed shortly after appearance of the pronuclei?
3. Is it recommended that the patient or donor oocytes can be frozen prior to performing the mitochondrial donation techniques? What are the advantages?
4. What KPIs should be assessed to determine the competence of an embryologist training in MST and PNT?

Learning Objectives

- Chromatin modifications during oocyte maturation
- Basic equipment necessary for nuclear or cytoplasmic transfer
- Problems that can be solved with nuclear and cytoplasmic transfer
- Future implications and concerns of nuclear and cytoplasmic transfers

73.1 Characteristics of Mammalian Oocytes

Mammalian oocytes are fascinating cells, and their relative big size makes them very convenient for different manipulations. In laboratory animals and also in ungulates, they can be obtained easily in sufficient number (e.g., from the slaughterhouse material). On the other hand, human oocytes are very rare. In humans, the collected oocytes are almost exclusively used for the production of test tube embryos and babies, and only minimum of IVF centers use spare oocytes for different micromanipulations, aiming to find and improve some approaches that can be used for some specific patients. Unfortunately, not all oocytes collected are morphologically and physiologically normal. When working with laboratory animals or ungulates and oocytes from a given collection is not good, we can simply discard them saying that the next collection will certainly be better. Logically, the situation in humans is completely different, and it is not so easy to discard those oocytes that are not absolutely perfect, especially in those patients where this situation is repeatedly observed. Thus, in such difficult situations, the micromanipulation approaches might represent a solution. However, if we want to manipulate abnormal human oocytes, we need also some normal oocytes from healthy donors. Another important aspect is that we still do not know if babies from manipulated oocytes will be absolutely normal as long-term follow-up studies are often not available. Because some very recent articles discussed the manipulations of mammalian oocytes and one-cell stage embryos in detail in our contribution, we will outline briefly, from a general point of view, the micromanipulation possibilities that can be applied almost immediately in human-assisted reproduction [1, 2].

73.2 General Morphology

The size of mammalian oocytes ranges from about 80 (mouse) to 120 μm (human, cattle, pig), so they are relatively large. But even in this case, they cannot be simply manipulated by hand. Therefore, good equipment is absolutely essential. In human-assisted reproduction, the oocytes are almost exclusively collected as mature, i.e., in metaphase II stage, when they can be used directly for fertilization. However, in general, the oocytes can be collected at different stages of maturation: either as immature with intact nucleus—germinal vesicle (GV), maturing with condensed chromosomes (metaphase I)—or mature (metaphase II). The choice of maturation stage for further manipulation clearly depends on the problem that needs to be addressed.

Immature oocytes contain the GV (nucleus) that is easily visible in rodent or human oocytes. The most prominent organelle that is visible in GVs is the nucleolus. In fully mature competent oocytes, the nucleolus is surrounded with a ring of chromatin (SN—surrounded nucleolus). On the other hand, in oocytes that are less or even not competent to mature, the chromatin is dispersed within the GV (NSN—nonsurrounded nucleolus) [3]. The oocytes are enclosed with zona pellucida and several layers of cumulus cells.

After an endogenous (exogenous) gonadotropin surge or when released from follicles and cultured under appropriate conditions, the oocytes begin to mature. Their nuclear envelope disassembles (germinal vesicle breakdown—GVBD); chromosomes condense and become gradually arranged in metaphase I. These processes are followed by a very short anaphase to telophase I transition, and the oocytes are thereafter arrested in metaphase II [4]. Two essential points must be mentioned here. First, the oocytes matured in vitro are not as good as those oocytes where this process underwent in vivo; therefore, in vitro matured oocytes usually have a lower developmental potential. Second, if we want to manipulate immature oocytes, we must remove their surrounding cumulus cells. This will even further decrease their developmental potential after fertilization [5]. However, when we need to solve, for example, the problem of absolute oocyte maturation arrest, i.e., the oocytes are unable to undergo GVBD, and we suspect that it is the cytoplasm that is responsible for this arrest, there is no other choice than to use these immature oocytes.

On the other hand, if oocytes are unable to undergo metaphase I to telophase I transition or when we suspect that their cytoplasm influences abnormal segregation of chromosomes (leading to aneuploidies), we can collect these oocytes from follicles at this stage (MI or shortly before). This later collection might be beneficial because the period of GVBD is essential for an establishment of oocyte developmental competence, and we may suppose that these oocytes are as good as those oocytes maturing completely in follicles. Logically, from the oocyte developmental competence point of view, best for manipulations are MII oocytes that matured completely in vivo.

73.3 Oocyte Maturation: Chromatin Modifications

As outlined above, the timing of oocyte collection might influence negatively their developmental potential. Although this might be caused by a variety of different factors and the effect of oocyte collection timing is extremely complex, it has been convincingly shown that the oocyte collection timing might influence the epigenetic status of oocytes.

The process of oocyte maturation is very dynamic from many aspects (cell cycle, distribution of organelles, etc.). This is certainly also true for different chromatin modifications.

Even though the epigenetic regulation of chromatin is very complex, in this section, we will focus mainly on histone acetylation as there is growing evidence indicating that the acetylation/deacetylation processes are in a close correlation with oocyte aneuploidies. In general, when probed for acetylation at different lysine residues within histones (H3/K9, H4/K12, H4/K5, etc.), it is evident that histones are highly acetylated in GV-stage oocytes. However, as soon as GVBD occurs and chromosomes condense, the labeling signal disappears, indicating that the process of chromosome condensation is associated with histone deacetylation. During the anaphase to telophase I transition, a weak signal on chromosomes can be observed again, but at metaphase II, no labeling can be detected [6, 7]. Interestingly, if the acetylation persisted during the process of oocyte maturation, an increased number of oocytes (embryos) had chromosomal abnormalities [8]. It is also apparent that aged oocyte chromatin becomes also gradually aberrantly acetylated, and in agreement with this, oocytes from older females tend to exhibit more aneuploidies than oocytes from younger females. It is commonly accepted that it is the abnormal oocyte cytoplasm that is unable to deacetylate the condensing chromatin, indicating that histone deacetylases (HDACs) are either present in insufficient quantities or are aberrantly regulated. In contrast to histone acetylation, the histone methylation pattern remains rather constant during the whole process of maturation [9]. As we mentioned above, these results were mostly obtained in the mouse, and thus, some minor differences can be expected when analyzing the oocytes from other species. To summarize, a link between the cytoplasm quality and/or oocyte collection scheme and epigenetic status of oocytes has been established; in turn, the epigenetic competence of oocytes might influence the frequency of aneuploidies. Thus, the micromanipulation techniques might solve the problem of poor oocyte cytoplasm quality; however, care should be taken when performing the oocyte collection, and especially a correct timing is necessary.

73.4 Technical Aspects

73.4.1 Necessary Equipment

Some very recent articles describe in detail the necessary equipment, media, steps, and settings of manipulation chambers when different oocyte or embryo manipulations are performed. For this reason, we will not discuss here exhaustively everything what is necessary. Essentially, every IVF lab performing the ICSI has the very basic equipment necessary for nuclear or cytoplasmic transfer—this means the inverted microscope with manipulators and injectors and, logically, also some stereomicroscopes and incubators. To perform more sophisticated manipulations, some additional instruments are however necessary. According to our opinion, the most important is the electrofusion machine because the diameter of nuclear material (either GVs or chromosomes) is rather large, and it cannot be simply injected into the host cytoplast without damage. Thus, in this case, the induced fusion between the nuclear material (karyoplast) and recipient cytoplast (enucleated oocyte) is recommended. For the visualization of chromosome groups, the PolScope optics seems to be very useful. The holding pipettes can be purchased from different companies. The injection pipettes can also be purchased, but it is our experience that it is much better if they are made directly by the person performing the manipulation. In this case, the pipette puller and microforge are necessary [1]. We strongly recommend some training with mouse or ungulate oocytes. Moreover, it is absolutely essential to study some manuals dealing with basic oocyte and embryo culture procedures and manipulations [10].

73.4.2 Brief Outline of Manipulation Methods

In general, and as mentioned above, the various manipulation schemes do not differ substantially from ICSI. What is however different, if we want to manipulate GVs or metaphase groups, is the composition of manipulation medium that must contain cytochalasin B (or D) to avoid the damage of biological material. However, the CB (D) is omitted from fusion media. Again, some excellent protocols describe in detail what to do and how to perform different manipulations [1, 11–13]. Logically, these protocols must be slightly modified depending on the origin of cells used and the type of manipulation. Essentially, this however only means to modify the diameter of injection pipette and possibly the fusion parameters.

73.5 Problems That Can Be Solved with Nuclear and Cytoplasmic Transfer

73.5.1 Possible Nuclear Transfer Combinations

In theory, the manipulation of mammalian oocytes can solve some serious problems, i.e., the inability of oocytes to begin to mature, metaphase I or metaphase II arrests, or the inability of oocytes to transform the injected sperm head into a paternal pronucleus [14]. In all those cases, we can expect that the oocyte cytoplasm is abnormal, and this means to transfer the nuclear material from an abnormal cytoplasm into a normal cytoplasm from which its own nuclear material has been removed previously (cytoplast). It is also speculated that the transfer of nuclear material from the cytoplasm which is unable to induce histone deacetylation will eliminate the possible abnormal chromosome segregation, leading to prevention of aneuploidies.

It is technically relatively simple to remove the nuclear material from evidently morphologically abnormal oocytes and to transfer it into the cytoplasm that is normal. Although technically simple, this procedure might bring some serious concerns. The most often discussed method is the transfer of

nuclear material from oocytes with mutated mitochondrial DNA (mtDNA) into the cytoplasts with normal mtDNA. In the next section, we will discuss the possible combinations of karyoplast-cytoplast transfer. Clearly, the choice of the combination used in the micromanipulation scheme largely depends on the problem that needs to be solved [15].

73.5.2 Immature Oocytes: GV Transfer

In assisted human reproduction, the oocytes are mostly collected as mature—metaphase II staged—where they can be used immediately for fertilization. However, mammalian oocytes can be collected from follicles as immature (GV staged) and matured in vitro. The same is true for human oocytes. The main disadvantage is that the quality of in vitro matured oocytes is much lower when compared to oocytes matured in follicles. If we want to manipulate immature oocytes, we must free them from enclosing cumulus cells. This will further decrease their developmental potential after fertilization. It must be noted that in almost all cases mentioned below, the nuclear material is transferred into a recipient cytoplasm in the form of the so-called karyoplast. This means that the isolated nucleus (chromosomes) is enclosed with a minimum volume of original cytoplasm enclosed with the plasma membrane. The oocytes without the nuclear material are called "cytoplasts."

Applications:

- Elimination of mutated mtDNA. This means that the GV is isolated from the cytoplasm containing mutated mtDNA and transferred under the zona pellucida of another oocyte that was enucleated previously and contains normal mtDNA. The introduction of GVs into cytoplasts is typically induced by electrofusion. The reconstructed oocytes are then cultured in vitro until they reach metaphase II stage when they are fertilized. The question that remains is how to eliminate the residual karyoplast mitochondria.
- Maturation arrest. Exceptionally, the collected oocytes are immature even after hCG stimulation, and they do not undergo GVBD in culture. We may suppose that their cytoplasm is defected and unable to produce some essential cell cycle regulation factor. In theory, this problem can be solved by transferring GVs from oocytes with defected cytoplasm into cytoplasm (cytoplasts) obtained by enucleation of normal oocytes. The reconstructed oocytes will be then matured in vitro. Possibly, the isolated GVs could be transferred into more maturation-advanced cytoplasts, i.e., obtained by enucleation of oocytes undergoing GVBD but before the exit from MI. Under the influence of cytoplast's chromosome condensation activity (CCA), GVBD will be induced, and chromosomes will condense and subsequently reach MII stage. However, it must be noted that transfer of less developmentally competent GVs with chromatin nonsurrounded nucleoli (NSN) will not increase developmental competence of reconstructed oocytes.
- Elimination of aneuploidies. The percentage of aneuploidies increases with the age of patients. Thus, it has been originally suggested that transfer of GVs from "old" oocytes into "young" oocyte cytoplasm will eliminate this problem. Experiments in the mouse however did not support this presumption.
- Repairing evidently defected oocytes. The gross morphology of some collected oocytes is sometimes evidently abnormal (e.g., their cytoplasm is not homogenous). Logically, even if these oocytes are able to mature, we cannot expect that further embryonic development will be normal. Theoretically, healthy-looking oocytes can be produced by GV transfer.

Above, we have mentioned some possible applications of GV transfer. Technically, and of course with some experience, this approach is rather simple. GVs can be located in the cytoplasm very easily without special optics (mouse, human). Moreover, GV karyoplasts can be efficiently stored in liquid nitrogen and used later on if, for example, the recipient cytoplasts are not available at the same time [16]. The main disadvantage is the fragility of immature oocytes. However, the reconstructed oocytes mature well in culture, and even some offspring were obtained in the mouse. At the same time, we must bear in mind that the period of GVBD seems to be very important for very early postfertilization steps—e.g., it has been shown to be important for the demethylation of paternal DNA—and it remains to be determined how and to what extent the embryonic development and normality of offspring will be influenced if GV transfer schemes are used to produce offspring.

73.5.3 Maturing Oocytes

The oocytes undergoing GVBD and not yet achieving the metaphase II stage are designated as "maturing." Saying simply, these oocytes can be either at prometaphase, metaphase I, anaphase I, or telophase I. Anaphase and telophase I stages are rather short, and for this reason, their manipulations will not be discussed here. The maturing oocytes can be obtained either from stimulated follicles (i.e., in humans after approximately 24 h post-hCG) or possibly when oocytes are cultured in vitro, again after approximately 24 h postinitiation of culture. Because in this case the oocytes underwent GVBD in follicles, their quality is much higher when compared to completely in vitro matured oocytes and is essentially the same when compared to completely in vivo matured oocytes. Another important point is that the absence of cumulus cells that must be removed prior to manipulation has a minimum influence on the final stages of oocyte maturation. Compared to immature oocytes, the maturing oocytes are refractory to damage. The main disadvantage is a very poor visibility of chromosome groups. This problem can be overcome, for example, when oocytes are stained with some vital DNA stains (Hoechst) and then irradiated with UV light. In human-assisted reproduction, we recommend the use of

PolScope optics enabling the visualization of spindles without UV.

Applications:

- In theory, the elimination of abnormal segregation of chromosomes during the anaphase to telophase I transition due to the inability of the original oocyte cytoplasm to deacetylate histones
- To overcome the possible metaphase I arrest

It is our opinion that this approach will be used only exceptionally (i.e., to overcome metaphase I arrest). Its further use and possible justification need additional studies not only in laboratory animals and ungulates. For example, it is critical to analyze the histone deacetylation processes in human oocytes and if the proper deacetylation can be indeed induced by transferring the chromosomes into appropriate cytoplasts.

73.5.4 Mature Oocytes

As mentioned above, human oocytes are mostly collected as mature, i.e., metaphase II staged. Logically, their maturation in follicles secures their best quality, although we cannot exclude that an abnormal follicular environment (hormone levels) especially in older patients is responsible for a compromised oocyte quality and the incidence of oocyte aneuploidies. As for MI, the mature oocytes (MII) are refractory to damage. Essentially, the manipulation of these oocytes is very similar to MI oocyte manipulation.

Applications:

- Elimination of mutated mtDNA by isolating metaphase II chromosome group from the cytoplasm with mutated mtDNA and its transfer into cytoplasts with normal mtDNA. This can be either done by electrofusion of karyoplasts with cytoplasts or by direct injection of a spindle with chromosomes into the cytoplast. The spindle isolation and reinjection, however, require considerable manipulation skill as the cytoplast can be easily destroyed. On the other, the isolated spindle contains only a minimum of mitochondria (possibly with mutated DNA).
- Overcoming the metaphase II arrest. In some rare cases, the mature oocytes are not activated by fertilizing (injected) sperm for unknown reasons (not globozoospermia). If the cytoplasm is responsible for this aberrant behavior, then in theory, this problem can be solved by transferring the MII group into normal cytoplasts.
- Eventually, if ovulated oocytes are evidently morphologically abnormal, their metaphases II can be transferred into cytoplasts obtained by enucleation of high-quality mature oocytes.

The main advantage of MII oocyte manipulation is that oocytes at this stage are generally more available. The main problem is that they can be easily activated parthenogenetically, especially when they are aged. This can be eliminated by omitting calcium from the manipulation media. It must be also tested if MII karyoplasts can be stored in culture or in liquid nitrogen without considerable damage and used for transfer after thawing.

73.5.5 Zygotes

In fact, the transfer (exchange) of pronuclei (PNs) between mouse zygotes was the first approach demonstrating the power of micromanipulation methods [17]. From a technical point of view, it is almost similar to GV-stage oocyte manipulation. The only difference is that PN-staged embryos are very resistant to damage and PN karyoplasts fuse very efficiently to cytoplasts when electrofusion is used (when compared to GV karyoplasts × GV cytoplasts fusion). There is, however, one very serious ethical aspect when we consider the use of this approach in humans. For pronuclear transfer, we need the same developmental stage cytoplasts, i.e., one-cell-stage embryos from which their own pronuclei will be removed. This actually means the destruction of the recipient embryo (possibly this might be considered by some people as to be "a new life"). This problem can be eventually overcome by transferring both pronuclei into cytoplast prepared from parthenogenetic zygotes. It is, however, our opinion that this combination will not be widely used in human ART.

73.5.6 Cytoplasmic Transfer

The cytoplasmic transfer in human-assisted reproduction has been pioneered by Barritt and his coworkers [18]. The primary aim was to improve developmental potential of oocytes which were evidently morphologically abnormal and to enhance their developmental potential after fertilization. Thus, a certain volume of cytoplasm from healthy oocytes has been injected into abnormal oocytes either separately or along with the fertilizing sperm. This procedure led to the production of several children, some of them with mitochondrial heteroplasmy (a situation when two or more distinct mitochondrial populations coexist within one cell). This clearly demonstrates that the injected volume of healthy cytoplasm transferred cannot secure the elimination of mutated mtDNA in the patient's oocyte. Furthermore, relatively high incidence of chromosomal abnormalities and certain birth defects led to the ban of this technique in ART.

73.5.7 Transfer of Organelles

Mammalian oocytes, as nearly every cell, contain many organelles, but their separate transfer or the exchange between oocytes is very difficult because they are practically invisible. The only exception is the nucleolus (nucleolus precursor body—NPB) which is well visible, for example, in human and mouse GV-staged oocytes. At this stage, typically only one nucleolus can be observed in the GV. On the other

hand, pronuclei in human zygotes contain several nucleoli, and this, of course, complicates their manipulation. The nucleolus becomes disassembled concomitantly with GVBD, so it cannot be detected in maturing or mature oocytes, and the nucleolar material is dispersed largely in the cytoplasm. It becomes visible again after chromosomes decondense and pronuclei are formed. In humans, it has been convincingly demonstrated that the number, distribution, and position of nucleoli can serve as an indicator of further embryonic development [19]. This brings a question whether nucleoli can be eventually transferred into zygotes with abnormal nucleolar pattern, with the aim to enhance their developmental potential [20].

The nucleolus can be relatively easily removed (enucleolation) from GVs of fully grown mouse oocytes. Similarly, mononucleolar mouse pronuclei can also be enucleolated. The oocytes or embryos without nucleoli do not develop, but when the nucleolar material is reinjected into previously enucleolated oocytes (zygotes), their developmental potential is restored [21]. Interestingly, when the nucleolus is injected into an interphase cytoplasm, it is rapidly targeted into nuclei. This significantly simplifies the whole possible nucleolus transfer procedure. The nucleolus, however, is not a separated entity residing in nuclei. As we already mentioned, the close association of chromatin and nucleolus (surrounded nucleolus) is a good marker of oocyte maturation competence. This association can be also observed in zygotes. It remains to be answered if the same or equivalent association will be established after the transfer of nucleolar material and how important is this association for complete embryonic development.

73.6 Future Implications and Concerns

The aim of this chapter was not to review exhaustively the field of oocyte and embryo manipulation methods. This has been done beautifully in some recent articles and book chapters [11–13]. Thus, we rather wanted to navigate the scientists and clinicians in this field and highlight especially those articles where relevant manipulations are described in depth. Essentially, these methodological articles deal mostly with mouse oocytes and embryos, but in general, the same can be performed, of course, with some minor modifications, also in human oocytes and embryos. As we mentioned above, we strongly recommend good training with laboratory animals and ungulate oocytes. From the technical point of view, the basic micromanipulation approaches are simple, and they only need some skill. On the other hand, there are some important questions that need to be answered before these methods can be used in human-assisted reproduction. The key question is how safe are these approaches? The fragmentary information we have mostly from animal experiments is clearly insufficient. However, for example, Takeuchi et al. reported a higher incidence of abnormalities in mouse offspring originating from GV transfer oocytes [22]. It is, on the other hand, well known that the mouse is very sensitive to different manipulations and culture conditions. Similarly, the increased incidence of chromosomal abnormalities and epigenetic defects has been observed in children from oocytes injected with foreign cytoplasm. Was this the effect of cytoplasmic injection, or was this the main reason that the injected oocytes were rather abnormal? Clearly, some additional experiments with the evaluation of offspring born are necessary here. In conclusion, the recent article by Tachibana et al. [23] where metaphase II chromosomes from the cytoplasm containing mutated mtDNA were transferred into cytoplasts with normal mtDNA with two healthy offspring obtained clearly demonstrates the power of micromanipulation approaches and the area of their possible clinical application in future. The first step we can find, according to our opinion, in the paper published by Craven et al. [24] is demonstrating the feasibility of pronuclear transfer in human zygotes and describing how the reconstructed zygotes further develop in culture.

Review Questions

1. How do the aberrations in histone acetylation/deacetylation process affect the oocyte aneuploidies?
2. What are the problems that can be solved by the nuclear and cytoplasmic transfers?
3. What are the concerns with the nuclear and cytoplasmic transfers?

Learning Objectives

- To know some of the data in animal models showing a relationship between the conditions of in vitro embryo culture and the phenotype of the offspring
- To know some of the data suggesting that in vitro embryo culture of human embryos may have an effect on the phenotype of the children born
- To know some of the data suggesting the composition of embryo culture media may have an effect on the phenotype of the children born
- To know other factors during in vitro embryo culture that may have an effect on the phenotype of the children born

74.1 Brief Background

Children born after assisted reproduction technology (ART) have a higher frequency of premature birth and low birth weight and a higher malformation rate, and there is evidence for an increased tendency for cardiovascular and endocrine disturbances. It is important to understand what extent is this due to maternal and paternal factors and what is the contribution of assisted reproduction as such?

In vitro fertilization (IVF) or in vitro culture (IVC) is one element of ART that is very different from what happens during natural conception. In animal models, ART has been shown to induce a shift in the phenotype of the offspring. In the human, we still need data from high-quality studies to be able to draw from conclusions.

Neither in animal nor in human studies has IVF or IVC been shown to change the genome (DNA) of the offspring. IVF or IVC does not seem to increase the frequency of mutations or chromosomal structure in the offspring. The discussion is to what extent the genetic information is used differently in the offspring. In other words, is there shift in phenotype in children born after ART? Change of phenotype here is understood as ranging from a change in the expression of genes and proteins in early embryos, changes in foetal growth trajectories, changes in physiological and endocrine parameters and psychosocial and psychomotor development. The current chapter will focus on the potential role of embryo culture and embryo culture media in modulation of the phenotype of the offspring after ART.

74.2 Influence of Nutrition of the Embryo Around the Time of Implantation

More than 50 years ago, a Norwegian county doctor working in the north of Norway made a pioneering observation. He could demonstrate that the nutritional and socioeconomic status during pregnancy in periods 1890s to 1920s had an influence on the likelihood of cardiovascular problems 40–60 years later [1, 2]. Based on this and his own observations, David Barker later formulated the DOHaD (Developmental Origins of Health and Disease) hypothesis [3]. It is now well documented that the nutritional status of the prospective mother at the time of implantations and in early pregnancy will have an effect on the health and development of the offspring [4–7]. In rodents it is demonstrated that even slight variations in the diet at the time of implantation will have an effect on cardiovascular parameters after birth [8, 9]. The composition of the intrauterine fluid is influenced by the diet of the mother changing the in vivo "embryo culture media" [10].

The (Forsdahl)-Barker hypothesis may be understood as a physiological response of the embryo to environmental factors [11]. This is most likely mediated through epigenetic change that may persist also in later generations [12–17].

In the light of the DOHaD hypothesis, one important question is to what extent will assisted reproduction including in vitro fertilization and embryo culture have an influence on the phenotype and the future health of children born.

74.3 The Effect of In Vitro Fertilization and In Vitro Embryo Culture in Animal Models

In ruminants, it is well known that fertilization and culture of embryos in vitro can lead to a change in phenotype such as increased birth weight, increased gestational length, pre- or perinatal death and large offspring syndrome [18–20]. In sheep, foetal overgrowth is thought to be due to dysregulation of the IGF2R gene [19].

In mice, in vitro fertilization results in changes in many organ systems. The effects of IVF and in vitro culture seem also to be dependent on the genetic background since different strains will show different effects. The changes observed range from change in gestational or body weight, low embryo viability, organomegaly, Type 2 diabetes and subfertility [21, 22] as well as behavioural changes such as hyperactivity [13, 14], reduced anxiety, poor spatial memory [23] and delayed preweaning and neurodevelopment [24]. In mice, a transgenerational effect on methylation of DNA and histones can be demonstrated [13, 14]. Culture of the embryos to the blastocyst stage will change the postnatal epigenome in mice including raised blood pressure and change in cardiovascular parameters.

74.4 Assisted Reproduction in Humans

Children born after IVF or ICSI have higher frequency of premature birth, lower birth weight, higher perinatal mortality and increased rate of malformations [11, 25–32]. Reduced birth weight is in general an indication of impaired foetal growth [33]. Malnutrition and smoking during pregnancy are linked to reduced birth weight and long-term effect on the health of the offspring. If the reduced birth weight of ART children per se is an indicator of long-term health consequences remains to be seen. At 2–3 years of age, the body weight of ART children is within the normal range indicating a catch-up growth in the first year of life [34].

A consistent finding in ART children is altered cardiovascular parameters. Similar to the observations in animal models, offspring after ART have shown increased blood pressure and changes in several cardiovascular parameters and suggest a cardiovascular remodelling during pregnancy that also persists after birth [35–39]. Glucose metabolism also changes accompanied with changes in insulin and IGF-I levels [40, 41]. These changes may suggest a predisposition for insulin resistance [42]. Blood lipids and body fat distribution are changed, and bone length in 7–8-year-old children is increased [35, 41, 43]. Entry into puberty seems to occur earlier in girls born after ART compared to children born after normal conception [44].

74.4.1 Change in Phenotype of the Offspring After ART in Humans: The Chicken or the Egg?

It is likely that there is a lot of factors that may contribute to the effects on the phenotype of the offspring after ART. Maternal and paternal genetic factors as well as obesity, maternal nutrition and recreational drugs may contribute to the phenotype of the offspring [45–47]. Infertility as such is associated with pregnancy complications such as pre-eclampsia, premature birth and increased malformation rate [48–52]. Ovarian stimulation and non-IVF ART will influence postnatal growth [53–55].

It is difficult to entangle the effect of ART as such from the effects of the population treated. One elegant approach to this problem is looking at couples that have two singletons, one from ART and one from a natural conception. A Norwegian registry study compared 4408 sibling singletons conceived either by ART or natural conceptions [32]. This registry contains information about confounding factors so the researchers could adjust for many of the factors that are known to influence outcomes such as gestational length, birth weight and neonatal morbidity. The study also compared the 4408 siblings with over 1.1 million children born in the same period after normal conception. The study confirmed previous observations that ART children are born earlier and have lower birth weight compared to natural conception. When comparing two singleton siblings born of the same mother, one after ART and one after natural conception, the difference was not anymore significant [32]. This study design was later used in a larger Danish study looking at 7758 siblings. They could demonstrate a small but significant difference between the ART sibling and the sibling born after normal conceptions; the ART sibling was born on average a little earlier and had a little lower birth weight [56].

ART is associated with an increased frequency of various placental pathologies such as placenta praevia [57], velamentous and marginal cord insertion [58] and pre-eclampsia and hypertensive disorder [29, 59, 60]. Using the model with sibling singletons, one after ART and the other after normal conception, Romundstad et al. could clearly demonstrate the major contributor to the increased frequency of placenta praevia is the ART procedure itself [57].

74.4.2 Is a Change in the Epigenome a Mediator of ART-Induced Changes in Phenotype?

After fertilization, large changes in methylation patterns and the epigenome take place [61], and the periconceptional environment is shown to modulate this process [62]. Embryo culture changes gene expression and phenotype [63–65]. Specifically, suboptimal culture conditions will have an influence on the epigenome of the embryo and the offspring [66], and different embryo culture media have different effects on the expression profile in embryos [67–69]. The data from animal studies are rather extensive showing that the nutrients available to the embryo around the time of implantation can have long-term consequences for development and postnatal health [8, 70]. It is likely that this is mediated through epigenetic changes, and it has been demonstrated that in vitro culture of animal embryos may have consequences for the maintenance of embryonic epigenome in the mouse [22, 71] and possibly also in humans [11, 19, 72–74]. It has been demonstrated that genes controlling growth such as IGF2/H19 and IGF2R are differently methylated after ART compared to natural conception leading to the large offspring syndrome [75–77]. Also in humans it has been demonstrated that ART led to changes in DNA and histone methylation [78, 79]. Children born after assisted reproduction show various epigenetic changes which is ascribed to the ART process [73, 80–84]. The placental epigenome is different in pregnancies after ART [85].

