Foreword

Exactly 40 years following the birth of the first IVF baby, Louise Brown, the extended and fully updated second edition of *In Vitro Fertilization* will see the light of day. This new edition, again edited by Drs. Nagy, Varghese, and Agarwal, convincingly captures the many advances in assisted reproduction technology, especially in the IVF laboratory. It is overwhelming to see the wealth of added knowledge since the publication of its first edition in 2012.

It is a privilege for me, as a clinician, to be asked to write the foreword for such an excellent and scholarly textbook, mainly focusing on the many developments in the ART laboratory. Reviewing the advances in ART since the late 1970s, it seems to me that the first few decades have been dominated by progress in the IVF clinic. Beyond any doubt, however, we all have wittnessed tremendous advances – away from the early days of "black box" fertilization and very early embryo development *in vitro* – in the laboratory during the most recent decade. I personally believe that a high-quality performance in the laboratory represents the key determinant for a successful IVF program. Quality management related to existing procedures, as well as the continued critical monitoring of possible benefits of novel technologies and the subsequent implementation of such new developments when proven beneficial, seem key determinants of a successful IVF laboratory.

The use of IVF continues to increase around the world, due to an ever-increasing global access to IVF care, the increasing use of ART in the treatment of different forms of infertility (like tubal disease, ovarian aging, or ovarian dysfunction), and – above all – the increasing central place of ART in conditions not directly related to infertility per se, such as the use of donor gametes in same-sex couples or singles; the cryopreservation of gametes, embryos, or gonadal tissue; genetic embryo testing in (often fertile) families suffering from genetic disease, and many others. Hence, the proportion of children born following ART will continue to increase in the years to come, and embryologists should be aware of their great responsibility toward the future health of ART offspring. Soon, at least one child in every primary school class will be generated by ART in the majority of countries worldwide.

Advances in the ART laboratory are everywhere, and they are all covered extensively in the 79 chapters of the current revised version of the book: the handling of sperm and oocytes, the many aspects of the process of fertilization, improved embryo culture media and culture conditions, and early embryo development. Moreover, many novel technologies have been developed for advanced embryo testing, and technologies are under way for automated and individualized embryo development assessment and handling (referred to by some as the "embryo hotel").

Novel information is being unraveled, stimulating embryologists to think outside the box, such as the potential influence of the patient and ovarian stimulation regimens on the quality of oocytes entering the laboratory. In addition, knowledge is accumulating regarding effects of the quality of embryos leaving the laboratory on implantation, miscarriage rates, and even pregnancy complications, perinatal morbidity, and possibly future health of IVF offspring.

Needless to say, I can highly recommend this authorative and comprehensive manual, primarily for everyone working in the IVF laboratory. Certainly, this book will also provide a wealth of useful information for everybody dealing with an IVF laboratory and may therefore fulfill the important role of bridging the gap between IVF clinicians and embryologists.

Bart C.J.M. Fauser MD, PhD, FRCOG
Emeritus Professor of Reproductive Medicine, University of Utrecht & University Medical Center Utrecht, The Netherlands

Preface

Ever since the first in vitro fertilization baby was born in Oldham, England, in 1978, the use of assisted reproductive technology (ART) to overcome infertility has increased exponentially with the simultaneous increase in the number of fertility centers in every part of the world. Since the first breakthrough, there have been several significant discoveries and improvements related to IVF technology, such as ICSI and vitrification (gametes, embryos, reproductive tissue), which has helped in increasing its efficiency severalfold.

The first edition of *Practical Manual of In Vitro Fertilization: Advanced Methods and Novel Devices* achieved an overwhelming success among clinical and laboratory professionals. It provided the most comprehensive update on all laboratory aspects of IVF, both theoretical and practical, in great detail and described several novel techniques that made the book also an outstanding reference for ART laboratory procedures.

The last six years has witnessed a steady stream of new discoveries and technological advancements in assisted reproduction laboratory methods and systems, such as automation, molecular testing, and gene editing, and with that growth, the necessity and demand for an updated new edition of this state-of-the-art textbook became readily apparent. For this second edition, the title shortened simply to *In Vitro Fertilization*, each section has been thoroughly revised and expanded to include the very latest evidence and practical guidelines, beginning with laboratory set-up, equipment, and management and moving on to detailed, thematic discussions of all relevant aspects of the IVF process: oocyte preparation and embryo culture methods, sperm processing and selection, insemination procedures, micromanipulation, embryo evaluation, grading and hatching, biopsy procedures, cryopreservation, and embryo transfer. The concluding sections present global perspectives on the regulation and licensing of ART laboratories; innovations, risks, and safety in ART; and molecular reproduction.

Every effort has been made to ensure that the information contained in this second edition is as up-to-date as possible, written by the most acclaimed and acknowledged professionals of our field – more than 160 experts in total, representing all continents of the world. Because of the wide range of topics and the comprehensive theoretical and detailed practical descriptions, this second edition is an ideal reference for all who are involved with assisted reproduction, including clinical embryologists, andrologists, reproductive endocrinologists, and scientists, regardless if one wishes to obtain a basic understanding or to digest an in-depth presentation. We ensure that this textbook will be a valuable resource for university students pursuing clinical embryology courses, too – chapters include clear learning objectives as well as review questions for self-guided study or group review.

We are thankful to Kristopher Spring, Senior Editor at Springer, for his ready support and advice, and Kevin Wright, Developmental Editor, for his continuous efforts in the day-to-day management of this large book project. We are grateful to Professor Bart Fauser for reviewing our book and authoring an outstanding foreword for the second edition. Furthermore, we are thankful to all of the exceptional contributors for sharing their knowledge and for being part of this great project.

1

1.1 Introduction

The history of in vitro fertilization (IVF) and embryo transfer (ET) dates back as early as the 1890s when Walter Heape, a professor and physician at the University of Cambridge, England, who had been conducting research on reproduction in a number of animal species, reported the first known case of embryo transplantation in rabbits, long before the applications to human fertility were even suggested.

In 1932, *Brave New World* was published by Aldous Huxley. In this science fiction novel, Huxley realistically described the technique of IVF as we know it. Two years later Pincus and Enzmann, from the Laboratory of General Physiology at Harvard University, published a paper in the *Proceedings of the National Academy of Sciences of the United States of America*, raising the possibility that mammalian eggs can undergo normal development in vitro. However, it was not until 1959 that indisputable evidence of IVF was obtained by Chang [1], who was the first to achieve births in a mammal (a rabbit) by IVF. The newly ovulated eggs were fertilized, in vitro by incubation with capacitated sperm in a small Carrel flask for 4 h, thus opening the way to assisted procreation.

Professionals in the fields of microscopy, embryology, and anatomy laid the foundations for future achievements. The recent rapid growth of IVF-ET and related techniques worldwide is further supported by the social and scientific climate, which favors their continuation.

Through the years, numerous modifications have been made in the development of IVF-ET in humans: refinement of fertilization and embryo culture media, earlier transfer of the embryo, improvements in equipment, use of a reduced number of spermatozoa in the fertilization dish, and embryo biopsy, among others.

The purpose of this chapter is to acknowledge those who initiated new steps in the development of the treatment protocols and techniques that we now use facilitating such simple and promising IVF-ET procedures.

1.2 Development of IVF

In 1965, Robert Edwards together with Georgeanna and Howard Jones at The Johns Hopkins Hospital in the USA attempted to fertilize human oocytes in vitro [2]. It took another 8 years until the first IVF pregnancy was reported by the Monash research team of Professors Carl Wood and John Leeton in Melbourne, Australia. Unfortunately, this resulted in early miscarriage [3]. Another step toward the goal of IVF was noted by Steptoe and Edwards who published a report on an ectopic pregnancy following transfer of a human embryo at the late morulae/early blastocyst stage [4]. However, a breakthrough and a huge achievement were noted in 1978 when the first ever IVF birth occurred in Oldham, England, on July 25, 1978. This birth was the result of the collaborative work of Patrick Steptoe and Robert Edwards [5]. A year later, the first IVF birth was noted in Australia by the joint Victorian Monash-Melbourne team that occurred at The Royal Women's Hospital [6]. This was followed by the announcement of Howard and Georgeanna Seegar Jones about the delivery of the first IVF baby in the USA, in 1981. This first IVF birth in the USA was achieved with the use of hMG for ovarian stimulation. The improvement of technology leads to the report of Jacqueline Mandelbaum with Dan Szollosi describing the microstructures of the human oocyte, which became known as "oocyte dysmorphia" [7].

To improve the results of the procedure, efforts were made in optimizing the stimulation protocols, improving the culture media, improving aspiration technique and holding of the oocytes, and improving fertilization techniques. The second part of this chapter describes the six fields that were developed in parallel, enabling to improve the pregnancy rate. These fields are stimulation protocols; culture media; aspiration technique, handling of the oocyte, and embryo replacement; improved fertilization; cryopreservation and storage of embryos and oocytes; and future manipulation of the oocytes and embryos.

1.3 Stimulation Protocols

Earlier IVF pregnancies were achieved from unstimulated ovulatory cycles, and the success rate remained low. It was later on suggested that in order to improve the fertilization and pregnancy rate, it might be possible to aspirate more than one egg, and this can be achieved during a cycle in which the ovary is stimulated by endogenous or exogenous gonadotropins. During the years, several protocols were developed, and each of it was tested in relation to the drug influence on the oocytes. Alan Trounson and his colleagues introduced the use of clomiphene citrate and hMG in the treatment protocols [8]. It was later on demonstrated that GnRH agonists can be used to eliminate premature luteinization and control ovarian stimulation [9].

It was Porter and his colleagues who were the first to use GnRH agonists in IVF treatment [10]. Three major protocols using GnRH agonist were developed: the long, short, and ultrashort protocols. Several years later following numerous studies, it was found that the long protocol gave the best results in terms of pregnancy rate.

The administration of GnRH agonists resulted in "flare-up" of gonadotropins from the hypophysis. In some women, this resulted in the development of follicular cyst. In order to reduce the scale of gonadotropin section following the administration of GnRH agonist, it was suggested to give GnRH agonist during the luteal phase, when serum progesterone is high, or under progesterone administration or during the oral contraception pill. Gonen, Jacobson, and Casper pioneered the use of combined oral contraceptives for follicle synchronization and cycle scheduling in IVF [11].

Following the development of the various stimulation protocols, it was noted that there is a possibility that the

steroid production during the luteal phase was not optimal, and it was Casper and his colleagues who were the first to describe the use of low-dose hCG for support of the luteal phase in ART cycles [12].

In order to simplify the stimulation protocol and to shorten it, efforts were invested in developing the GnRH antagonist. Rene Frydman was the first to report the use of the GnRH antagonist, Nal-Glue, to prevent premature LH rise and progesterone in controlled ovarian hyperstimulation treatment [13]. This specific drug was not developed further due to the side effects. Following further efforts, the third generation of the GnRH antagonist was developed, and the first established pregnancy using recombinant FSH and GnRH antagonist was reported in 1998 by Itskovitz-Eldor and his colleagues [14].

The increasing needs in infertility treatment created the needs to develop new sources for gonadotropins. Recombinant FSH became available in 1992, and very soon after, pregnancy was established using recombinant drug for ovarian stimulation [15, 16].

Following the development of the technology to produce recombinant FSH, it became only a matter of time until the recombinant LH and hCG became available. Pregnancy after treatment with three recombinant gonadotropins was reported by Agrawal and colleagues in 1997 [17].

Final oocyte maturation is usually achieved by hCG administration 30–36 h prior to the ovum pickup. Several additional developments were noted when Emperaire et al. published their observation that the final stage of ovulation induction can be induced by endogenous LH released by the administration of an LHRH agonist after follicular stimulation for in vitro fertilization [18]. Gonen et al. in their publication have shown that GnRH agonist can be utilized for final oocyte maturation in GnRH antagonist protocols and reducing the risk of ovarian hyperstimulation syndrome [A].

Double stimulation during the follicular and luteal phases has been introduced by Kuang et al. In this protocol, ovarian stimulation and egg retrieval are followed by a second stimulation and retrieval utilizing the antral follicles left after the first stimulation cycle in order to increase oocyte yield. For the first stage, clomiphene citrate and letrozole were used for ovarian stimulation in conjunction with human menopausal gonadotropin (hMG). GnRH agonist was utilized for final oocyte maturation before oocyte retrieval. For the second-stage ovarian stimulation, hMG and letrozole were administered daily from the day of, or the day after, oocyte retrieval. Letrozole administration was stopped when the dominant follicles reached diameters of 12 mm, and medroxyprogesterone acetate 10 mg was added beginning on stimulation day 12 to avoid oocyte retrieval during menstruation. GnRH agonist was utilized again for final oocyte maturation. All the embryos were vitrified and transferred later during a thawed cycle [D].

The abovementioned developments summarize 40 years of gradual development in production of drugs and methods of administration.

In addition, a new technology was developed, which involved in vitro maturation of the oocyte (IVM). Chian et al. demonstrated that hCG priming prior to immature oocyte retrieval in women with PCO increases the maturation rate and produces high pregnancy rates of 40% per IVM started cycle [19].

It seems today that the various protocols and the various drugs available for ovarian stimulation enable the treating physicians to individualize treatment to the specific patient.

1.4 Culture Media

Optimal culture medium, which reflects the changing needs of the developing embryo, is of importance for the success of IVF treatment. The environment of the oviduct/uterus changes dramatically as the zygote/embryo travels. The culture media need to meet the metabolic needs of preimplantation embryos by addressing energetic and amino acid requirements in a stage-specific manner.

The first advanced culture medium was introduced in 1980 [20]. In 1985, Quinn and Warnes published a formula entitled human tubal fluid (HTF) that mimics the in vivo environment to which the embryo is exposed [21]. Gardner introduced sequential media and blastocyst transfer, which now greatly assists in the move to single embryo transfer [22, 23].

The development of a completely chemically defined protein-free embryo culture medium and the births of the first batch of babies generated from the fertilization of eggs collected and inseminated in the medium using spermatozoa also prepared in the same protein-free medium in both conventional IVF and ICSI were introduced in 2000 [24], and since then the medium remained almost the same.

1.5 Aspiration Technique and Handling of the Oocyte and Embryo Replacement

Several techniques for oocyte aspiration have been developed to obtain the largest number of mature oocytes with the least risk to the patients causing minimal damage to the ovary. This was stated with laparoscopic retrieval introduced by Steptoe and Edwards in 1978 and laparotomy for infertility-related conditions [25].

Susan Lenz and Jurgen G Lauritsen examined and proposed the transabdominal transvesical oocyte aspiration using an ultrasound-guided needle [26].

A year later, Gleicher and his group reported the first vaginal egg retrieval using an abdominal ultrasound [27].

Matts Wikland together with Lars Hamberger and Lars Nilsson in Gothenburg, Sweden, described the possibility of using a vaginal sector scanner (transvesical or transvaginal technique) for oocyte aspiration [28]. At the same time, Strickler et al. [29] described embryo transfer using abdominal ultrasound guidance. This technique gained additional support from the work done by Feichtinger et al. [30], and it remained the main technique for egg collection until today.

1

1.6 Improved Fertilization

In the process of fertilization, it was first reported by Trounson and his group that there is a need for a delay between oocyte collection and insemination to allow oocytes collected to complete maturation [31]. In parallel, the possibility of using the natural environment of the human tube for the process of fertilization and development of the embryo leads to the development of the gamete intrafallopian tube (GIFT) procedure, and it was Asch and his colleagues, in 1984, who were the first to report a pregnancy following translaparoscopic GIFT procedure [32].

Much effort was invested trying to improve fertilization when this could not occur naturally when the egg and the sperm were introduced at the Petri dish in the laboratory. These efforts were started when researchers try to fertilize human oocytes by microinjection of a single sperm under the zona pellucida [33], which was followed by the report of a healthy delivery using the same technique in 1988 by Ng and his colleagues [34]. Further achievement was noted when pregnancy was obtained from micromanipulation using zona drilling or mechanical partial zona dissection [35]. However, a breakthrough was achieved when Palermo and his colleagues from the group in Brussels report of the first pregnancy after intracytoplasmic sperm injection (ICSI) [36].

In order to improve fertilization results after repeated IVF failure or at advanced maternal age, it was suggested to use the cytoplasmic transfer technique. This is based on an assumption that a vital molecule, such as ATP or cell cycle-related kinase, or an organelle, such as mitochondria, is deficient at a critical stage in early development.

The technique aims to improve egg and embryo quality by the donation of ooplasm from supposedly fertile oocytes to patients whose cells are of poorer quality. Transfer of enucleate cytoplasm has been used, and Cohen et al., in 1997, were the first to report on a birth after such a procedure [37].

1.6.1 Embryo Selection

Embryo selection is a key point in IVF success. Since our ability to select genetically normal embryo was limited, invasive and noninvasive techniques have been developed.

1.6.2 Noninvasive Selection

In their pioneering work, Wong et al. have shown a correlation between time-lapse image analysis and gene expression profiling. The timing of events during embryo formation is positively correlated to blastocyst formation [E].

The utilization of proteomics to analyze embryo's euploidy was suggested by McReynolds et al. (2011). They revealed that the presence of lipocalin-1 is increased in the secretome of aneuploid human blastocysts. The data were obtained through mass spectrometry (MS) and subsequently confirmed through enzyme-linked immunosorbent assay (McReynolds 2011) [F].

1.6.3 Invasive Selection

A new era in the field of IVF, i.e., preimplantation genetic diagnosis (PGD), was open with the announcement of Handyside and his colleagues who first reported on the biopsy of human preimplantation embryos and sexing by DNA amplification [49]. This was followed by the report of pregnancies from biopsied human preimplantation embryos sexed by Y-specific DNA amplification [50]. Still in the same field of PGD, Verlinsky was the first to report on the possibility to do a polar body biopsy, transfer the embryo, and achieve pregnancy [51].

Embryo biopsy at different stages (polar body biopsy, cleavage stage (Day 3), or blastocyst) has been used for single gene mutation (preimplantation genetic diagnosis (PGD)) or for comprehensive chromosome screening (preimplantation genetic screening (PGS)). The clinical pregnancy rate for single screened blastocyst was comparable to two unscreened blastocysts dropping the twins rate to 0 (Forman et al. 2013) [G]. Although this technique is promising, it is not the routine practice till date, and further studies are needed.

1.7 Development of Cryopreservation and Storage of Embryos and Oocytes

In 1983, the group of investigators at the Monash IVF Centre reported on the first human pregnancy and birth following cryopreservation, thawing, and transfer of an eight-cell embryo. This embryo freezing technique was developed in Cambridge, England, on cattle, and with minor adaptations, it was adjusted to humans [38]. Few years later, in 1990, Gordts and his colleagues reported on the first successful human cleavage-stage embryo vitrification followed by a successful delivery [39]. However, until this period of time, it was difficult to cryopreserve oocytes, and only in 1999, the birth following vitrification of human oocyte was reported by Kuleshova et al. [40]. During the same year, Porcu and her colleagues reported on the first birth from cryopreserved oocytes and testicular sperm [41]. A major development was noted when Bedaiwy et al. reported in 2006 on the successful cryopreservation of intact human ovary with its vascular pedicle [42]. This was followed in 2008 by the announcement of Porcu and her colleagues on cryopreserved oocytes in cancer patients and the first ever birth of healthy twins after oocyte cryopreservation and bilateral ovariectomy [43].

1.8 Manipulation of the IVF Procedure and Technique to Solve Various Causes of Infertility

In 1983, the Monash IVF team achieved the first birth in a woman without ovaries by using donor eggs, creating artificial menstrual cycles, and a special hormonal formula for the first 10 weeks of pregnancy [44]. This came along with the first successful delivery following egg donation [45]. Still in

the same year, in vitro maturation (IVM) and fertilization of morphologically immature human oocytes in an IVF setup was developed and published [46]. However, it took 11 years until the first live birth as a result of IVM following transvaginal ultrasound-guided oocyte collection was reported. Further development of the technique was reported by Barnes et al. who achieved a blastocyst development from IVM oocyte that was fertilized by ICSI and underwent assisted hatching before transfer. This technique resulted in a healthy birth [47].

Utian et al. in 1985 were the first to describe a successful IVF surrogate pregnancy. This technique enables women without a functioning uterus to have a biological offspring. This includes women with an absent uterus as in Müllerian agenesis, Mayer–Rokitansky–Küster–Hauser syndrome, women posthysterectomy, and those with nonfunctioning uterus such as in Asherman syndrome.

The intended parents' embryo is transferred to the surrogate mother after synchronization of her uterine lining, as done with donor egg recipients. After the birth, the baby is given to its biological parents (Utian et al. 1985) [B].

Fertility preservation for cancer patients whose expected chemotherapy treatment (especially alkylating agents) might harm their ovarian reserve is gaining popularity. The improved prognosis and longevity with the increased concern of the quality of life made these treatments an integral part of the assessment and treatment of cancer patients. One concern with estrogen-sensitive breast cancer patients is the supranormal levels of estrogen during ovarian stimulation. New stimulation protocols utilizing letrozole (an aromatase inhibitor) were first reported by Oktay et al. (2005). The letrozole enables a full stimulation with lower estrogen levels and excellent results (Oktay et al. 2005) [C].

The role of assisted hatching is still controversial, and the indication for the procedure is not very clear. However, in 1985, Cohen and his colleagues reported in *The Lancet* about a birth after replacement of hatching blastocyst cryopreserved at the expanded blastocyst stage [48]. It was later on suggested to use this specific technique of assisted zona hatching to breach the zona pellucida and promote the natural process of hatching when the prognosis is poor [52].

1.9 Summary

The field of IVF was developed dramatically during the last 30 years, and what was considered to be a miracle has become a common practice around the world. The field is still being developed in multiple directions to find solutions for couples who are infertile, those wishing to conceive at an older age, and those needing to delay pregnancy for medical reasons.

We can expect further developments in the drug development, reduce the difficulties involved in stimulation of the ovaries moving into natural cycles, and obviously find a way to define the best embryo for replacement, which might give the patients the highest chance to become pregnant.

Learning Objectives

- To evaluate the requirements for staffing, of an ART laboratory
- To review facility design, engineering, equipment, and material requirements
- To discuss building materials and details of facility burn-in
- To prepare for procedures, maintenance planning, and risk management

2.1 Introduction

There are several alternatives for planning and operating an assisted reproductive technology (ART) laboratory; one setup may have little in common with another but may prove to be equally efficacious. Although this is important to remember as one ventures into establishing a new clinic, a poor design or plan may be hard to correct later. Facilities for ART range from a makeshift IVF laboratory with a minimum of equipment to a fully equipped laboratory specifically designed for ART and additional space dedicated to cryostorage, clinical care, and research. This chapter does not cover improvised laboratories, converted surgical areas or research facilities, or remote egg collection sites with transportation of gametes and embryos from other locations. Neither do we cover the application of simple, but ingenious, cost-reducing culture systems such as those described by Jonathan van Blerkom and coworkers in 2014 [1] or intravaginal culture (IVC) originally pioneered by Ranoux et al. (1988) [2] and redeveloped by INVO Bioscience more recently [3]. While such models can be successful, applications require egg retrieval and embryo transfer facilities. Whether these alternative approaches can achieve optimal results is still being investigated [1–4]. In vitro fertilization (IVF), intracytoplasmic sperm injection (ICSI), preimplantation genetic testing (PGT), and cryopreservation cannot be readily applied to alternatively cultured gametes and embryos [4, 5].

This chapter concerns the conventional all-inclusive laboratory that is adjacent or in immediate proximity to oocyte retrieval and embryo transfer facilities, with emphasis on the special problems of construction. For questions on culture system, culture medium and supplementation, selection methods and handling and processing of gametes and embryos including freezing and vitrification, the reader is referred to other relevant chapters in this textbook. The authors over the years have addressed the topics presented here in various formats and in other book chapters and papers. This chapter follows the format presented in Cohen et al. (2017) with additional data, advice, and information provided where appropriate [6].

2.2 Personnel and Experience

While the physical space dedicated to a purpose-built gamete and embryo culture facility deserves special consideration, it is the staff that will carry out the procedures and is essential to the success of the entire operation. Successful clinical practice in general, and ART in particular, is almost entirely dependent on the skill and experience level of medical and laboratory personnel. For the laboratory staff, enthusiasm is another key factor to success, especially because there are still few formal teaching and skills examination programs in place for a specialty in ART. Most clinical embryologists are trained via an apprenticeship program, but such institutions are rare and there are no internationally accepted guidelines. Good clinical outcomes require a close assessment of individual abilities, so laboratory staff, directors, and embryologists must consider their experience in the context of what will be required of them [7].

IVF clinics should participate in external proficiency testing programs and develop their own system of tracking staff performance in crucial clinical and laboratory procedures such as embryo transfer, ICSI, and embryo biopsy. Certain regulatory bodies such as the College of American Pathologists (CAP) and the American Board of Bioanalysis (ABB) in the USA and the Human Fertilisation and Embryology Authority (HFEA) in the UK provide standards of operation for laboratories, accreditation, or licensing for embryologists or laboratory directors. The HFEA in particular provides licensing for individual procedures such as ICSI and embryo biopsy. Licensing, however, is controversial because it does not guarantee skill or success and the licenses are not always recognized across borders from one country to another. Auditing and accreditation of laboratories, however, may have played a positive role in improving outcomes, because they encourage standardization and require a commitment to a quality management program that includes quality control and assurance. This improvement is clear in reported implantation rates in the USA [8].

Tradition also plays its role. For example, in some Asian countries, embryology directors are usually medical professionals. Thus, academic titles are often seen as being more important than practical experience. What then qualifies someone to be a laboratory director or an embryologist? The answer is not a simple one. In general, current licensing authorities including the ABB consider individuals trained in general pathology or reproductive medicine and holding an MD degree as well as individuals holding a PhD degree qualified to be laboratory directors if they meet some additional requirements. However, pathologists do not necessarily have experience in gamete and embryo cell culture, and some reproductive medicine specialists, such as urologists and immunologists, may have never worked with gametes and embryos. Although some medical doctors with laboratory experience do successfully direct laboratories, in many countries, the rules make it possible for anyone with a medical degree to direct a laboratory without having any proficiency in gamete and embryo handling! Once there are rules, even ones that make little practical sense, it may be hard to change them.

2.3 Staffing and Staff Training

There is considerable disagreement about what should be required experience for embryologists. Hands-on experience in all facets of clinical embryology is an absolute

requirement when starting a new program. Even highly experienced experimental embryologists and animal scientists should be directly supervised by experienced clinical embryologists. The period during which close supervision must continue depends on the types of skills required, the daily caseload, and time spent performing procedures. Clearly, performing 100 cases over a 1-year period is a very different circumstance than performing the same number over 6 weeks; the period of supervision then should be adjusted accordingly.

The optimal ratio of laboratory staff to the expected number of procedures is debatable, and unfortunately, economics play an all-too-important role here. However, with the incorporation of new technologies and treatment modalities in routine care, the complexity of IVF laboratory operations has increased substantially over the past decade, in turn requiring more careful consideration of staffing levels [9]. According to some calculations, while a "traditional" IVF cycle required roughly 9 personnel hours, a contemporary cycle can require up to 20 h for completion. Thus, the number of embryologists required for safe and efficient operation of the laboratory has also increased. Recently, based on a comprehensive analysis of laboratory tasks and their complexity level, an Interactive Personnel Calculator was introduced to help laboratory directors and administrators determine staffing needs [9]. This calculator is helpful, but it applies to one model of operation and would have to be modified to fit other models or special circumstances. For instance, a clinical approach that employs natural cycles or minimal stimulation yielding limited egg numbers is a very different model, compared to controlled ovarian stimulation with high oocyte yields. These differences notwithstanding, overall, it is safe to say that the ratio of laboratory staff to caseload should be high so that embryologists can not only safely perform procedures, but dedicate time to quality control and continued education and training in order to maintain the high standards required for success. The challenge of keeping these standards within national health systems or in the face of insurance mandates that must provide a wide range of services on a minimal budget is real, but should not be insurmountable. Needless to say, patients usually do not benefit from such constraints, as a comparison of results in different health service systems in Western countries would suggest. There are limitations to such comparisons, but live birth per embryo and cumulative data from fresh and cryopreservation cycles are considered objective assessments [10].