A study of global DNA methylation levels in the placenta of pregnancies after assisted reproduction revealed significant differences related to the conditions in the ART laboratory. Treatment-related factors like O_2 concentration during culture, conventional IVF versus ICSI, culture length (3 days versus 5 days) and cryopreserved versus fresh embryos had their specific effects on the methylation levels [86].

74.4.3 Children Born After ART: A Slightly Different Phenotype?

The changes in phenotype observed in children born after ART are not entirely similar to known syndromes or diseases such as childhood diabetes-I. Cardiovascular parameters and glucose metabolism suggest an increased long-term health risk, while the blood lipid profile an body fat distributions suggest the opposite. It is therefore difficult to predict the health profile of ART children when they become 50–60 years old. They may be similar to children exposed to famine in early foetal life; they may have a health profile within the normal range or have a health profile different from what we have seen until now, but not necessarily to the worse [41, 87].

74

74.5 In Vitro Culture of Human Embryos, an Effect on Phenotype of the Offspring?

Available evidence from animal and human studies shows that in vitro fertilization and embryo culture are associated with phenotypic changes. Putative contributors to this are procedures such as ICSI and cryopreservation, physiochemical factors, pollutants and the composition of embryo culture media (Table 74.1).

74.5.1 Embryo Culture

74.5.1.1 Gas Phase

In the fallopian tube, the oxygen concentration is around 5% and lower that in the ambient air. In the early days of IVF, fertilization and embryo culture was performed with reduced oxygen concentration. This was abandoned, largely out of convenience and cost and the majority of clinics culture embryos with 20% oxygen. Currently, there is accumulating evidence that the culture in 5% oxygen gives better development rates, better embryo quality and, in some studies, better pregnancy rates compared to 20% oxygen [88–94]. Similarly to other cell types, embryos have a system that regulates expression of many genes in response to the oxygen concentration in the cell [95–98]. In human embryos, the gene expression profile in embryos cultured at 20% O_2 is different from that of embryos cultured in 5% O_2 [69]. A complicating factor is that it seems that the effect of varying the O_2 concentration on the gene expression profile of human embryos also is dependent on the culture media used [68].

74.5.1.2 Temperature

In human IVF, gametes and embryos are exposed to changes in temperatures and pH that they do not encounter in vivo. Oocytes are very sensitive to reduced temperatures due to instability of the meiotic spindle. Already at temperatures around 30 °C, the spindle breaks down and shows limited capacity to reassemble following warming up to 37 °C again [99, 100]. Zygotes and embryos tolerate temperature fluctuations better, but each time the temperature is outside the physiological range, embryo metabolism is affected. Data suggest that in vivo, the temperature in the female reproductive tract is slightly lower than 37 °C [101]. A prospective randomized study comparing culture at 36 or 37 °C did give different results in terms of blastocyst development rates [102].

74.5.1.3 pH

The pH in the fallopian tube changes throughout the menstrual cycle, 7.1–7.3 in the follicular phase and rising in the luteal phase due to accumulation of HCO_3^+. It may be argued that early embryos are adapted to a high rather than a low pH. The internal pH in oocytes is 7.4, and cleavage-stage embryos have less capacity to compensate for acidic

Table 74.1 Summary of effects of in vitro fertilization and in vitro embryo culture on the phenotype of the offspring in two animal species and humans

Species	Intervention	Effect
Rodents and ruminants 	In vitro fertilization and in vitro culture	Effects on epigenome including transgenerational effects Changes in foetal growth, gestational length and birth weight Low embryo viability, increased perinatal morbidity and mortality Organomegaly, Type 2 diabetes, changes in cardiovascular parameters, behavioural changes
	Composition of culture media	Influence on embryo epigenome
Humans 	In vitro fertilization and in vitro culture	Reduced gestational length and birth weight Increase in placental dysfunction
	Extended in vitro culture (blastocyst)	Increase in birth weight, increased malformation rate
	Cryopreservation of embryos	Influence on embryo epigenome Increased birth weight, increased perinatal morbidity
	Culture with 20% O_2 compared to 5% O_2	Influence on embryo epigenome
	Composition of culture media	Influence on embryo epigenome Influence on birth weight

challenge than alkaline challenge. It is only at the blastocyst stage that embryos attain the capacity also to compensate for acidic challenges [103].

It is still unclear what effect, if any, the transient changes in temperature and pH have on the phenotype of embryos or the offspring. One can argue that environmental stress in general is less desirable and should be avoided.

74.5.1.4 Air Quality and Organic Pollutants

In animal models, a variety of organic pollutants have been shown to induce a shift in the phenotype of the offspring. A classical model is a mouse where the expression of the Agouti gene is regulated by methylation in the promotor region. This model can be used to look for factors that may change imprinting and gene expression during embryo culture [65, 104]. Bisphenol A is an endocrine disruptor and modulator of gene expression and will influence the phenotype of the offspring if present at sufficient concentrations in the culture period [104]. Bisphenol A is almost ubiquitous, and the concentration in the urine of women undergoing IVF has been related to their reproductive health [105]. Bisphenol A is used in the manufacture of a variety of plastic components including polycarbonate plastic intended for in vitro culture. To what extent this has been or is an issue for IVF laboratories is not known, but at least when using culture ware intended for human IVF, bisphenol A concentration during embryo culture seems to be low [106]. Volatile organic compounds (VOCs) are present in ambient air. Urban air and indoor air may contain concentrations of these components high enough to influence growth of embryos in vitro. Each IVF lab must evaluate the quality of the air in the laboratory as well as any gas used for the incubators [107] .

Culture Length

Days in culture may have an effect on phenotype. Several reports indicate that there is a difference between transfer of cleavage-stage embryos and blastocysts. Concerning implantation rates, many clinics claim that they have higher implantation rates after blastocyst transfer compared to cleavage-stage transfer. This may increase the rate of elective single embryo transfer that has been clearly shown to be beneficial for the health of the offspring [108, 109].

An argument against blastocyst transfer is the slightly higher incidence of pregnancy complications and concerns for the health of the offspring. In pregnancies following blastocyst transfer, the frequency of pre-eclampsia is moderately increased compared to pregnancies after transfer of cleavage-stage embryos [110]. There is an increased frequency of preterm birth [111, 112], but despite this, the birth weights are slightly higher, and the frequency of offspring large for gestational age (LGA) is increased following blastocyst transfer [113, 114]. This difference may be partly explained by the skewed sex ratio in favour of males [115, 116]. The rate of congenital malformations is slightly higher after blastocyst transfer [117]. Published data are not in agreement concerning a putative increase in the rate of monozygotic twins after blastocyst transfer [118]. It is possible that this conflicting result is that the rate of monozygotic twins is dependent on culture factors [119]. On the positive side, blastocyst culture allows embryos to be self-selected. The ability to grow to a normal blastocyst with good morphology is a sign of embryo competence. If it is indicated to perform embryo biopsy, a trophectoderm biopsy at the blastocyst stage is less harmful to the embryo than removal of a blastomere at the cleavage stages [120]. High survival and post-warming implantation rates have been obtained after vitrification of blastocysts [121]. For many ART clinics, the positive sides of blastocyst culture are perceived to be more important than the negative aspects, and culture to the blastocyst stage is the preferred option.

Cryopreservation

Gene expression studies have found a difference between cryopreserved/thawed embryos and fresh embryos [122]. A consistent finding is that transfer of cryopreserved embryos (FET) is associated with an increase in birth weight, an increase in the frequency of macrosomia and offspring being large for gestational age (LGA) [113, 123, 124]. Despite the fact that the body weight of children after FET is more similar to children born after normal conception, they have an increased frequency of perinatal morbidity and mortality compared to children after normal conception [49, 124, 125]. A study of singleton siblings born after ART, one after transfer of fresh embryos and one after cryopreserved embryos, shows clearly that it is the cryopreservation of embryos that is associated with the increased birth weight of the offspring [126].

Initial reports indicated that pregnancy and delivery complications were more frequent after transfer of vitrified blastocysts compared to slow-freeze [127]. Later reports could not confirm this, and vitrification of blastocyst does not seem to negatively affect pregnancy and delivery complications and neonatal health [128–130].

74.5.2 Embryo Culture Media

The embryos undergo a complete remodelling of its genome and epigenome during development from fertilization to the blastocyst stage. At the blastocyst stage, cells are allocated to the trophectoderm (TE) and the inner cell mass (ICM) lineages [83]. Culture condition including culture media may modulate these events and have an influence on the foetal growth and subsequently the birth weight.

All cells, including early embryos, have the ability to adapt their gene expression and metabolism to the available nutrients. Amino acids and glucose are particularly important, using the AMP-activated and mTOR-related kinases to exert the effect on the epigenome [131, 132]. A culture media low in nutrients may induce epigenetic changes that promote a thrifty phenotype. When the embryo is transferred to the high-nutrient environment in the uterus, this may lead to overgrowth. The reverse may also occur when the in vitro culture media are very rich in nutrients.

In the beginning, culture media for human IVF ranged from simple salt solutions such as Earle's or Tyrode's solution, quite often prepared by the ART laboratory, to commercially generic tissue culture media such as HamF10. These media were usually supplemented with serum or protein extracts of animal or human origin. It is perhaps surprising that even after nearly three decades of commercial production of embryo culture media, there is little standardization. Many ART laboratories use combinations of culture media from different manufacturers: aspiration media from one manufacturer, fertilization media from a different manufacturer and cleavage stage from still another source, etc. This is unfortunate since most manufacturers try to harmonize their different products to avoid a too abrupt change in the composition of the environment when moving zygotes and embryos from one step in the process to the next. Mixing of different media systems also makes it difficult to evaluate a relationship between the composition of a given culture media/system and phenotype of the offspring.

Commercially available culture media vary widely in their composition [133]. ◘ Table 74.2 shows the composition of two commercially available embryo culture media; one of them contains 13 ingredients and the other over 80 ingredients. These ingredients are generally added as various salts, and the concentration of each of them might vary between the commercially available culture media. These culture media differ in the content of substances like amino acids and vitamins which is known to influence methylation levels and the epigenome [134, 135]. With such a big difference in the composition of culture media, it should come as no surprise that the embryos respond differently when it comes to expression of genes. This is clearly illustrated in a study by Kleijkers et al. Human zygotes and embryos were prospectively randomized to be cultured in either human tubal fluid (HTF), a relatively simple culture medium, or Vitrolife G5, a modern relatively complex culture medium. Embryos not selected for transfer or cryopreservation at Day2/3 were cultured to Day 6 and then analysed for genome-wide gene expression [68]. ◘ Figure 74.1 shows the differential gene expression in embryo culture in the two culture media in the study of Kleijkers et al. Only genes with a differential gene expression above 5 (5 times more) or below 5 (5 times less) in embryos cultured in G5 compared to embryos cultured in HTF are shown in ◘ Fig. 74.1. It is still unknown whether such a difference in the gene expression profile blastocyst cultured in vitro has any long-term consequences for the health of the offspring.

From animal experiments, ammonium build-up in culture media may have an effect on the phenotype of the offspring [136]. The ammonium stems from breakdown of amino acids, glutamine in particular. This is primarily a non-enzymatic reaction that occurs faster at 37 °C than at 4 °C. One way of alleviating this problem is to add glutamine as a dipeptide which is chemically more stable [137]. Looking at modern embryo culture media, the rate of ammonium build-up at 37 °C varies considerably between different media from negligible to a rapid increase of ammonium up to levels known to have a potential influence on the offspring [138]. This fact should be taken into consideration concerning choice of both culture media and of culture protocols.

◘ **Table 74.2** The chemical composition of two commercially available embryo culture media. One "simple" in the sense that it contains few ingredients, the other "complex" with many ingredients. Protein supplements such as hSA are added to both culture media

Simple	Complex						
Bicarbonate	Adenine	Cobalt	Folic acid	L-Aspartate	L-Threonine	Pantothenate	Sulphate
Calcium	Ascorbic acid	Copper	Gentamicin	L-Cysteine	L-Tryptophan	Penicillin	Taurine
Chloride	Aurintricarboxylic acid	Cyanocobalamin	Guanine	L-Glutamic acid	L-Tyrosine	Phenol red	Thymine
Citrate	Acetic acid	Citrulline	HEPES	L-Glutamine	L-Valine	Phosphorus	Thiamin
D-Glucose	Aluminium	Chromium	h-r-Insulin	L-Glycine	L-Ala-L-Glut	Potassium	Thioctic acid
Magnesium	Bicarbonate	Cytosine	Hypotaurine	L-Histidine	Linoleic acid	Putrescine	Uracil
Penicillin	Calcium	D-Biotin	Hypoxanthine	L-Isoleucine	Magnesium	Pyruvate	Vanadium
Phenol red	Citrulline	D-Glucose	Inositol	L-Leucine	Manganese	Pluronic-F-68	Zinc
Phosphate	Cholesterol	D-Pantothenate	Iron	L-Lysine	Molybdenum	PVP 10	
Potassium	Choline	EDTA	Lactate	L-Methionine	Nickel	Pyridoxine	
Sodium	Chloride	Ethanol	L-Alanine	L-Phenylalanine	Nicotinamide	Riboflavin	
Streptomycin	Citrate	Ethanolamine	L-Arginine	L-Proline	Ornithine	Selenium	
Sulphate	Cobalamin	Estradiol	L-Asparagine	L-Serine	Maleic acid	Sodium	

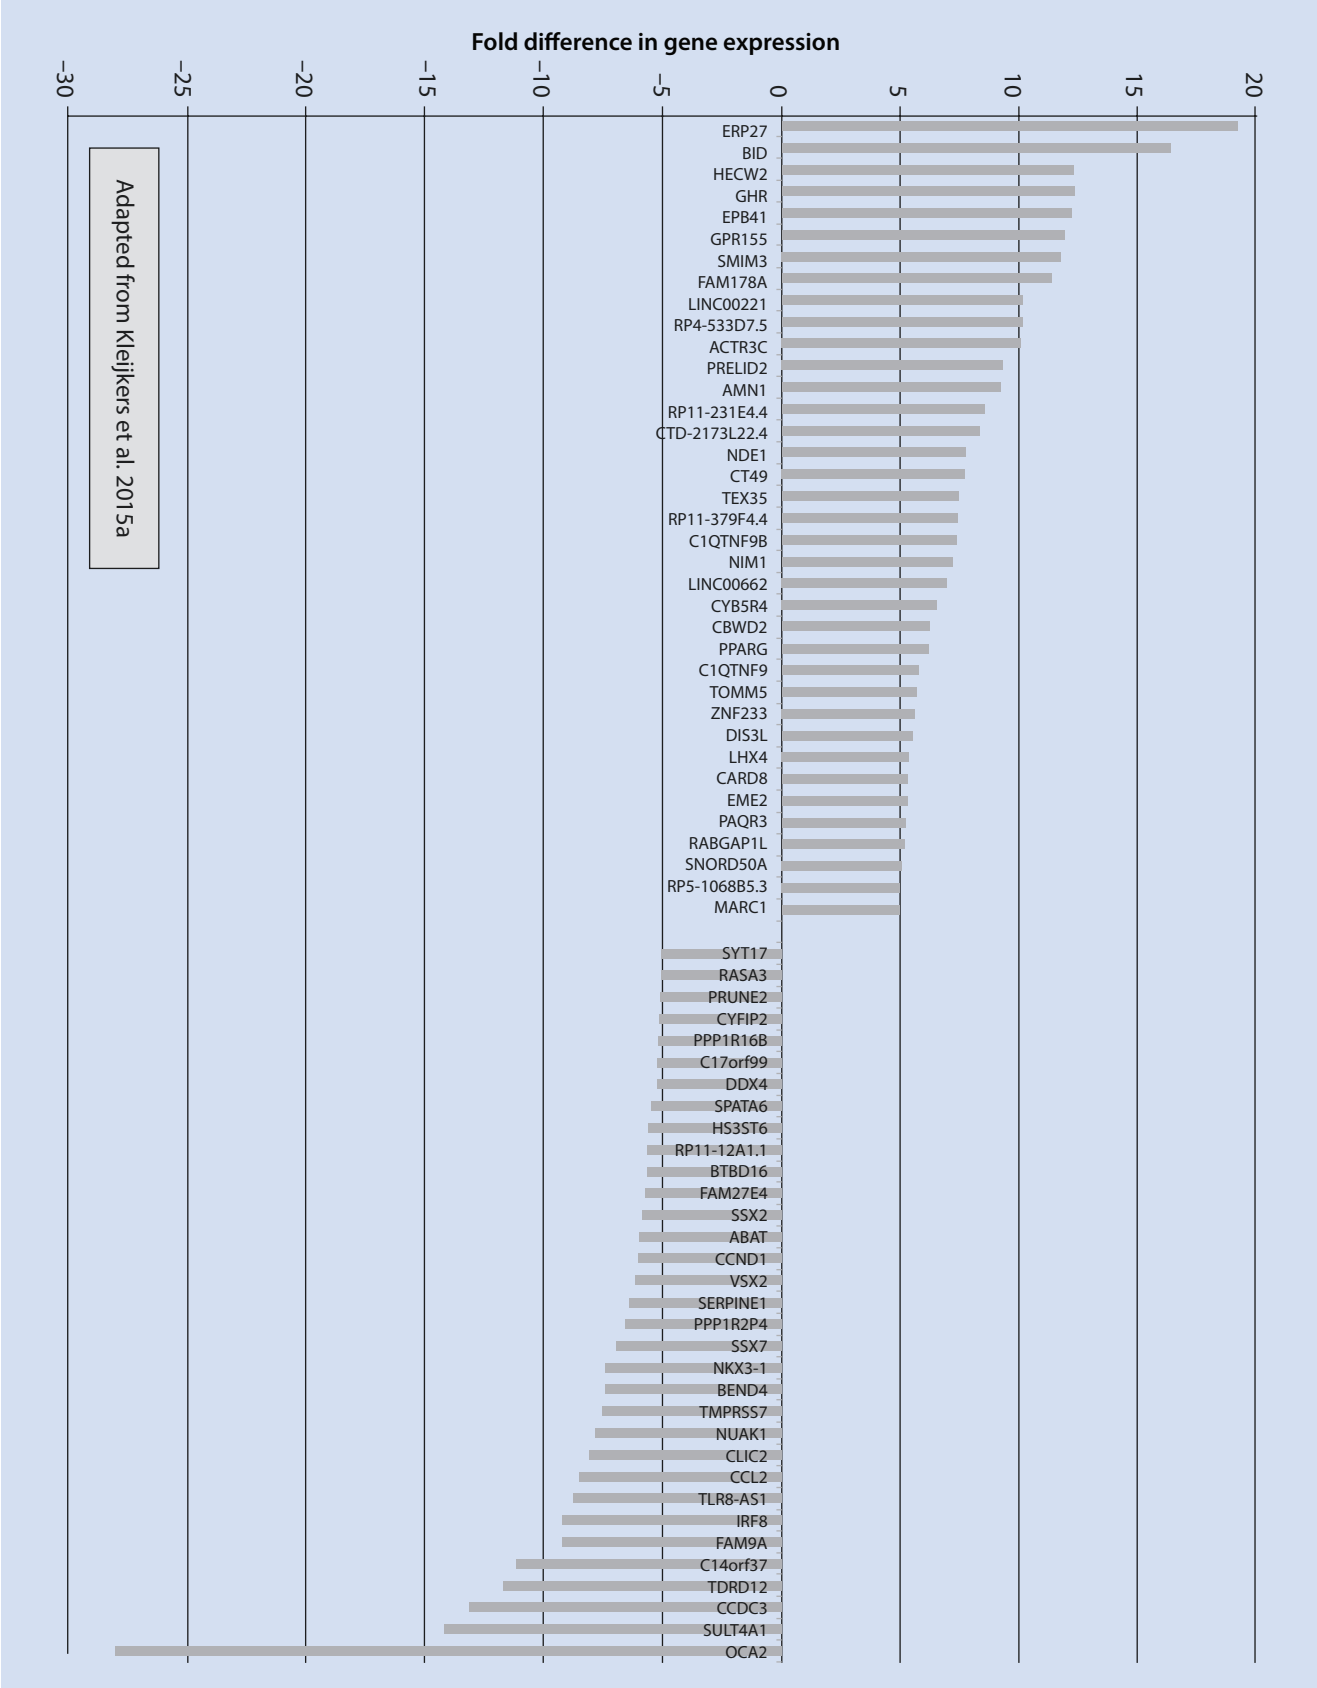

Fig. 74.1 Differential gene expression between blastocysts cultured either in Vitrolife G5 Plus or human tubal fluid (HTF). Only genes showing a more than fivefold difference in gene expression are shown in the figure. Positive values: five higher expressions in embryos cultured in G5 relative to embryos cultured in HTF. Negative values: expression lower in embryos cultured in G5 compared to HTF. (Adapted from Kleijkers et al. [68])

In some commercially available culture media, peptide growth factors such as insulin and granulocyte colony-stimulating factor (GC-CSF) have been added in relatively high concentrations. Growth factors may alter embryonic growth and lineage allocation to the inner cell mass (ICM) or trophectoderm (TE). In animal models, the presence of insulin in the embryo culture media will change the expression of imprinted genes [139]. In vivo, embryos are exposed to many growth factors in a timely fashion both concerning concentrations and timing in relationship to developmental status. Deliberately adding potent growth factors in superphysiological concentrations to embryo culture media should therefore be done with utmost care.

Most embryo culture media are supplemented with protein supplements. These supplements also vary in their chemical composition and will contain variable amounts of bioactive molecules [140, 141]. Commercially available protein supplements usually contain octanoic acid as a protein stabilizer. In animal experiments, octanoic acid is demonstrated to influence the phenotype of the offspring when used in the same concentrations as in human embryo culture [142]. Moreover, the source of protein supplements may also influence the phenotype of the offspring. In a retrospective study, Zhu et al. noticed that the birth weight of the offspring was related to the protein source added to the embryo culture media [143]. A protein supplement such as hSA contains amino acids including glutamine. Ammonium build-up is one possible explanation for the observation that the birth weight of the offspring seems to be related to the time since the culture medium was produced. Birth weight of children from embryos that have been cultured in medium close to the expiry date was lower than when embryos were cultured in freshly produced media [144].

74.5.2.1 Embryo Culture Media and the Phenotype of the Children Born

Most retrospective studies have found no differences in birth weights or other characteristics of the offspring related to the culture used for IVF/ICSI. The design and the control groups vary between these studies, and it is difficult to evaluate to what extent one could control for known confounders in these studies. See extensive review by Zandstra et al. [145].

A Danish retrospective study comparing the outcome after IVF/ICSI with different embryo culture media could not find any differences in birth weights. They however reported a significant relationship between birth length and the culture media used [146]. One would assume that Ponderal Index (measure of leanness) also was related to the culture media. In a large registry study, Eskild et al. could demonstrate the different culture media had different effects on placental weights, birth weights as well as placental/birth weight ratio [147].

It is evident that there are many confounding factors when one tries to correlate the chemical composition of a given culture media and the phenotype of the offspring. Many of the known confounders have been mentioned earlier in this chapter. Additionally, it is reasonable to assume that there are confounders yet to be identified. The same challenges face almost any study of a given intervention in ART and the development and health of the offspring. A way around this problem is to do properly designed controlled prospective randomized studies, the gold standard being a multicentre prospective randomized double-blind study, a complicated, laborious and expensive study design but widely recognized as the best concerning controlling for confounders in clinical trials.

One prospective randomized study comparing two single-step media (SSM; Irvine and Global, Life Global) was stopped prematurely due to inferior implantation rates in the SSM group. The children born as a result of the study were followed up until the age of 4.

A worrying find in this study is that psychomotor development of the children differs according to the embryo culture media used [148].

A few properly designed prospective randomized studies looking at a possible effect of embryo culture media on the birth weight of the offspring have been published (Table 74.3). The first study that demonstrated a difference in birth weight was that of Dumoulin et al. published in 2010 [149]. In this study they detected a 245 g difference in birth weight and a significant difference in Z-score between children born after IVF/ICSI and embryo culture either in Vitrolife G1.3 or Cook K-SICM [149]. Carrasco et al. later did a similar, but smaller, prospective study looking at the same two culture media [150]. In this study, the differences in birth weights and Z-score were in the same direction but smaller than that found in the study by Dumoulin et al. and failed to reach significance. Ziebe et al. did a large multicentre study comparing Medicult Embryo Assist with or without added GM-CSF and could not see any differences in birth weights [151]. In 2016, Kleijkers et al. published the outcome after a large multicentre prospective randomized double-blind study conducted in the Netherlands [152]. In this study, a total of 836 couples undergoing IVF/ICSI was prospectively randomized to have fertilization and embryo culture carried out in two different culture media: Vitrolife G5 Plus or human tubal fluid (HTF) supplemented with 10% albumin. Comparing the birth weights of the singletons born, there was a significant difference of 181 gram and a significant difference in the Z-score. Children born after the embryos have been cultured in HTF were the heaviest [152].

Not all studies looking at a possible contribution of the embryo culture media used to the birth weight of the children found effects. This is not surprising. Some of the retrospective studies performed had suboptimal design, and some of the prospective studies were powered only to detect fairly

Table 74.3 Prospective randomized studies looking at possible effect of embryo culture media on the birth weight of children after IVF

Study	Design	Media comparisons	Number of children included	Outcome	*P* value
Dumoulin et al. (2010)	Single centre, open, prospective randomized	Vitrolife G.1 Cook K-SICM	110 78	Birth weight different	$P < 0.005$
Carrasco et al. (2013)	Single centre, open, prospective randomized	Vitrolife G.1 Cook K-SICM	49 49	No difference in birth weight	Not significant
Ziebe et al. (2013)	Multicentre, double blind, prospective randomized	Medicult Embryo Assist with GM-CSF added Medicult Embryo Assist no GC-CSF added	163 141	No difference in birth weight	Not significant
Nelissen et al. (2012)	Single centre, open, prospective randomized	Vitrolife G.1 Cook K-SICM	168 126	Birth weight different	$P = 0.006$
Hassani et al. (2013)	Single centre, open, prospective randomized	Medicult ISM1 Vitrolife G1.5	86 78	Birth weight different	$P < 0.001$
Kleijkers et al. (2016)	Multi centre, double blind, prospective randomized	Vitrolife G5 HTF	184 159	Birth weight different	$P = 0.005$

large differences. It is also entirely conceivable that embryo culture media from two different manufacturers are quite similar in their composition and are least when it comes to ingredients that may have an influence on birth weight. Comparing these two culture media would not reveal any difference. Additionally, birth weight might not be the best estimate to show a culture media-related effect on the phenotype of the offspring [146].

74.6 Summary

In summary, available evidence suggest that embryo culture media may have an effect on the epigenome of embryos, the growth trajectory of the foetus and the birth weight of the child (Fig. 74.1, Table 74.3). It is however far too early to predict the long-term effect on health of the children born. One of the unknowns is the relevance of the shift in birth weight induced by certain embryo culture media compared to other well-known factors like cigarette smoking and malnutrition that also have an influence on foetal growth. Furthermore, we do not have information about which of the ingredients in an embryo culture media that may modulate birth weight or whether the effect(s) are related to the concentration of some key ingredients. Most manufacturers of embryo culture media do not give full information about the composition of their media. This makes it almost impossible to formulate hypothesis concerning cause and effect concerning the relationship between embryo culture and the phenotype of the offspring. This is one of the reasons why the European Society for Human Reproduction and Embryology advocates full transparency concerning the composition of embryo culture media [153].

Review questions

1. What is the likely mediator of the effect of environmental factors around the time of implantation?
2. What is the basic rationale behind the DOHaD hypothesis?
3. Does the composition of embryo culture media play any role in early embryo gene expression?
4. Is the composition of commercially available culture media harmonized?
5. What is the relevance of the DOHaD hypothesis for evaluating the composition of embryo culture media?
6. What is the effect of cryopreservation of human embryos on the birth weight of children born?

Traceability in ART

Tom Beckitt and Tammie Roy

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_75

Learning Objectives

- To introduce the reasons for traceability in assisted reproductive technology (ART) laboratories and the primary reasons for its importance
- To discuss the general concepts of manual and electronic traceability systems
- To provide an overview of the features included within some of the currently available electronic systems
- To present the general expectations of electronic traceability systems
- To propose potential future developments of, and additions to, electronic traceability systems and the value that each progression will bring to the field of ART

75

75.1 Reasons for Traceability in ART

Traceability procedures, including witnessing of processes and sign-off by additional staff members, are integral practice within ART laboratories worldwide.

Traceability is important for the reassurance of laboratory and clinical staff and for maintaining efficient workflow, but in a heavily regulated sector, it is also required to conform to regulations set by national and international authorities. Auditing by regulatory bodies is commonplace, and any instances which signify a failure to comply can result in considerable penalties and, in cases where major non-conformances are discovered, in the closure of ART clinics.

Without the use of adequate witnessing procedures, there have been instances of severe mistakes which have led to the implantation of the wrong embryo and the development of a foetus inside the incorrect patient.

While these major non-conformances are rare and almost all ART clinics consistently adhere to regulations, ensuring compliance using manual, non-electronic systems is often cumbersome and time-consuming. Furthermore, manual witnessing is not the most efficient method when considering laboratory workflow because it does not allow the additional possibility of monitoring activities in the laboratory as part of the standard witnessing procedure.

In contrast, electronic methods not only assist laboratories with adhering to regulations but also provide online, workflow monitoring, enabling staff to see the impending tasks and monitor their progress, providing managers with a tool to assist with scheduling those tasks. In recent times, there have been noteworthy additions to the functionalities included in electronic systems, which have further improved laboratory processes.

75.2 Methods of Traceability in ART

In ART laboratories worldwide, traceability is maintained through the use of either manual procedures or electronic systems.

75.2.1 Manual Procedures

Most manual procedures of witnessing in ART laboratories involve multiple identification of samples by two or more trained staff. Every time sperm, oocytes or embryos are moved, additional employees are required to be able to confirm that each handling step is performed correctly and that the dishes, tubes and other consumables are correctly selected.