2.4 Embryologist Tasks

The job description for the embryologist ideally includes all embryology and andrology tasks. Embryologists are often involved in other important tasks as well, including communications with patients, follicular monitoring, genetic counseling, equipment maintenance, purchasing and receiving, and administration. However, it should be realized that these tasks may detract from their main responsibilities. First and foremost, the embryologist's duty should be to perform gamete and embryo handling and culture procedures. Secondly, but equally important, the embryologist should maintain quality control standards, both by performing routine checks and tests and by maintaining detailed logs of incidents, changes, unexpected events, and corrective measures. Across all these duties, the following seven positions can be clearly defined: director, supervisor, senior embryologist, embryologist, trainee, assistant, and technician. There may also be positions for others to do preimplantation genetic diagnosis, research, quality control supervision, or administrative work. Obviously, not all of these separate positions are necessary for smaller centers, and some tasks can be combined.

Although a seemingly unimportant detail, one of the most important jobs in the IVF laboratory at Bourn Hall Clinic in Cambridge, UK, during the first few years of operation in the 1980s was that of a professional witness and embryology assistant. This position was the brainchild of Jean Purdy, the third member of the team, whose work led to the birth of Louise Brown. The embryology assistant effectively enforced and oversaw the integrity of the chain of custody of gametes and embryos during handling, particularly when large numbers of patients were being treated simultaneously. The "witness" also ensured that embryologists performed only those procedures for which they were qualified. Interestingly, recent studies suggest that this crucial concept has not been universally and fully understood or adopted by IVF laboratories. In one group of laboratories [11], "limited and consequently virtually ineffective" witnessing processes were only abandoned in favor of a more robust witnessing program after implementation of a Failure Mode Effect and Analysis (FMEA) showed a high risk of error in gamete and embryo identification. The authors stated that, "Only after FMEA optimization has the witness embryologist been formally recognized as a committed role, specifically trained for witnessing shift work." Hopefully, the publication of this and other similar studies [12] that show the effectiveness of a witnessing system will encourage more laboratories to re-examine their practices and allocate adequate resources in ensuring safety and efficiency of all procedures performed by the laboratory.

2.5 Facility, Design, and Budget

As an important preface to this section, we must emphasize that setting up a new laboratory or renovating an existing facility must be a close collaborative effort between a team of experienced embryologists, medical doctors, and program administrators and a team of engineers, architects, and contractors. Without this collaboration, the ultimate success of such endeavors is put in jeopardy.

In the early days of IVF, some clinics were built in remote areas, based on the premise that environmental factors such as stress could affect the patient and thereby the outcome of treatment. Today's laboratories are commonly placed in city centers and large metropolitan areas in order to serve larger populations. It is clear that the choice of a laboratory site is

2

of great importance for a new program. The recent development of better assays for determining the baseline quality of the environment facilitates site selection. There is now awareness that some buildings or building sites could be intrinsically harmful to cell tissue culture [13–15]. The direct effect of poor air quality and presence of volatile organic compounds (VOCs) on IVF outcomes has been demonstrated by recent studies of novel filtration systems and other counter measures [16, 17]. A recent consensus meeting on these specifics in relation to air quality was convened in Cairo in 2017, the results of which have been published [18]. A laboratory design should be based on the anticipated caseload and any subspecialty. Local building and practice permits must be assessed prior to engaging and completing a design.

There are four basic types of design:

1. Laboratories adjacent to clinical outpatient facilities that may be used part of the time. Other types of procedures may be performed in the procedure room or surgical suite (this may complicate air handling).
2. Clinics with inter-facility egg transport using portable warming chambers.
3. Fully integrated laboratories with adjacent clinical areas and procedure and transfer rooms dedicated exclusively to assisted reproduction.
4. Moveable temporary laboratories.

Before developing the basic design for a new laboratory, environmental factors must be considered. While air quality in modern laboratories can be controlled to a degree, it can never be fully protected from the exterior environment and adjoining building spaces. Designers should first determine if the building or the surrounding site is scheduled to undergo renovations, demolition, or major changes of any kind in the foreseeable future. City planning should also be reviewed. Past environmental data and trends should be reviewed, and accessibility of the IVF laboratory to maintenance staff should be ascertained. Activity related to construction can have a significant negative impact on the laboratory, so the possibility of future construction in the vicinity should be considered. Prevalent wind direction, industrial hazards presence, and general pollution levels (such as ozone measurements) should also be determined. Even when these factors are all deemed acceptable, basic air sampling and determination of VOC concentrations is necessary inside and outside the proposed building area. The outcome of these tests will determine which design requirements are needed to remove VOCs from the laboratory area. In most cases, an over-pressured laboratory (at least 0.10–0.20 inches of water) that uses a high number [7–15] of fresh air changes (FACH) per hour is the best solution, because it also provides for proper medical hygiene. The laboratory walls and ceiling should have the absolute minimum number of penetrations. This generally requires a solid ceiling, sealed lighting, and airtight utility connections. Contrary to many vendors' representations, commercial suspended ceilings using double-sided tape and clips are not ideal. Doors will require seals and sweeps and should be lockable. Ducts and equipment must be laid out in such a way that routine and emergency maintenance and repair work can be performed outside the laboratory with minimal disruption to the laboratory. Air handling must not use an open plenum design. In the ideal case, 100% outside air with chemical and physical filtration will be used with sealed supply and return ducts. Recommended conditions and more than 50 consensus points for air handling and facility operational aspects are discussed in detail in the Cairo consensus paper on the IVF laboratory environment [18].

While providing cleaner air, 100% outside air sourcing will maximize the life of a chemical filter and will provide a lower concentration of VOC in the IVF laboratory's air. In climates where temperatures routinely exceed 32 °C with >= 85% relative humidity, 100% outside air could result in an unacceptable level of humidity (>60%), which could allow mold growth. In these cases, the use of limited return air from the lab is acceptable. A 50% outside air system with 15–30 total air changes per hour does work well, and the relative humidity becomes very controllable. To place this in perspective, traditional medical operating room design in the USA calls for 10–15% outside air.

The air supply equipment may supplement outside air with re-circulated air, with processing to control the known levels of VOCs. On rare occasions, laboratories will require full-time air recirculation, while most may actually find the outside air to be perfectly clean at least most of the time. Outside air is often erroneously judged to be polluted without proper chemical analysis, while inside air is usually considered "cleaner" because it may "smell" better or seem less polluted due to the lack of a horizon [10]. However, in most laboratory locations, conditions are actually the reverse, and designers should not "follow their instincts" in these matters. Humidity must also be completely controlled according to climate and seasonal variation. The system must be capable of supplying the space with air with a temperature as high as 30–35 °C at less than 40% relative humidity. Air inlets and outlets should be carefully spaced to avoid drafts that can change local "spot" temperatures or expose certain equipment to relatively poor air or changes in air quality. Laminar flow hoods and micromanipulation workstations should not be located too close to air supply fixtures to avoid disruption of the sterile field and to minimize cooling on the microscope stage. Semi-enclosed workstations based on Class 2 cabinets or neonatal isolette incubators can be considered to optimize the work environment and bridge the gap between the incubator and the workstation. A detailed layout and assessment of all laboratory furniture and equipment is therefore essential prior to construction and has many other benefits.

Selection of an experienced and subspecialized (and flexible) architect and a mechanical engineer for the project is essential. Confirm what their past experience has been in building biologically clean rooms. The use of "environmentally friendly" or "green" products has been suggested by some designers. The reliance on "natural" products does not ensure a clean laboratory. In one case, wood casework with a green label was found to be a major source of formaldehyde. Floor coverings using recycled vinyl and rubber were

selected for their low environmental impact, without considering the significant release of trapped gasses by the material.

Supervision of the construction is also critical. Skilled tradesmen using past training and experience may not follow all of the architect's instructions. The general contractor and the builders must be briefed on why these novel construction techniques are being used. They must understand that the use of untested methods and products can compromise the project (and the payment of their fees!) Contractual agreement is recommended. They must be informed of preferred products used in IVF laboratory construction. A summary of this is provided elsewhere [18].

Just as the organization and flow of traffic in a world-class restaurant result in a special ambience where more than just the food is the attraction, appropriate modular placement of equipment ensures safety and comfort in the over-pressured IVF laboratory. Placement of stacks or small volume box or benchtop incubators, gamete handling areas (laminar flow units or isolettes), and micromanipulation stations should minimize distances that dishes and tubes need be moved. Ideally, an embryologist should be able to finish one complete procedure without moving more than 3 meters in any direction; not only is this efficient but also it minimizes accidents in a busy laboratory. Some newer laboratories apply modular design, where each technician remains in a small dedicated area. Design and implementation of a work area incorporating CO_2 and nitrogen supplies, a workstation, refrigerator, and incubators is feasible even without the embryologists having to walk between storage cabinets and equipment. Such a modular design can be duplicated multiple times within a larger air handling area allowing the handling of large numbers of gametes and embryos. For logistical reason, sperm preparation and cryopreservation may be placed in adjacent areas. The number of modules can easily be determined by the expected number of cases and procedure types, the average number of eggs collected, and the number of embryologists expected to work simultaneously. Each person should be provided with sufficient workspace to perform all procedures without delay. Additional areas can contain simple gamete handling stations or areas for concentrating incubators. Cryopreservation and storage facilities are often located in a separate space, although this is not strictly necessary; if separated, these areas should always be adjacent to the main laboratory. Storage spaces could be separated further using closets or rooms with negative pressure and air ventilation. Another separate laboratory or module may contain an area for culture medium preparation, sterilization, and water treatment; however, the need for such an area is diminishing now that commercial manufacturers provide all the basic needs of an IVF laboratory. Administration and other aspects of patient care should be performed in separate offices on a different air handling system from the main laboratories.

Last but not least, it is preferable to prepare semen in a separate laboratory altogether, adjacent to one or more collection rooms. The andrology laboratory should have ample space for microscopes, centrifuges, refrigerator, and safety cabinets. Proper separation of patient samples during processing is essential, and some elemental design features may be considered before the first procedures are carried out. Some thought should go into planning the semen collection area. This small room should be at the end of a hallway preferably with its own exit; it should be soundproofed, not too large, with a sink. Clear instructions of how to collect semen for ART should be provided in the room. The room should also be adjacent to the semen preparation laboratory, preferably with a double-door pass-through for samples. This pass-through should have a signaling device so the patient can inform the laboratory staff that the sample is ready; it also permits male patients to leave the area without having to carry a specimen container. Remote semen collection is a routine procedure in many clinics. It may be efficient and safe but requires that patients strictly follow clinic instructions (► www.sart.org).

2.6 Equipment and Storage

A detailed list of equipment should be prepared and checked against the planned location of each item; it can later be used as the basis of maintenance logs. It is important to consider the inclusion of crucial equipment and spare tools in the laboratory design, to allow for unexpected malfunction. Similarly, two or more spare incubators should not be seen as excessive; at least one spare follicle aspiration pump and micromanipulation station (equipped with laser) should also be included. There are many other instruments and pieces of equipment, the malfunction of which would jeopardize patient care, although some spares need not be kept on hand as manufacturers may have them available; however, such details need to be repeatedly checked as suppliers' stock continues to change. It may also be useful to team up with other programs or an embryology research laboratory locally so that a crucial piece of equipment can be borrowed in case of unexpected failure.

The number and type of incubators should be carefully considered [19]. The ratio of incubators to patient procedures depends on incubator size and capacity, and it varies considerably from program to program. It is clear that the number and type of incubator, routine maintenance, and cleaning as well as the length and number of incubator door openings may affect results. In principle, the number of cases per incubator should be kept to a minimum; we prefer a limit of four cases per large standard box incubator. The smaller box incubators should not handle more than two to three cases. Several new desktop incubators now have separate slots for handling one patient at a time. This is a good development. Several other incubators can be used for general purpose during micromanipulation and for other generic uses to limit further the number of incubator openings during extended culture. Strict guidelines must be implemented and adhered to when maintaining distinct spaces for separating culture dishes or tubes of different patients. Tracking of incubators and even shelves or compartments within each incubator is recommended so their performance can be evaluated on an ongoing basis. Separate compartments within a small-type

box incubator may be helpful and can be supplied by certain manufacturers. Servicing and cleaning of equipment such as incubators may have to be done when the laboratory is not performing procedures. Placement of incubators and other pieces of equipment on large castors may be helpful in programs where downtime is rare. Pieces of equipment can then be serviced outside the laboratory. New incubators and pieces of equipment that come in contact with gametes and embryos must be "burned-in" or "off-gassed." Protocols vary per equipment type and manufacturer [18].

When there are several options available to the laboratory designer, supply and evacuation routes should be planned in advance. One of the most susceptible aspects of ART is cryopreservation and cryostorage [20]. In case of an emergency such as fire or power failure, it may be necessary to relocate the liquid nitrogen-filled dewars without using an elevator or to relocate the frozen samples using a temporary container. This may seem like an extreme measure, especially in the larger laboratories that stockpile thousands of cryostored samples, but plans should be made and risk management is essential given the possibility of catastrophic failures, which have been reported [20]. It may be possible to keep a separate storage space or room near the building exit, where long-term-storage samples, which usually provide the bulk of the storage, can be kept; this would require daily monitoring and alarming of a facility that is not part of the laboratory. Liquid nitrogen tank alarms with remote notification capability should be installed on all dewars holding gametes and embryos. A minimum of two monitoring systems is highly recommended.

The route of delivery of liquid nitrogen and gas cylinders must be relatively short, without stairways between the laboratory and the delivery truck, and should be sensibly planned in advance. Note that the flooring of this route is usually destroyed within months because of liquid nitrogen spills and wear caused by delivery containers, so the possibility of an alternative delivery corridor or installation of special LN2-resistant flooring should be considered for these units.