Not only are methods such as this time-consuming (often requiring additional signage and paperwork compared with electronic systems), and somewhat inefficient, they also create additional risks in laboratories, such as interrupting other scientists in the course of their duties to identify a sample, or lead to difficulties when minimal staff are working during quiet periods. In the latter of those situations, the presence of a manual witnessing system can mean that additional staff are present for the sole reason of witnessing procedures. This can be costly and, for small clinics, can be a regular occurrence, leading staff to seek less quality-focused methods of overcoming the requirement for witnessing. An example of this is where some laboratory staff check labels on consumables once, look away for a few seconds and then look again to confirm that they are correct. Evidently, this type of process increases the likelihood of human error and of 'involuntary automaticity', where errors occur because laboratory staff see what they expected to see [1]. Therefore, manual procedures should be avoided wherever possible by the implementation of electronic witnessing systems.

75.2.2 Electronic Systems

Electronic witnessing systems aim to further reduce the risk of error during sample handling (increasing peace of mind for laboratory staff) and have the secondary purpose of enabling laboratory workflow to be electronically monitored, ensuring maximum efficiency. There are two types of electronic witnessing, which include the use of either Radio-frequency Identification Labels (RFID) or barcodes and compatible scanners.

75.3 Currently Available Electronic Systems

There are several options available on the market to satisfy the needs of customers wishing to implement an electronic witnessing system, utilising both RFID and barcodes, some of which are briefly summarised below:

RI Witness™ is a product available from Research Instruments which automatically tracks and records data across the whole laboratory using RFID tags contained within consumables and readers contained within microscope stages and incubators. At each work area, a small LCD touchscreen is available to monitor workflow and ensure that traceability of sperm, oocytes and embryos is maintained. Furthermore, media product containers are also allocated an RFID tag,

which ensures that the correct media is used for each and every stage of ART cycles. RFID is unique to RI Witness, and although this innovation has its advantages, it also requires a significant investment from the clinic, both financially – to fit RFID readers into existing equipment – and in terms of downtime, while equipment is adapted and laboratories alter their workflows to incorporate the new system. Clinics must also purchase specific consumables or self-adhesive RFID tags, and as those RFID tags cannot be stored in liquid nitrogen, a separate system must be employed to monitor traceability of cryopreserved samples [2].

Matcher, developed by IMT International, is a barcode system which integrates the use of digital photography within the laminar flow hoods where procedures are performed to capture all of the activities that occur during each ART procedure. At each stop point of the cycle, the consumables are scanned to ensure traceability and ensuring that the correct dishes, tubes and media are being used. This system also has options for workflow management and offers flexibility, as the barcodes can be attached to any existing lab consumable [3].

Trusty™, by Optimal IVF, consists of software which can be loaded onto computers and used to assign a unique number to any patient cycle. This unique ID is then translated to a barcode, which can be printed onto multiple labels for use at all points of ART cycles. Barcode scanners are purchased separately and used to ensure each consumable is correctly selected. The system also eliminates the requirement for paper-based systems by collating all information onto the stand-alone system to maintain traceability [4].

The OCTAX Ferti Proof system by Vitrolife monitors and logs all actions during an ART cycle using a QR code scanning system. As scanning progresses throughout the day, batch numbers of consumables are recorded, and reports can be generated accordingly, in order to monitor workflow. Similarly to the other electronic systems available on the market, Ferti Proof removes the need for paper-based documentation. This system requires some printers and scanners to be purchased and distributed throughout the clinic, and thus there is some capital investment required; however, the overall amount required is significantly less than for an RFID-based system [5].

Gidget, available from Genea Biomedx, is the most recent addition to the market. The system utilises both QR codes (2D) for laboratory consumables and linear barcodes for cryodevices, and hence, labels can be scanned after cryostorage. The system is also completely portable and can be used anywhere in the laboratory, or indeed across other departments, with handheld scanners being carried by laboratory staff and linking via Wi-Fi to a server. The details which have automatically synchronised to the server can then be displayed on screens in the laboratory to show, in real time, the status of each patient currently on cycle, adding to the visibility for staff and managers and allowing them to further monitor and enhance workflow. Full audit reports can be generated from the synchronised data, within which each session in the system is allocated a unique ID number. In addition, the Gidget system is fully customisable so that individual laboratories can incorporate their standard procedures and workflow into the system, meaning that the system is personal to the processes in each laboratory, and further, it is adaptable to laboratories, so it does not require additional equipment to be purchased or contain fixed rules which cannot be modified by users or Laboratory Managers. This adaptability extends to the possibility for staff to use any desktop or laptop computer which is registered on the server to add or modify patient entries, as well as on the handheld devices. The adaptability aspect of the system also means that there is a relatively low cost involved with its implementation.

Although the system relies on the use of QR codes and barcodes, there is also the presence of a manual witnessing functionality if the labels containing these are damaged in any way, where identification by two staff can be performed. Although this is similar to a manual procedure, both of the staff members involved in the double identification must scan their personal QR code so that the system records that the process was performed correctly and automatically include it within the audit report.

In relation to label mismatches, the possibility exists for user accounts to be logged out and the patient's cycle locked if they mismatch two patient identification labels, at which time their supervisor or other specified management personnel with a higher access level to the Gidget system would need to reinstate their access and, if desired, add comments to explain the reason for 'unlocking' the cycle that will be visible in the audit report. This is beneficial because it prevents users from manually overriding their mistake, or indeed from the failure actually occurring, and can also highlight if specific personnel require additional training. For minor breaches which do not constitute a failure in the process or any risk to the patient, such as forgetting to scan the lid of an embryo-containing dish, a warning is displayed on the handheld device. This means that laboratory staff are made aware of errors and can ensure to correct them, without the general workflow being unnecessarily adversely affected to a significant degree.

A disadvantage of the system is that it is not possible to upgrade 'over the air' to new versions once the system is purchased, meaning that a skilled service technician must visit to upgrade software, contributing to an additional cost for the clinic. It is likely that in future releases of the system, over-the-air upgrades will be possible, allowing clinics to upgrade to the latest software at their convenience and with minimal associated cost.

75.4 Expectations of an Electronic Traceability System

The introduction of electronic traceability systems into laboratories should be seamless, further supporting the requirement for adaptable systems which are ready for 'go-live' as soon as they are switched on to minimise downtime and which do not entail purchasing of additional or replacement

equipment. They should save time over manual methods which they are intended to replace, make audits easier to perform and enable trained scientists to work in a smarter, more streamlined manner.

Ultimately, the use of the system should provide a secondary, automatic pair of eyes, hence reducing the potential for human error and ensuring compliance with regulatory guidelines and legislation. It should also, at a very minimum, capture 'near misses' in laboratory processes to identify the more error-prone elements of workflows, enabling laboratory managers and directors to consistently improve the quality of their systems and procedures. The overall benefits of a system which provides a solution such as this are for laboratory staff to have complete peace of mind, for Laboratory Managers and Directors to consistently improve efficiency in their workflows and for both groups to ensure that traceability is of a standard which leads to audits being passed every time.

75.5 Future Developments in Electronic Traceability Systems

Further to the current expectations of an electronic traceability system for ART laboratories, there are also several, exciting prospects which could be added in the future.

These possibilities are far and wide but in particular, laboratory workflows could be streamlined more effectively and processes made more efficient with the addition of inventory tracking, where consumables such as media and oil would be scanned when used and customisable warnings given to users when stock was becoming low or when batches were about to expire. The same data obtained for this purpose could be utilised elsewhere, such as for monitoring oil and media consumption in order to reduce cost or to highlight if clinical endpoints have been detrimentally affected since the introduction of a specific batch of consumable. Tasks performed by scientists could also be monitored by Laboratory Managers to determine where additional training may be required, therefore increasing overall efficiency.

A secondary addition to any of the aforementioned systems could be that of cryostorage monitoring. A feature which is to be included in the next version of Gidget, Genea Biomedx' electronic traceability system, is the monitoring of embryos which are stored in liquid nitrogen. The handheld devices will not only be able to monitor inventory but will also monitor the available capacity of liquid nitrogen tanks and the temperature of each specific embryo-containing cryodevice. Moreover, the specially designed handheld device which is used to pick up containers from within the liquid nitrogen will flash green when the correct vessel has been selected and flash red when it has not, therefore reducing human error and eliminating the possibility of collecting the wrong embryo for thawing.

As we move forward with the use of pre-implantation genetic diagnosis, the possibility of tagging individual embryos and/or tissue is perhaps an exciting prospective option. At present, traceability systems are often patient-specific rather than embryo-specific, thus making it difficult to monitor the fate of embryos throughout the whole confluent of additional or complementary procedures.

Overall, the workflow aspect of electronic traceability systems can be improved further, with the inclusion of options for displaying preparatory tasks and giving Laboratory Managers the ability to allocate resources at the correct times and to the correct tasks. With some companies' options, there is the possibility of linking the electronic traceability system with other equipment. In the case of Genea Biomedx, this includes the Geri Connect and Geri Assess products, the former of which allows remote monitoring of embryos contained within Geri incubators and the latter which allows both manual and automatic annotation of embryos based on morphokinetic parameters, therefore enabling the screen in the laboratory which highlights workflow to also display details of embryos' fate and the resultant impact on workflow. Additionally, laboratory workflows can be considerably enhanced by the integration of traceability systems with electronic medical record (EMR) systems that clinics already have in place, ultimately leading to a more streamlined, efficient workflow, allowing for greater control of quality procedures and significant time and cost savings.

Review Questions

1. Why is traceability required, and why is adequate control of witnessing procedures important?
2. What options are available for ensuring traceability in ART laboratories?
3. Which electronic systems exist for ensuring traceability is conducted properly and efficiently?
4. What should a clinic expect from their chosen electronic traceability system?
5. How could the current electronic traceability systems be expanded, and what possibilities exist for future development?

The Role of Mitochondria in the Establishment of Developmental Competence in Early Human Development

Jonathan Van Blerkom

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_76

Learning Objectives

- To recognize the pleiotropic roles mitochondria play in the maintenance of normal cell function
- To recognize which roles operate during human oogenesis and preimplantation embryogenesis to establish or compromise developmental competence
- To understand the meaning and role(s) of cellular energy expressed primarily in the form of mitochondrial-derived ATP as a primary driver of developmental competence for the human oocyte and preimplantation embryo
- To understand the difference between mitochondrial mass and mitochondrial DNA content as they relate to competence

While morphological and performance characteristics of oocytes and early human embryos during culture in vitro have long been the mainstay of clinical IVF for evaluations of developmental competence, new technologies based on genomic, proteomic, and metabolomic analysis have begun to enter assessment schemes by providing a wide array of target genes whose expression levels, measured at the mRNA and protein level with commercial and custom-made microarrays, may be competence associated. The relative merits of morphology and different "omic"-related methods for competence assessment and selection remain to be determined from comparative outcome findings. Whether they can be readily incorporated into the IVF laboratory and whether quantitative measurements at the biochemical and molecular levels can provide a level of confidence that is superior to what an experienced observer would normally conclude from detailed microscopic findings. However, morphology and metabolomics are the most likely to be developmentally related and to reflect the normality of molecular and cellular functions during oogenesis and preimplantation embryogenesis.

An understanding of the biological origins of developmental competence in the oocyte and how it is maintained through the pre- and early postimplantation stages of human embryogenesis has been an ongoing theme of research in clinical IVF. More recently, the notion that mitochondria may be involved in human oocyte and preimplantation embryo competence has led to a resurgence of interest in the role of this cytoplasmic component as a central player in the regulation and normality of early human development. While the respiratory role of mitochondria as the site of oxidative phosphorylation and ATP production is universally recognized by the common use in the literature of terms such as "the powerhouse of cells," these organelles have pleiotropic functions including β-oxidation, steroidogenesis, reactive oxygen species (ROS) generation, oxygen sensing, and participation in the regulation of calcium homeostasis, signal transduction, determination of cytoplasmic redox state, and apoptosis [1–3]. For the oocyte and embryo, specific mitochondrial parameters such as mtDNA copy number and cytoplasmic bioenergetic levels have been correlated with or related to the frequency of aneuploidy and the success of fertilization and preimplantation embryogenesis [4–12]. Given the multiple and varied roles that mitochondria have in normal cell function, it is not too surprising that they are an ideal candidate as a developmental common denominator, for competence studies in human oogenesis and embryogenesis and as such form the basis for this review.

76.1 Mitochondrial Functions and Activities in the Mammalian Oocyte and Early Embryo

Mitochondria in the mammalian oocyte and early preimplantation-stage embryo, including the human, are functionally similar but structurally undeveloped when compared to forms present during the blastocyst stage or in somatic cells, such as those of the cumulus oophorus and corona radiata. Human oocyte mitochondria are usually spherical to slightly oval in shape and about 1 μm or less in diameter [13, 14]. While active in ATP synthesis, the levels of generation are assumed to be relatively low, which would be consistent with the occurrence of few short cristae located at the periphery of an electron-dense matrix. Prior to cavitation, mitochondria usually become elongated and progressively develop well-formed cristae that traverse a matrix of lower electron density. By the expanding blastocyst stage, they assume forms characteristic of highly active (energetic) organelles typical of differentiated cells. An early indication that the normality of mitochondrial development may be a factor in the inability of cleavage human stage embryos to initiate cavitation comes from fine structural studies of human embryos that arrest development during cleavage, in which few, if any, stage-appropriate forms are detected [15, 16]. Although electron microscopic findings provide an intriguing correlation with developmental arrest in the human, a cause–effect relationship cannot be concluded solely on the basis of fine structure.

76.2 Developmental Significance of Mitochondrial DNA Content

More recent investigations of the involvement of mitochondria in human oocyte and embryo competence have correlated stage-appropriate development and performance in vitro with mtDNA content. In this instance, the association between mtDNA copy number and the capacity or level of ATP generation found in somatic cells is assumed to be similar. This assumption seemed to be validated in initial reports by the finding of low copy numbers in oocytes that failed to mature to metaphase II in vivo or fertilize in vitro [6, 17]. However, reported mtDNA contents range from the low ten thousand to over one million in normal-appearing MII oocytes [11, 18, 19], which can be problematic in determining threshold levels that may be stage-specific or, more importantly, developmentally relevant. For example, the threshold mtDNA copy number suggested to be normal for a competent MII human oocyte by Zeng et al. [12] is significantly higher than the level

proposed by Santos et al. [17] for competence. Further confounding the threshold issue is that mitochondrial mass and mtDNA copy number are often used interchangeably, and if each organelle contains one or two genomes at MII [20], the expected numerical complement of mitochondria implied by these findings might be in high hundreds of thousands [19]. However, while mitochondria are the most abundant organelles in the mature oocyte, fine structural images [14] and analysis of living cells with mitochondria-specific fluorescent probes [21] suggest a normal complement in the tens of thousands. Indeed, if mtDNA copy numbers at the high end of this range correlated with complement size, it would be evident at the fine structural level by virtue of a mitochondrial density that would occupy virtually the entire cytoplasm, which has not been the case in reported fine structural studies.

The simplest explanation that reconciles differences in mtDNA content and mitochondrial mass is that multiple genomes exist in each organelle, especially at MII, when most measurements have been made. This interpretation has been supported by counting individual mitochondria in each cell of fully expanded blastocyst-stage mouse and human embryos and in trophectodermal outgrowths of mouse embryos, with different mitochondria-specific fluorescent probes that target different mitochondrial sites or properties [21]. The assumption upon which these studies were based is that while mtDNA levels may fluctuate during oogenesis and preimplantation embryogenesis (see below), in aggregate, the relative number of mitochondria present in the periimplantation-stage blastocyst should reflect the complement present in the MII oocyte because mitochondrial replication begins after implantation [22], and to date, fine structural studies of normally progressing preimplantation-stage embryos show no degenerate forms or indications of mitochondrial replication [15]. Results derived from different mitochondria-specific fluorescent probes indicate that the 100-cell human blastocyst (ICM and trophectoderm) contains approximately 18,000–25,000 mitochondria. Previous electron microscopic analyses of normal-appearing MII human oocytes suggested that a mitochondrial complement around 25 K may be normal; however, mtDNA copy number derived from sibling oocytes detected genomic copy numbers between ~110,000 and ~240,000 [23].

Recent studies of mtDNA content during porcine oocyte maturation may clarify the apparent numerical discrepancy between mitochondrial complement size and mtDNA copy number. Spikings et al. [24] reported that similar to the situation in other species, a significant burst of mtDNA replication occurs during preovulatory maturation in the porcine, which results in an increase in genomic content that is several fold higher than levels measured at the germinal vesicle stage. However, such an increase is not observed in rat oocytes that matured in vitro [25], suggesting that the stage-specific upregulation of mtDNA synthesis may operate through signals transmitted to the immature oocyte at the outset of maturation through cumulus and coronal cells, which, in turn, may be responding to signal transduction cascades initiated by LH.

The above findings suggest that each mitochondrion in a normal-appearing MII-stage human oocyte likely contains multiple genomes which, if confirmed by additional studies, would go a long way in reconciling apparent differences between organelle mass and mtDNA content. The importance of reconciling mitochondrial mass and mtDNA content is not only to clarify apparent confusions in the literature but rather also to have a firmer basis for relating mitochondrial properties in the human oocyte and early embryo with competence. Low mtDNA copy numbers have been a suggested etiology of maturation and fertilization failure for human oocytes and for poor embryo performance in vitro [12, 26]. A better understanding of the extent to which fertilization or early embryo failure is related to an acute increase in mtDNA content during the terminal stages of oogenesis (i.e., preovulatory maturation), rather than to an actual organelle deficiency, could point to regulatory defects in the stage-related expansion of mtDNA. Confirmation for the human could make the signaling pathway for mtDNA expansion a focus of study for competence rather than the apparent endpoint, mtDNA content. In this regard, a potentially important finding of Spikings et al. [24] may have implications for the human: during cleavage, approximately 80% of the elevated mtDNA content measured in the mature oocyte was no longer detectable, suggesting that degradation of mitochondrial genomes (but not mitochondria) is a normal process during early development.

What could be the developmental significance of a process that rapidly increases the number of mitochondrial genomes during preovulatory maturation only to degrade them after fertilization? Given the comparatively undeveloped structure of oocyte mitochondria, a transient increase in mtDNA could alter the dynamic relationship between ATP supply and demand during certain stages of oogenesis and early embryogenesis when energy demands may be needed to support cytoplasmic remodeling, circulation, chromosomal segregation, and polar body formation [3]. In this regard, species-specific differences may exist in how differential energy demands may be supplied during the preovulatory and early embryonic stages. In the mouse, for example, spatial changes in mitochondrial density appear to be satisfied by the active translocation of mitochondria to the perinuclear region beginning around germinal vesicle breakdown [27, 28]. Van Blerkom and Runner [27] first proposed that active translocation in the mouse oocyte may be an adaptive mechanism that can elevate ambient levels of ATP in specific areas of the cytoplasm where demand is transiently higher. As discussed below, an increase in the magnitude of $\Delta\Psi_m$ or mtDNA copy number may be other strategies to achieve a similar end in species where significant cytoplasmic remodeling and redistribution of mitochondria are not apparent, such as in the human oocyte.

In certain instances, upregulation of mtDNA replication has been generally considered a compensatory mechanism to increase ATP production under conditions of reduced respiratory function resulting from the acute or chronic effects of toxic insults such as excessive superoxide production. A

similar phenomenon of increased mtDNA content has also been reported for sperm and oocytes. May-Panloup et al. [10] reported that the mtDNA content of human sperm with abnormalities known to compromise fertility was significantly higher than in normospermic samples. This was confirmed by Song and Lewis [29] for asthenozoospermic individuals, who also showed that the loss of DNA integrity was higher in affected men, which most was likely due to fragmentation and guanosine oxidation (8oxyG) resulting from excessive levels of mitochondrial superoxide production. In this instance, the increase in average mtDNA content was suggested to compensate for mtDNA mutations or fragmentation that may affect the electron transport chain and therefore respiratory (ATP generation) capacity. If an increase in mtDNA copy number occurs when mature sperm are in the ejaculatory pathway, potential upregulation of ATP production would not reverse structural alterations in plasma membrane integrity and function induced by lipid peroxidation, nor would it correct nascent mutations or defects in mtDNA integrity. The notion that increased mtDNA copy number may be a natural compensatory mechanism would seem to be contradicted by the clinical finding that even if such a process occurs, the sperm are still functionally compromised with respect to motility, and the affected men are still classified as infertile or subfertile.

Wang et al. [30] reported that fully grown MII oocytes obtained from streptozotocin (STZ)-induced diabetic mice show alterations in mitochondrial fine structure such as rupture of the outer membrane, changes in internal membrane organization, and organelle swelling. These defects are consistent with reduced mitochondrial function resulting from respiratory chain defects which, depending upon extent, could activate the mitochondria-dependent apoptotic pathway. However, against a background of mitochondrial alteration and damage, the mtDNA content of diabetic oocytes measured by quantitative real-time PCR was significantly higher than levels in untreated controls [31]. Similar to what may be an adaptive survival mechanism in other cells, increased mtDNA content was postulated by these investigators to be a compensatory mechanism to maintain ATP at levels required to support oocyte maturation and early development in the presence of respiratory chain dysfunction. However, a compensatory explanation does not account for the pronounced delay in meiotic maturation to MII observed in these mouse oocytes. In this regard, reduced mitochondrial function associated with disorders in the electron transport chain and abnormalities in stage-specific translocation and spatial remodeling of mitochondria, which have been proposed to focally balance ATP supply and demand during mouse oocyte maturation [27, 32], were suggested by Wang and Moley [31] to contribute to meiotic spindle malformations and errors in chromosomal segregation during oocyte maturation in the diabetic mouse model. The transmission of structurally or functionally compromised mitochondria would likely have toxic effects on development during the preimplantation stages that cannot be relieved by increasing mtDNA copies. Since a burst of mtDNA replication appears to be a normal feature of preovulatory maturation [24], the extent to which, if any, the mtDNA content in diabetic oocytes reflects this process, or is substantially different from levels detected in unaffected oocytes, remains to be determined. A similar issue concerns whether levels of mtDNA degradation during cleavage in STZ diabetic mice differ from controls. It seems unlikely that mitochondria in the oocytes of diabetic women are functionally compromised, as this disease is primarily associated with defects in follicular growth, ovulation, and maintenance of gestation, rather than disorders in oocyte maturation, fertilization, and early embryonic development. However, the assumption that mitochondrial function is normal in this instance remains to be investigated at the fine structural, biochemical, and mtDNA levels.

The notion that an inherent mechanism that upregulates mtDNA replication in order to compensate for bioenergetic deficiencies associated with sublethal mitochondrial dysfunction may be particularly relevant for women of advanced reproductive age. Maternal age is the foremost factor associated with the probability of natural cycle pregnancy and gestation to term birth, and it is no different with respect to outcome in assisted reproduction. A high proportion of oocytes obtained for IVF after ovarian hyperstimulation and ovulation induction in women of advanced maternal age are immature or, if mature, have a high probability of being aneuploid. If fertilized, the resulting embryos often arrest or develop abnormally during the preimplantation stages and are more likely to undergo demise after implantation than is the case for younger women. The possibility that mitochondrial mutations resulting in respiratory dysfunction may contribute to an age-related reduction in fertility and fecundity first received support from the studies of mtDNA by Keefe et al. [33], who reported that the frequency of a common mitochondrial deletion, the 4977 bp deletion (corresponding to nucleotide pairs 8482–13,460), was increased in the oocytes of older women. This common deletion also occurs in rhesus macaque oocytes and has been suggested to contribute to impaired mitochondrial ATP production [34]. Whether the relative size of the deletion, which is larger in the rhesus (5704 bp) than human (4977 bp), is related to the extent of detectable respiratory dysfunction is unknown. However, Muller-Hocker et al. [16] did not detect an increased frequency of either point mutations or the 4977 bp deletion in women of advanced maternal age (>40). These investigators did report fine structural morphometric results that indicated a significant increase in mitochondrial density occurred in older oocytes and that the diameter of mitochondria was also larger than measured in oocyte mitochondria of younger women. While the increase in mitochondria diameters may be due to slight swelling resulting from a $\Delta\Psi_m$ that is insufficient to maintain normal volume homeostasis [2, 35], their findings also showed no age-related functional defects in respiratory chain enzymes. Whether an increase in mitochondrial numbers and changes in organelle diameters indicate a compensatory mechanism to increase ATP production in the oocytes of women of advanced maternal age, as suggested by Muller-Hocker et al. [16], remains to be con-

firmed. However, unlike the upregulation of mtDNA content in functionally compromised sperm, a similar compensatory mechanism does not appear to occur in "older" human oocytes [36].

Correlating oocyte and embryo developmental ability with levels of mtDNA copy number, organelle complement, and bioenergetic capacity has been the basis of recent mitochondrial studies in animal models such as the bovine [37–39], pig [9], mouse [27], and human [12, 17]. For the human, a determination of threshold levels for each of these mitochondrial parameters has been suggested to represent possible analytic tools that could be used to diagnose fertilization or developmental failure. However, establishing a cause–effect relationship with regard to developmental competence may be problematic and more apparent than real. With respect to stage-specific bioenergetic thresholds, Van Blerkom et al. [4] reported that experimentally reducing net cytoplasmic ATP contents in the mouse by approximately 50% did not inhibit maturation from the germinal vesicle (GV) to MII stages, and while these treated oocytes were fertilizable in vitro, a high proportion of embryos arrested shortly after fertilization and none progressed to the blastocyst. Presumably, postfertilization developmental arrest was associated with irreversible mitochondrial damage with adverse downstream consequences. In contrast, Wai et al. [40] showed that mouse oocytes with as few as 4000 mtDNA copies were fertilizable and capable of developing to the blastocyst stage but died shortly after implantation. They concluded that (1) a threshold level of 40,000–50,000 mtDNA copies in the MII mouse oocyte was required to support development during the early postimplantation period and (2) high copy numbers in the mature oocyte were necessary in order to distribute mitochondria and mtDNA to the cells of the early implanting embryo prior to the initiation of mtDNA replication and organelle biogenesis. For the bovine, Chiaratti and Meirelles [39] reported no quantitative difference in mtDNA content between competent and incompetent embryos. However, in an elegant experiment, these authors removed ~64% of the mitochondria from MII oocytes after compartmentalizing these organelles to one pole of the oocyte by centrifugation. They found that oocytes, depleted of mitochondria by this extent, were fertilizable and competent to develop to the blastocyst stage. For these blastocysts, mtDNA contents were similar to nonmanipulated controls. The compensatory strategy employed by mitochondrially depleted embryos to restore normal mtDNA levels by the blastocyst stage is to upregulate the expression of TFAM and NRF1, two critical genes in mitochondrial function that control mtDNA replication and transcription, respectively. Chiaratti and Meirelles [39] reached two important conclusions for preimplantation development in the bovine: (1) an intrinsic mechanism exists in the early embryo to provide a threshold mtDNA content required for blastocyst formation, and (2) competent embryos can regulate mtDNA content regardless of copy numbers present at MII. The degradation of mtDNA detected during the cleavage stages [24] may be part of a self-regulatory mechanism to maintain a threshold mtDNA content required to support postimplantation development prior to mtDNA replication and mitochondrial biogenesis [40]. Because of the high degree of similarity between mammals with respect to the developmental biology of oocyte maturation, fertilization, and preimplantation embryogenesis, the above strategies for establishing a developmental threshold for mtDNA copy number may also apply to the human and, if confirmed, could indicate that the developmental consequences of a bioenergetic deficit may not be evident at MII or during the early stages of embryogenesis. However, testing this supposition experimentally using the same inhibitor treatments or invasive manipulations [39] to downregulate mitochondrial metabolism or reduce mitochondrial complement would require IVF and embryo culture. It is doubtful that such experiments would be considered acceptable or indeed ethical.

Although the above findings demonstrate molecular strategies used by the oocyte and early embryo to up- or downregulate mtDNA copy numbers, it is unclear how levels that may be below or in excess of a postimplantation threshold are recognized at the cellular level. As noted above, reported mtDNA contents between MII human oocytes in the same cohort can differ by over an order of magnitude, and similar differences have been reported for other species [38]. While speculative, one possibility may be related to the redox state of the cytoplasm and the influence mitochondria have on redox homeostasis, which in turn can regulate the activity of redox-dependent signaling pathways and other redox-sensitive regulatory factors (e.g., transcription factor, see below). The extent to which, if any, the redox state of the ooplasm or embryo cytoplasm can be related to mtDNA copy number and stage-specific mtDNA expansion or degradation warrants investigation.

76.3 Roles of Mitochondrial Reorganization During Early Development

Oncosis is a survival strategy that can be employed by some cells in order to adapt to transient reductions in ATP generation, such as during ischemic episodes [41]. In these instances, cytoplasmic remodeling results in mitochondrial translocation to the center of the cell, usually around the nucleus, and to balance ATP demand with reduced bioenergetic capacity, portions of the cortical cytoplasm are extruded as blebs that are largely devoid of mitochondria. The extruded cytoplasm remains connected to the underlying cell by cytoplasmic bridges. If normoxic conditions return and ATP levels rise, mitochondria disperse and the cytoplasmic extrusions are resorbed; if the restoration of normoxic conditions is within a cell type-specific tolerance, survival is indicated by the restoration of normal function. This novel mechanism of adaptation to transient anoxia or severe hypoxia has been suggested to operate in cleavage-stage human embryos that exhibit very similar cellular responses and characteristics [42]. One of the more remarkable features of human embryo performance during the early cleavage

stages in vitro are instances of fragment "disappearance" during subsequent culture, resulting in embryos that appear largely morphologically normal and stage-appropriate [23, 43]. This phenomenon has been observed by time lapse, even in embryos with fragmentation levels classified as high grade, where resorption restored stage-appropriate morphology and the affected cell(s) underwent division [42].