Liquid nitrogen containers and medical gas cylinders are preferentially placed immediately adjacent to the laboratory in a closet or small, ventilated room with outside access. Pipes and tubes enter the laboratory from this room, and cylinders can be delivered to this room without compromising the laboratory area in any way. Providing liquid nitrogen and even liquid oxygen vapor to triple gas incubators is nowadays a preferred option since vapor is cleaner and more affordable than compressed gas. This allows liquid nitrogen vapor to be pumped into the cryopreservation laboratory using a manifold system and minimal piping. Lines should be properly installed and insulated to ensure that they do not leak or allow condensation and conserve energy at the same time. Medical gasses can be directed into the laboratory using prewashed vinyl/Teflon-lined tubing such as fluorinated ethylene propylene or FEP, which has high humidity, temperature, and UV radiation stability. Lines should be properly marked every meter indicating the incubators supplied in order to facilitate later maintenance. Alternatively, solid manifolds made from stainless steel with suitable compression fittings can be used. Soldered or brazed copper lines used in domestic plumbing applications should be avoided wherever possible; copper lining can be used but should be cleaned and purged for a prolonged period prior to use in the laboratory. Copper line connections should not be soldered as this could cause continuous contamination. This recommendation may conflict with existing building codes, but non-contaminating alternatives can be found. A number of spare lines hidden behind walls and ceilings should be installed as well, in case of later renovation or facility expansion.

Large programs should consider the use of exterior bulk tanks for carbon dioxide and liquid nitrogen. This removes the issues of tanks for incubators or cryopreservation. These tanks are located where delivery trucks can hook onto and deliver directly to the tank. Pressurized gas lines or cryogenic lines then run the carbon dioxide or liquid nitrogen to the IVF laboratory for use.

Placement of bulky and difficult pieces of equipment should be considered when designing doorways and electrical panels. Architects should be fully informed of all equipment specifications to avoid the truly classic door-width mistake. Emergency generators should always be installed, even where power supplies are usually reliable. The requirements can be determined by an electrical engineer. Thankfully, these units can be well removed from the laboratory but must be placed in well-ventilated areas that are not prone to flooding. Additional battery "uninterruptible power systems" (UPS) may be considered but can be of limited capability or expensive when the requirement is to run the entire clinic for 1 day or longer. Buildings should also be checked for placement of the main power inlets and distribution centers, especially because sharing power lines with other departments or companies may not be advisable. Circuit breakers should be easily accessible to laboratory staff or building maintenance staff. General knowledge of mechanical and electrical engineering of the building and the laboratories is always advantageous. Leaving all the building mechanics and facilities to other individuals can be counterproductive. Laboratory staff need to be involved with facilities management and be updated with construction decisions in and outside the building in a timely manner.

Ample storage spaces should always be planned for IVF laboratories. In the absence of dedicated storage space, laboratory space ends up being used instead, filling all cabinets and negating any advantages of the original design. The dedicated storage area should be used to stock all materials in sufficient quantity to maintain a steady supply. A further reason to include storage areas in laboratory design, sufficient on its own to justify the space, is that new supplies, including sterile disposable items, release multiple compounds for prolonged periods. This "outgassing" has been determined to be a major cause of air pollution in a number of laboratories in which supplies were stored inside the lab. Separate storage space therefore provides the best chance of good air quality, especially when it is supplied by a separate air handling system.

It should be large enough to handle bulky items as well as mobile shelving for boxes. One should be careful to avoid the natural inclination to save extra trips by bringing too many items into the laboratory, or the gains made by careful design may be lost. As a possible makeshift solution, storage cabinetry in the laboratory can be designed with separate negative pressure air handling in order to minimize release of VOCs from off-gassing package materials.

2.7 Microscopes and Visualization of Cells

Though dissecting microscopes are crucial for the general handling of gametes and embryos, inverted microscopes are key during morphology assessment and micromanipulation. Proper visualization of embryos is key to successful embryo selection for transfer or freezing; if the equipment excels, visualization can be done quickly and closely. Even so, appropriately detailed assessment is still dependent on the use of an oil overlay system to prevent damage by prolonged exposure. Each workstation and microscope should be equipped with a camera as well as a monitor. Still photos can be placed in the patient file or uploaded electronically in the database, and video footage like time-lapse permits speedy review of embryonic features with colleagues after the gametes are safely returned to the incubator; this is also helpful for training of new embryologists. Interference optics such as Hoffman and Nomarski are preferable because they permit the best measure of detail and depth. Novel visualization of internal elements such as spindles using polarized microscopy requires additional equipment but can be incorporated into routine operation [21].

Development of new time-lapse microscopy technologies has made continuous and uninterrupted monitoring of embryo development a reality. This is not just an invaluable teaching and learning tool, but also provides a permanent record for patient care. However, equipment costs are high and, for many laboratories, prohibitive. Equipment for time-lapse technology can be sizable and may require separate consideration in terms of lab design, bench space, and CPU placement.

2.8 Construction, Renovation, and Building Materials

Construction and renovation can introduce a variety of compounds into the environment of the ART laboratory, either temporarily or permanently. Either can have major adverse effects on the outcome of operations [13, 14, 16–18]. The impact of the exterior environment on IVF success has been demonstrated. Pollutants can have a significant negative effect on success in an IVF laboratory [13, 22]. These effects can range from delayed or abnormal embryonic development, reduced or failed fertilization, and reduced implantation rates to pregnancy loss and failure of a treatment cycle. Many of the damaging materials are organic chemicals that are released or outgassed by paint, adhesives from flooring, cabinets, and general building materials, as well as from laboratory equipment and procedures. It is important to realize that the actual construction phase of the laboratory can cause permanent effects on clinical outcomes. Furthermore, any subsequent renovation activity in adjacent areas may also have an effect. Neighboring tenants can be informed of the sensitivity of gametes and embryos in culture. At the very least, changes undertaken in adjacent areas should be supervised by IVF laboratory personnel to minimize potential damage. However, new construction immediately outside the building is considerably more problematic. City works such as street construction are very hard to predict and nearly impossible to control. A good relationship with the neighbors should be maintained and a working relationship with building owners and city planners should be established so that the IVF laboratory is kept informed of upcoming changes.

2.9 Preparation for Construction

For the construction of a new laboratory or if changes are to be made to areas adjacent to the IVF facility, the following guidelines should be followed [6, 18]. First, the area to be demolished and reconstructed needs to be physically isolated from the IVF laboratory (if this is not the new IVF laboratory itself). The degree of isolation should be equivalent to an asbestos or lead abatement project. The isolation should be done through (1) physical barriers, consisting of polysheeting supported by studding where needed; (2) limited access to the construction area and the use of an access passageway with two doors in series; (3) removal of all construction waste via an exterior opening or proper containment of waste before using an interior exit; (4) negative air pressure in the construction area, exhausting to the exterior, far removed from the laboratory's air intake, and properly located with regard to the prevailing winds and exterior airflow; (5) extra interior fans during any painting or the use of adhesives to maximize removal of noxious fumes; and (6) compiling and logging of Safety Data Sheets (SDS) for all paints, solvents, and adhesives in use.

Follow-up investigations with manufacturers and their representatives may be helpful because specifications of equipment may be changed without notice. The negative pressurization of the laboratory space requires continuous visual confirmation via a ball and tube pressure indicator or simply paper strips. Periodic sampling for particulates, aldehydes, and organics could be done outside the demolition and construction site, provided this is economically feasible. Alternatively, tracer gas studies can be done to verify containment. The general contractor of the demolition and construction should be briefed in detail on the need to protect the IVF facility and techniques to accomplish this. When possible, the actual members of the construction crew themselves should be selected and briefed in detail. Large filter

units using filter pellets of carbon and permanganate can be placed strategically. Uptake of organics can be assayed, but the frequency of routine filter changes should be increased during periods of construction activity.

2.10 Selection of Building Materials

Many materials release significant amounts of VOCs, and a typical list includes paints, adhesives, glues, sealants, and caulking materials, which release alkanes, aromatics, alcohols, aldehydes, ketones, and other classes of organic materials. This section outlines steps to be taken in order to reduce these outgassing chemicals. Any and all interior painting throughout the facility should only be done on prepared surfaces with water-based paint formulated for low VOC potential. During any painting, auxiliary ventilation should be provided using large industrial construction fans, with exhaust vented to the exterior. Paints that can significantly influence air quality should be emission tested (some suppliers already have these test results available). Safety Data Sheets are generally available for construction materials. Suppliers should be encouraged to conduct product testing for the emission potential. The variety of materials and applications complicates the testing process, but several procedures have been developed to identify and quantify the compounds released by building materials and furnishings. Interior paints must be water-based, low-volatile paints with acrylic, vinyl acrylic, alkyd, or acrylic latex polymers. Paints meeting this specification can also contain certain inorganic materials. Paints with low volatiles may still contain low concentrations of certain organics. No interior paint should contain formaldehyde, acetaldehyde, isocyanates, reactive amines, phenols, and other water-soluble volatile organics.

Adhesive glues, sealants, and caulking materials present some of the same problems as paints. None of these materials used in the interior should contain formaldehyde, benzaldehyde, phenol, and like substances. Although water-based versions of these are generally not available, their composition varies widely. Silicone materials are preferred whenever possible, particularly for sealants and caulking work. A complete list of guidelines for material application during construction of a tissue culture laboratory is available elsewhere [23].

2.11 "Burning In" of the Finished Facility and Outgassing of New Equipment

New IVF laboratories and new facilities around existing laboratories are occasionally affected by complaints of occupants who experience discomfort from the chemicals released by new construction and furnishings. Some materials may outgas for years. Effects on gametes and embryos must be avoided by using nontoxic materials and filtration [6, 18, 22, 23]. The ambient levels of many of these materials can be reduced by "burning in" the facility. A typical burn-in consists of increasing the temperature of the new area by 10–15 °C, if possible, and increasing the ventilation rate; even higher temperatures are acceptable. The combination of elevated temperature and higher air exchange aids in the removal of the volatile organics. Upon completion of the construction, the air handling system should be properly configured for the burn-in of the newly constructed area. As previously stated, the system must be capable of supplying the space with air with a temperature of 30–35 °C, at less than 40% relative humidity. The burn-in period can range from 10 to 28 days, and the IVF laboratory should be kept closed during this time. If these temperatures cannot be reached by the base system, use auxiliary electrical heating to reach the minimum temperature. During burn-in, all lighting and some auxiliary equipment should be turned on and left running continuously. Naturally, ventilation is critical if redistribution of irritants is to be avoided; the whole purpose is to purge the air repeatedly. Auxiliary equipment should of course be monitored during the burn-in.

The same burn-in principle applies to newly purchased incubators or other laboratory equipment. Removal of volatile organics is especially important in the critical microenvironment of the incubator. Whenever possible, it is advantageous to purchase incubators months in advance of their intended initial use and to operate them at an elevated temperature in a clean, protected location, preferably not an IVF facility. An existing embryology laboratory is not an appropriate space for burn-in of a new incubator. Most of the equipment available for use in an ART laboratory has not been designed or manufactured to be VOC-free. Special attention must be invested in new laboratory equipment to eliminate or reduce VOC levels as much as possible before first use. Manufacturers should be encouraged to design IVF-specific equipment and choose parts with low emission potential. Most manufacturers do not address the issues of VOC outgassing in product manuals even if the equipment has been expressly designed for the IVF field. Unpacking, cleaning, and operating equipment prior to final installation in a lab for outgassing the "new car smell" is always recommended.

Incubators should be unpacked, inspected, cleaned, outgassed, operated, re-cleaned, calibrated, and tested well in advance. The process can take several months but is an essential task rewarded with the most suitable culture system the selected incubator model can provide. When possible, operating incubators at elevated temperatures above the typical culture temperature will hasten the release or burn-off of VOCs. Extended operation between 40 and 45 °C works well to burn off VOCs if this is within the manufacturer's recommended temperature range. Incubator model VOC loads can vary greatly. Accurate VOC testing may be expensive and time-consuming but is recommended to test a specific incubator model to determine the

new unit's typical VOC characteristics and how much time outgassing may require.

Handheld VOC testing devices are available and can be used to help monitor the decline of total VOCs but cannot match the level of accuracy of an environmental organic chemist's testing. Handheld VOC meter technology generally is not sensitive enough to monitor low molecular weight classes of VOCs, but they are reasonably affordable and easily used and can sometimes provide confirmation of some VOC reduction.

New incubators are generally tested with a mouse embryo assay (MEA) replicating a culture system as part of a new incubator commissioning process. Most laboratories today use some variation of an oil culture system. The oil can serve as an excellent filter against potential VOCs, but may not protect a culture system from the full range of VOC exposure. In particular, low molecular weight compounds such as aldehydes may affect the culture system negatively. Incubator MEA commissioning should include both an oil and an open exposed media test to help evaluate the incubator preparation procedures. The dual oil/no oil approach works well for humidified incubators, but may not be applicable if a dry non-humidified culture system is used. Most non-humidified dry culture systems are designed to recirculate chamber air and incorporate a VOC filtration strategy. Open culture generally cannot be used with non-humidified incubators. The manufacturer's recommendations should be followed. Non-humidified incubators may require extended off-gassing and should be tested prior to use to confirm they do not have a VOC issue. Chemical VOC filters should be replaced after burn-off prior to any MEA testing. The humidification of a benchtop incubator was tested in a recent randomized clinical trial [24]. It was shown that pregnancy was significantly increased when the incubator was humidified, even though the manufacturer did not recommend it. However, this work needs further confirmation.

Laminar flow hoods and isolettes are also an important potential VOC source that should not be overlooked. They should be given ample time to operate and outgas as they can contribute to a lab's VOC contamination load. HEPA and chemical filters should be selected for low VOC manufacturing traits and also may require off-gassing. Care must be taken when outgassing laminar flow hoods and isolettes as they require a HEPA-filtered environment or replacement of their filters when transferred to an IVF lab.

After the burn-in is complete, a commissioning of the IVF suite should be conducted to verify that the laboratory meets the design specifications. The ventilation and isolation of the laboratory should be verified by a series of tests using basic airflow measurements and tracer gas studies. The particulate levels should be determined to verify that the high-efficiency particulate air (HEPA) system is functional. Particulate sampling can be performed using USA Federal Standard 209E. Microbial sampling for aerobic bacteria and fungi is often done in new facilities using an Andersen sampler followed by microbiological culturing and identification. The levels of VOC contamination should be determined. Possible methods are included in the US Environmental Protection Agency (EPA) protocols using gas chromatography/mass spectroscopy (GC/MS) and high-performance liquid chromatography sensitive at the microgram per cubic meter level [25–30].

2.12 Maintenance Planning and Sterilization

Even the best systems and designs will eventually fail unless they are carefully maintained. The heating, ventilation, and air conditioning (HVAC) will require filter changes, coil cleaning, replacement of drive belts, and chemical purification media. The most prevalent failure concerns the initial particulate filter. These are inexpensive filters designed to keep out large dust particles, plant debris, insects, etc. If such filters are not replaced promptly and regularly, they will fail, allowing the HVAC unit to become contaminated. The HEPA filters and chemical media also require inspection and periodic replacement. Maintenance staff should report their findings to the IVF laboratory.

The ART facility must have cleaning rooms for surgical instruments. Ongoing use of an autoclave is not a problem as long as the released steam is rapidly exhausted to the outside. This keeps the relative humidity in the facility to controllable limits. Autoclaves should not be placed on the IVF laboratory's HVAC system, but rather in a room that is built using tight construction and is exhausted directly outside of the building. The use of cold sterilizing agents is not advised. Aldehydes such as glutaraldehyde and *ortho*-phthalaldehyde from the autoclave can be transported inside the IVF laboratory.

2.13 Insurance Requirements

Assisted reproductive technologies have become common practice worldwide and are regulated by a combination of legislation, regulations, or peer-generated practice standards [18]. The rapid evolution and progress of ART reveal new legal issues that require consideration. Even the patients themselves are changing, as it becomes more acceptable for single women and same-sex partners to seek and receive treatment. Donation of gametes, embryos, and gamete components, enforcement of age limits for treatment, selective fetal reduction, preimplantation genetic diagnosis, surrogacy, and many other practices in ART present practitioners and the society at large with challenges, which are often defined by social norms, religion, and law and are specific to each country.

Furthermore, financial and emotional stresses often burden patients seeking treatment in countries where medicine is not socialized and infertility treatment is not covered by insurance. This translates into an increasing number of ART lawsuits related to failed treatments in spite of generally improved

success rates [8]. Laboratory personnel and the laboratory owner should therefore obtain an insurance policy of sufficiently high level and quality commencing prior to the first day of operations. Litigation-prone issues need special consideration and include (I) cancellation of a treatment cycle prior to egg retrieval, (II) failure to become pregnant, (III) patient identification errors [31], and (IV) cryostorage mishaps [20]. Adverse events can occur even if experienced practitioners consider themselves at low risk of exposure. Prior to engaging in the practice of ART, protocols must be established to identify potential problem areas and establish countermeasures.

2.14 Conclusions

It may be surprising how many professionals continue to pursue the establishment of new ART clinics at a time when competition is fierce, financial benefits are small, and existing ART services may appear to be approaching saturation in many areas and countries. Appearances can be misleading, however, and ART centers of excellence that deserve the trust and confidence of patients and serve as models for other practices are always needed.

This chapter provides some guidance for those who aspire to establish such outstanding, well-thought-out, and planned ART practices. Although it cannot safeguard practitioners against adverse events, it introduces concepts in proper design, construction, and operation of ART facilities that are of fundamental importance to treatment success; these guidelines have been painstakingly compiled through decades of practical experience and research. The approach is best adopted as a whole rather than dissected into its components and adopted in part or selectively. Resisting the urge to cut corners in the wrong places avoids future headaches and positions an ART program on the path to success.

Building the Laboratory

Dean E. Morbeck and Marlena Duke

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_3

Learning Objectives

- To understand the key differences in laboratory design for different size clinics.
- Describe the essential elements of the plumbing, electrical, and alarm systems.
- Process for validation before patient care.

3

3.1 Introduction

As new in vitro fertilization (IVF) laboratories continue to appear in private practice settings, it is paramount that the reproductive endocrinologist and laboratory director are well-versed in laboratory design. Unlike large institutions, where specialized engineers and contractors are available to design and build clean room-quality operating rooms and laboratories, professionals in the assisted reproductive technologies (ART) must navigate a specialty for which they have little training or experience.

Unfortunately, there are limited resources and references available to ART professionals when setting out to build a new laboratory. Standards for IVF laboratories published by professional societies and accrediting agencies are mostly lacking, and those that exist are superficial at best. Both ESHRE and ASRM provide minimal guidelines for laboratory space and design [1, 2]. This leaves the individual responsible for the design and supervision of building the laboratory to rely on other sources, particularly standards that exist for operating rooms and clean rooms. These two types of rooms represent the range of quality one should aspire for their facility: the operating room at a minimum and the class 10 or class 100 clean room as the maximum. Even within these types of facilities, there are aspects of design and management that are unique to an IVF laboratory.

This chapter focuses on the critical aspects of building a laboratory in a private practice setting as part of an ART clinic. The details presented here will delve into issues of laboratory design and construction, with the notable exception of the heating, ventilation, and air conditioning (HVAC) system. The goal of the well-designed IVF laboratory is an environment that fosters both good working conditions and air quality compatible with excellent IVF outcomes. Air quality is a function of HVAC design, room design, choice of building materials, and activities conducted therein and adjacent to the laboratory. Air quality management deserves its own chapter and merits emphasizing the importance of hiring a design-build engineer who specializes in HVAC requirements for clean room facilities. There are other subtle aspects of laboratory design and build that are not covered in this chapter, and the reader is encouraged to review other literature on the subject [3–10].

3.2 Laboratory Layout

3.2.1 General Considerations

Careful thought should go into the design and organization of the laboratory in order to minimize risks to gametes/embryos while maximizing embryologist comfort, efficiency, and use of space. Workstations should be organized and positioned in a manner that allows one embryologist to complete one procedure without moving more than 3 meters in any direction [6]. Though ideal, this design is often constrained by the size of the space available and the number of IVF cycles performed in a given time period.

Workload is an important consideration for the design of the laboratory and is influenced not only by how many IVF cycles are done in a year but whether the program batches their cycles and the amount of preimplantation genetic testing (PGT) is performed. The workload as a function of cycles per day dictates the number of dissecting microscopes and inverted microscopes with micromanipulation needed as well as the number of incubators required. For the latter, a standard that most embryologists adhere to is no more than four patients per standard CO_2 or triple-gas incubator, though this limit is becoming a function of incubator design, with new benchtop models and time-lapse incubators providing dedicated chambers to each patient. The layout of the laboratory is often constrained by space limitations and affected by personal preference.

Ideally, embryology laboratories are divided into two or more rooms to separate workspaces. Usually, the main embryology procedures are performed in one room adjacent to both the operating room and possibly other support rooms for semen preparations, micromanipulation, embryo biopsy and tubing, cryopreservation, media preparation, or supply cleaning. This layout facilitates the desired air pressure differential by enabling the main embryology room to have positive airflow to the adjacent areas. A commonly overlooked component of IVF laboratories is adequate storage space. Many embryologists prefer to purchase large lots of key supplies, which allows simplified tracking of exposure of patient tissues to contact materials. Additionally, many laboratory supplies are plastics, which release volatile organic compounds (VOCs) that may adversely affect embryo development. Therefore, embryologists prefer to allow the plasticware to off-gas in a separate storage area before use. Thus, it is important to have dedicated space for bulk storage and then bring only small amounts of the supplies into a support room prior to introducing them into the embryology laboratory proper.

The following are design approaches to two different size IVF laboratories.

3.2.2 Small IVF Center (<500 Cycles/Year)

Small IVF laboratories are by far the most common, since most IVF centers in the USA have one or two physicians who perform 100–150 retrievals each year. While this number is typical, some solo practitioners perform as many as 300 or more cycles per year. These small ART programs often batch patients into four to six "series" per year, with a series lasting for 1–4 weeks. Most large programs are open nearly year-round, so programs that batch 100 patients in four 2-week series are similar in workload to a practice that performs 600 cycles per year. As you might expect, limiting incubator

utilization to four patients per unit will require more incubators per annual patient volume in the batched style of practice relative to the program that performs cycles year-round.

Design of the laboratory layout depends on the amount of equipment and the number of workstations. The smallest IVF program requires, at a minimum, the same amount of equipment as a program that performs <300 oocyte retrievals on a year-round basis. All IVF laboratories should have at least two incubators, though with smaller benchtop incubators this can easily be increased to three, where one large, traditional upright incubator is used for equilibrating dishes and benchtop incubators are for embryo culture. As the IVF volume grows, the laboratory can add another full-sized incubator or purchase more benchtop incubators to function as working incubators.

In addition to two incubators, the small IVF laboratory requires one embryology and one andrology workstation. The embryology workstation consists of a dissecting microscope and an inverted microscope with micromanipulators. The most common configuration of these two microscopes is the dissecting microscope in a laminar flow hood and the inverted microscope on a vibration-free table. While this is the most common setup, there are many variations including placing the dissecting microscope in an isolette, placing both dissecting and inverted microscopes in a hood or omitting the laminar flow hood from the plans entirely. The choice of a laminar flow hood is based on air quality and experience: good HEPA filtration in the HVAC usually circumvents the need for hoods, whereas a certified clean room design makes them unnecessary [5].

A typical design for the small laboratory consists of two to three rooms: one for embryology, one for biopsy/PGT, and the other for cryostorage and preparation of sperm. The equipment in the second room includes a centrifuge, a compound microscope with 20x and 40x objectives, cryopreservation instruments, liquid nitrogen storage dewars, and a refrigerator. If there is a separate andrology laboratory that performs sperm preparations for IVF, this room can be used for setting up dishes for the embryology laboratory. Otherwise, media and dishes from the second laboratory should be carried to the embryology laboratory in anticipation of culture preparation. Air pressure should go from the embryology laboratory to the andrology laboratory to the hallway. Similarly, air pressure should move from the embryology laboratory to the operating room to the hallway.

There are two common designs for access between the embryology laboratory and the operating room (OR). For programs with enough space, a full-sized door connects the two rooms, and this allows a circulating OR technician to carry follicular aspirates directly into the laboratory during the retrieval procedure and an embryologist to carry the embryo transfer catheter directly to the physician for the transfer procedure. Having a door also allows the use of portable IVF workstations. Alternatively, programs with limited space often have only a pass-through window to transport tubes from the OR through to the laboratory during the oocyte retrieval. This also requires a hand-off of the transfer catheter through the window, but otherwise is advantageous in that it limits the airflow between the rooms and maximizes space utilization. For small programs, this works well except in the situation where the catheter is after-loaded by the embryologist.

3.2.3 Large IVF Center (>500 Cycles/Year)

Although small IVF laboratories are more common overall, the number of laboratories that perform >500 cycles/year as well as laboratories that perform >1000 cycles/year increases as the demand for fertility services continues to grow. These large laboratories often not only serve the physicians managing the practice but affiliate physician offices as well. Because of the high volume of cases, large IVF centers are usually open year-round or only closed for one or two brief maintenance periods per year.

In order to design a laboratory with efficient and comfortable workflow, the first step is to determine the estimated number of cycles the laboratory is expected to perform in a given time period. The estimated caseload will determine the required size of the laboratory proper and the quantity of adjacent support rooms. The amount of workstations, microscopes, micromanipulators, and other equipment is a factor of caseload as well. Large IVF laboratories with numerous physicians must develop a system to regulate the maximum number of cases per day or per week so that incubators are not overfilled 1 week and almost barren the next.

A detailed layout of the equipment must be undertaken before finalizing any constructions plans. Workflow must be carefully considered so long walks are minimized between workstations (hoods or isolettes) and incubators. Separate workstations are critical to avoid collisions of embryologists carrying dishes. Unfortunately, space may be limited when IVF centers are located in a city center. Ideally, extra space can be incorporated in original construction plans to allow for later expansion and adding workstations and incubators without interrupting workflow. Laboratory doors should always be wide enough to allow for new equipment delivery as needed.

The large IVF laboratory should consist of a main embryology room containing the bulk of the incubators, workstations, and micromanipulators. There is no magic number of incubators required for a specific caseload. A center performing 500 cases per year may find half a dozen incubators adequate, while 2 dozen incubators or more may be required to accommodate a center juggling 2000 cases annually. Patients reactive for infectious diseases may require isolation of their gametes during culture, which necessitates more incubators. Periodic cleaning of incubators requires extra incubators to handle the load of those temporarily out of service. It is most important to factor in the frequency of incubator door openings, rather than incubator capacity, because limiting incubator openings will better maintain the desirable culture conditions of temperature and pH for all patient material contained therein. For the large laboratory, the number of workstations, such as a laminar flow hood or isolette fitted with a dissecting microscope, is simple to calculate. To maintain an effi-

cient pace without delay while waiting for a place to perform procedures, approximately 1 workstation is needed for every 200–300 cases. Placing a customized plexiglass divider in a traditional large laminar flow hood allows the creation of two workstations each with its own microscope to maximize the use of space.

Support rooms adjacent to the main embryology laboratory are convenient to separate work areas and allow for sequential step-downs in air pressure. Some laboratories have a dedicated micromanipulation room containing a workstation, inverted microscope with manipulators, and a working incubator to utilize during procedures. The large laboratory will need at least two micromanipulation stations to accommodate high utilization of ICSI and PGT procedures. Semen processing is almost always conducted in a separate room. The room containing one or two semen processing workstations should be positioned near the collection room(s). It is highly recommended to have two collection rooms if space allows. A separate cryopreservation room is desirable for the cryopreservation equipment, storage dewars, workstation, and working incubator. Often the long-term frozen material which can fill dozens of dewars is maintained in a secondary secure room with easy street access in case of an emergency or natural disaster. Regardless of the amount of support rooms designed around the main embryology laboratory, the OR must be directly connected to embryology by way of a door or pass-through or both depending on the preference of the laboratory and physician team.

3.3 Room Construction

The goal for the physical construction of the IVF laboratory is to build an environment that is free of factors that might directly affect gamete and/or embryo viability. Thus, it is important to carefully consider all construction materials used to build the laboratory. Second to the HVAC design and build, this section is one that requires close attention by the laboratory director to ensure the building contractor understands the critical nature of the IVF laboratory.

A primary goal during construction of the physical structure of the laboratory is to avoid the use of materials that will release embryotoxic gasses for an extended period following completion of the construction. As will be described later, the laboratory should be given time after the completion of building to off-gas and be validated prior to clinical use. Because different materials off-gas at different rates, it is critical to choose building materials carefully and to verify that the selected materials are used.