Light microscopic [44] and fine structural analyses [42] offer a possible explanation for the restoration of apparently normal cell function—the spherical fragments occur in columns that are interconnected to one and another and to the underlying cell by cytoplasmic bridges. The fragments contain few mitochondria that are mostly high potential and derived from the subplasmalemmal cytoplasm [45]. Van Blerkom et al. [42] suggested that abnormal patterns of cytoplasmic remodeling, possibly resulting from corresponding disorders in cytoskeletal organization, could locally reduce mitochondrial density in the pericortical cytoplasm in some cleavage-stage blastomeres. In contrast, remodeling does not appear to influence mitochondria in the subplasmalemmal cytoplasm, as discussed below. The compartmentalization of this cytoplasm into columns of interconnected extrusions (blebs) may be a local response to a focal ATP deficit. Restoration of a more normal distribution of mitochondria, especially in the cortical cytoplasm, was suggested to relieve the local bioenergetic deficit and return normal cell function, which is the situation when the oncosis-inducing stress is relieved. The persistence of fragments on cells that underwent a significant reduction in volume was considered to result from the failure of mitochondria to redistribute, and in these instances, high-density mitochondrial aggregates are observed in more central regions of the cytoplasm.

Whether by stage-specific up- or downregulation (degradation) of mtDNA content, active mitochondrial translocation, or perhaps an oncotic-like mechanism, adaptive strategies exist in cells to survive short-term ATP deficits and balance regional changes in the demand–supply equilibrium, and these mechanisms may also be employed by human oocytes and early embryos. The utilization of adaptive strategies is likely embryo-specific because within cohorts cultured in the same environment, not all are affected. This long-standing and consistent observation in clinical IVF demonstrates that at the blastomere level, the normality of development can differ from the embryo as a whole, which can develop progressively in the presence of cells that appear developmentally compromised owing to unique intracellular conditions, physiology, or genetics. At present, clinical and experimental findings from human IVF indicate the importance of mitochondrial function as a primary driver of normal development, although threshold levels of ATP generation and their relationship to mtDNA copy number remain unclear. This is not surprising considering that from the earliest classes one takes in biology, mitochondria are defined as the "powerhouses" of the cell, and this descriptor is still used in many scientific publications. However, what has emerged from studies of mitochondrial function in mammalian oocytes and nascent embryos is that how "power" is distributed within the cell and can be adjusted to meet local changes in demand is as important in understanding cell function during early development as is the power source [3]. Typically, studies of the bioenergetic state of the human oocyte and early human embryo have focused on ATP content at a particular stage. For example, several studies indicate that an ATP content around 1.8 pM may be a steady-state level consistent with competence for the oocyte competence and early human embryo [4, 12]. However, the values obtained represent the net cytoplasmic content at the time of measurement because rates of ATP turnover are rarely determined, and developmental competence is assumed because ATP quantitation requires cell lysis. Therefore, conclusions about developmentally significant threshold levels represent comparative values derived from oocytes that fail to mature in vivo or in vitro, or fertilize in vitro, or from embryos that arrest cell division or show apparent common performance and developmental abnormalities during cleavage, such as grossly unequal cell divisions, high-grade fragmentation, or blastomere multinucleation. If adaptive mechanisms are employed during early development to overcome bioenergetic deficits, they are apparently insufficient in a compensatory context in these instances.

76.4 Mitochondrial Inheritance After Fertilization

Although ATP measurements appear to provide a general impression of bioenergetic states that could be of clinical value if related to stage-specific threshold levels, performance defects such as those noted above cannot be assumed, a priori, to have such an etiology. For example, measurements of ATP levels in human embryos that arrest development at the pronuclear to 8-cell stage do not consistently or necessarily have ATP contents that differ significantly from their normally progressing counterparts (e.g., dispermic fertilization) or from normally fertilized siblings cryopreserved at the pronuclear stage and cultured through the cleavage stages after thawing (unpublished). In contrast, the failure to develop into a normally compacted morula that can initiate cavitation, or the inability of a cavitated embryo to progress to the expanded blastocyst stage, which is an energy-intensive process, is more likely to have an origin associated with mitochondrial structural or functional defects [15, 16]. While quantitation of the ATP content(s) of whole embryos may not be informative in a diagnostic sense, or capable of identifying a specific cause of embryo arrest or developmental abnormality, semi-quantitative assessments of mitochondrial mass in individual blastomeres may have clinical value in this regard. Van Blerkom et al. [43] showed that quantitative values for bioenergetic state and comparative mitochondrial mass could be assessed in the same blastomere(s) with highly sensitive organelle-specific fluorescent probes used for the latter. Examination of mitochondrial fluorescence alone in intact 2- and 4-cell stage embryos showed disproportionate mitochondrial segregation with subsequent performance

in vitro related to stage (2–8 cell) and extent. These investigators suggested that the origin of this pattern of disproportionate mitochondrial inheritance was related to the symmetry of peripronuclear mitochondrial aggregation at the 1-cell stage. For normally developing fresh and thawed embryos between the 2- and 16-cell stages, the relative intensity of mitochondrial fluorescence and net cytoplasmic ATP content were largely similar between blastomeres. Subsequent studies have shown that blastomere-specific differences in the relative intensity of mitochondrial fluorescence are a comparatively common theme for embryos that developed no further than the 4- or 8-cell stage, with blastomere-specific differences in relative intensity up to 80% observed (unpublished). These findings suggest that a focus on noninvasive methods of assessing mitochondrial mass at the blastomere level could provide important clues related to competence for the entire embryo.

76.5 Functional Compartmentalization of Mitochondrial Activity

Several lines of investigation indicate that intracellular mechanisms that readjust ATP supply and demand within the oocyte and early blastomere may be a critical determinant of the normality of development. Local changes in ATP demand can be met by transient changes in mitochondrial distribution using active (cytoskeletal elements such as microtubules) and passive (intracellular circulation) mechanisms that affect organelle density and ambient bioenergetic state [2, 3, 46]. An increased potential across the inner mitochondrial membrane is also associated with higher levels of ATP generation, and in some cultured cell lines, changes in $\Delta\Psi_m$ have been reported to be location dependent. In certain instances, high-potential mitochondria are localized to the cell margins where the plasma membrane is motile, with lower potential forms in the interior, especially around the nucleus [47]. These investigators reported that subplasmalemmal mitochondria shift from high to low potential at zones of intercellular contact, but when contact is interrupted, return to high potential where the cell margins are free. In these cells, changes in ATP demand required to support plasma membrane dynamics at the free margins of a cell appear to be met locally by increasing $\Delta\Psi_m$ rather than by mitochondrial translocation to increase organelle density. In other cells, local changes in demand are accommodated by mitochondrial aggregation, which by virtue of altering ambient cytoplasmic redox state (see below) can increase focal levels of respiration in the aggregate [46]. A similar focal change in $\Delta\Psi_m$ in subplasmalemmal mitochondria has been reported for early cleavage-stage mouse embryos [48]. At the zone of gap-junction-mediated contact between blastomeres, the corresponding mitochondria are low potential but become high potential when the cells are separated. Mitochondria at the free margins are high potential. When repositioned 180° at the two-cell stage, such that the formerly free margins are in contact, high-potential shifts to low potential, and vice versa.

Mechanisms of mitochondrial redistribution, translocation, and aggregation detected in cultured cells also occur during early development. In some species, such as the mouse [27, 28] and hamster [49], microtubule-mediated mitochondrial translocation [32] during oocyte maturation and early postfertilization development results in the formation of a relatively dense sphere of mitochondria around the developing nuclear region of the oocyte and juxtaposed pronuclei of the 1-cell embryo. Van Blerkom and Runner [27] first proposed this pattern of cytoplasmic remodeling readjusts ATP supply to accommodate higher ambient energy demands associated with the evolving nuclear region in both oocyte and nascent embryo. In the maturing mouse and human oocyte and pronuclear stage embryo, mitochondria in the subplasmalemmal cytoplasm have an apparent $\Delta\Psi_m$ that is significantly higher than exhibited by the vast majority of mitochondria within the cell [48]. It is worth mentioning that mitochondria which are actively translocated to the perinuclear region during oocyte maturation in the mouse are low potential and that the high-potential forms in the subplasmalemmal region do not participate in this redistribution [48] and remain spatially stable and at a comparatively high potential from the oocyte through the cleavage stages [50].

Although the subplasmalemmal domain contains less than ~3% of the complement of mitochondria in the mature oocyte, their loss by minor fragmentation from this domain is apparently irreversible, and depending upon the degree of loss, adverse developmental effects including delayed or arrested cell division have been reported [50]. Similarly, failure to assume a high $\Delta\Psi_m$ at MII, or a domain of high-potential forms that is scant and largely discontinuous, has been associated with sperm penetration failure in the human after conventional IVF [48, 51]. It has been suggested that high potential and a subplasmalemmal localization may provide higher ambient concentrations of ATP to support ATP-driven plasma membrane activities that include sperm penetration and migration of the incorporated sperm nucleus [3, 52]. Reversibly reducing $\Delta\Psi_m$ in this domain was inconsistent with penetration until high potential was restored [50].

76.6 Intracellular Free Calcium and Mitochondrial Activity

The above findings suggest that mitochondrial potential, location, and density are mechanisms by which ATP may be differentially generated, distributed, and utilized within the cytoplasm of the oocyte and early embryo, and defects in each element of this energy management system could affect competence depending on stage and extent. As noted above, the absence of high $\Delta\Psi_m$ in the subplasmalemmal domain at MII is associated with penetration failure for both fresh [48, 50] and thawed human oocytes [51]. Local changes in the

concentration of intracellular free calcium is another critical element in the regulation of mitochondrial ATP production and, for the human, may be directly related to developmental abnormalities that can occur well beyond the preimplantation stages [53]. Mitochondria are excitable organelles [54] that respond to changes in ambient free calcium levels by releasing or sequestering calcium, and the level of response can be related to the magnitude of $\Delta\Psi_m$. Mitochondria respond to calcium released from intracellular stores, such as the smooth-surfaced endoplasmic reticulum (sER), through the calcium-induced calcium release pathway (CIRC) [55, 56] and from calcium released by mitochondria themselves through the mitochondrial calcium-induced calcium release (mCIRC) [57]. It has long been known that calcium is a regulator of mitochondrial ATP synthesis [58]. Dumollard et al. [59] demonstrated that by experimentally manipulating calcium release from sSER, ambient calcium levels and mitochondrial activity were tightly coupled in a regulatory manner that could up- or downregulate levels of respiration in the newly fertilized mouse oocyte. The benefit for the oocyte or early embryo of such tight coupling is that local, stage-specific ATP demands can be met without involving the entire mitochondrial complement, which has the potential of increasing levels of ROS (superoxide). In the mouse and human oocyte and early embryo, fine structural analyses show cisternae of the sER in contact with mitochondria [14], especially in the pericortical/subplasmalemmal cytoplasm where of mitochondria surround sER aggregates [23, 48]. Van Blerkom et al. [48, 60] suggested that the fertilization-induced influx of calcium may increase mitochondrial activity in the subplasmalemmal domain and possibly initiate mCIRC along the circumference of the oocyte, which could locally assist in the cortical granule exocytosis and other calcium-dependent activities associated with sperm penetration. The validity of this notion remains to be determined experimentally.

Little is known about spontaneous abnormalities in calcium release at the earliest stage of human fertilization and whether defects in calcium signaling [61] or levels could have downstream effects on mitochondrial activity or the normality of embryogenesis. Typically, studies of changes in cytoplasmic free calcium involve preloading oocytes with a fluorescent calcium reporter such as Fluo-4 AM [51, 60] followed by activation with a calcium ionophore (e.g., A23178; [3, 56]) or insemination by intracytoplasmic sperm injection (ICSI) [62, 63]. The normal pattern of free calcium fluorescence observed by scanning laser confocal microscopy after human oocyte activation is shown in Fig. 76.1a–d. Shortly after ionophore exposure, the relative intensity of fluorescence increases throughout the cytoplasm (Fig. 76.1b, c) before decaying to levels (Fig. 76.1d) that existed in reporter-labeled oocytes prior to activation (Fig. 76.1a). In contrast, within the same cohort(s) of MII oocytes activated 2–4 h after follicular aspiration and hyaluronidase-mediated corona and cumulus cell denudation, the rise in fluorescent intensity in some oocytes was regional (asterisk, Fig. 76.1e–f) rather than a uniform. In most instances, the intensity of calcium fluorescence declined to background levels at rates similar to those observed in oocytes with a uniform rise. The oocytes shown in Fig. 76.1e, h are representative examples of a pattern of cytosolic calcium fluorescence that was an exception. Fluo-4 AM fluorescence was detectable for at least 2 h after levels returned to background in similarly treated oocytes, such as those shown in Fig. 76.1d, g. The average net ATP content measured 4 h after activation in oocytes with these aberrant patterns of free calcium fluorescence was significantly higher by ~30–50% (3.3 pM, ±0.6 pM, n = 23) than normal for MII human oocytes [4] that exhibited a uniform calcium rise (1.8 pM, ±0.3 pM, n = 15). A very similar phenomenon occurs in MII human oocytes cryopreserved by programmed (slow) cooling which, after thawing, are preloaded with this calcium probe and ionophore activated. Preliminary findings indicate that while <4% of fresh oocytes display this abnormal pattern (1/27), distinct regions of intense fluorescence occurred in approximately 42% (13/31) of oocytes that were of similar (normal) appearance at cryopreservation and activated 2–4 h after thawing (similar to Fig. 76.1e–h). However, ATP levels measured at 4 h after activation were not significantly different from levels measured in similar oocytes prior to cryopreservation [51].

The above findings suggest the possibility that oocyte-specific defects in sER function may be associated with the slow cooling cryopreservation, but freezing per se does not appear to affect global cytoplasmic ATP content after thawing. In this regard, the unusual patterns of calcium rise and the corresponding increase in net cytoplasmic ATP content observed in fresh oocytes could support the notion of tight metabolic coupling between sER-derived calcium and mitochondrial ATP production discussed above. The absence of a similar increase in ATP content in thawed oocytes could indicate cryopreservation-induced damage to mitochondria that makes them less responsive to calcium at the 4-h time point or an abnormal increase in ATP demand that requires higher levels of production that is not evident when total net cytoplasm ATP content is measured. Whether oocyte cryopreservation by slow cooling irreversibly alters mitochondrial organization at the fine structural level is unclear. While some reports have described alterations that could compromise function [64], others have not [65, 66], and in our experience, mitochondria in MII human oocytes cryopreserved by slow cooling that remain intact during the first hour after thawing appear unchanged from their fresh counterparts (unpublished). This is not to say that mitochondria are not damaged during slow cooling cryopreservation, but the damage may be reversible or occur at a level that does not alter respiratory capacity reflected by net cytoplasmic ATP content. Whether calcium-dependent signaling pathways are perturbed by this method of cryopreservation is unknown, but cellular bioenergetic state seems unperturbed.

The most compelling evidence to date of an association between atypical sER calcium release and ATP production occurs in ionophore-activated MII human oocytes that contain a single, large, centrally located disk-like inclusion composed of cisternae of the sER [67] (asterisk, Fig. 76.1i, k).

After preloading with the calcium reporter and exposure to A23187, activation is rapidly followed by an intense flare of fluorescence (2 min, asterisk, Fig. 76.1j) that coincides with the position of the inclusion. The intensity of fluorescence remains elevated for approximately 2–3 h (2 h, Fig. 76.1l), which is significantly longer than observed in unaffected oocytes [60]. Preliminary results indicate that net cytoplasmic ATP content measured at 1–4 h was ~2.0 to 2.5-fold higher than normal (3.3–4.6 pM) and remained elevated for at least 22 h before abruptly dropping to levels ≤50% of normal (0.6–0.8 pM).

The most remarkable characteristic of these oocytes was the behavior of the inclusion during prolonged culture as detected by time lapse. Figure 76.2 shows selected images at the indicated times after activation of an MII oocyte with a large sER inclusion. The arrows show the direction of movement of the disk, with the black arrows denoting movement detectable within the plane of focus and the white arrows denoting the direction of movement when the disk moves out of and returns to the plane of focus. Over this 22-h period, the disk moves throughout the cytoplasm going out of and back into the plane of focus, often oscillating back and forth within a 20–35 micron region. The calculated rate of movement during this time was relatively constant at ~1.0–1.5 μm/min. Exposure of oocytes to inhibitors of oxidative phosphorylation [60] caused this motion to cease within minutes, but resumed when the inhibition was relieved, if the duration of inhibitor did not exceed ~30 min. A close inspection of these representative images shows that the movement of the disk (indicated by a white asterisk) is accompanied by

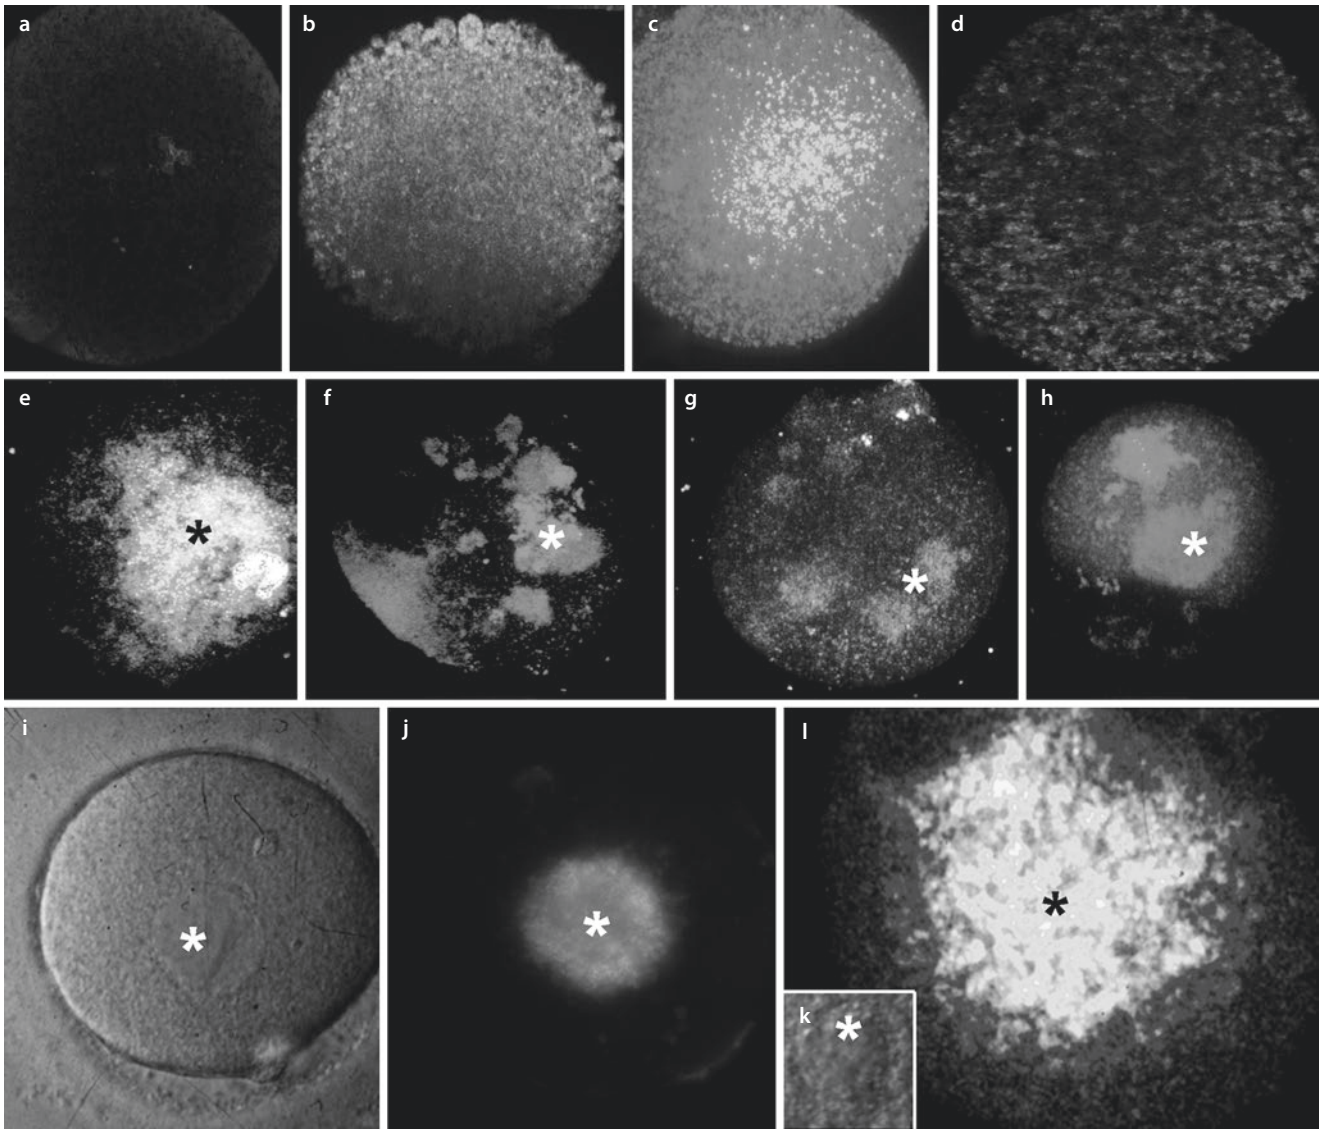

Fig. 76.1 Normal **a**–**d** and abnormal **e**–**h** patterns of increased levels of intracellular free calcium (*asterisk*) after ionophore activation of MII human oocytes. **j**, **l** Show a highly intense and prolonged flare of fluorescence, detected by a fluorescent calcium reporter, which corresponds to calcium released from a single, large aggregate of sER cisternae (*asterisk*, **i**, **k**). This sER aggregate defines an abnormal human oocyte phenotype, and its occurrence during IVF has been associated with unusually high levels of ATP generation and genomic imprinting disorders in newborns

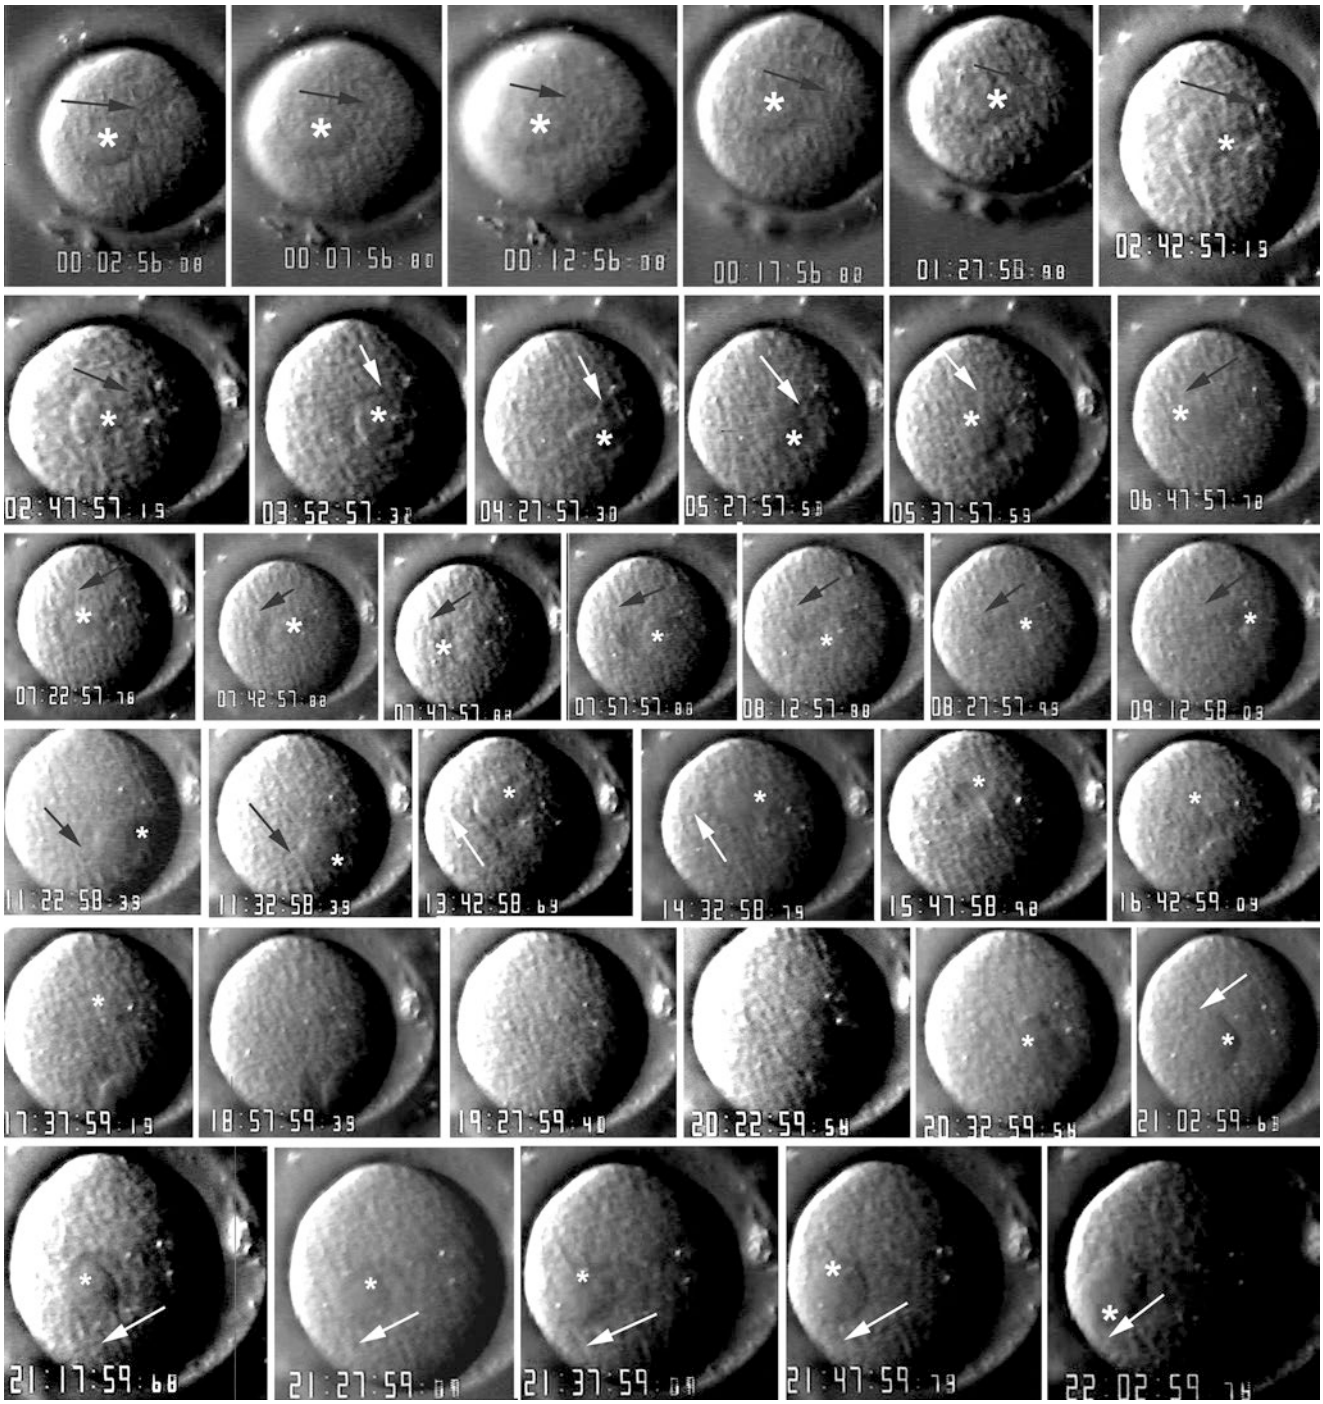

Fig. 76.2 Representative time-lapse images showing the movement of a single, larger sER inclusion (*asterisk*) in an MII human oocyte over a 22-h period. The *arrows* indicate direction at different times (indicated in *lower left*) as the inclusions move out of and into the plane of focus. This usual and persistent behavior is suggested to be supported by an enhanced cytoplasmic bioenergetic state associated with the maintenance of unusually high levels of mitochondrial ATP synthesis

corresponding dynamic changes in the cytoplasm immediately in front of and behind this structure (e.g., arrow, 17 min 56 s; black asterisks, 21 h 17 min 59 s to 21 h 47 min 59 s).

Time-lapse imaging has shown that after fertilization in the human, cytoplasmic motility increases in general and within the pericortical cytoplasm in particular [68]. However, a similar intensity and persistence of movement, such as displayed by these inclusions, have not been reported. It is tempting to speculate that the abnormal pattern of calcium release and the persistence of calcium-driven fluorescence affect the fluidity of the cytoplasm, perhaps by altering calcium-dependent structural elements responsible for cytoplasmic organization and circulation [2]. Together with an unusually elevated bioenergetic state, the condition of the cytoplasm may become permissive for and enhance dynamic movements of cytoplasmic components. In this regard, the

behavior of the sER inclusion may be governed and directed by mechanisms similar to those that promote the movement of the sperm nucleus after penetration and pronuclear migration during the 1-cell stage [52]. In these instances, pronuclear migration is associated with normal levels of calcium release that are periodic (so-called calcium transients) and begins with an initial increase at the earliest stage of the fertilization process. Although likely, the extent to which defects in these transients (occurrence or amplitude) are associated with fertilization failures in human IVF where the sperm nucleus remains (unexpanded) in the pericortical cytoplasm [69], or where pronuclear migration and juxtaposition do not occur [52], remains to be determined. However, whether the abrupt cessation of the SER disk movement described above reflects reactive oxygen toxicity to mitochondria resulting from the generation of superoxide in excess of the intrinsic antioxidant capacities (e.g., mitochondrial superoxide dismutase) is one possibility under investigation.