Choice of flooring is standard for operating rooms and clean rooms: seamless sheet vinyl that has an integral base flashed at least 4 inches up the wall. Where pieces of flooring meet, the seam is sealed. This type of flooring seals odors out from materials used in the subfloor and the base of the walls. Compared to tile flooring, it is easily cleaned and does not allow water to seep under the walls. Flooring should also be flashed onto the base of cabinets in the laboratory, again to prevent a breeding ground for microbes. Steel is the material of choice for cabinetry in the IVF laboratory.

Walls should be low-odor, washable, and non-shedding. Choices for material for walls include plaster and plastic wallboard. While the latter does not have to be painted, only water-based paints formulated for low-VOC potential should be used. Epoxy paints can also be used, but they may require longer off-gassing periods. Similar to the flooring, the walls should be sealed. While most sealants are likely to off-gas VOCs, sealants made of silicone materials are a better choice if available.

Prior to the introduction of clean room technology, solid plaster ceilings, with minimal openings for fixtures, were considered acceptable for IVF laboratories. While this approach provides an airtight, non-shedding surface, it also presents challenges. Optimal HVAC design does not require access above the IVF laboratory; however, it is not always possible to avoid placement of ductwork or other mechanical systems above the IVF laboratory. Clean rooms typically use tiled ceilings with strip sealing to make them airtight. Unlike standard ceiling tiles used in commercial and residential applications, clean room ceiling tiles are non-shedding and can be sealed.

In addition to supply ducts, usually as terminal HEPA filters, openings in the ceilings should be limited to canned lights. Short-wavelength light, like that emitted from fluorescent light bulbs (470–480 nm), has been shown to be detrimental to cell culture and embryo culture [11–14], though it is not clear if this applies to all lighting in the room or just light emitted from the microscopes [13]. Most IVF laboratories use either incandescent light bulbs or cover fluorescent lights with UV sleeve protectors [6]. All lights and utility connections should be sealed and airtight.

3.4 Laboratory Support Systems

More than any other laboratory, the embryology laboratory requires an extensive support network of plumbing, electrical, and alarm systems. These systems, similar to the many configurations available for laboratory design, are scalable and available in both low- and high-tech options. While some regulatory agencies such as the College of American Pathologists (CAP) require certain critical equipment to be alarmed, no standards exist for these systems.

3.4.1 Plumbing

One of the biggest advantages of constructing a new IVF laboratory is the ability to place gas outlets strategically throughout the laboratory for incubators and gassing devices. Small laboratories may find this approach cost-prohibitive, but the advantages outweigh the additional cost. While covers can be used for tanks in the laboratory proper, the tanks are still dirty and present a physical hazard. With the clear benefit of reduced oxygen for embryo development in vitro [15], CO_2

and N_2 lines at a minimum should be placed at each location that will hold an incubator. With the advent of incubators that use premixed gas, an "air" line should also be placed at each port [16]. This allows the use of trigas (89% N_2/6% CO_2/5% O_2) for gassing dishes as well as for incubating units that require premixed gas.

Placement of the gas tank room can also be optimized with new construction, thus allowing easy access for the supply company to change out tanks while not disturbing operations in the laboratory or clinic. The tank room requires an oxygen sensor/alarm and automatic switching stainless steel manifolds. The number of couplings per manifold per gas will depend on the number of incubators in use but typically is two tanks per side. While stainless steel lines are preferred, copper lines can be used as long as the lines are not soldered [8].

Since reduced O_2 incubators use nitrogen to displace atmospheric O_2, a large supply of nitrogen is needed. Nitrogen gas can be provided in at least three ways: via compressed N_2 in cylinders, from a nitrogen generator that fills a compressed tank, or from the vapor phase of a liquid nitrogen tank. Because of the volume required, nitrogen cylinders should only be used when only two incubators are in use; otherwise, tank change-outs will be a daily chore. A nitrogen generator is an effective alternative, but the units are loud, relatively large, and require maintenance. Using the nitrogen vapor of liquid nitrogen tanks plus compressed nitrogen cylinders as backup on a manifold provides the most cost-effective and practical solution. Nitrogen tanks can also serve as an emergency backup for topping off Ln2 storage dewars. Although low-pressure LN2 tanks (psi < 30) may be required for some controlled rate freezers, it is essential to use high-pressure LN2 tanks (psi >150) when supplying N_2 for triple-gas incubators to maintain a constant pressure in the line for several incubators at once. Failure to supply adequate nitrogen will cause both the O_2 and the CO_2 levels to increase in the incubators, thus affecting not only oxygen tension but pH as well.

3.4.2 Electrical System

Much of the equipment in the IVF laboratory is electronically controlled and therefore should have protection against power surges, fluctuations in power quality, and power outages. Any equipment that contains a computer is subject to abrupt, periodic loss of function as a result of changes in electrical current. Although it is now commonplace to have all personal computers on a surge protector or even an uninterruptible power supply (UPS), it is probably even more important to protect laboratory equipment that have microprocessors and perform essential functions.

Two pieces of equipment that may be the most sensitive to unstable power supply are incubators with infrared gas sensors and controlled rate freezers. If there is a power surge or a variation in current during a programmed embryo freeze, the rate of freezing is altered, and this may affect the viability of the embryos. While a surge protector will prevent abrupt changes in power, the controlled rate freezer will not tolerate a power loss, even the short loss of power when the system switches to emergency backup. Thus, controlled rate freezers must be connected to a UPS.

Complete power outages due to a variety of causes are not uncommon and require alternative power supplies. While it is feasible to put critical equipment on their own UPS, most UPS have a limited amount of time for which they can provide power. During a weather emergency, such as a hurricane, tornado, or blizzard, extended power outage can occur and long-term backup power is better achieved by a natural gas or propane-powered generator. Key outlets and lighting, and in some cases the HVAC system, are put on backup generator power. The amount of power required will determine the size of the generator. These generators provide peace of mind but come with their own maintenance issues. Backup generators must be "exercised" on a weekly or monthly basis and their fuel supply maintained. Propane or natural gas tanks are difficult to monitor, so they are commonly changed on a schedule. A better alternative is a natural gas line that should provide constant supply in the event of an emergency. With the advent of vitrification, a further backup for extended power failures is the ability to rapidly vitrify all stages of embryos, thereby reducing the amount of backup energy required.

3.4.3 Alarm System

A system that provides prompt notification when a device fails is critical for IVF laboratories. Like many of the systems in the IVF laboratory, there are several options available. The Sensaphone call-out device is one of the more commonly used systems because of its simplicity. Various models have different capabilities, but a basic unit can monitor up to eight different channels/inputs, including sound in the room. When a variable such as incubator pH goes out of range, after a user-defined delay, the Sensaphone begins calling a programmed list of telephone numbers. It will continue to call the list until someone keys the "cancel" code. While this system is inexpensive and effective, its biggest limitation is that it does not track the actual values. Some newer incubator models periodically record digital readings and alarm history for later display and in combination with the Sensaphone would give an adequate representation of laboratory conditions. Alternatively, there are computerized systems that record all vital data and allow for more thorough quality control.

In addition to electrical and gas outlet placement, careful planning should be used for alarm contact placement. This is becoming less of a problem with new alarm systems that use wireless technology.

3.5 Other Laboratory Features

As technology advances, so do the options available for IVF laboratories. Whereas 10 years ago computers were rarely found in IVF laboratories and some thought they did not belong there, the introduction of electronic medical records

(EMR) and time-lapse imaging has made computer capability in the laboratory a near necessity. Fortunately, wireless technology removes the burden of having to strategically place Ethernet outlets at the time of build-out. The challenge most laboratories now face is providing space for computers. Retractable shelves for laptops are one option, but many times, a hardwired alternative is necessary for computers connected to microscope cameras.

Cameras on microscopes not only are used for documentation of embryos or oocytes for the EMR but also provide an image that can be displayed in the laboratory for teaching purposes or in a waiting room for the patient's partner to view during a retrieval or transfer. In the same manner, it is common to put an intercom system so the embryologist can provide feedback to the physician during procedures.

As each decade since the birth of Louise Brown has brought significant change to laboratory practices in IVF, most recently the addition of time-lapse and blastocyst biopsy, we can expect more changes that will likely dramatically change how space is used in the laboratory. These changes will make some of the topics presented here moot, just as vacuum lines are no longer needed for media preparation and filtration [10].

Introduction of small benchtop incubators during the past 20 years [16] and more recently time-lapse imaging [17, 18] provides a paradigm shift for both space utilization and gas delivery. Detrimental effects of door openings and handling dishes on temperature and pH fluctuations are thus minimized.

3.6 New Construction: Validation Before Patient Care

New laboratory construction is analogous to a new car: the plastics, paints, and adhesives are new and give it the "new car" smell. While some may find this desirable in a car, these odors are VOCs and they pose a serious threat to embryo culture. In order to hit the ground running, it is critical to provide ample time for "burning in," air testing, cleaning, and, finally, quality control testing.

The rate of off-gassing new construction can be increased by "burning in" the facility. Since the compounds of interest are volatile, their rate of dissipation increases with higher temperatures and air exchange rates. Typical burn-in involves increasing the room and equipment temperature by 10–20 °C with high rate of air exchanges for 10 days or more [4, 6]. During this time, all equipment and lighting should be used to assure everything is working properly and enhance the effect of the higher temperatures.

The next step is the first of two tests to determine if your careful design, planning, and oversight of the building process provide low VOC and low particulate "good quality" air that is desirable for an embryology laboratory. Several HVAC tests, including but not limited to VOC testing, HEPA filter verification using particle counts and tracer studies, and pressure verification, will tell you if your collaboration with the engineer and contractor yields the desired results. Specifics for air quality should be in the original contract (see chapter on "Air Quality Management") and if the specs are not met, then you should stop at this point and correct the problem.

Once the facility passes the air quality tests, it is time to proceed with preparing for embryology culture testing. A final cleaning of ceiling, walls, and floors should be completed first. Incubators should have already been running for at least a few weeks or months to burn them in as well.

The final step in the validation prior to clinical use is quality control testing using an animal model. While there are many opinions regarding the utility of different bioassays, the one-cell mouse embryo assay (MEA) has been shown consistently to be the most sensitive, and it appears this sensitivity can be further improved via time-lapse imaging [19] or extending the assay to 144 h [20]. After completing all the aforementioned steps in this carefully planned project, the newly constructed laboratory space should be ready to provide an excellent culture environment.

3.7 Conclusions

This chapter describes many of the critical components of laboratory design and construction, including specifications that at this time are neither standard nor regulated for IVF laboratories. Knowledge of these factors is essential for ART professionals planning a new facility or redesigning an existing one.

Without question, the single most important component of a new facility is the indoor air quality for the IVF laboratory and incubators. Since indoor air quality is influenced not only by the HVAC design and install but the components used for laboratory construction, it is critical that sufficient care is given to the choice of design, materials, and construction. Thorough research and a hands-on approach provide a measure of security for when the laboratory goes "live" – that moment of truth when you witness the fruits of your labor: good fertilization and embryo development and many happy patients.

Review Questions

1. What designs are used to connect the laboratory to the operating room and what are the benefits of each?
2. Alarm systems should be present for which equipment?
3. What can be done to assure a new construction is suitable for patient use?

Learning Objectives

- Legislation on ART laboratory air quality
- Qualification, classification, and monitoring of air quality
- Equipment and methods for particle testing
- Methods and frequency of microbiological monitoring
- Prevention, detection, and removal of volatile organic compounds (VOCs)

4

4.1 Legislation

Requirements for air quality aim to prevent (cross) contamination of cells, tissues, or tissue-based products intended for administration to a recipient, as well as exposure of laboratory personnel to communicable disease agents. In the beginning of this century, both the US and European authorities issued regulations to ensure quality and safety of human tissues and cells in general. Concerning assisted reproductive technology (ART), the legislation differs between the USA and Europe and is subject to interpretation.

In 2001, the US Food and Drug Administration (FDA) promulgated rules intended to prevent the spread of communicable diseases by establishments manufacturing human cells, tissues, and cellular- and tissue-based products (HCT/Ps)[1]. As defined by title 21 of the Code of Federal Regulations (CFR) Part 1271, HCT/Ps include semen and other reproductive tissues (21 C.F.R. § 1271.3(d)). The cGTP demands a hygienic environment with strict control of temperature, humidity, and pH and, when appropriate, of air quality. Cleanliness of air implies control of ventilation, filtration, and an aseptic working process guaranteed by cleaning, disinfection, and maintenance of equipment used for this purpose [1]. However, subparts D and E of the cGTP describing the processing of tissues and cells, as well as the requirements for personnel and facilities, are not mandatory for reproductive HCT/Ps [1]. The 2006/86/EC European Commission directives, based on the 2004/23/EG European quality and safety standards for human tissue and cells, do include reproductive tissues and cells in the scope [2]. While aseptic processing is optional in US ART establishments, it is mandatory in Europe. Facilities that process tissues and cells in an open system (air contact) without subsequent microbial inactivation process require EU GMP grade A (ISO 5) air quality for particle and microbial colony counts, as defined in the European Guide to Good Manufacturing Practice (EU GMP) Annex 1 [3]. Additionally, the background environment of the processing zone needs to be appropriate for the cells or tissues concerned, at least EU GMP grade D. Less stringent environmental conditions may be acceptable if the risk of transmitting microorganisms is lower by processing the cells or tissues than by transplanting them in the recipient or if the cooling effect of the grade A laminar airflow is harmful to the tissue or cells. Based on a risk assessment, tissue establishments should specify the air quality of the processing zones and surrounding areas. Several factors such as the particular type of tissue, the processing method being applied, the presence of contaminants, or the final destination of the tissue should be taken into consideration.

Since the implementation of the air quality standards, ART establishments have neglected to perform controlled studies on particulate and microbial air quality. Today, there is still little evidence that particulate filtration avoids communicable disease transmission through reproductive HCT/Ps. Either the risk is really low, or transmissions have been underreported [4]. The concentration of the volatile organic composition (VOC) of the air undoubtedly has an influence on the embryo development and clinical pregnancy [5–10]. However, chemical air filtration, unlike filtration of particulates, is far from standardized [11].

4.2 Qualification, Classification, and Monitoring

4.2.1 Qualification

Qualification of instruments, facilities, utilities, or systems is required to verify their proper function. The qualification activities should consider their whole life cycle from defining the user requirement specifications (URS) through decommissioning. The main stages are defining the URS, installation, operation, and performance qualification. The selection of the test methods used for demonstrating compliance should be based on the user requirements, operating parameters, and selected limits. Requalification can be done after failing, modification, or on a periodic time interval to demonstrate that the instruments, facilities, utilities, or systems are still operating according to the design.

4.2.2 Classification

The classification is part of the qualification process of clean rooms and clean zones and should be clearly differentiated from monitoring operational processes. Classification is a method of assessing the level of air cleanliness against a specification for a clean room or clean zone device (EU GMP, US cGMP) by measuring the airborne particle concentration (Table 4.1). Classification is typically done on a yearly basis by a testing organization in compliance with the ISO14644-1 standard [12]. Classification has to be performed both at rest and in operation. At-rest state does not give any information about the aseptic performance in operation when different sized particles are introduced into the clean room by the personnel and their material and subsequently resuspended from the floor [13]. A worst-case process simulation can be used for operational qualification.

4.2.3 Monitoring

Monitoring of the ART clean room or clean zones can be performed by personnel of the institution, either from the ART, hygienic, or quality departments. Monitoring basically consists

of the enumeration of particles, microorganisms, and VOCs during processing to ensure that the people, process, and the environment remain in control during operation. Europe and the USA apply different recommended microbiological levels (Tables 4.2 and 4.3). Additionally, the measurement of airflow, pressure difference, temperature, and humidity is recommended within ART laboratories.

Before starting, a monitoring program needs to establish the sampling frequency and locations, the number of samples per location, the sample volume, and test methods. This way of working, not yet familiar to ART, derives from pharmaceutical guidelines and other standards concerning clean rooms and associated controlled environments. The ISO 14644-2 [14] and ISO 14698-1 [15] can guide the ART establishments in the setting up of a monitoring program.

Table 4.1 Air cleanliness classification – USA and Europe

Classification			Maximal number of particles/m³
ISO 14644-1 US cGMP USP <1116>	EU GMP at rest	EU GMP in operation	Particle size ≥0.5 µm
ISO 5	A	A	3520
	B	–	3520
ISO 6	–	–	35,200
ISO 7	C	B	352,000
ISO 8	D	C	3520,000

4.3 Practical Implication and Technical Aspects

4.3.1 Particle Testing

4.3.1.1 Equipment

The concentration of airborne particles is measured with a light-scattering discrete-particle counter and includes both nonviable (dust, fibers, skin flakes) and viable (microorganisms) particles. Several light-scattering devices are commercially available. The selection of the device is guided by purpose, frequency, and volume of sampling. The flow rate of a particle counter is crucial since it determines the time needed to collect the minimum sample volume. Particle counters can be designed for continuous or discontinuous measurement. Instruments for continuous measurements are assigned to one specific sample location and mostly used for the monitoring of aseptic environments (EU GMP grade A, ISO5) and their backgrounds. Portable particle counters can be used for both continuous and discontinuous measurements. Their flow rate of 1–3.5 cubic foot per minute (cfm), with 1 cfm corresponding to 28.3 L/min, permits classification and monitoring. Handheld particle counters with a low flow rate, ranging from 0.1 to 1 cfm, are exclusively designed for discontinuous measurements. Handheld particle counters are for time sake less used to monitor cleaner environments such as ISO5 or better. Their main application lies in the localization of the source of airborne particles.

A GMP grade A environment implies continuous monitoring of particle counts [3, 16]. Since probes have to be positioned within a distance of 12 inches (30 cm) of the exposed product in order to give evidence for aseptic processing, as advised for liquid sterile fill [16] and the need for equipment

Table 4.2 Recommended limits for viable airborne particulate – USA and Europe

Classification		Maximal amount of CFU in the environment[a]					
ISO 14644-1 US cGMP USP <1116>	EU GMP	US cGMP		USP <1116>		EU GMP

[d]It should be noted that for grade A the expected result should be 0 cfu recovered; any recovery of 1 cfu or greater should result in an investigation

in ART clean rooms is high, portable or handheld particle counters can be an alternative.

4.3.1.2 Sample Volume

The required volume per sample depends on the cleanliness and the functional state of the environment. For monitoring purposes, the minimal sample volume (Vs) is not specified, neither in the ISO14644-2 [14] nor in the European or US GMP guidelines. For classification, however, it is elaborated in the ISO14644-1 [12] guideline as $V_S = \frac{20}{C_{n,m}} \times 1000$. The idea behind this formula is that a sufficient volume of air has to be sampled in order to detect at least 20 particles if the concentration of the largest particle ($C_{n,m}$) were at the class limit.

For example, $\frac{20}{29{,}300} \times 1000 = 0.68L$ is required in an ISO 8 (EU GMP grade D at rest) environment, where the maximal concentration for particles larger than 5 μm is 29,300/m^3 air. The ISO14644-1 guideline also demands to increase the calculated volume to minimal 2 liters within minimally 1 minute sampling time [12].

4.3.1.3 Sampling Locations

For classification purpose, the minimum number of sample locations is defined in the ISO14644-1 guideline annex A [12]. The clean zone must be divided in sections of equal area. Within each section, a sample location should be selected considering it to be representative of the characteristics of that section.

For monitoring purposes, the minimum number of sample locations is not defined in either the ISO14644-2 or the European or US GMP guidelines. Use an appropriate risk assessment tool to understand and evaluate the critical sample locations in function of the air cleanliness required, ART-specific processes, and product locations.

4.3.1.4 Frequency of Particle Testing

Classification is typically done on a yearly basis by a testing organization in compliance with the ISO14644-1 standard [12].

According to pharmaceutical guidelines, a GMP grade A/ISO5 environment implies continuous monitoring of particle counts [3, 16]. Since the risk of transmitting microorganisms is lower by processing reproductive tissues than by transplanting them in the recipient, periodic monitoring of the concentration of airborne particles is acceptable.

4.3.2 Viable Particles

Airborne microorganisms (viable particulate) can be collected, recovered, and grown either after active sampling of a known volume of air permitting quantification or passively using open sedimentation agar plates. Surface imprints on contact agar dishes serve to validate and monitor the disinfection process. Both the EU GMP and US cGMP guidelines specify these methods for the monitoring of viable particulate of air, surface, and personnel [3, 16]. These tests can be performed for different reasons, each requiring a specific approach. Technical details are, however, seldom described in the literature. If so, they apply to the manufacturing of medicines or medical devices and are recommended but not mandatory. The ART institution has to decide which methods to use for microbial monitoring and demonstrate their efficiency by own historical data and risk analysis, often

asked for by inspectors as mentioned by Clontz [17]. In this section, we will discuss how to set up a routine microbial monitoring program for ART clean rooms.

4.3.2.1 Frequency of Microbiological Monitoring

The monitoring frequency depends on the classification: the lower the maximum permitted viable particulate, the higher is the frequency of monitoring. GMP guidelines do not go into detail. The EU GMP asks frequent monitoring, the US cGMP near (e.g., daily, weekly, monthly, quarterly) and long-term oversights [3, 16]. The USP <1116> go more into detail and suggest frequencies for each type of microbial sampling for aseptic processing areas and nonadjacent aseptic areas [18]. It is generally accepted that the processing of tissue or cells in ART implies a significant lower risk of transmitting bacterial or fungal infections to the recipient than embryo transfer. Publications and case reports dealing with infected ART culture dishes are scarce. The added value of routine aseptic process monitoring (in operation) seems therefore questionable. However, this low incidence may be partly due to underreporting. Kastrop routinely performed microbiological examination in all turbid culture dishes for an 8-year period from 1997 onward [19]. He registered infected cultures in 0.68% IVF and ICSI cycles combined, although exclusively occurring in IVF cycles with an incidence of 0.86%. Interestingly, in one third of them, the same microorganism, based on antibiotic resistance, was isolated from the semen. In two-thirds of ART culture infections, the source was elsewhere. Regular environmental monitoring of the process core and background is therefore recommended.

4.3.2.2 Microbiological Sampling Locations

Guidelines for microbial monitoring such as ISO14698-1 and ISO14698-2, US cGMP, EU GMP, or USP do not elaborate the minimum number of locations for microbial monitoring. General information is provided for designing dynamic sample plans based on risk assessment and trending performance. From a practical point of view, it is interesting to combine some sampling locations chosen in the classification plan with locations based on risk assessment in order to design the environmental monitoring plan and use these locations repeatedly for viable as well as nonviable particulate. This gives the opportunity to collect trending data regarding the overall environmental performance of the clean room. However, counts of viable and nonviable airborne particulate are not correlated [20]. For aseptic process monitoring, specific sampling locations must be chosen in function of the process, workflow, and/or, temporarily, incidents.

4.3.2.3 Active Air Sampling of Viable Particles

The USP, EU GMP, and US cGMP consider active air sampling as the standard method for microbiological monitoring of classified environments [3, 16, 18]. Active air sampling, better known as monitoring of airborne viable particles or also bio-aerosol collection, aims to harvest biological particles able to become a colony-forming unit from the air. Active air sampling devices project aspirated air on a culture plate or strip. Preservation of the biological integrity and growth capacity of the microorganisms following impact is critical. Differences in technology and procedures between instruments result in different collection efficiencies [20–26]. Current air samplers are thought to underestimate bacterial concentrations, especially those of single bacterial cells with 0.5–1.0 µm diameter [26]. Technical innovations are expected to improve precision and sensitivity and might change absolute numbers of detected organisms. The choice of an air sampler can be determined by the validation of the instrument, either by the manufacturer or by a third party, in agreement with annex B of the ISO14698-1 that deals with collection efficiency [27]. The cutoff size (d_{50}) determines the collection efficiency of small bio-aerosols and should be as low as possible, considering that one-third of the viable particulate generated by clean room dressed operators is less than 2.1 µm [28].

4.3.2.4 Passive Air Sampling of Viable Particles

In passive air—or sedimentation sampling—open Petri dishes with culture medium are put in the clean room at working height for a specific time period. Following culture, colony-forming units (CFU) are counted. Results are reported in general as number of CFU per 4 hours exposure time [3, 16]. It is a cost-effective and easy to establish monitoring method, unfortunately with some disadvantages. Despite quantitative results, passive air sampling is considered a qualitative method. Since microorganisms deposit on the Petri dish due to airflow patterns and movements of personnel, it does not represent the concentration of airborne particulate. Settling plates have been shown 17 times less efficient than active air sampling, especially in clean environments such as laminar airflow cabinets [29]. Because of the inherent variability of microbiological sampling methods, the USP introduced the incident rate at which environmental samples are found to contain microbial contamination (%) instead of focusing on the number of colonies (◘ Tables 4.2 and 4.3) [18].

The EU GMP and US cGMP advise 4 hours exposure time [3, 16]. In practice, this is not always possible due to dehydration of the culture medium. Dehydration depends on the composition and volume of the culture medium but also on the airflow rate and pattern.

During the validation of our microbiological monitoring program, we studied this phenomenon on 30 mL Tryptic Soy agar plates with a diameter of 90 mm (Heipha Diagnostika reference 030826e) (unpublished data). Petri dishes were weighed before and after exposure in either a horizontal (flow rate of 0.46 m/s) or vertical laminar airflow cabinet (flow rate of 0.40 m/s) for different time periods. As expected, the weight loss relative to the original weight increases with the exposure time and gets to 10.7–11.7% in horizontal flow and 9.3–11.2% in vertical flow after 4 hours exposure. A 13% loss in water content has been shown to be correlated with an 8% loss of viability of test organisms [29], indicating again that each method has its advantages and disadvantages. Passive air sampling is required for aseptic process monitoring in the EU but optional in the USA [3, 16].

4.3.2.5 Monitoring of the Disinfection Program Using Contact Agar Dishes

EU GMP [3] and USP [18, 30] demand surface monitoring of facilities, furniture, equipment, and garment at the end of processing and after sanitation. Surface monitoring can be performed by the contact plate method or by swabbing. In the most commonly used contact plate method, an open Petri dish (diameter of 55 mm) overfilled with culture medium containing biocide-neutralizing agents is pressed against the surface for several seconds, allowing the organisms to adhere to the agar. In case of non-flat surfaces, 24 to 30 cm^2 surface area has to be swabbed [18]. The swabbing method is less standardized and more operator dependent than the contact plate method. Regularly performed surface monitoring shortly after cleaning and disinfection is a cost-effective method to validate the sanitation program, as well as a screening method for outbreaks of spore-forming microorganisms due to the exclusive use of some biocides [31]. The EU GMP [3] encourages the combined use of different types of biocides.

4.3.2.6 Selection of Microbiological Culture Medium

The international standard for biocontamination control in clean rooms and associated environments ISO14698-1 advises the use of a nonselective culture medium, permitting growth of the expected microorganisms and containing additives to overcome the residual effect of biocides and cleaning agents [15]. The in-house flora of an ART environment is predominantly composed of microorganisms indigenous to humans and not different from the one in industrial clean rooms [32]. Therefore, the culture medium has to be appropriately validated for the growth of diverse bacteria and fungi [16]. Both the USP and European Pharmacopoeia (Eur.Ph.) describe several adequate culture media for the sampling and quantification of microorganisms in controlled environments or nonsterile products [18, 33]. The eventual need for a selective culture medium for yeast and molds, such as Sabouraud Dextrose Agar, has been a matter of debate for years [17]. The USP has proposed the Soybean-Casein Digest (SCD) Agar or Tryptic Soy Agar (TSA) as an all-purpose solid medium for the recovery and quantification of most environmental microorganisms in clean rooms, both bacteria and fungi [17, 18]. The use of only one type of culture medium will simplify the monitoring program and minimize the costs. Alternative media as listed in the USP <1116> or Eur.Ph. <2.6> can be used if validated for the purpose intended [18, 33].