These findings indicate that abnormalities in calcium release may have downstream developmental effects if calcium-dependent signaling pathways or processes are perturbed. Two reports, one experimental and the other clinical, strongly support this possibility. The studies of Ozil and Huneau [53] showed that the developmental consequences of increasing the level of calcium released after ionophore activation of rabbit oocytes were not evident until organogenesis, where multiple system anomalies and defects resulted in fetal demise. It is important to emphasize that preimplantation development was normal. For the human, oocytes with a large SER aggregate such as shown in Fig. 76.1i, k are fertilizable by ICSI, but few embryos develop normally during the preimplantation stages and, if transferred, most cease to develop [70]. However, what is disturbing about some of the births from oocytes of this type is the occurrence of genomic imprinting disorders that have been suggested to be associated with aberrant calcium signaling at the outset of development [71]. Concerns about developmental normality and a high potential for imprinting disorders have resulted in the recent conclusion by a joint ESHRE/alpha panel of experts that human oocytes with SER inclusions, such as those described above, should never be inseminated [72].

76.7 Mitochondria and Signal Transduction Pathways

Similar to differentiated cells [73], a structural relationship between the SER and mitochondria [14, 48] in the oocyte and early likely includes regulatory functions other than calcium homeostasis and mitochondrial energetics. What is critical to understanding the extent to which abnormalities in calcium release at fertilization may affect human development is a determination of if, and how, the flow of regulatory information within the ooplasm may be perturbed and, for the early embryo, whether bidirectional information flow between the cytoplasm (e.g., transcription factors and activators) [74] and nucleus (e.g., mRNA) is altered. In this context, the identification of defects in signal transduction may provide fundamental insights into the origin of developmental competence for the oocyte and how it may be lost or compromised after fertilization. For the fresh oocyte, the occurrence of calcium release abnormalities appears to be a relatively low-frequency event, and the question remains why only some oocytes are affected. For thawed oocytes, however, the frequency is significantly higher, and the extent to which this abnormality is protocol related is unclear, and the results of fine structural analyses conflict with respect to cooling and freezing protocol. While some studies report no evident alterations in sER structure or organization [65], others have described apparent swelling of the cisternae and changes in spatial organization [75] that could contribute to the atypical response to ionophore activation shown here. While it is likely that an optimized protocol of oocyte cryopreservation that minimizes damage to or alteration of sER integrity and function will be forthcoming, for some oocytes, defects in sER function may be an inherent problem associated with fertilization failure or abnormal preimplantation embryogenesis. How these defects may influence mitochondrial function, cytoplasmic bioenergetic state, and local stage-specific free energy availability are the types of developmentally significant questions that, while currently unanswered, may be fundamental to understanding the cell biology of the human oocyte and early embryo.

76.8 Mitochondria and Cytoplasmic Redox State

An important regulatory influence of mitochondria in somatic cells is their effect on the redox state of the cytoplasm. The normal state of the cytoplasm is a reducing environment, and cells employ different mechanisms to maintain redox homeostasis in the presence of mitochondria-derived oxidative stress. The pathogenesis of certain diseases is based on the inability of these mechanisms to cope with oxidative stress, such as superoxide toxicity, and at the cellular level, an inability to counter a shift toward an oxidative environment can lead to signaling disorders and bioenergetic insufficiency leading to dysfunctions in cytoplasmic bioactivities, apoptosis, or pathological cell death. Mitochondrial redistribution and localization is one means by which location-dependent ATP supply and demand requirements can be met, and potentially higher levels of superoxide production that may occur with cytoplasmic mitochondrial aggregation or remodeling are normally addressed by mitochondrial and cytoplasmic antioxidants (e.g., superoxide dismutase and glutathione).

Location-related differences in mitochondrial density that alters cytoplasmic redox potential may also regulate redox-sensitive signaling pathways and in some species, such as the sea urchin, are essential for specification of the oral-aboral axis, which involves redox-dependent signaling path-

ways. The establishment of this axis in the fertilized egg is regulated by an asymmetrical mitochondrial distribution in the oocyte and in the early embryo, where a redox gradient is formed by virtue of differential mitochondrial density [76, 77]. These investigators reported that the portion of the sea urchin embryo that inherits the highest density of active mitochondria is strongly biased toward oral axis specification owing to the location-specific expression of the oral axis determining transcription factor, *nodal*. According to this model, a "transcription factor" gradient is established in the blastomeres of the early embryo in which the function of different redox-sensitive transcription factors, such as *nodal*, is dependent upon a redox threshold within the redox gradient established by differential mitochondrial density. In this context, the cytoplasm of the oocyte and early blastomeres may be functionally compartmentalized as a normal consequence of relative mitochondrial density.

A similar phenomenon, albeit on a much smaller scale, has been observed in differentiated somatic cells where mitochondria aggregate in different locations in order to increase ambient ATP availability to accommodate transient changes in local energy demand [46]. Spatial remodeling of mitochondria is a dynamic process and, in active cells, may undergo continuous redistribution. Changes in mitochondrial density may also alter local cytoplasmic redox state and, as a result, locally affect bioactivities with different redox-sensitive thresholds. This form of dynamic cytoplasmic mitochondrial reorganization was suggested by Aw [46] to be a type of microzonation in which local activities could be functionally compartmentalized within the cytoplasm in response to changes in cell activity or exogenous signals such as cell contact. Changes in mitochondrial density that alter the ambient redox state may also increase respiratory activity by the aggregated mitochondria if local pH is also reduced (by ATP hydrolysis), which Aw [46] suggests can increase the efficiency and rate of uptake of intermediately metabolites. Dynamic changes in $\Delta\Psi_m$ may be another example of mitochondrial microzonation. As described above, Diaz et al. [47] showed that the magnitude of $\Delta\Psi_m$ in mitochondria at the margins of cultured cells was cell contact dependent with a downregulation of this transmembrane potential occurring in areas of intercellular contact and communication. As previously noted, similar finding was reported for the cleavage-stage mouse embryo [48], where mitochondria in the subplasmalemmal cytoplasm corresponding to regions of intercellular contact and gap-junction-mediated intercellular communication were low potential while those beneath the free margins of the plasma membrane were high potential. In this study, experimental manipulations of early cleavage-stage embryos showed that the magnitude of $\Delta\Psi_m$ in these regions could be up- or downregulated as a function of the presence of or absence of intercellular communication and contact. It may be worthwhile to determine whether differences in redox state occur in these regions and, if confirmed, whether the absence of adequate cell contact or communication influences $\Delta\Psi_m$ and the normal functions of redox- and ROS-sensitive signaling (e.g., JAK-STAT) [78] in this region. This may be especially relevant in certain early cleavage-stage human embryos where the apparent absence of normal cell contact and communication appears to lead to aberrant development in vitro.

Findings from cultured cells and early embryos such as the sea urchin clearly demonstrate that in addition to ATP production, mitochondria have central regulatory roles in signal transduction through calcium and redox-sensitive pathways and, by creating microzones that may alter local physiology, can create cytoplasmic compartments with different functional characteristics. Evidence suggesting that similar cell biological activities occur in the mammalian oocyte and early embryo has come from the characterization of dynamic, stage-specific changes in mitochondrial distribution and from the detection of differential $\Delta\Psi_m$ that is location-based. Preovulatory cytoplasmic maturation of the oocytes of certain species, such as the mouse, involves stage-specific mitochondrial translocation to the perinuclear nuclear region [27, 28] that, in the mouse, is directed by microtubular arrays emanating from perinuclear microtubular organizing centers [32]. The formation of a relatively dense sphere of mitochondria around the developing nuclear region after germinal vesicle breakdown has been suggested to increase ambient ATP levels but may also alter the perinuclear redox state to promote formation of the first and second meiotic metaphase spindles, chromosomal segregation, and polar body abstriction [21]. Here too, the notion of thresholds may be developmentally significant as excessive or inadequate perinuclear aggregation may have coincident effects on bioenergetic and redox state that are inhibitory for maturation to MII [27, 79] or contribute to disorders in chromosomal segregation leading to aneuploidy [5, 80, 81]. In addition to the mouse [27], perinuclear aggregation has also been reported for the pronuclear and early cleavage stages in other mammals such as the pig, hamster, nonhuman primate, and the human [43, 82, 83]. Indeed, a pronounced peripronuclear accumulation of mitochondria occurs in the human, and asymmetries in distribution have been related to disproportionate mitochondrial inheritance during cleavage [43]. In contrast to the mouse oocyte, mitochondrial translocation to the developing nuclear region of the maturing human oocyte is less pronounced, perhaps owing to the absence of definitive microtubular organizing centers, especially in the perinuclear region. In addition, virtually all information concerning the cytoplasmic dynamics of human oocyte maturation has come from observations made in vitro with immature oocytes, most of which had failed to reinitiate meiosis or arrested meiosis prior to MII after ovulation induction. Reliance on in vitro matured oocytes for these studies is understandable because extracting oocytes at specific stages of preovulatory maturation after ovulation induction in stimulated or natural cycles (which would be preferable) is unlikely to be the type of experiment whose inherent value can be ethically justified. However, a limited number of fine structural images of human oocytes that were at the GV stage at aspiration, or remained so during culture in vitro, often show unusually high densities of perinuclear mitochondrial

aggregation [14]. Confirmation that an abnormal perinuclear redox state may be responsible for the failure of meiosis to resume or progress to MII would go a long way in providing new insights into how maturational and fertilization competence is established and, for the human, possible follicle-specific influences that promote or inhibit early development.

76.9 Mitochondrial Inner Membrane Potential and Functional Microzonation

The notions of microzonation and functional compartmentalization would be more compelling as developmentally significant aspects of oocyte maturation and early embryogenesis if they could be correlated with known abnormalities in cytoplasmic organization that have negative developmental consequences—the so-called cytoplasmic dysmorphisms described for human oocytes [67, 70]. At present, differential $\Delta\Psi_m$ appears to be one aspect of mitochondria that may support these notions [2, 21]. In the human and mouse MII oocyte, high-potential mitochondria are normally localized to the subplasmalemmal cytoplasm where they form a distinct circumferential domain detectable with $\Delta\Psi_m$-sensitive (potentiometric) fluorescent probes such as JC-1 [48, 84, 85]. In the human, the absence of high potential in this domain in fresh [48] and thawed MII-stage oocytes [51] has been suggested to be a proximal cause of penetration failure in conventional IVF. A similar phenomenon has been reported for the mouse where sperm penetration is reversibly inhibited by experimentally down- and upregulating $\Delta\Psi_m$, respectively, in this domain [86]. In the mouse and human, this domain is spatially stable in the oocyte and remains so during early cleavage, and in the human, spatial stability is indicated by the absence of high-potential forms after loss by minor fragmentation [50]. While their energetic contribution to net cytoplasmic ATP levels in the MII oocyte is negligible, which would be expected considering the domain contains <3% of the total mitochondrial complement, as noted above, their loss or reduced potential in this specific region appears to have important implications for development. The possibility that this extended domain (microzone) of mitochondria may have specialized functions during early development (functional compartmentalization) is suggested by the extent of loss, either naturally occurring or experimentally induced, on the subsequent ability of the affected blastomere(s) to participate in embryogenesis. The loss of high $\Delta\Psi_m$ organelles to a few small fragments had no discernable effect on embryogenesis, whereas loss from one or more regions that significantly diminished mitochondria from this domain, or where the distribution of high-potential mitochondria was scant or discontinuous, was associated with the failure of the affected blastomere to divide. However, loss to this extent is not necessarily lethal, as the affected blastomeres typically remained undivided as the remainder of the embryo progress through the preimplantation stages. At the fully expanded blastocyst stage, the presence of a cleavage-sized cell in the perivitelline space or less commonly the blastocyst cavity may originate from an early, nonlethal, loss of high-potential mitochondria from a single blastomere.

Wilding et al. [87] reported that clusters of high-potential mitochondria occurred within the cytoplasm of arrested/degenerating human blastomeres, but not in the subplasmalemmal cytoplasm. This phenotype has been rarely observed in our experience but could be associated with a premorbid state that may lead to apoptosis, as this cell death pathway generally involves an abrupt collapse of high $\Delta\Psi_m$ leading to the release of calcium and cytochrome c. In contrast, pathological cell death usually results from a persistently low $\Delta\Psi_m$ that corresponds to a bioenergetic state that is unable to meet the minimal ATP demands required to maintain cell function. In this regard, most unfertilized human oocytes will remain intact for days in culture, and changes in mitochondrial fine structure, such as loss of cristae and changes in matrix electron density that become apparent after day 4 or 5, are consistent with a significant drop in net ATP content and scant high potential in the subplasmalemmal domain [3]. Typically, these oocytes lyse on or after day 6 or 7, indicating that cell death is likely due to an energetic deficiency associated with necrosis rather than by the induction of apoptosis [45].

While there is compelling evidence that a subplasmalemmal domain of high-potential mitochondria exists in the mature human oocyte and cleavage-stage embryo and appears to be involved in sperm penetration, why perturbation of this microzone at the blastomere level has adverse consequences remains to be determined. One possibility suggests that higher ambient levels of ATP may be required to support dynamic membrane activities involving transporters, ion channels, and plasma membrane reorganization between the oocyte and embryonic stages. Another possibility that warrants investigation is that this domain is involved in signal transduction pathways and those that are redox- or ROS-sensitive in particular [3]. If confirmed, findings of this type may add a new dimension to our understanding of what competence entails during the earliest stages of human development. Likewise, they may provide novel diagnostic methods to assess subtle causes of fertilization failure, embryo arrest, and abnormal performance in vitro that may be related to maternal age or for some patients, to repeated negative outcomes in IVF cycles.

The role of mitochondria in the regulation of cytoplasmic redox state may be one that is unfamiliar to clinical practitioners, but is nevertheless a fundamental property that, as more information emerges, will likely become another factor to be recognized in the establishment of competence. Likewise, the relationship between mtDNA copy number at MII and whether numerical expansion occurs during the preovulatory stages may have important influences on mitochondrial activity in the oocyte and redox state and ROS/redox-sensitive signaling during fertilization and early embryogenesis. A similar activity may occur during the cleavage stages where high-potential mitochondria remain localized in the subplasmalemmal cytoplasm. It remains to be determined whether loss of these mitochondria to fragmentation, or failure to

resume high potential after thawing [51], impacts the local redox state or redox-sensitive signaling at the level of the plasma membrane and subplasmalemmal cytoplasm.

A potentially important finding demonstrating that cytoplasmic redox potential can be altered by exogenous factors comes from the recent study of Dumollard et al. [88], who reported that the normality of preimplantation embryogenesis in vitro was supported by a redox potential that involved cytosolic and mitochondrial metabolism of pyruvate and lactate—the former a cytosolic oxidant and mitochondrial reductant and the latter a strong cytosolic reductant. The potential developmental significance of these findings is that cytoplasmic redox potential can be altered by varying the concentration of intermediate metabolites normally found in embryo culture medium, such as pyruvate. In this context, seemingly minor modifications to culture medium that may change the oxidation/reduction equilibrium in a stage-dependent manner could be unrecognized factors that directly impact human embryo performance and viability during the preimplantation stages. Novel fluorescent probes that can assess intracellular redox state in living cells [89] may be sufficiently sensitive to detect local state changes that may be associated with stage-specific events such as fertilization and intercellular communication and possibly with modifications to medium composition or culture conditions. In this regard, it will be relevant to determine the extent to which, if any, metabolomic assessments of spent culture medium that have been proposed for clinical IVF [90] are detecting redox changes that could influence competence. What is particularly interesting about this possibility is that it could add redox homeostasis to the calculus of assessing outcome if differences are oocyte−/embryo-specific or cohort-wide and perhaps suggest novel treatments that can be implemented to target functional disorders that are redox (mitochondrial)-driven.

76.10 Summary and Future Prospects

While a considerable body of evidence supports a central role of mitochondria in early human development, questions other than those discussed above are worthy of mention. What is the normal number of mitochondria in an oocyte, and is there a threshold for competence? Often, mitochondrial mass and mtDNA copy number are used interchangeably, which can confound this issue as mtDNA copy numbers can vary widely, often by over an order of magnitude, between MII oocytes in the same cohort [2, 11, 18, 23]. Variations in mtDNA content between oocytes within the same and different cohorts may reflect differential levels of mtDNA expansion among mitochondria rather than numerical differences in mitochondrial complement. Resolution of this issue will require morphometric analyses, preferably with superfluous MII oocytes whose cytoplasm is characterized as normal [72]. A second question is whether mtDNA expansion occurs during preovulatory maturation, at what stage(s), and whether mtDNA degradation occurs during cleavage and how it may be regulated [24]. Whether the finding of lower mtDNA content found in rat oocytes that matured in vitro [25] pertains to the human needs to be determined if IVM is to become a standard practice in clinical IVF.

At present, while these issues are speculative, they do indicate the types of questions that may provide basic information about cell biology of the human oocyte during the terminal stages of development and at the earliest stages of embryogenesis. Against this background, the extent to which differential mitochondrial potential or activity may influence local redox state and, by extension, putative redox-sensitive or redox-dependent signaling pathways may be among the most relevant because the effects of altered signaling during embryogenesis in other developing systems, such as those described above, can be both immediate and downstream, and there is no reason to expect the human to be an exception. The basic cell biological processes and interactions discussed here for mitochondria, and emerging principals of cytoplasmic organization such as microzonation and functional compartmentalization, may be central to how developmental competence is established and maintained and, if confirmed for the human, could offer new directions for studies of the impact or regulatory influence on competence of the follicle-specific biochemical milieu. This is an exciting area of research with clear clinical implications, and it is highly likely that as investigations proceed, additional influences of mitochondrial activity and function will be recognized and incorporated into novel protocols or algorithms designed to assess developmental potential and normality.

Review Questions

1. What are mitochondria considered a primary nexus of normal cellular activities that for the human oocyte and nascent embryo are currently considered to be critical determinants of developmental competence?
2. What evidence suggests that the magnitude of the inner mitochondrial transmembrane potential ($\Delta\Psi m$) is important in establishing developmental competence for the meiotically mature oocyte and early human embryo?
3. Why might spatial compartmentalization of differential mitochondrial activities be a necessary occurrence in the oocyte and early embryo with respect to the establishment of normal developmental competence?
4. How are mitochondria in the oocyte and early embryo involved in redox and calcium homeostasis and why might this be developmentally important?
5. What possible functions might bidirection signaling between mitochondria and the nucleus have in the developing oocyte and early embryo, including the human, that could determine normal developmental competence prior to fertilization?

6. Considering current estimates of normal mitochondrial mass and mtDNA content in a human MII oocyte, the multiple roles mitochondria have including a bioenergetic one, and notions of differential spatial compartmentalization, why might the addition of a relatively small number of exogenously derived oocyte mitochondria be expected to shift from developmentally incompetent to developmentally competent, or not?

Cytoskeletal Architecture of Human Oocytes with a Focus on Centrosomes and their Significant Role in Fertilization

Heide Schatten, Vanesa Y. Rawe, and Qing-Yuan Sun

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_77

Learning Objectives

- Centrosome functions in human oocytes and during fertilization
- Cytoskeletal dynamics during fertilization and development
- Intracytoplasmic sperm injection (ICSI)
- Assays for centrosome functions
- Regulation of sperm aster formation
- Centrosome structure and functions
- The role of specific centrosome proteins in MII oocytes and embryo development

77

77.1 Introduction

In humans and most mammalian species, fertilization takes place at the MII stage (metaphase of second meiosis) in which oocytes are arrested after maturation. Oocyte quality is critically important for successful fertilization, and a variety of different criteria have been used to assess oocyte quality although in many cases the reasons for fertilization failure remain unclear and cannot be determined based on presently available morphological and molecular/biochemical data [1–8, 66]. However, it is important to evaluate specific factors that are known to play a role in oocyte quality and affect successful fertilization. The most prominent structure of the MII oocyte is the MII spindle containing the maternal chromosomes aligned at the metaphase plate and connected to kinetochore microtubules (kMTs) and to acentriolar centrosomes at the opposite spindle poles. Along with nucleation of kMTs from spindle pole centrosomes are pole-to-pole microtubules that are important for chromosome separation (Fig. 77.1). The integrity of the spindle fibers as well as centrosome integrity is an important criterion for oocyte quality as it reflects the general condition of the individual oocyte including oocyte aging that may also occur during the process of IVF [9, 10, 67–74, 76, 77].

Spindle pole centrosomes, whether with or without centrioles, contain numerous centrosome proteins that play a role in specific but also complex centrosome functions as will be detailed in the following sections. The sperm (Fig. 77.2), on the other hand, contains as prominent microtubule cytoskeletal structure the sperm axoneme (sperm tail) and the basal body (a pair of centrioles), one of which (the proximal centriole) will be important for sperm aster formation after fertilization while the other (the distal centriole) is tightly connected to the sperm tail and serves as the nucleation material for the sperm axoneme as will be detailed below. The oocyte and sperm both contribute important cytoskeletal components that are critical for successful fertilization.

The following sections will review the centrosome and microtubule cytoskeletal organization in human oocytes and also in animal models including the pig and bovine models from post-maturation through fertilization and development to first cell division. It should be noted that while the mouse has been used for many genetic studies, it is not a useful model for cytoskeletal organization and fertilization as it differs profoundly in essential aspects compared to all other mammalian species and will not be included in the present chapter.

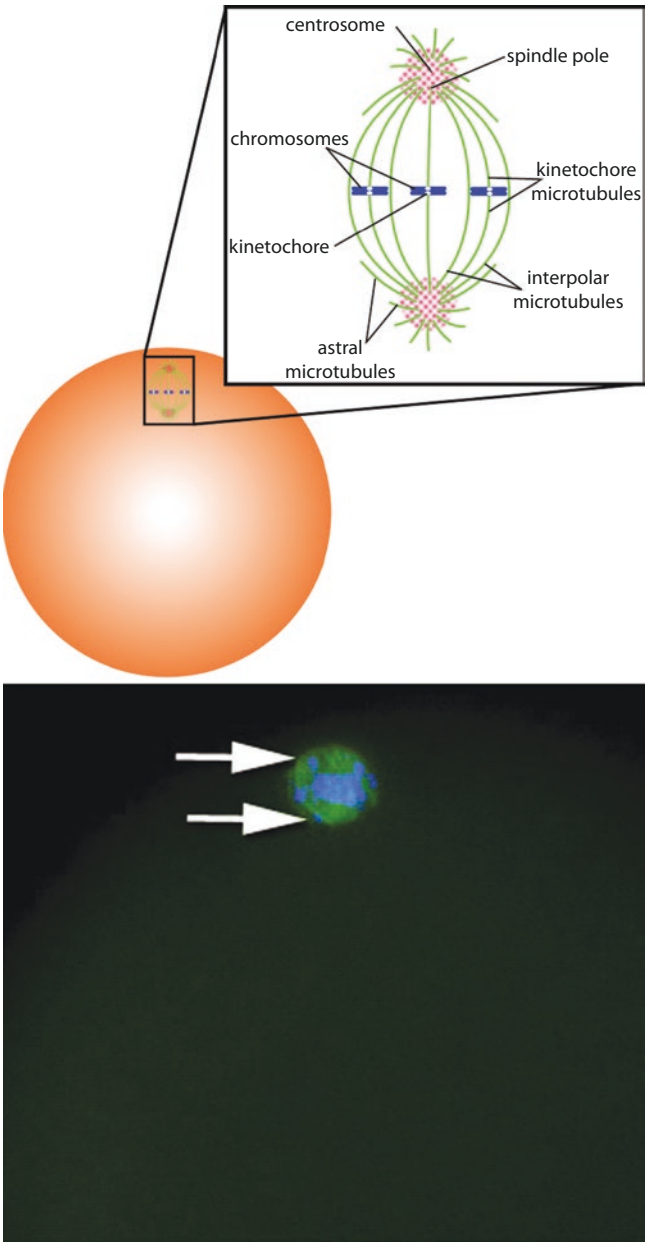

Fig. 77.1 Schematic diagram and immunocytochemistry of MII oocyte before fertilization. The MII spindle is organized from acentriolar centrosomes that nucleate kinetochore and pole-to-pole microtubules that are regulated by a complex set of kinases to hold the MII spindle in shape and prevent deterioration. In most mammalian species, the MII spindle displays perpendicular organization to the egg cortex (parallel orientation in the mouse). Abnormal alignment of chromosomes (blue) can be seen with fluorescence microscopy (arrows, bottom panel). MII spindle microtubules can be detected using antibodies to either alpha or beta tubulin (green)

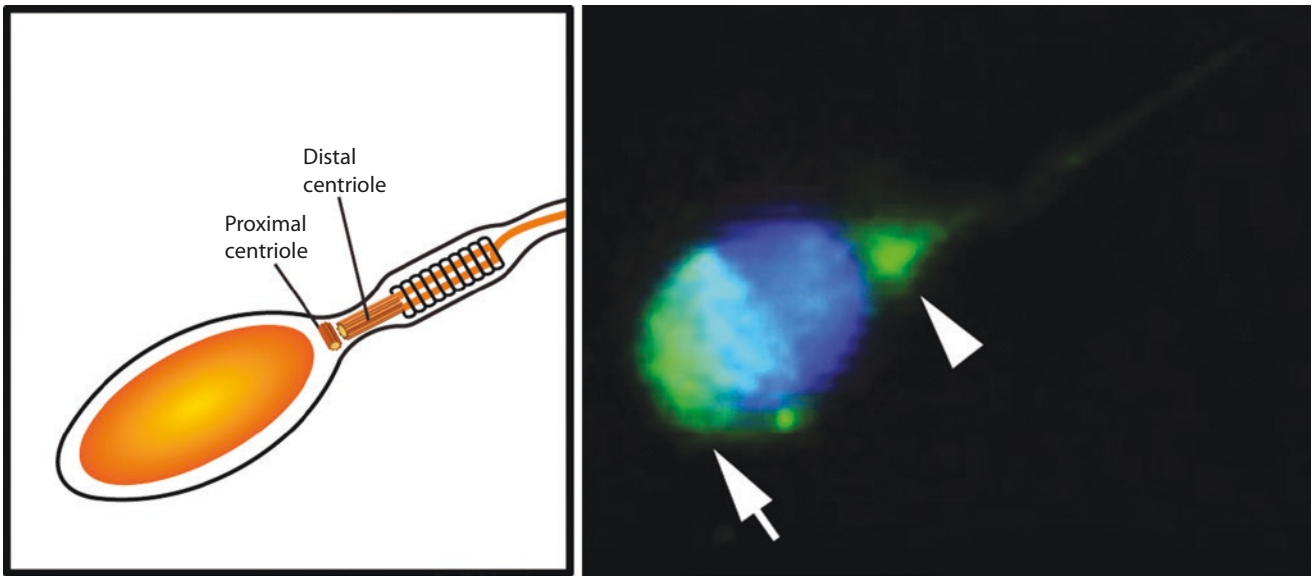

Fig. 77.2 The sperm in most mammalian species contains a proximal and a distal centriole; the proximal centriole is closely associated with the sperm nucleus and will serve as microtubule-organizing center (MTOC) after fertilization, while the distal centriole displays a degenerated microtubule organization and nucleates the axoneme in the sperm tail. A minimal amount of centrosomal material is associated with the sperm centrioles including gamma-tubulin and centrin. Right panel shows ejaculated human spermatozoa labeled with p31 antibody (against proteasome as described in text). Two populations of proteasomes can be observed on the ejaculated spermatozoa: in the acrosomal region (arrow) and in the sperm tail connecting piece (arrowhead). Release of a functional sperm centriole that acts as a zygotic microtubule-organizing center may rely on selective proteasomal proteolysis during sperm penetration, suggesting an important role of sperm proteasomes in zygotic development [11]

77.2 Characteristics of Centrosomes and the Microtubule Cytoskeleton in MII Oocytes, in Spermatozoa, and After Fertilization

The cytoskeleton is mainly composed of three classes of cytoskeletal fibers, i.e., microfilaments (MFs, also called actin filaments or F-actin, 5–9 nm in diameter), microtubules (MTs, 25 nm in diameter), and intermediate filaments (IFs, 10 nm in diameter) as well as numerous cytoskeleton-associated components that play a significant role in cellular functions. However, the centrosome is a critical part of the cytoskeleton and plays a major role in coordinating various cytoskeletal and cellular functions (reviewed in [5, 10, 12–15]. This section reviews the role of centrosomes and the MT cytoskeleton in the MII oocyte and in sperm cells.

77.3 Centrosome Proteins

The structure and composition of centrosomes have been reviewed in several previous papers [5, 10, 12–15] and will only briefly be introduced here. The centrosome is an important microtubule-organizing center (MTOC) that either directly or indirectly is responsible for multiple cellular functions. Lacking a defining membrane that is typical for other cell organelles, the centrosome is a highly dynamic structure that very efficiently communicates signaling functions through its microtubule-organizing capabilities. Numerous centrosome core proteins and centrosome-associated proteins play a role in centrosome functions and direct or control cell cycle-specific events.

A typical somatic cell centrosome is composed of a large number of centrosome proteins surrounding a pair of perpendicularly oriented cylindrical centrioles, therefore referred to as pericentriolar material (PCM). In reproductive cells, the oocyte and the sperm's centrosomal material is reduced during gametogenesis (reviewed by Manandhar et al. [16]), and the mature egg and sperm contain specific centrosome proteins that reconstitute a complete functional centrosome after fertilization. The oocyte does not contain centrioles, but it does contain centrosome proteins, while the sperm contains the centriole surrounded by a small amount of specific centrosome proteins including γ-tubulin and centrin.

The centrosomal core material consists of a fibrous scaffolding lattice whose three-dimensional architecture is primarily maintained through specific protein-protein interactions. It is a highly dynamic structure that compacts and decompacts for cell cycle-specific requirements in which different microtubule patterns are organized depending on the centrosome architecture. Highly compacted centrosomes organize focused microtubule formations, while an expanded centrosome structure organizes various expanded microtubule formations. Gamma-tubulin and the γ-tubulin ring complex (γ-TuRC) are mainly responsible for the nucleation of microtubules, while pericentrin plays a role in recruiting γ-tubulin to the centrosome complex.

Microtubules are anchored with their minus ends to the centrosome core structure ([17]; reviewed in Schatten [5, 10, 12, 74]), and microtubule numbers and lengths are regulated and reorganized throughout the cell cycle; microtubule growth is regulated by distal plus-end addition of tubulin subunits ([18]; reviewed in Schatten [12]; [5, 10, 74]). Microtubules play a role in translocation of vesicles, enzymes, and macromolecular complexes that allow rapid modifications of centrosomal material and impact cell cycle-specific functions in which centrosomal proteins are recruited and dispersed throughout the cell cycle. Rapid microtubule growth and transport along microtubules is especially important for the rapid formation of the sperm aster after fertilization that involves microtubule motor proteins and accessory proteins to reach the female pronucleus for pronuclear movements and apposition and for the union of the pronuclei containing maternal and paternal genomes ([19, 78]; reviewed in [5, 10, 12]).

77

77.4 MII Oocytes

The MII oocyte is the end result of a complex process of oocyte maturation that is critical for MII stage-oocyte quality (reviewed in [1, 5, 16, 20–23]). During oogenesis, centrioles that are present in oogonia become disintegrated, and the mature oocyte is devoid of centrioles in most species. However, centrosomal components are present in the MII spindle and in reduced amounts in the cytoplasm (reviewed in Manandhar et al. [16]) that can be visualized in parthenogenetically activated oocytes ([24]; reviewed in Schatten and Sun [13, 14]).

As the oocyte has lost centrioles during gametogenesis, the MII spindle is organized by acentriolar centrosomes consisting of numerous centrosome proteins including the well-known centrosome proteins γ-tubulin, centrin, and the nuclear mitotic apparatus (NuMA) protein. In most species (not in the mouse), the MII spindle is localized perpendicular to the cell surface, and it is a barrel shape to pointed spindle structure (parallel to the egg surface in the mouse which along with many other features re-emphasizes the differences in mouse oocytes compared to most other mammalian species; reviewed in Schatten and Sun [5, 10, 13, 14, 88, 96]).

Although it appears static in immunofluorescence and TEM images, the MII spindle is a highly dynamic structure that maintains its shape by a complex set of regulatory kinases and other regulatory proteins [5, 9, 10, 13, 14, 25, 69, 76, 79–82, 88, 96]. The main functions of the MII spindle are to precisely separate chromosomes and extrude one set of chromosomes into the polar body so that a diploid chromosome set is restored after fertilization during which the sperm contributes the paternal set of chromosomes. Any failure in MII spindle functions can result in cell and developmental abnormalities resulting in abortion, disease, or developmental defects [5, 9, 69, 76, 83]. The MII spindle is therefore an important key structure that requires precise regulation, receiving signals from the surrounding cells, the ooplasm, and the sperm during fertilization. An intact MII spindle as shown in Fig. 77.1 (top panel) is an important criterion to assess oocyte quality. Misaligned chromosomes (arrow in bottom panel of Fig. 77.1) can be visualized as a result of dysfunctional microtubules and molecular motor proteins associated with spindle abnormalities [26].

77.5 Spermatozoa

The components involved in sperm centrosomal functions have previously been reviewed in detail [5, 10, 13–16, 27–30, 88, 96]. Briefly, when spermatids transform into mature sperm, a partial reduction of the sperm centrosome occurs in that the proximal centriole (PC) is retained completely in the sperm with proximal localization to the nucleus, while the distal centriole (DC) becomes partially reduced, and it becomes associated with the sperm axoneme in the midpiece and tail (Fig. 77.2). This distal centriole becomes restructured in that it loses the triplet microtubule organization while a central pair of microtubule doublets becomes apparent, as is characteristic for the axoneme (reviewed in Schatten and Sun [13–15]). Sperm aster organization during human fertilization requires a sperm-derived centriole that must first disengage from the sperm tail connecting piece. Release of the proximal centriole is carried out by sperm (and oocyte) proteasomes during fertilization (right panel Fig. 77.2; [11]).

77.6 The Importance of Centrosomes for Fertilization and Implications for ICSI

As stated above, the precise formation of the sperm aster is critically important for pronuclear movements and for the union of male and female pronuclei as diagrammed in Fig. 77.3. The sperm centriole and surrounding centrosome material is particularly important as it provides the dominant structure onto which oocyte centrosome proteins accumulate to form a functional zygotic centrosome for the formation of the zygote aster. After release of the proximal centriole by proteasomes [11], precise nucleation of microtubules includes precise amounts of γ-tubulin ring complexes (γ-TuRC) composed of γ-tubulin and accessory proteins that are associated with the centrosome core structure and nucleate precise amounts of microtubules in the rapidly changing sperm aster [5, 10, 15, 31, 84–88, 96]. γ-Tubulin needs to be recruited from the oocyte to increase sperm aster size and length in a cell cycle-specific manner that results in the functional zygote aster important for pronuclear apposition. Over-recruitment of γ-tubulin will result in nucleation of too many microtubules, while under-recruitment of γ-tubulin will result in reduced aster formation that both may result in aster formation abnormalities and decreased developmental potential. Studies in the bovine system have revealed that sperm aster formation and

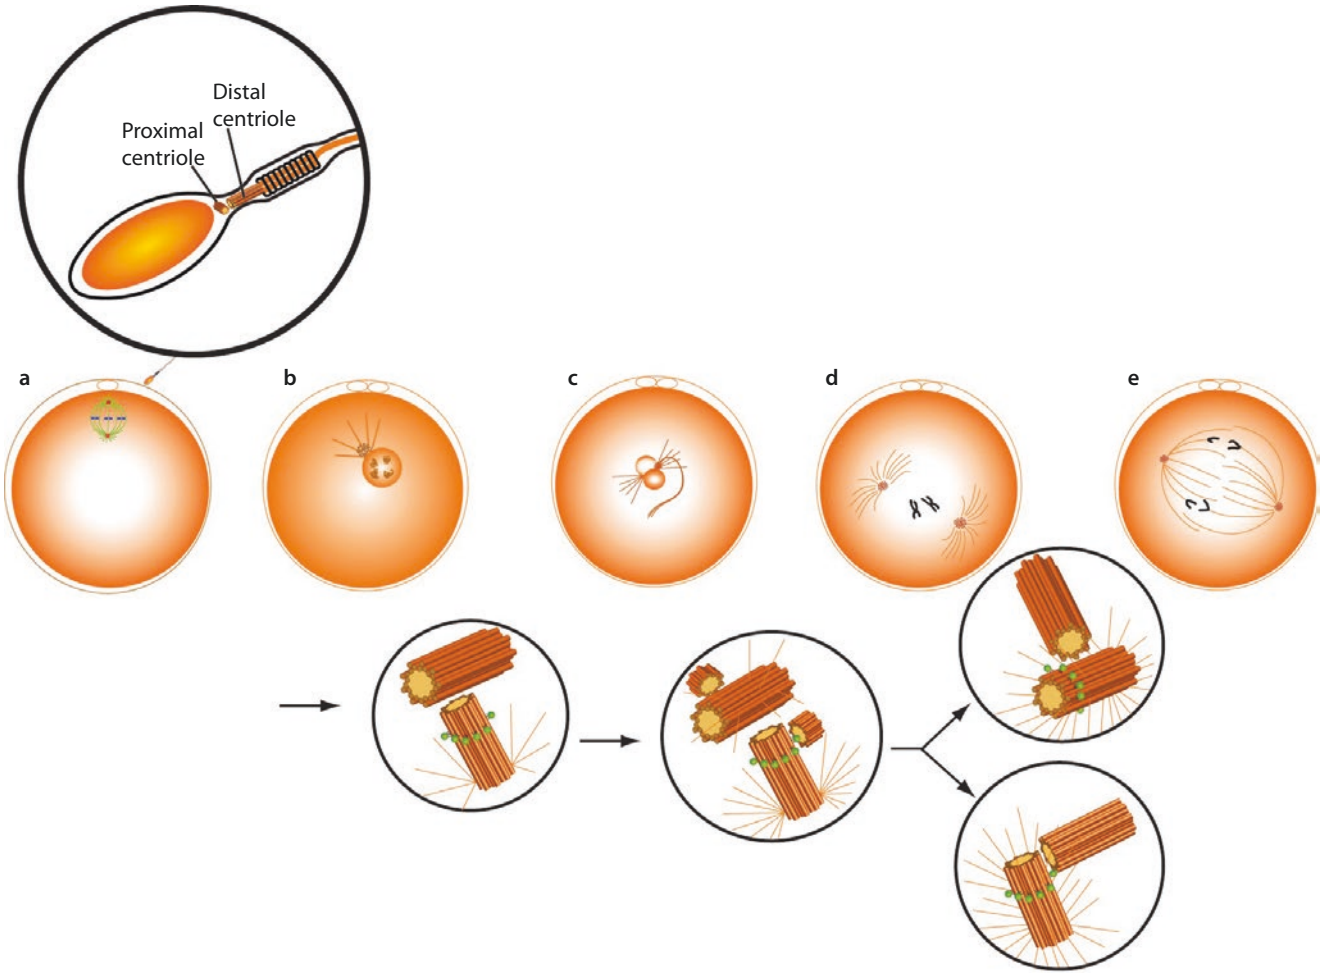

Fig. 77.3 Schematic diagram of the centriole–centrosome complex from fertilization to first cell division. **a** Sperm before fertilization contains a proximal and distal centriole. The meiotic spindle in the MII stage oocyte contains acentriolar centrosomes; **b** sperm aster formation from the sperm's proximal centriole–centrosome complex; **c** after pronuclear apposition, replication of the centriole at pronuclear stage; **d** after syngamy, the duplicated centriole–centrosome complex migrates around the zygote nucleus and relocates to opposite poles to form the centers of the mitotic spindle poles; **e** mitosis of the first cell cycle. Enlarged centriole complex: prior to fertilization, spermatozoa display two distinct centriolar structures with the proximal centriole located within the connecting piece next to the basal plate of the sperm head. This centriole displays a pinwheel structure of nine triplet microtubules surrounded by pericentriolar components. The degenerated distal centriole is organized perpendicular to the proximal centriole and aligned with the axoneme or sperm tail. **b** Shortly after sperm incorporation into the oocyte, a sperm aster is formed from the proximal centriole that allows pronuclear apposition. **c** After pronuclear apposition, the sperm centrioles duplicate during the pronuclear stage (in subsequent cell cycles during the G1/S phases); mother and daughter centrioles form procentrioles, fibrous material that is associated with the proximal region and grows into daughter centrioles (in subsequent cell cycles during the S and G2 phases), resulting in two pairs of centrioles that indicate duplication of centrosomal material. This pattern of centriole duplication is termed semiconservative duplication, as each daughter cell retains one of the mother's centrioles while a new daughter centriole is formed. Centriole and centrosome cycles are tightly coupled, and centrosome duplication occurs at the time centrioles duplicate. **d** The duplicated centrioles separate and migrate around the zygote nucleus to form the opposite poles of the first mitotic spindle. (Modified from Schatten and Sun [15])

size correlated to in vitro embryonic development to the blastocyst stage in which the degree of sperm-derived centrosome and aster organization affected male fertility and early development in a bull-dependent variation [31]. We do not yet know the full range of requirements for optimal sperm and zygote aster formation, but we do know that various factors require precise orchestration that involves phosphoproteins [32] and a variety of other centrosome-associated components that have been studied to a better degree in somatic cells (reviewed in Schatten [12]; Schatten and Sun [5, 10, 13–15, 88, 96]). In somatic cells, perhaps more than 100 different proteins play a role in centrosome and centrosome-directed cell cycle regulations including numerous regulatory components (kinases, phosphatases, and others) that associate with centrosomes during various cell cycle stages. The studies in somatic cells may indicate that over 100 different types of centrosome proteins may be involved in the dynamically changing centrosome composition during aster formation in the fertilized egg. Further studies are needed on basic and molecular levels to determine the full range of requirements for sperm and zygote aster formation to potentially improve in vitro fertilization.

Specific centrosome proteins that we know to play a critical role in centrosome and sperm functions during fertilization include pericentrin and centrin. In somatic cells, pericentrin along with several other proteins plays a role in centrosome and spindle organization [33–35]. Pericentrin forms a complex with γ-tubulin and depends on dynein for assembly onto centrosomes [35]; pericentrin gene mutation results in recruitment loss of several other centrosomal proteins. Centrins are members of a highly conserved subgroup of the EF-hand superfamily of Ca^{2+}-binding proteins. They are important for centriole functions and play an essential role in centrosome duplication ([36–38]; reviewed in [5, 10, 12, 16, 39]). Progress is being made to characterize other centrosome proteins that play a role in centrosome functions during fertilization, but our knowledge on this aspect of fertilization is still very limited.

One other protein that has proven critical for reproduction is the nuclear mitotic apparatus (NuMA) protein that is localized to the MII spindle in the mature oocyte. As NuMA is a nuclear matrix protein during interphase, it is detected in the decondensing sperm nucleus after fertilization [5, 10, 21, 22, 26, 40, 41].

Dispersion of NuMA into the cytoplasm occurs after nuclear envelope breakdown (NEBD), followed by NuMA association with mitotic centrosomes [5, 10, 21, 22, 40]. NuMA is never associated with the interphase centrosome; NuMA localization in the decondensing sperm nucleus after fertilization has clearly been shown for human oocytes [26] and for pig oocytes [40]. Studies in cloned pig and mouse embryos revealed that NuMA contributed by the donor nucleus plays a role in the formation of the mitotic apparatus during first cell division [5, 10, 21, 22, 40–42]. In aging or deteriorating oocytes, NuMA becomes dislocated from the MII spindle. NuMA abnormalities have previously been reported for cloning failures in rhesus monkeys [43].

77.7 Intracytoplasmic Sperm Injection (ICSI) and Assays for Centrosome Functions in ART

Intracytoplasmic sperm injection (ICSI, first reported by [44]) has allowed a novel treatment overcoming male factor infertility primarily related to sperm motility or other unknown factors. The benefits and possible complexities associated with ICSI are important to know (reviewed by Hewitson [45]), as 50% of IVF cycles are now employing ICSI in many IVF clinics (reviewed in [3, 5, 8, 30]). Some of the benefits using ICSI include the possibility to co-inject factors that may be causes of male factor infertility problems which have already been attempted in exploratory studies using the cat as model by co-injecting centrosomal material to restore complete centrosome function (detailed below). Future studies are needed to determine specific factors that are required to restore specific sperm functions after ICSI. Clearly, assessment of centrosomal material in sperm is important. As the important role of centrosomes in ICSI has been recognized, possible therapies have been proposed to restore defective centrosome functions. One of the most frequently used assays to determine sperm centrosomal integrity and functioning comes from indirect studies using heterologous fertilization models in which human sperm and bovine oocytes are used to assess sperm aster formation indicative of centrosome functions [31, 46]. Several heterologous ICSI systems have been employed by various investigators (reviewed in [47, 48]) in which human sperm were microinjected into either rabbit [49, 89, 90] or bovine [19, 50–53] oocytes. These assays established a relationship between infertility and sperm centrosomal dysfunction [54]. Such assays have especially been useful to assess centrosome functions in globozoospermia (characterized by sperm with round heads and lack of an acrosome and acrosomal enzymes and a disorganized midpiece; [55]) in which low rates of sperm aster formation were seen when heterologous ICSI with bovine oocytes was used (15.8%). Understanding the cellular events during mammalian fertilization is a major challenge that is important to pursue for improving future infertility treatments in humans [56, 57]. Figure 77.4 shows several examples of fertilization failures in human zygotes assessed by immunocytochemistry and confocal microscopy. Studies in the domestic cat [58] revealed short or absent sperm asters after ICSI with testicular spermatozoa compared to ejaculated spermatozoa that produced large sperm asters after ICSI. The diminished pattern of aster formation from the testicular sperm centrosome was associated with delays in first cleavage and reduced development to morulae and blastocyst stages, indicating that the size of the sperm aster may predict developmental competence. This aspect is important in light of recent live imaging studies that revealed the critical timing of cell divisions for IVF success rates and embryo development (reviewed in [3, 5, 6, 8]).

The studies in the domestic cat revealed that replacement of testicular sperm centrosome by a centrosome from an ejaculated spermatozoon resulted in higher rates of embryo development comparable to data from ejaculated spermatozoa which indicates that it may be possible to restore centrosome functions with donor centrosomes although ethical questions need to be addressed before proposing such therapies for couples in which infertility is a result of centrosome-related sperm dysfunctions. These studies also point to the possibility that sperm-related centrosome dysfunctions may be associated with incomplete centrosome maturation that is important for centrosome functions and sperm aster formation. Immature sperm centrosomes may play a role in the failure of injection of round spermatids into oocytes (ROSI) that has been unsuccessful when used in IVF procedures [59]. Taken together, these studies reveal a significant role for centrosomes in fertilization indicating developmental potential.

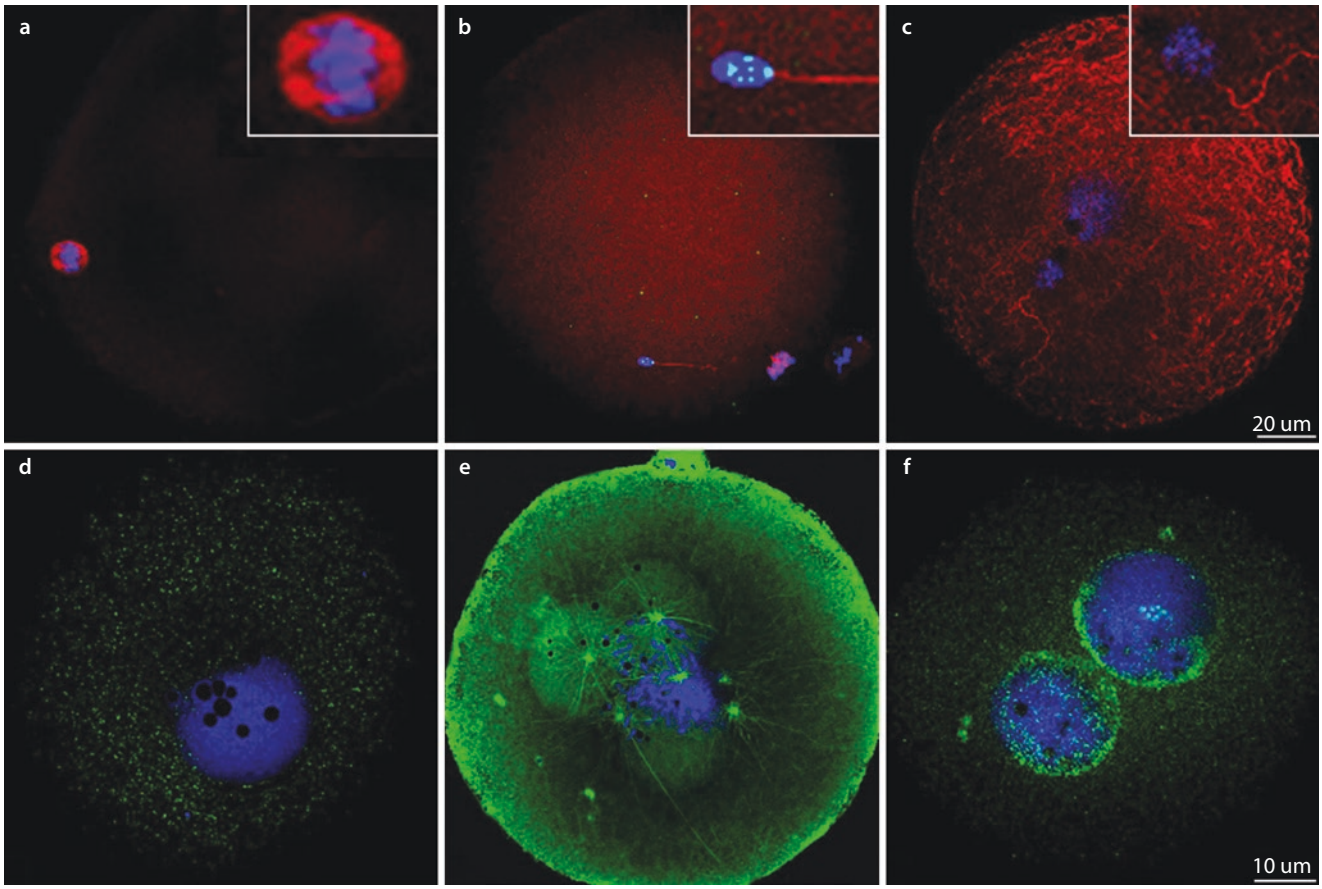

Fig. 77.4 Cytoskeletal organization and DNA configuration after failure and abnormal fertilization during IVF and ICSI. **a** Oocyte meiotic spindle (red: microtubules) with chromosomes (blue: DNA) at the metaphase plate. Inset in the upper right corner displays higher magnification detail. No sperm penetration is visualized. **b** The sperm head failed to form the male pronucleus, and the female chromosomes are still condensed at the meiotic spindle (lack of oocyte activation). Interestingly, fragmented sperm head is visualized after processing sample using TUNEL staining (see detail in the upper right corner, green). **c** Example of failure or incomplete male pronuclear formation at 18 h of ICSI. Microtubules (red) are extended through the entire oocyte cytoplasm as a result of oocyte activation. Male DNA was not completely decondensed (detail at the upper right corner), while female pronucleus underwent decondensation (asynchronous pronuclear development). **d** Formation of one pronucleus following ICSI (blue: DNA), presumably due to the lack of extrusion of the second polar body. **e** Development of three pronuclei after IVF due to polyspermy. Multiple MTOCs are shown in green as detected with anti-tubulin immunofluorescence staining for microtubules. **f** Arrested formation of two pronuclei. Male and female pronuclei are in close apposition at the center of the oocyte's cytoplasm. Nuclear envelopes are seen in green

77.8 Technical Aspects and Practical Considerations

The best characterized centrosomal core protein is γ-tubulin. In *oocytes*, its accurate distribution indicates spindle integrity, as it becomes displaced from the poles when spindles become deteriorated as is the case in aging oocytes (reviewed in Miao et al. [9]).

As indicated above, accurate centrosome function is critical for oocyte maturation, fertilization, and embryo development. As the overall success rate for ART is still low (35–40% in many clinics; up to 60% in others) [91–95], it will be important to study the cell and molecular mechanisms underlying oocyte maturation and fertilization as we still only have an incomplete understanding of cell and molecular criteria to evaluate embryo quality. Our understanding on centrosome formation, composition, and functions in human oocytes is especially poor, and we do not yet have sufficient information on centrosome/cytoskeletal functions and dysfunctions during fertilization and embryo development (reviewed in Schatten and Sun 2011a, b; [5, 10, 88, 96]). We have previously shown that human oocyte maturation, fertilization, and embryo development depend on accurate composition of centrosomes in which NuMA plays a critical role [26]. Previous studies revealed that accurate association of γ-tubulin with the meiotic spindle poles is essential for accurate spindle formation in human oocytes and that dispersion of γ-tubulin from the spindle poles is associated with oocyte aging [97] or with otherwise compromised oocytes that are not competent to be fertilized.

Aging of oocytes can occur during the preparation process which can play a role in human IVF procedures, either in research or in clinical settings. Here, the interpretation of results is particularly critical. As indicated above, during

oocyte aging centrosome integrity is lost in that proteins become dissociated from the centrosome core structure in all non-rodent mammalian species studied so far including humans which results in loss of meiotic spindle integrity. The dispersion of γ-tubulin [97] and NuMA [26] from the centrosome core structure can result in γ-tubulin dispersion and a γ-tubulin association with microtubules [75]. Most prominent and characteristic features in aging non-rodent mammalian (including human) oocytes are numerous small γ-tubulin and NuMA aggregates in the ooplasm. Such cytoplasmic asters are not seen in fresh non-rodent oocytes while, in contrast, they are characteristic for fresh rodent (mouse) oocytes, as rodent oocytes employ different mechanisms for meiotic and early mitotic spindle formation. In the mouse, cytasters are part of the mechanisms employed to form the MII spindle [98, 99, 107] while these cytoplasmic asters that are typical for young mouse oocytes disintegrate during oocyte aging in the mouse [9]. These differences and characteristic features of rodent and non-rodent oocytes are important to know when performing human IVF studies.

The analysis of meiotic spindle integrity is critical for the evaluation of oocyte quality. In recent years, as the demand for IVF and need for IVF success rates have increased, new noninvasive live cell imaging methods have been developed to better assess oocyte quality by imaging and evaluating meiotic spindle integrity as well as other features in maturing and matured oocytes. Several new imaging modalities have been developed to overcome previous limitations (reviewed in [3, 5, 6, 8]). These methods are likely to find applications in IVF clinics to increase IVF success rates.

The still most widely used noninvasive method for the assessment of spindle integrity in IVF clinics is PolScope imaging that has been applied to evaluate human oocyte MII spindle quality [25, 60]. In other test model species including the pig and bovine, immunofluorescence microscopy is typically used to evaluate spindle integrity using anti-tubulin antibodies for microtubules and antibodies to the MII centrosomal proteins γ-tubulin, centrin, and NuMA. Images of an abnormal and normal human oocyte MII spindle are shown in Fig. 77.1 bottom panel and Fig. 77.4a, respectively. It is important to observe that oocyte aging does not occur during the process of in vitro fertilization. In the pig model, several patterns of oocyte aging have been observed which are shown in Fig. 77.5. In humans, such patterns have been observed in deteriorated oocytes, and it has been shown that γ-tubulin and NuMA both dissociate from the spindle poles causing spindle abnormalities [97, 26]. Except for MII spindle evaluation using PolScope optics, future studies may consider live cell imaging with fluorescent centrosome labels such as GFP-centrin which has already been shown effective in pig studies [42].

One other aspect to assess oocyte quality for live cell non-invasive non-harmful imaging is imaging of mitochondrial distribution using multiphoton microscopy that has been employed in hamster oocytes and resulted in successful production of offspring [61]. Such approaches have not yet been used for human oocytes because of ethical considerations, but it may be possible.

Assessment of *sperm* is easier compared to oocytes, as abundant material is available that does not fall under ethical constraints. In sperm, γ-tubulin and centrin are both localized to the basal body and can be analyzed by immunofluorescence or immunoblotting in testing sperm samples. Conventional EM can easily be applied to assess sperm morphology [27, 28], and immunoEM can be applied to determine the accurate localization of γ-tubulin and centrin on ultrastructural levels.

To evaluate *sperm aster functions after fertilization*, still the best indirect assays for centrosome functions available so far are studies of heterologous fertilization in which human sperm is tested for its fertilizing capabilities using bovine eggs as test material. Fertilization can be assessed reliably well in bovine oocytes in which the sperm forms a microtubule-based aster that is indicative of successful fertilization. As mentioned above, the different sizes of sperm asters indicate the sperm's fertilization capabilities and developmental potential. This assay also provides an indirect test for the sperm's centrosomal contributions; its functions can be assessed independent of the human oocyte's centrosomal

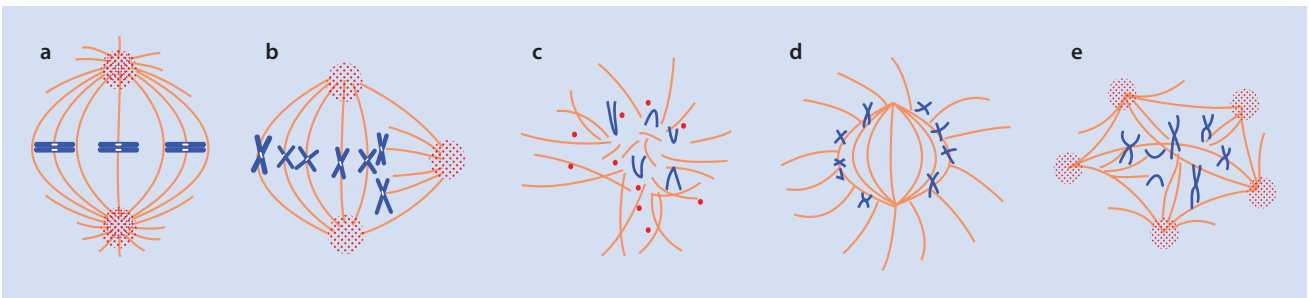

Fig. 77.5 Differences in MII spindle shapes between fresh and aged oocytes. Aged oocytes can display close to normal spindles **a** or highly abnormal spindles **b**–**e**. **b** Tripolar spindle. **c** Highly disorganized spindle with scattered centrosomes and chromosomes. **d** Large irregular spindle in transverse view exhibiting dense staining for tubulin with chromatin attached to the outer edges of the spindle in a rosette formation. **e** Multipolar spindle. Red = centrosomes, green = microtubules, blue = chromosomes. (Modified from Miao et al. [9])

components that may be a contributing factor for infertility, as the oocyte provides γ-tubulin and other regulatory factors that are essential for accurate sperm and zygote aster formation. The heterologous sperm aster tests will allow predictions on sperm or oocyte centrosomal defects. It indicates the sperm's potential to contribute to the fertilization success. If subsequent sperm aster formation is unsuccessful in human oocytes, defects in the oocyte's centrosomal components may need to be considered among other oocyte components that contribute to centrosome and sperm aster regulation. To remedy centrosomal defects, theoretically, various regulatory factors can be co-injected along with ICSI although we currently only know little about factors that play a role in sperm and zygote aster regulation in human oocytes. Experimental manipulation is possible in the heterologous human sperm-bovine oocyte system such as activation by changing pH and calcium factors. While the bovine system has been used for heterologous studies, the pig is increasingly being used as it displays many similarities with human fertilization (reviewed in [5, 10, 13–15, 88, 96]).

As mentioned above, cellular organization of mitochondria has been used by Squirrell et al. [61] to select oocytes for analysis with multiphoton microscopy, a safe method to evaluate live oocytes, and follow development. The observed fertilized oocytes were implanted into a hamster and resulted in subsequent live birth of healthy offspring. Live cell imaging of mitochondria in human oocytes might be worth consideration, as accurate distribution patterns have been associated with positive developmental potential [10, 62, 100, 101]. As mitochondria research in oocytes and developing embryos has progressed significantly [2], new approaches have become available to manipulate mitochondrial functions in oocytes to increase IVF success rates in IVF clinics (reviewed in Ishii [2]; and references therein).

The methods for immunofluorescence microscopy to analyze the microtubule cytoskeleton in human sperm and oocytes have been described in extensive detail by Rawe and Chemes [63]; the following sections in the present chapter are focused on centrosome detection and build on the previous descriptions for microtubules [63] in which media/chemicals, antibodies and staining, consumables and disposables, equipment, and tools have been described in detail. For the centrosome studies of human non-fertilized oocytes and zygotes by electron microscopy (EM), immunocytochemistry (ICC), and fluorescence microscopy in sperm and during ICSI, oocytes and zygotes of cells from couples undergoing ICSI provided the test material for our studies after written consent (described in Rawe and Chemes [63]). Briefly, for the study of human non-fertilized oocytes and zygotes by ICC and fluorescence microscopy during ICSI, cumulus cells are removed followed by removal of the zona pellucida, formaldehyde fixation, permeabilization, antibody labeling, and mounting and visualization of formaldehyde-fixed samples [63]. Examples of applying these methods are shown in Fig. 77.4.

77.8.1 Analysis of Sperm by Electron Microscopy and Immunofluorescence Microscopy

Sperm pathologies comprise a variety of structural and functional abnormalities that are among the many criteria underlying male factor infertility. Abnormally shaped flagella are among the clearly visible pathologies in severely asthenozoospermic men as reviewed by Chemes and Rawe [28] in which dysplasia of the fibrous sheath is most common. Sperm abnormalities can easily be determined with transmission electron microscopy (TEM) of a sperm sample to determine the degree of abnormalities. Centrosomal components can be determined by immunofluorescence microscopy to centrosomal proteins present in sperm before fertilization. Comparison with control sperm samples is recommended. Currently known sperm centrosomal markers are γ-tubulin, MPM2 (phosphoprotein marker), and centrin. Reduced amounts of centrin have been reported in male factor-related fertilization failures [64].

To analyze sperm, a fresh sample of ejaculated sperm is centrifuged and washed in PBS for 5 min as detailed in Rawe and Chemes [63]. After removing supernatant, the pellet is resuspended in PBS. For EM, these samples can now be processed using routine TEM methods as available in electron microscopy facilities.

The procedures for TEM include dilution of sperm in PBS (0.1 M, pH 7.4) (1:4 = sperm/PBS) at room temperature followed by thorough mixing. Next, sperm solution is transferred to a conical tip centrifuge tube and centrifuged at 1500–2000 rpm for 10 min. For fixation, 3% glutaraldehyde in PBS is added at 4 °C for a fixation time of 3–5 h, followed by two rinses in PBS for 30 min each. For second fixation, 1.3% osmium tetroxide (OsO_4) is added at 4 °C for a 2 h incubation time and two subsequent rinses for 30 min each in PBS. Dehydration follows in an ascending series of ethanol at room temperature (50%, 70%, 90%, 95%, 4x100%) for 20 min each followed by three rinses in propylene oxide (20 min each) as transition fluid. Embedding is performed in Epon-Araldite with steps including a mix of 1:1 propylene oxide/Epon-Araldite (2 h), fresh Epon-Araldite changes followed by curing for 24–48 h in EM molds. The materials are available from EM companies with detailed instructions included. Thin sectioning with an ultramicrotome and analysis in a TEM instrument is typically performed in electron microscopy facilities.

Routine TEM methods can be followed by ultrastructural immunocytochemistry to determine the presence of cytoskeletal and centrosome components related to ultrastructure. For the ultrastructural immunocytochemistry procedure, sperm pellets are fixed for 1 h at 4 °C in 5% formaldehyde in PBS (0.1 M, pH 7.4), rinsed in buffer, and dehydrated in an increasing series of ethanol as described for conventional TEM. Infiltration and embedding are performed using LR-White resin, medium grade for polymerization at 60 °C for 24 h. Sections are mounted on 300-mesh nickel grids and

dried at room temperature. Blocking buffer consists of TBS and 10% normal goat serum. Incubation in first antibody is performed by floating grids on a drop of antibody solution and left overnight at 4 °C making sure the samples are not dried out by keeping them in a humidified chamber. Three washes in TBS for 1 h at 4 °C are followed by incubation for 1 h at 4 °C with blocking buffer containing 15 nm colloidal gold-labeled secondary antibody. Sections on grids are then counterstained with 1% osmium tetroxide followed by 1:1 aqueous uranyl acetate/acetone. For negative controls, primary antibodies are either omitted or replaced with primary antibody preadsorbed with excess antigen.

For immunofluorescence microscopy, 100 µl of sperm suspension is placed on a poly-L-lysine-coated coverslip on a slide warmer at 37 °C. After 15 min, sperm are settled and attached to the coverslip which allows easy transfer into fixative (either 2% paraformaldehyde (PFA) in PBS at room temperature pH 7.2–7.3 or 100% methanol chilled to −20 °C) for 40 min. Next, coverslips containing sperm are carefully placed into 6-well dishes (face up) containing 2% PFA in PBS and 1% Triton X-100 to permeabilize sperm cells. Next, for antibody staining, several technical approaches are possible, and one easy approach is to remove the coverslips containing sperm from the six-well plates and place each one on the center cross of a four-well petri dish. A blocking solution is applied for 40 min incubation to bind residual free aldehyde groups. After carefully removing the blotting solution, primary and secondary antibodies are applied as described for oocytes and zygotes. Antibodies for centrosomal proteins include γ-tubulin and centrin.

77.8.2 Analysis of Oocytes by Electron Microscopy and Immunofluorescence Microscopy

The methods for the analysis of oocytes and developing embryos by electron microscopy and immunofluorescence have been described in previous papers and chapters [26, 40–42, 102, 101], and follow the basic methods described above for sperm. In this section, we will only briefly describe the important steps that are different for oocytes and the developing embryo, and we will refer to specific papers in which methods have been described more fully. Excellent methodological details are provided in the methods paper by Rawe and Chemes [63] with step-by-step protocols for sample preparation of human oocytes and embryos. Included are details for materials (media/chemicals, antibodies, consumables and disposables, equipment, tools) and methods (study of human non-fertilized oocytes and zygotes by immunocytochemistry and fluorescence microscopy during ICSI; removal of cumulus cells and zona pellucida, formaldehyde fixation, permeabilization, and antibody labeling; mounting and visualization of formaldehyde-fixed samples, methanol fixation, and antibody labeling; mounting and visualization of methanol-fixed samples). These methods include fixation and processing of single oocyte cells or embryos handled in drops using a mouth pipette, as frequently only few human oocytes and zygotes are available for research. Other methods utilize embedding of oocytes and zygotes in soft agar [102] which is useful when processing for electron microscopy but not for immunofluorescence microscopy. For immunocytochemistry as well as for electron microscopy, all samples need to be completely freed from cumulus cells and the zona pellucida before fixation with formaldehyde or methanol (Zhong et al. [102]; Rawe and Chemes [63], a methods chapter that contains a separate note section for detailed experimental recommendations).

Briefly, for formaldehyde fixation, permeabilization, and antibody labeling, samples are placed in a one-well dish containing 500 µl drops of the respective solutions. Washing between steps is performed by transfer into different drops of washing/blocking solution. When fixing in methanol instead of formaldehyde, 100% methanol is used for 10 min at −20 °C followed by storing coverslips in PBS and 0.1% Triton X-100. Permeabilization is not necessary when using methanol fixation. However, it is important to avoid chilling of samples before fixation when microtubules are being examined, as microtubules are highly sensitive to cold temperature and will depolymerize, resulting in negative results (i.e., absence of microtubule detection).

Antibodies are applied by placing oocytes in 30–50 µl drops of the appropriate dilution of the antibody for 40 min at room temperature or for 1 h at 37 °C under oil. Different temperatures and times are also used by different investigators with no noticeable difference in results. After rinsing and transferring samples into drops of washing/blocking solution, fluorochrome-conjugated secondary antibody is applied in drops for 1 hour at room temperature in the dark, as employed by many investigators, but different times and temperatures are also possible as used by different investigators.

After rinsing again with washing/blocking solution, DNA labeling and visualization follow using confocal microscopy. DNA labeling can employ TOTO-3 at 10 µg/ml for 25 min at room temperature, DAPI or Hoechst 33342 staining at 5 µg/ml Vectashield. For precise details please see methods paper by Rawe and Chemes [63] that contains a detailed notes section to point out potential difficulties and solutions. Here we will address important aspects to consider when performing immunofluorescence staining with centrosomal and anti-α-tubulin antibodies.

The following will provide methods that we have successfully used for detecting microtubules with anti-α-tubulin antibody and centrosomes with anti-γ-tubulin antibody in porcine oocytes [102] which also work for human oocytes.

For *immunofluorescence microscopy of microtubules and centrosomes*, we used antibodies to α-tubulin (1:50; Sigma, Cat # F2168) to stain microtubules and γ-tubulin (1:300; Sigma, Cat# T5192) to detect centrosomes. The zona pellucida of oocytes and embryos was removed using 0.25% pronase, followed by washing in PBS and fixation in 4% (W/V) paraformaldehyde in PBS for 45 min at room temperature.

Three washes in PBS followed before permeabilization in 50% methanol (5 min), 100% methanol (5 min), and 100% acetone (5 min). Extracted oocytes and embryos were rehydrated in 1% BSA PBS for 2 days. Blocking with 3% BSA for 1 h was employed before staining of samples with the primary antibodies, three washes with 1:100 antirabbit IgG second antibodies (F1263, Sigma), and counterstaining with 1 mg ml–1 DAPI in Vectashield mounting medium (Vector Laboratories, Burlingame, CA) to stain DNA. Oocytes/embryos were then mounted on glass slides. All samples were observed with a Zeiss Axiophot, and images were processed with Photoshop software.

For immunofluorescence microscopy it is critically important to perform the appropriate control experiments including the use of primary or secondary antibodies alone to avoid false positives and false negatives. Equally important is the use of unmasking antigens for immunohistochemistry, as epitopes can be masked and not detected by the antibody. Several methods are available to include unmasking of antigens in the immunohistochemistry protocols which are heat-mediated antigen retrieval (also known as heat-induced epitope retrieval or HIER) and enzymatic antigen retrieval.

Enzyme-induced methods are employed using enzymes such as proteinase K (20 g/ml in buffer, pH 8), trypsin (0.5% in dH20), pepsin (0.1% in 10 mM HCl), pronase (0.5% or 0.1% in dH20), and protease (0.5% in dH20) or heat-induced methods which require heat treatment followed by cooling. Chemicals used in this process are citrate buffer (10 mM sodium citrate, 0.05% Tween 20, pH 6), citrate-EDTA buffer (10 mM sodium citrate, 2 mM EDTA, 0.05% Tween 20, pH 6.2), EDTA (1 mM EDTA, 0.05% Tween 20, pH 8), Tris-EDTA (10 mM Tris base, 1 mM EDTA, 0.05% Tween 20, pH 9), and glycine-EDTA (50 mM glycine-HCl, 0.01% EDTA, pH 3.5).

We have employed microwave unmasking (95–98 °C for 10–15 min) to reliably detect NuMA in porcine oocytes [40].

Unmasking of antigen control experiments is especially important when negative results are obtained that may or may not be expected or when different results are obtained by different investigators, as has been the case for γ-tubulin staining in meiotic spindles of human oocytes.

It is also important to point out that different methods can give different results which call for thorough control experiments to eliminate false positives and false negatives. This includes using different fixation methods when immunofluorescence microscopy is performed and includes the above-mentioned antigen recovery methods when negative results are obtained. While most experiments are easy to perform in animal models such as the bovine or porcine system, because of the limited number of available human oocytes, critical control experiments are oftentimes not performed. This may explain the negative results for γ-tubulin that could not be detected at the MI and MII spindle poles under the reported conditions in human oocytes [65] which are different from other studies on human oocytes in which centrosomes were clearly detected as indicated by γ-tubulin staining [97]. Different culture conditions or different preparation methods may explain the different results; future experiments including antigen recovery experiments may provide clarifications on the specific association of γ-tubulin with the acentriolar centrosomes at the meiotic spindle poles of fresh (young, not aging) human MI and MII stage oocytes.

For ultrastructural studies using transmission electron microscopy, oocytes and embryos were fixed for 1 h in 2% glutaraldehyde in 0.1 M PBS buffer, pH 7.4, with 0.05% saponin, and 0.2% tannic acid at various time points. Oocytes and embryos were washed three times and centrifuged at 800 g for 5 min. The supernatant was then gently aspirated while being careful not to disturb the pellet. Then, two percent agar warmed to 50 °C was gently added on top of the pellet and centrifuged to keep the pellet compact. After cooling of the pellet-containing agar, the pellet and a small volume of agar surrounding the pellet were cut out and stored in PBS.

Oocytes and embryos were then rinsed with 0.1 M PBS and postfixed in 1% OsO_4 for 60 min [103–106]. Samples were dehydrated as described above and embedded in Epon resin [105, 106]. Samples were thin-sectioned, followed by uranyl acetate and lead citrate staining before analysis with transmission electron microscopy.

77.9 Conclusions and Future Perspectives

Centrosomes are critically important for sperm and oocyte functions and for successful fertilization after insemination in physiological, IVF, and various ART procedures such as ICSI. Numerous fertilization failures are associated with centrosome dysfunctions and can either relate to sperm centrosomal defects, oocyte centrosome defects, or to regulatory failures after fertilization. Heterologous fertilization models with human sperm and bovine or porcine oocytes will be most useful to more fully analyze sperm and egg centrosomal functions resulting in successful sperm aster and zygote aster formation. Assessing the dysfunctional factors will be important for therapeutic advances. Exploratory studies performed in the cat already revealed that it is possible to restore functional centrosomes in centrosome-related fertilization failures although detailed basic research as well as functional studies are still needed to provide promising new therapies to possibly increase IVF and ICSI procedures related to centrosome dysfunctions.

Acknowledgments The authors gratefully acknowledge Donald Connor's professional help with the illustrations.

Review Questions

1. What is the role of centrosomes in human MII oocytes?
2. What are essential centrosomal and cytoskeletal components contributed by sperm during human fertilization?

3. Why is the mouse an unsuitable model to analyze human sperm quality using heterologous fertilization?

4. When is ICSI used to overcome male factor infertility?

5. Which factors play a role in meiotic spindle aneuploidy?

6. How does oocyte quality affect fertilization?

Molecular Mining of Follicular Fluid for Reliable Biomarkers of Human Oocyte and Embryo Developmental Competence

Jonathan Van Blerkom

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_78

Learning Objectives

- Why follicular fluid is considered a viable source of biomarkers for oocyte and preimplantation embryo developmental competence in clinical IVF?
- The types of molecules in follicular fluid that have shown promise as competence biomarkers.
- Which analytical methods for biomarker detection and quantitation may be the most practical for routine IVF programs to introduce for competence assessment.
- Problems associated with clearly establishing a physiologically significant and predictive relationship between follicular fluid components and developmental competence.

Current advances in the development and application in clinical IVF of microanalytical imaging, genetic, and biochemical technologies lead to the interesting possibility that in the near future, competence assessments of human oocytes and embryos will be algorithm-based rather than operator-based. In such a future, selection for insemination and single embryo transfer would rely on a combination of findings assessed at selected phases of oocyte and early embryonic development. For the embryo, quantifiable biometric characteristics of developmental performance in vitro obtained by time-lapse imaging would include pronuclear morphology and nucleolar organization, the timing and uniformity of cleavage divisions, the presence of micro- and multinucleation in blastomeres, and an accurate value for the degree of cytoplasm lost to fragmentation, if any [1]. Biochemical criteria for competence selection could come from a variety of current methods such as microanalysis of spent culture medium to detect molecular signatures [2–4], levels of gene expression by cumulus cell [5, 6], and genetic status determined by high-resolution genomic analyses from blastomere and trophectoderm biopsies [7]. In this future, the human factor is necessarily relegated to ovum pickup, perhaps fertilization, and most likely embryo transfer.

Whether this scenario is a realistic one remains to be seen, as earlier and sanguine predictions of biochemical or physiological biomarkers of oocyte competence have yet to be fulfilled [8, 9]. However, the need for competence assessment, whether driven by instrumentation or observer, arises from an undeniable biological fact; namely, that with respect to outcome, each human oocyte and each human embryo have a unique developmental potential and that often, competence is already compromised in the mature and fertilizable oocyte [10]. This notion has been repeatedly validated by millions of IVF cycles performed over the past three decades. Although not unexpected, the results of the chromosomal assessments of meiotically mature (metaphase II, MII) human oocytes and early cleavage-stage embryos with different high-resolution methods have consistently demonstrated high frequencies of aneuploidy, often with multiple chromosomal anomalies (trisomies and monosomies) affecting the same oocyte [11], and for the early embryo, aneuploidy and other developmentally lethal chromosomal segregation disorders (e.g., mosaicism [12, 13]). The occurrence of these defects still comes as a surprise to even the most experienced observer when morphologically normal and stage-appropriate oocytes and preimplantation-stage embryos are found to be chromosomally abnormal.

If computerized biometric analyses of oocytes were to become standard methods to select oocytes for insemination and embryos for transfer, the underlying causes of differential competence, such as aneuploidy, would need to be detectable in observer-free systems. It is doubtful that morphological characteristics that may be associated with competence (e.g., polar body volume, zona birefringence, cellular debris in perivitelline space [1]) can identify aneuploidies and other chromosomal defects either in the oocyte or in the early embryo. Likewise, there is no compelling clinical or experimental evidence to date which suggests that early embryos carrying specific chromosomal or single gene defects produce unique molecular signatures detectable in spent culture medium or, for that matter, can be identified by the over- or underexpression of specific mRNAs or proteins in a biopsied blastomere. This may change as human embryos with known chromosomal and genetic defects are subjected to highly sensitive analytical methods that can characterize biochemistry in microliter volumes or the molecular biology of a single cell (see below).

78.1 Follicular Fluid Biomarkers of Oocyte Developmental Competence

The efficacy and sensitivity for competence selection at the human oocyte and early embryo stages that may be afforded by molecular and metabolomic analyses remain to be demonstrated. In this regard, their use for purposes of selection may be problematic as both activities represent dynamic processes that can be subject to the conditions of culture. As discussed in detail by Menezo and Guerin [14], levels of gene expression, metabolism, and other bioactivities are not only oocyte and embryo specific but can also be significantly influenced by culture medium composition (e.g., amino acids) and the conditions of culture (e.g., oxygen tension). It can be concluded from this report that because of the dynamic nature of the interaction between the environment and the cellular processes that produces potential competence biomarkers, each needs to be evaluated critically in general and for embryos in particular, as early development from fertilization through the preimplantation stages is entirely in vitro. In addition, cost vs. benefit calculations need to be taken into account based on unambiguous demonstrations of improved outcome, as well as the ease with which genetic microarray, metabolomic, proteomic, and time-lapse imaging methodologies can be incorporated into the routine clinical IVF laboratory.

It has long been thought that competence biomarkers should exist in the follicular fluid given the differences in maturational state, fertilizability, and development competence observed in oocytes aspirated from follicles that show equivalent patterns of growth and development under

exogenous gonadotropin stimulation (controlled ovarian hyperstimulation, COHS). The underlying issue in the search for competence markers in follicular fluid is related to the relative contribution of external influences that can be demonstrated to be developmental regulators or drivers for the oocyte vs. intrinsic differences that occur in oocytes themselves (i.e., at the molecular, cellular, and chromosomal levels). In this case, adverse downstream developmental consequences that may occur after fertilization would be expected to be independent of the biochemical environment within the follicle.

The search for external influences on competence has logically focused on the intrafollicular environment to which the oocyte is exposed. However, the fluid obtained for analysis may not represent conditions that could influence competence during the relatively prolonged FSH-dominated phase of follicular growth and development, but rather what occurs some 36 h after ovulation induction, typically with HCG rather than LH. Further complicating this type of analysis is that the vast majority of IVF cycles are hyperstimulated, and comparisons to natural (spontaneous) are virtually nonexistent, and COHS treatment could distort relative concentrations of regulatory factors, especially when fluids are pooled rather than analyzed individually for each follicle.

With these caveats in mind, what has made the follicular fluid so appealing for investigations of regulatory influences on human oocyte developmental potential is that the biochemistry is both dynamic and extraordinarily complex, a mixture of steroid hormones, growth factors, gonadotropins, cytokines, ions, amino acids, lipids, reactive oxygen species, enzymes, and other bioactive molecules that are produced in situ from the mural and cumulus granulosa or which pass through the blood follicle barrier as transudates from the perifollicular capillary bed [15–33]. It is clear even from this relatively short list of reports that qualitative and quantitative analyses of human follicular fluid demonstrate no shortage of molecules that could be biomarkers of competence, including those with regulatory and signaling functions. One of the foremost challenges in undertaking this type of investigation is the necessity to distinguish between potential targets for investigation that (a) actually influence or regulate oocyte processes and lead to competence, (b) those whose bioactivity is specific to the somatic cells of the follicle, or (c) are secretory products of the cumulus and mural granulosa destined to enter systemic circulation and whose activity is extrafollicular. However, since the beginning of clinical IVF in 1978, and despite a relatively enormous literature on this subject, few have been shown to have meaningful predictive value for selection, and at present, follicular fluid is not used for analytical purposes and is discarded by most programs. Another basic question that is rarely addressed in reports of the utility of follicular fluid for competence assessment is whether a potential biomarker can be shown to function through a signaling cascade that operates in the oocyte. In this regard, the presence of a particular growth or regulatory factor cannot be assumed, a priori, to be targeted to the oocyte, however appealing such a notion may be to those involved in competence studies. Perhaps, this is why so many reports of suggested biomarkers have been contradictory with respect to competence and outcome.

Further complicating the identification and characterization of bioactive molecules and regulatory factors that may be clinically useful as competence biomarkers in clinical IVF is whether they directly influence the developmental biology of the human oocyte or the cumulus and coronal cells. The presence of an intervening acellular zona pellucida is both a physical barrier between the oocyte and the follicular milieu and a biological filter that limits the diffusion of molecules to those up to ~60,000–70,000 daltons. Here, the relevant issue is the particular manner by which they enter the perivitelline space (the immediate environment of the oocyte) or pass into the cytoplasm directly from the corona radiata and proximal cumulus oophorus (the somatic cell compartment) by means of gap junctions between the oolemma and the transzonal processes (TZPs, see below).

The likely pathway for the transmission of potential regulatory molecules is by means of TZPs, which arise early in oogenesis (coincident with zona pellucida formation) and occur as dense circumferential network of slender extensions of the corona radiata, the cells that reside on the zona pellucida and, to a lesser extent, from cells of the cumulus oophorus in proximity to the corona radiata [34]. These processes permit bidirectional communication between the developing and fully grown oocyte and its somatic cell component by means of gap junctions formed by connexin 37 hexamers. Transmission electron microscopic images of the TZPs show longitudinal arrays of microfilaments that extend from the cell body to the site of contact with the oolemma, and it has been suggested that they provide an internal architecture to facilitate directional transport [35]. More recently, the presence of mitochondria in TZPs has been demonstrated in living cumulus-oocyte complexes stained with mitochondria-specific fluorescent probes [36] with elongated, high-potential organelles detected along the entire length of the TZPs. Mitochondria located in proximity to the TZP terminus on the oolemma could supply ATP directly to the oocyte through gap junctions and supplement the endogenous bioenergetic capacity of the GV-stage ooplasm in the subplasmalemmal and pericortical cytoplasm, where the demand for ATP may be higher than in more interior regions [36].

While intercellular communication by the TZP pathway persists up to the luteinizing hormone (LH)-induced resumption of arrested meiosis, gap junctions are primarily involved in metabolic and electrical coupling between cells and function in this regard by regulating the flow of small molecules that act as secondary messengers. These junctions generally restrict passage of molecules to those approximate 1000 daltons, such as cyclic AMP, ATP, ions (e.g., calcium), and small polypeptides, but not proteins the size of most growth factors, including gonadotropins. Therefore, the potential developmental influences of regulatory proteins and other factors suggested to affect oocyte competence that exceed the molecular weight limitation of gap junctions are unlikely to do so

by this direct pathway of intercellular communication. So what does the oocyte actually "see" at its surface and how do extrinsic regulatory signals or developmental cues arrive in the perivitelline space, given the notion of the zona pellucida as a selective molecular filter, if not a barrier to certain macromolecules? For proteins excluded by gap junctions to affect the oocyte, receptor-mediated signal transduction at the level of the oolemma and uptake by endocytosis are the obvious means.

The central issue here that is worth repeating is that investigations of follicular fluid designed to identify molecules that may be involved in the acquisition of developmental competence need to consider the mechanism by which they can directly or indirectly affect the biology of the oocyte. For example, despite the withdrawal of TZPs from the oolemma at the outset of resumed meiotic maturation, the processes and the cells from which they originate remain intact and functional, as indicated for the latter by the presence of mitochondria that retain high potential [36]. Scanning electron microscopy of the underside of the zona pellucida in maturing and mature human oocytes shows a dense circumferential network of residual processes in the perivitelline space that in the native state remains in close proximity to the oolemma [34]. Therefore, synthetic and secretory activity by the corona radiata and proximal cumulus granulosa likely continues during preovulatory maturation, and putative influences from the follicular fluid on cumulus and coronal cells that could influence the oocyte likely persist. However, it remains to be determined whether biosynthetic activities that could affect the human oocyte change qualitatively or quantitatively in vivo under the influence of LH during the ~36-h-long preovulatory period. If such changes are confirmed, the long-held notion that termination of TZP-mediated communication at the GV-stage signals a fundamental shift from maternal to oocyte regulation of development may need to be reconsidered.

The persistence of information flow between residual somatic cells and the oocyte during preovulatory maturation may be a currently unrecognized aspect of how competence is established, especially if the molecular nature of this information flow changes as maturation progresses to ovulation. At present, there is no evidence to suggest that as long as granulosa cells continue to secrete proteins into the perivitelline space during the preovulatory period, uptake by the oocyte (receptor mediated or endocytotic) is not functional during its maturation [37].

The intent of the preceding discussion was to emphasize that the presence alone of well-characterized growth factors and other regulatory molecules in human follicular fluid is insufficient to assume that the oocyte is the target or that they influence developmental competence. It may be for these reasons that despite the complex array of potential regulatory factors in follicular fluid noted above, to date, unambiguous evidence for developmentally significant effects on oocyte competence has remained elusive. It may well be that the principal target for growth factors in follicular fluid is the granulosa compartment, first by upregulating cell proliferation and steroidogenesis by mural granulosa and subsequently, to prepare both mural and residual cumulus granulosa for the transition to a vascular corpus luteum [38]. This is likely the function of angiogenic factors such as VEGF [39] and leptin [16], which occur at relatively high concentrations in preovulatory human follicular fluid.

While the follicular fluid can be a "gold mine" of potential regulatory factors, the fluid is discarded by virtually all IVF programs. Further complicating any scheme of molecular analysis is the unavoidable fact that follicular aspiration is not a "clean" process, and for analytical purposes, each follicle must be aspirated individually and with rinses of the aspiration needle between punctures to prevent cross-contamination with residual fluid and blood. The collection of neat aspirates can be time-consuming and can significantly extend the length of the ovum pickup procedure, especially when numerous follicles require puncture. The collection of individual aspirates also entails the tracking of the corresponding oocyte from fertilization through transfer, which, while feasible, adds considerable time and effort to the laboratory routine. Therefore, the selection of potential biomarkers of competence requires some degree of confidence that based on the known bioactivities of a candidate molecules; there is a high probability that its function, either through the cumulus and coronal cells or on the oocyte directly, will be developmentally significant.

With the possible exception of Mullerian-inhibiting hormone (see below), no single component of the follicular fluid has met these criteria to date, and reports that some might, such as VEGF and leptin, have not been proven or are controversial [40–43]. Likewise, it remains to be determined whether mRNA profiles of cumulus cells, collected either free floating in aspirated follicular fluid or mechanically detached from the oocyte in vitro, are sufficiently predictive of outcome as to warrant the additional infrastructure required for microarray analysis and, more importantly, meaningful interpretation. Comparisons of mRNA expression profiles that can show differences between individual oocyte-cumulus complexes from the same or different ovaries offer a promising approach to competence selection, but whether it is clinically applicable will only become apparent when a core set of genes with known functions is identified and, on the basis of outcome, demonstrated to consistently distinguish between mature oocytes.

Recent studies of Mullerian-inhibiting hormone (AMH) concentrations in follicular fluid and outcome results after IVF suggest that this molecule may indeed be a competence biomarker. AMH is a dimeric glycoprotein member of the transforming growth factor (TGF)-β superfamily whose expression by granulosa cells in large preantral and small antral follicles is upregulated at the transcriptional and post-transcriptional levels. Serum levels of AMH have received considerable attention as an indicator of ovarian reserve and for predicting the unique response of women to controlled ovarian stimulation, as well as biomarker of oocyte developmental competence [44, 45]. There is accumulating evidence that follicle-specific levels measured in aspirates at ovum

retrieval may indeed be related to outcome after transfer (reviewed by Van Blerkom and Trout [9]). Based on IVF outcomes, Eldar-Geva et al. [46] proposed that of all the factors identified in follicular fluid up to that date, only AMH appeared to be a reliable biomarker of developmental competence for the oocyte and resulting embryo.

While the collection and preparation of follicular aspirates impose special requirements to assure the validity of AMH quantitation, the availability of commercial ELISA-based assays permits rapid results that can be used as an independent variable in oocyte and embryo selection schemes that include such traditional parameters as stage-appropriate development, performance, and morphology during in vitro culture. However, despite the growing evidence of the value of follicular AMH determinations, confirmation of optimistic reports that this protein hormone can be a highly meaningful predictor of outcome will become evident only after more IVF programs combine follicle-specific AMH concentration with outcome results from the corresponding oocyte. It may take some time to confirm or reject AMH in this regard, as most IVF centers adopt a new protocol only after sufficient confirmation is forthcoming, which is typically not from their own independent studies but from the often laborious efforts of a very few investigators.

AMH is an attractive candidate as a biomarker of competence because it is likely that levels within a specific range reflect the normality of granulosa cell development and function, which, in turn, would be expected to influence the normality of the oocyte as the follicle develops and enters the preovulatory pathway. As a member of a signaling cascade (TGF-β superfamily) that has been extensively investigated in multiple species, AMH represents an ideal candidate for detailed gene expression and function studies designed to characterize precisely how it may regulate or influence the acquisition of human oocyte competence.

78.2 A *Holistic* Approach to Follicular Fluid in Competence Selection

Analytical methods that offer a detailed molecular profile of neat follicular fluid have the real potential to provide a detailed biochemical "picture" of the intrafollicular milieu that may ultimately be of greater clinical utility as a biomarker of competence than are levels of individual molecules, including AMH. Methodologies such as mass spectroscopy, nuclear magnetic resonance (NMR), and Raman spectroscopy (near-infrared spectroscopy, NIR) can display molecular profiles or signatures of a wide array of molecules (e.g., amino acids, metabolite small bioactive peptides, and proteins) whose levels can be correlated with embryo performance in vitro and outcome after transfer [47–50]. Similar to the rationale upon which metabolomic analysis of spent culture medium has been proposed for purposes of preimplantation-stage human embryo selection [2, 4], this "holistic" approach to follicular fluid analysis looks at both the end products of cellular activities and the presence of molecules that enter the follicle during its growth. Because instrumentation to perform NMR and NIR analysis can be adapted for use in the clinical IVF laboratory, it is likely that yet another algorithm will ultimately replace the observer for both oocyte and embryo selection, assuming that predictability levels are ultimately found to be robust. This should not be considered a negative in clinical IVF because current empirical assessments of competence based on cumulus characteristics (size, degree of expansion, the presence of foci of red blood cells, cytoplasmic density) are all that can be effectively noted, but their relevance with respect to outcome is unclear, controversial, and in some instances, more apparent than real [1]. While the human element becomes the means by which an analytical end is achieved, the potential for establishing standard, objective criteria for selection based on molecular profiles derived from the high-resolution methods noted above should be welcomed in clinical IVF laboratory. However, only the continued accumulation of outcome-based findings will demonstrate whether the current optimism that they can indeed be robust and reliable predictors of competence is justified.

78.3 Perifollicular Blood Flow as a Noninvasive Predictor of Oocyte Competence

Interest in Doppler ultrasonographic analysis of perifollicular blood flow rates to assess the normality of follicular growth and oocyte competence has been episodic since it was first introduced in clinical IVF in the late 1980s and early 1990s (see reviews by Gregory [51]; Van Blerkom and Trout [9]; Van Blerkom [52]). While most of the early reports were generally positive with respect to oocyte and embryo selection, few clinical IVF programs incorporated Doppler analysis in their follicular monitoring schemes, even when the capacity to obtain spectral imaging and quantitative values of follicle-specific blood flow was available in their instrumentation. Renewed interest in this noninvasive method of follicular analysis may be attributed in part to two factors: (a) the need for oocyte selection criteria that are independent of cumulus morphology at aspiration, especially where the number of oocytes that can be inseminated (or embryos transferred) is mandated by law and (b) the introduction of new generations of ultrasound equipment that produce high-resolution, 3D digital images that can be manipulated in real time. The ability to digitally isolate individual follicles and view blood flow patterns along the entire circumference of the follicle wall may be an important diagnostic tool and is in contrast to older 2D imaging modes, in which blood flow images and quantitative parameters (e.g., resistivity index) were obtained from selected cross-sections.

The physiological basis for assuming that perifollicular blood flow measurements offer some insight into the normality of follicular development and the competence of the corresponding oocyte is that expansion of the existing

perifollicular vascular bed is normal aspect of folliculogenesis in follicles in the ovulatory pathway. Expansion of the microvasculature network appears to involve specific angiogenic growth factors such as VEGF and leptin (see above) produced by cumulus granulosa cells under the influence of FSH and LH [53]. VEGF also increases the permeability of capillaries (it was originally termed vascular endothelium and permeability factor) that might enhance the transduction of blood-borne regulatory factors into the follicle. Higher rates of blood flow would also increase rates of oxygen diffusion into the follicle, as well as the rate at which follicular components (steroids, growth factors, etc.) enter systemic circulation. Increased follicular oxygenation may be an important regulatory influence for the steroidogenic activity of the mural granulosa cells that line the follicular wall and are in close proximity to the perifollicular microvasculature. Despite numerous studies of follicular vascularity and steroidogenesis, it remains to be determined whether the level of estradiol measured in serum during follicular growth or of progesterone after ovulation induction can be related to follicular blood flow characteristics in general or whether high-flow follicles contribute disproportionately to levels measured in serum.

Differences in blood flow rates detected by Doppler imaging have been positively correlated with corresponding differences in the dissolved oxygen content of follicular fluid measured in neat aspirates obtained after ovulation induction in COHS cycles for IVF [54]. Although the reported differences are relatively small (i.e., between ~1 and ~4%), they may be physiologically significant insofar as reducing the extent of hypoxia that normally exists within the follicle [53] which, in turn, could influence the bioactivity of both mural and cumulus granulosa cells [54]. Molecular studies indicate that follicle-specific levels of VEGF in follicular fluid appeared to be related to corresponding expression levels of elements of the hypoxia-inducible transcription factor-signaling pathway (HIF) [9, 53], which regulates levels of VEGF expression [55]. It has been suggested that the activation of HIF may be associated with FSH stimulation of granulosa cell expansion and that the level of dissolved oxygen within the early antral follicle could be rate limiting for both granulosa cell proliferation and steroidogenic function [53]. Although speculative, one indirect action of FSH on granulosa cells could be at level of the mitochondria, which, as the oxygen sensors of a cell, could respond by increasing superoxide production to levels that are regulatory with respect to the activation of the HIF pathway [56]. Collectively, progressive increases in dissolved oxygen content during the early follicular phase may regulate granulosa cell proliferation, levels of steroid production by the mural granulosa, and protein growth factor synthesis and secretion by the cumulus granulosa. This notion is supported by the findings of Shrestha et al. [57], who distinguished between "good" and "poor" beginners on the basis of perifollicular blood flow rates measured during the early stages of follicular growth in cycles of controlled ovarian stimulation for IVF. Based on outcomes after embryo transfer, they concluded that flow rate, implantation potential, and developmental competence were related to such an extent that a poor beginning could justify cycle treatment cancelation during the early stages of stimulation.

It is worth noting that while increased intrafollicular oxygen tension levels seem relatively small (<1% to approximately 4%) [54], they may be of a magnitude sufficient to influence the function and activity (e.g., gene expression levels) of the mural and cumulus granulosa cells during follicular growth. For the cumulus granulosa in particular, levels of biosynthetic activity during the follicular phase could indirectly influence the normality cytoplasmic, nuclear, and oolemmal maturation during preovulatory period. In this regard, significantly lower frequencies of aneuploidy at MII have been reported when the dissolved oxygen content measured at aspiration was approximately 4%, as compared to similar-sized follicles with poor flow characteristics and an oxygen contents ≤~1% [54].

One of the more unexpected findings to come from the early studies of perifollicular blood flow was the extent to which follicles of equivalent size at the time of aspiration, including those adjacent follicles, exhibited completely different quantitative flow values and in some reports, high-flow follicles occurred in one ovary, in a single follicle on one ovary, or in multiple follicles on one or both ovaries. Thus, blood flow rate could not be predicted on the basis of follicle size or location without Doppler analysis [54]. In order to quantify perifollicular blood flow rates, relatively simple grading systems were proposed using a score (A, B, C; 1–4) or grade (high or low grade) that was based on degree to which flow could be measured, either in a midline section or at multiple points, along the circumference of the follicle [51]. Correlations between blood flow characteristics, fertilization, embryo performance in vitro, and outcome indicated that oocytes from high (type A; class 3 or 4) grade follicles were more likely to result in pregnancy than those from low-flow (grade) follicles (see reviews by Gregory [51]; Van Blerkom and Trout [9]). However, while usually positive correlations between outcome and perifollicular blood flow rates appeared in the literature (see above), indicating that this metric could be used as an independent factor for oocyte and embryo selection [58], Doppler ultrasonographic analysis of perifollicular blood flow characteristics has not been widely incorporated in infertility assessment and treatment. In the past, the apparent lack of interest in this methodology may be due to the requirements for instrumentation that could perform Doppler studies, the added time, and expertise needed to obtain accurate values with conventional 2D imaging or that the association with outcome was not sufficiently high as to warrant a significant change in protocol.

Renewed interest in blood flow measurements largely parallels the introduction of digital 3D ultrasonographic imaging in which Doppler software is often included with the instrument. Many, but not all studies, have confirmed an association with outcome and for some significant reductions in spontaneous miscarriages, supporting earlier findings that

aneuploidy may be less likely in oocytes that mature in high-grade follicles (reviewed by Van Blerkom and Trout [9]; Van Blerkom [52]). While not all reports have been sanguine with respect to the utility of Doppler imaging in IVF treatments, reports of improved outcomes, including higher ongoing pregnancy rates and reduced frequencies of miscarriage, do suggest that its inclusion in ovarian monitoring and oocyte and embryo selection schemes is beneficial and can provide a quantitative measure of follicular development that is independent of growth rate. What 3D imaging has shown however is that in comparison to single cross-sectional 2D views, perifollicular blood flow in high-grade follicles cannot be assumed to involve the entire circumference of the follicle [9]. In these instances, high flow can be focal and discontinuous with relatively large regions of the follicular wall showing little, if any, significant velocity. While these follicles would likely be classified as high grade by 2D Doppler ultrasonography, they are more likely moderate to low grade; whether the corresponding oocytes have a lower competence with respect to implantation and outcome than their counterparts from follicles where blood flow is largely continuous and circumferential remains to be determined. Therefore, the simple follicular classification schemes noted above might need to be revised and standardized in order to account for subtle differences in perifollicular blood flow in apparently high-grade follicles that may be significant with respect to competence selection.

Perhaps, the most convincing evidence for the use of Doppler analysis of follicles will come from the type of NMR and NIR profiles of follicular fluid noted above, assuming that such studies will be able to show molecular signatures and levels that can produce algorithms that clearly correlate with outcome. In the meantime, where this technology exists, its use for follicular assessment should be considered as the first step in sequential assessments of competence that after fertilization include the usual morphological characteristics of pronuclear through blastocyst-stage embryos [1].

The notion that subjective observations of early human development commonly used to assess embryo viability will be succeeded by objective criteria that can be expressed in a numerical form that is predictive of outcome, such as proposed for NIR values obtained from spent embryo culture medium, is an appealing one because it would be derived from quantitative measurements of follicular characteristics (e.g., blood flow rate and pattern assessed by 3D Doppler imaging) and biochemical profiles of neat follicular fluid [59]. A change of this type in how the clinical IVF laboratory is engaged in competence assessments should be viewed positively and in terms of the potential to improve outcome and, more importantly, equalize outcomes among programs.

78.4 Summary and Perspectives

The search for biomarkers of oocyte and embryo developmental competence has been ongoing since IVF was combined with COHS to become a practical and widespread treatment for human infertility. The early optimism that measures follicle-specific steroid hormone, protein growth factor, cytokine, and other bioactive molecules detected in the complex biochemical mix that is the follicular fluid could be biomarkers of gamete, and embryo competence has not been supported by a large body of research. Thus, the biochemical and physiological environment to which the cumulus-oocyte complex is exposed to prior to ovulation is represented by the fluid discarded by most clinical IVF laboratories. Whether the current enthusiasm for some factors, such as AMH, may prove to be the exception remains to be determined. In the same respect, whether molecular surveys of gene expression in cumulus cells, either at the mRNA or at the protein levels, have sufficient predictive power to warrant adoption as a routine protocol for assessment remains to be seen. While there is no shortage of potential targets for analysis, and studies to screen targets and identify a core set of proteins or genes that may be related to competence are ongoing in this field, it is unclear at present whether they will have sufficient predictive power for oocyte and embryo selection to justify the considerable increase in expense (e.g., custom microarrays, equipment, and technical expertise) and effort (e.g., biopsy and preparation of cumulus cells) that may be required.

The "holistic" or spectrophotometric approach to competence assessment with NMR, NIR, or similar analytical methodologies is intended to obtain a comprehensive molecular snapshot of the intrafollicular milieu at the time the oocyte is retrieved. In this instance, it is the "big picture" that is relevant rather than whether the function of a putative biomarker is on the somatic cells or female gamete or both. The appeal of this line of investigation is twofold: first, the results can be both qualitative and quantitative, and second, the molecular profile displayed should be consistent with the intrafollicular biochemistry in which the oocyte matured to MII and achieved fertilization competence. In this respect, its utility lies in the fact that the analysis is done at a critical developmental endpoint for the oocyte, the transition from intrafollicular life, where the components in the follicular fluid are those derived from serum or produced in situ, to a different biochemical milieu within the Fallopian tube, where fertilization will occur.

The importance of obtaining quantitative values is that if specific components are shown to be competence associated, it may well be that it is their concentration rather than simply their presence that is associated with the acquisition of developmental viability. What will determine the success of this approach is whether comparative analysis of individual follicles reveals a relatively small number of biomarkers that can reliably distinguish oocytes that develop into embryos that progress from gestation to birth from those that do not.

In an ideal world, follicular biochemistry and the competence of the corresponding oocyte would be equivalent, which is more likely the situation in litter-bearing mammals such as rodents and rabbits, where the number of newborns

is usually equivalent to the number of follicles that develop in natural cycles. However, this is clearly not the situation in the human, and it has been long known that developmental competence is embryo specific, and more recent evidence demonstrates that this specificity arises in the preovulatory oocyte. This gives reason for optimism that investigations capable of displaying a comprehensive picture of the biochemistry of each follicle's fluid will be informative and clinically beneficial in infertility treatment. This might also suggest new avenues of study related to the site(s) and function of potential competence-determining biomarkers that would increase significantly our understanding of the developmental biology of the human oocyte and the dynamic changes at the nuclear, cytoplasmic, and plasma membrane levels that lead to viability.

Protocols and procedures evolve in science and medicine and clinical IVF will not be exempted from the inevitable forces of change that can be envisaged for this field in the near term. If outcomes are universally improved, then basing the most fundamental of all decisions in clinical IVF, namely, which oocyte to inseminate and which embryo to transfer, on algorithms rather than empirical criteria should be welcomed, even if the long-standing and central role of the human observer is diminished or eliminated.

Review Questions

1. Which follicular fluid components that have been related to competence may be the most informative and easily quantifiable for the typical clinical IVF program?

2. What are the apparent physiological consequences of variability in the expression of angiogenic factors at the transcriptional and translation levels and (i) how might they be detected noninvasively and (ii) be related to oocyte and preimplantation embryo developmental competence?

3. What are the logistical issues that are likely to be associated with the collection and preparation of individual fluid aspirates during the oocyte retrieval phase of an IVF cycle?

4. At present, what highly compelling evidence related to outcome exists that would warrant follicular fluid analysis in routine IVF practice for selective purposes?

5. Going forward in considering the biochemical and molecular complexity of follicular fluid, what other classes of components, such as lipids or bioactive peptides, might be useful to investigate as potential competence biomarkers and why?

Learning Objectives

- To present the technical aspects of artificial oocyte activation in livestock embryo production
- To learn the engineering of livestock genome by transgenesis
- To describe the xenograft-ICSI technique

We summarize the use of micromanipulation techniques in the production of livestock mammals, focusing on intracytoplasmic sperm injection (ICSI) and the pig, *Sus scrofa*. ICSI is a powerful method for assisted fertilization. It is typically employed where semen characteristics are insufficient for conventional in vitro fertilization (IVF), in which sperm and eggs are mixed and fuse in culture. Unlike IVF, ICSI mechanically delivers the sperm deep inside the egg cytoplasm by injection through a micropipette.

Mammalian ICSI was first demonstrated in hamster oocytes [1] and subsequently applied to humans to overcome impaired fertility [2]. In livestock, ICSI is also used as a procedure for fertilization, but its purpose is not restricted to impaired male fertility. Although circumstances do not ordinarily justify ICSI for breeding normal livestock, there are clear exceptions. Where sperm-containing ejaculates cannot be obtained, a small number of sperm may be obtained by biopsy, with ICSI as the method of choice for delivery into oocyte. Owing to its technical robustness, ICSI is especially beneficial where the breeding male stock has high genetic merit. These applications are now considered in greater detail.

79.1 The Application of Intracytoplasmic Sperm Injection

The potential of ICSI in the conservation of genetic resources, transgenesis, and animal production using sex-sorted spermatozoa has all long been recognized [3]. However, ICSI in livestock animals is less widely applied than it is in humans due to the low success rate coupled to the prohibitive costs involved. This low success rate likely reflects the complexity of interactions between gamete components. Some of these interactions are ectopic, since ICSI introduces sperm plasma and outer acrosomal membranes in addition to acrosomal contents—all components that do not enter the oocyte during natural fertilization. The formation of male pronuclei after ICSI is affected by these ectopic components [4], and to address this, a range of methods have been employed that deplete sperm membranes before ICSI (e.g., [3]). Methods include sperm treatment with triton X-100, dithiothreitol (DTT), progesterone, repeated freezing and thawing without cryoprotectant, or piezo-driven pulses. These methods all damage membranes leading to loss of motility, but the use of *living*, motile spermatozoa is not necessary in delivery by ICSI. The methods that set out to damage membranes are not essential in human and mouse ICSI.

In livestock animals, oocytes are usually removed from ovaries collected at the abattoir and matured in vitro (IVM) because direct collection of sufficient oocyte numbers following maturation in vivo is prohibitively time-consuming and costly. For example, porcine ovulation after hormone treatment yields ~35 oocytes (i.e., in vivo-matured oocytes) per animal at a cost of JP ¥40,000–50,000 (US $455–569 as of July 2010), whereas a single ovary obtained from the abattoir for ~JP ¥150 (US $2) yields 10 oocytes after IVM. Although relatively large numbers of oocytes can be stably sourced via IVM, their developmental potential is probably slightly lower than that of oocytes matured in vivo (Table 79.1). Nevertheless, IVM oocytes support development to term at comparable rates, making them considerably more cost-effective.

79.2 Overcoming Technical Difficulties

Discrepancies between the developmental potential of oocytes derived in vitro and in vivo may also reflect their respective abilities to support physiological oocyte activation, which includes metaphase II (mII) exit and cell cycle progression [5]. In humans and mice, ICSI using sperm from healthy donors is generally sufficient to induce oocyte activation. In livestock animals, additional artificial activation stimuli (parthenogenetic agents) may be required to induce viable embryonic development (Table 79.1), for reasons that are largely unclear. Activation stimuli include electrical pulses, ethanol, calcium ionophore, or specifically ionomycin combined with the protein kinase inhibitor, 6-dimethylaminopurine (DMAP) (Table 79.1). The necessity of supplemental activation factors after ICSI in livestock presumably reflects one or more deficiencies of IVM oocytes, perhaps caused by the failure of injected sperm to trigger release Ca^{2+}, but this cannot always be the case [6, 7], and there is little direct evidence for it. There are no reports of Ca^{2+} release in pig ICSI, but demembranated pig spermatozoa contain the activating factor, phospholipase C zeta, and readily activate mouse eggs leading to pronuclear formation [8]. This suggests that the failure involves a maternal effect, although porcine oocytes can also be induced to undergo Ca^{2+} release [9]. However, unlike mouse oocytes, those of pigs and some other livestock species (including cattle) do not respond to the parthenogenetic agent, $SrCl_2$, so there may be fundamental differences that are not readily explained by differences in the oocyte maturation protocols (e.g., in vitro vs. in vivo or mouse vs. pig). In cattle, there is a single report that ICSI induces abnormal Ca^{2+} oscillations and activation, with the majority of oocytes unable to undergo any Ca^{2+} oscillations at all [10]. These findings seem germane to the low success rates of ICSI in livestock species to date.

Table 79.1 Experience with micromanipulation techniques in farm animal species

Species	Oocytes	Sperm	Activation	No. embryos transferred (recipients)	No. offspring (pregnancies) [% embryos]	References
Pig (*Sus scrofa*)	In vivo	Fresh	Sperm	69 (3)	3 (1) [4.3]	Martin [21]

Cattle (*Bos primigenius*)	IVM	Fresh	Sperm	8 (7)	3 + 1?(4) [50.0]	Wei and Fukui [26]
Cattle	IVM	Fresh	Ethanol	nd (10)	5 (5) [–]	Horiuchi et al. [27]
Cattle	IVM	Frozen	Sperm	11 (6)	1 (2) [9.1]	Galli et al. [28]
Cattle	IVM	Frozen	Ethanol	19 (17)	9 (10) [47.4]	Oikawa et al. [29]
Cattle	IVM	Frozen	Ionomycin + DMAP	11 (8)	1 (1) [9.1]	Oikawa et al. [29]
Cattle	IVM	Fresh	Ethanol	61 (54)	24 (28) [39.3]	Horiuchi [30]
Sheep (*Ovis aries*)	IVM	Fresh	Sperm	38 (17)	9 (6) [23.7]	Gomez et al. [31]
Horse (*Equus ferus*)	In vivo	Fresh	Sperm	31(12)	2 (3) [6.5]	Cochran et al. [32]
Goat (*Capra aegagrus*)	No reports					

The retrieval of eggs—or ovum pickup (OPU)—is available for the nonsurgical collection of cattle and goat oocytes matured in vivo. However, with the exceptions of pig and horse (Table 79.1), there are few, if any, reports of ICSI in livestock animals using in vivo-matured oocytes. The application of ICSI in livestock animals has gradually increased, notwithstanding that the efficiency remains low—a source of optimism for those who wish to improve the efficiency further.

79.3 Using Micromanipulation to Engineer Livestock Genomes

One potential prize for such an improvement is the enhancement of transgenesis (the generation of animals with completely or partially prescribed genome alterations). Microinjection of DNA directly into zygotic pronuclei has been used for several years in livestock animals [11, 12], but zygotes (1-cell embryos) are difficult to obtain and manipulate (those of species such as *S. scrofa* are opaque, due to high lipid content), and the efficiency of integration and transgenerational transmission of the foreign DNA remains low [13]. Relatively recently, this problem has been addressed by somatic cell nuclear transfer (NT) (Fig. 79.1). Broadly, somatic cells—for example, ear punch or embryonic fibroblasts—may be cultured and subjected to genetic modification in vitro by transfection with a suitable DNA construct, prior to their use as nucleus donors. This enables the structure and expression level of the resulting integrant to be determined so that the best can be expanded clonally. In this way, donor cell cultures containing ~100% of the desired integrant can be used for NT, yielding high rates of transgenesis [14].

Perhaps the most powerful application of the transfection-NT approach is in the production of gene-targeted livestock animals [15]. In mice, targeted genomic mutagenesis by homologous recombination is widely achieved using embryonic stem (ES) cells, but widely accepted ES cells have not yet been established from livestock animals. The rate of homologous recombination in most somatic cells is typically lower than that in mouse ES cells, with the notable exception of the chicken cell line, DT40 [16]. However, this relative inefficiency may not hold for acutely isolated embryonic cells; gene targeting is efficient in pig embryonic fibroblasts, resulting in the production of gene-knockout pigs by NT (unpublished data). Thus, the transfection-NT combination holds considerable promise in transgenic livestock production.

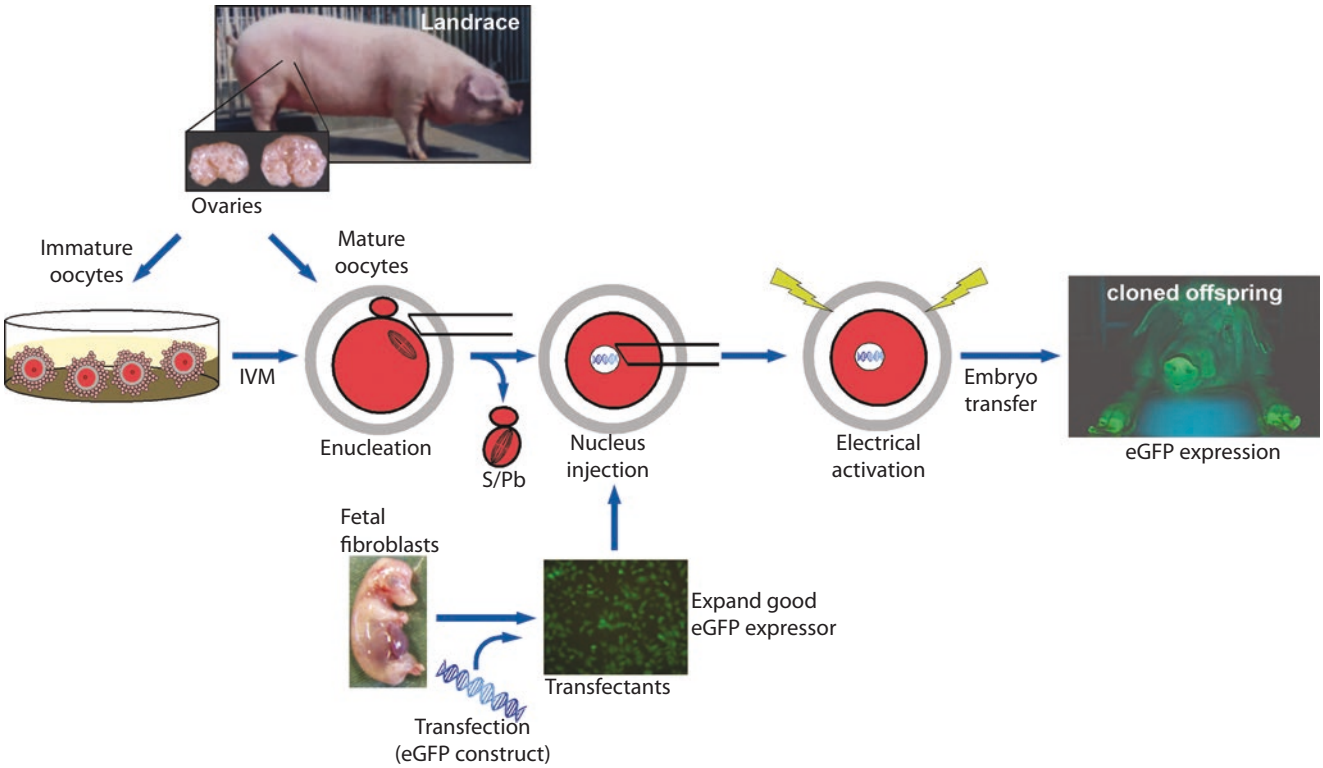

Fig. 79.1 Production of the enhanced green fluorescent protein (eGFP) transgenic pigs by somatic cell nuclear transfer. Fetal fibroblasts were transfected, and cells expressing high levels of eGFP were selected for use as nucleus donors. This method results in cloned pigs that almost always exhibit broad, high-level eGFP expression. *S/Pb* spindle/first polar body

ICSI provides an alternative to transfection-NT for the production of transgenic livestock animals, although, so far, not gene-targeted ones. In this method, spermatozoa are incubated with the transgene DNA construct to form a sperm–DNA complex that is injected into the egg; in effect, the sperm acts as a carrier for the transgene, at least in the mouse [17]. This technique is advantageous in the stable incorporation and expression of large (>100 kb) DNA constructs such as yeast artificial chromosomes (YACs) that are not amenable to transfection or viral delivery [18]. The successful production of nontargeted transgenic pigs following both ICSI and NT techniques has been reported, albeit without using artificial chromosomes [19].

79.4 ICSI in Large Animal Xenografting

Recently, viable piglets have been produced with spermatozoa from immature testicular tissue xenografted into immunodeficient mice [20]. In these experiments, testes from 6- to 12-day-old piglets (i.e., prepubertal pigs) were minced and grafted into the testes of immunodeficient mice. It was possible to collect porcine spermatozoa from the engrafted host mice 133–280 days later and utilize them for porcine ICSI. Although only 6 piglets from 2 recipients in 23 trials were obtained, all grew normally. The xenograft-ICSI technique has several potential applications. It represents one avenue for the conservation of species and other genetic resources and suggests a new means to sustain lineages—especially genetically modified ones—that otherwise propagate with high rates of male neonatal mortality.

Review Questions

1. Describe the methods to overcome the oocyte activation problems in livestock ICSI.
2. Explain the methods to engineer the livestock genome.
3. What are the potential applications of animal xenografting and ICSI?