Additives inhibiting residual biocides and cleaning agents are an essential component of the culture medium. The choice for a sanitation and disinfection program with a specific cleaning agent and biocide must be well considered. Besides beneficial microbiological control, it can have negative consequences for ART in terms of pregnancy rate [6, 9, 34]. The concentration of residue left on the surfaces after cleaning depends on the type of biocides and the sanitation program. Alcohols, hydrogen peroxide, or peracetic blends deposit fewer residues than quaternary ammonium compounds, biguanides, chlorine dioxide, or hypochlorite-containing agents. On the other hand, alcohols and peracetic blends do generate considerable amounts of VOCs hazardous for embryos, leading to a decreased pregnancy rate [6]. Since low residue concentrations can interfere with microorganism recovery, commercial suppliers offer ready-to-use culture media with a company-specific mixture of one or more neutralizing agents. The diverse composition and concentration of these neutralizing agents makes them incomparable between suppliers. At present, none of the commercial neutralizer is able to inactivate all biocides. Sutton tested 6 neutralizing broths against 13 commercially available biocides, and none of them proved adequate for all tested index organisms (*Trichophyton mentagrophytes, Pseudomonas aeruginosa, Bacillus subtilis, Staphylococcus aureus, Clostridium sporogenes, Salmonella choleraesuis,* and *Escherichia coli*) [35]. It is the task of each tissue establishment to demonstrate that the residues generated by their sanitation program do not interfere with microorganism recovery. Different protocols can be used, and among them are the methods of Clontz or Bleisteiner [17, 36]. The former compares the growth of microorganisms recovered from coupons either previously coated with the biocide/cleaning agent or not before inoculation. The recovery phase is performed in the presence or absence of neutralizing agents. In the method described by Bleisteiner, the same number of colony-forming units is inoculated on three culture plates, two of them supplemented with neutralizing additives and one of these also treated with biocide/cleaning agent. Bacterial growth in the plate supplemented with neutralizing additives and treated with biocide/cleaning agent should be at least 50% in the untreated plate supplemented with neutralizing additives.

4.3.2.7 Incubation Conditions

Recovery and incubation conditions have to be compatible with the sampling method in order to permit growth and identification of viable microorganisms and validated as such. Ideal culture conditions differ between microorganisms, 3–5 days at 30–35 °C for bacteria versus 5–7 days at 20–25 °C for fungi and molds [15–17]. Therefore, some centers collect duplicate samples, which double sampling time and reagent costs. Alternatively, one general culture medium such as TSA can be incubated under biphasic conditions [32, 37].

4.3.3 Volatile Organic Compounds

The impact of poor laboratory air on the culture of human gametes and embryos are widely accepted [38–40]. VOCs are natural or synthetic chemicals that can vaporize under normal atmospheric conditions. The compounds that the human nose can smell are generally VOCs. In 1997, Cohen was the first to perform an assessment of chemical air contaminants in an IVF environment and to report a negative correlation between VOC levels and human embryo development [6]. He also showed that unfiltered outside air may

be chemically cleaner than HEPA-filtered laboratory air or air obtained from incubators. The sources of this contamination can be localized outside or in adjacent rooms [5, 6]. Elevated aldehyde concentrations in laboratory air after the use of road sealants to resurface a parking were shown to be correlated with detrimental mouse embryo development [34]. Emissions from motor vehicles and building renovations influence embryo quality and clinical outcome of ART [34]. Other known sources of VOCs are paints, varnishes, petroleum products, pesticides, glues, and cleaning products. But VOCs can also be emitted from materials used within the laboratory. VOCs can accumulate from gasses used for incubators or anesthesia, from plastic Petri dishes, cleaning agents, or alcohols such as methanol and isopropyl alcohol.

4.3.3.1 Prevention

The best policy to reduce the level of VOCs in the laboratory air is prevention, starting with selection of location and in the planning phase of design and selection of building materials for their low VOC-releasing property [41]. Common products used for furniture such as formica, pressed wood, or fiberboard release formaldehyde and should be avoided. Sealants and toxic glues should be avoided. Special attention should be paid to floor coverings, which often are glued and can release VOCs over a long time period. Water-based low odor paint formulated for low VOC content should be used for interior painting [42]. If epoxy paints are required for regulatory reasons, low VOC products are advised.

Ideally, the lab is equipped with an overpressured heating, ventilating, and air conditioning (HVAC) system coupled with air purification systems with active carbon and oxidation using potassium permanganate and/or photooxidation, as well as physical filtration to remove eventual VOCs from outside air. Boone reported effects on fertilization, embryo development, and clinical pregnancy rate, decreasing following construction activity adjacent to the ART laboratory and increasing after moving the ART laboratory to a class 100 clean room with ultra-low penetration air (ULPA) and active charcoal filters as well as ultraviolet light in the air flow [5]. Filter efficiency needs to be monitored on a regular basis since saturated filters gradually release their accumulated VOCs into the filtered air.

Concerning laboratory activity, a strict policy should be adapted to prohibit disinfection alcohol, isopropanol, and ether. Products for cleaning and disinfection of floors and surfaces require special attention. Alcohol-based detergents should be avoided. Nonembryotoxic alternatives are nowadays available based on H_2O_2 or electrolyzed brine. Validation of our sanitation program based on detection of VOC and microbiological counts directed us to the alternating use of an alcohol-free quaternary ammonium compound blended with a biguanide and an alcohol-free amphoteric surfactant for daily floor disinfection. Styrene can be released from polystyrene culture dishes into the air of the incubator [6]. As a preventive measure, disposable culture materials can be removed from their plastic wrapping in a dedicated area, thereby releasing previously accumulated volatile compounds (out-gassing). Material used for incubators releases VOCs. New incubators can contain high levels of VOCs that should be removed before use [43]. Gasses from metal bottles containing compressed gasses can contain up to 60 different VOCs, the most obvious being benzene, refrigeration agents, and isopropyl alcohol [43]. Activated carbon and potassium permanganate in-line filters should be placed on the gas lines to the incubators. Some clinics have a policy to avoid the use of perfume, although, to our knowledge, there are no scientific data to support this, neither could we measure any VOCs being released from staff wearing perfume (unpublished data).

4.3.3.2 Detection of VOCs

There are several methods to detect VOCs in the laboratory air. In order to identify and quantify VOCs, an air sample is required for detailed analysis [6]. Gas chromatography and mass spectrometry of gaseous samples collected in stainless steel sampling canisters [6] permit quantification and identification of organic compounds, but cannot be performed in a routine ART setting due to the complexity of the method and the specific equipment needed. It is offered on a commercial basis in the ART field by, e.g., Alpha Environmental Inc. [44]. The stainless steel vacuum containers are placed in the laboratory for a fixed period of time and sent for analysis. Alternatively, chemical sensor badges [45] can be placed in the laboratory for 24 hours and sent to a company for analysis. In this case, air diffuses through a microporous membrane inside the badge, where vapors are collected on specific absorbents. This technology has been developed for indoor air quality and can analyze more than 100 chemicals. Both the spectrophotometry/mass chromatography and badge methods take snapshots of air quality at a single time point. Multiple measurements are required for monitoring and analyzing variations in VOC composition and concentrations. For regular monitoring, instruments that merely detect and/or measure VOCs without identification can be of help. These instruments, based on photoionization detectors (PIDs) with a broad detection range, are ideal instruments for detecting sources of VOC contaminations in laboratory air. There are no established safe levels in human IVF, but it is a good precaution to minimize the VOC concentration in laboratory air. PIDs in the ppb range are now available, and these can be connected to any equipment monitoring and alarming system.

Formaldehyde in laboratory air can be quantified and continuously measured by colorimetric/photometric portable testing devices with very low detection limits (10 ppb).

4.3.3.3 Removal of VOCs

VOC removal has been shown beneficial in bovine ART. Higher blastocyst rates were obtained in VOC than HEPA-filtered incubators by Higdon [7], while increased pregnancy rates without blastocyst effect were shown in the presence of an intra-incubator air purification unit by Merton [9]. Fertilization rates did not change in either study. VOCs

can be effectively removed by solid carbon and potassium permanganate filters [6]. Commercial systems are available for gas bottle inlets, intra-incubator, as well as whole laboratory air purification since filters can be included either in the central air-handling system or in separate stand-alone units [46–48]. The efficacy of filter-based stand-alone systems in a clean room environment with high air change frequency has to be demonstrated, similarly to the recently developed combined stand-alone systems using charcoal/permanganate filters or active charcoal filtration with HEPA filtration and photocatalytic oxidation, which seem promising in a preliminary report [47, 49]. In existing laboratories without VOC filtering HVAC systems, stand-alone systems can be considered.

Recently, dielectric barrier discharge (DBD) devices with cold plasma technology are developed, which provide air disinfection. They are highly effective in situations where there is a need to reduce airborne pathogens but at the same time reduce particles, aldehydes, and VOCs.

Review Questions

1. What is the difference between clean room classification and monitoring?
2. What is the frequency of environmental monitoring?
3. What technique should be used for environmental monitoring?
4. What can be done to prevent the presence of VOCs in ART laboratories?
5. What techniques are used for VOC removal from laboratory air?

Organization and Workflow in a Fertility Clinic

Amparo Ruiz

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_5

Learning Objectives

- To understand the unavoidable connection of the workflow with the strategic plan.
- To provide basic concepts to understand that good workflow and organization are key ingredients in customer satisfaction and pleasant working environment.
- To see how the workflow must be based on the main objective of a given company.
- To discuss the organization of the activity, time, and people.

5

Key Points

- The organization of a clinic must be based on the policy of each one, depending on the mission, vision, and values of the company.
- It is necessary to define the strategy of the company to develop all the organization and workflow accordingly.
- The organization and workflow may be a dynamic process, continuously adapting to the situation and conditions of the clinic.

5.1 Introduction

The perfect organization of a clinic, or whatever company, is not uniquely true. It must be based on the policy of each one. Depending on the mission, vision, and values of the company, the organization must be defined.

A strategic plan is essential in each company or clinic, because the entire management and workflow organization must be based on the strategy definition. Any single decision regarding the organization of the activity, staff, and time, must be oriented directly or indirectly, to facilitate the accomplishment of the defined strategy.

Workflow is considered as the set of tasks and the set of people or resources needed for those tasks, which are necessary to accomplish a given goal. The set of tasks will be chronologically organized in processes that the people must follow. An organization's workflow is comprised of the set of processes it needs to accomplish, the set of people or other resources available to perform those processes, and the interactions among them.

Usually, as a fertility clinic grows up, the staff adapts the processes to the increasing tasks, in an informal way. Frequently, people trust in their own memory or the goodwill of their colleagues and, indeed, in slow or standard activity days, it works well, or even, if some tasks are forgotten, the clinic schedule will adjust them.

In a slow activity journey, if the nurse sees a patient sitting without anyone having registered her arrival at the clinic, somehow will find the time to attend her without relevant disturbance in the overall schedule.

However, when the waiting room is full and the doctor is late, it may be felt throughout the organization. When the number of small interruptions outweighs the amount of planned work done in a given hour, that impact is felt in slower progress, lower job satisfaction, and potentially lower quality of care.

It looks that usually all people know what needs to get done. Where organizations differ is in how they do it. The examination of how an organization accomplishes its tasks often concerns the organizations' workflow.

Many workflows are already designed in health organizations, mainly those related to basic and general services, but the more specialized and innovative activities, the less designed workflow. This is especially true in fertility clinics or units, wherein not only new techniques arise continuously but also numerous small clinics grow very quickly. Due to these specific circumstances surrounding assisted reproduction clinics, it is not rare to see workflows that arise organically and evolve in a quite logical and even efficient way. But with the increase of the complexity of the unit, interactions among the different departments, overlapping in schedules, and priorities arise, revealing the weakness of an organizational system, designed without an in-depth analysis based on the company's strategic plan.

One important aspect in the evolution of fertility – and not only fertility – clinics is the necessity of introducing or updating a health-care information technology (health IT) into clinical practice. Of course, it is necessary and has undoubtable benefits. However, the introduction of a new or improved health IT absolutely always causes disruptions in the existing workflows. One of the drawbacks when introducing an IT is the possible resistance to change by many employees. But in the other end is the frequent simplicity of adapting the whole workflow to the way their screens and steps are organized. Organizations that are thoughtful about workflow design are more likely to be successful in adapting to health IT [1].

Nevertheless, in health and other services industries, the patient care and personal knowledge of the patient, and even the feeling in the relationship, is another strong source of information that must be included in the organization and workflow. This valuable information can be lost when poor workflows impede communication and coordination or increase interruptions [2].

5.2 Strategy Definition

5.2.1 Analysis of the Organization Philosophy

Thinking on how to organize all aspects of whatever company, its character marks its style, just as it happens in the way of life of each person. Nevertheless, the resources we have will be key elements in how we apply a style of organization, so let's have in mind that resources are scarce and should therefore be used efficiently [3].

As both material and human resources are limited, you cannot do or cover everything. You will have to choose an option, a path. But whatever option you choose, you will always have to abide by the rules of the game set by the need to use these scarce resources in the best possible way, as efficiently as possible.

In the case of organizations that provide health care, we must bear in mind that these services are not only useful for the individuals who receive them but also for society in general; they have a social nature regardless of whether the provider is public or private. Sometimes, the determining factors of this social service may clash with the purely economic factors [4], making the whole situation more complex. But, apart from this peculiarity, every organization, whether medical or not, be it a Reproduction Unit or otherwise, must have a certain strategy, and this strategy will influence the organization and workflow.

From the business point of view, the strategy describes how a company intends to achieve its objectives with the ultimate aim of creating sustained value over time for its members, clients, and citizens [5].

Thus, any organization that offers a product or service to the market has a particular competitive strategy and is positioned in a certain way before its potential clients and its competitors, and all of this irrespective of whether the organization is aware of it or not.

There are numerous advantages in having a clear strategy, developed through an adequate process for planning, deployment, and control, particularly because it implies that the actions of the organization's different departments act in a coordinated way in order to complete a series of targets set, allowing us to monitor how close we are to achieving these goals. This process is called strategic planning.

5.2.2 Strategic Plan

Although it is not the objective of this chapter to detail the development of a strategic plan, we will mention that there are many diagrams that can guide us in this respect, the most typical and common way to present the aforementioned strategic planning process is through a circular diagram of five stages [6], which are as follows:

1. Initial or strategic thinking phase: Definition of the key concepts of the organization, particularly the mission, vision, and values.
2. Internal and external analysis: Studying the fundamental parts of the company and its environment, aiming to link them to each other. It means looking around us to see where we are, and then, we will analyze internally to see, according to our capabilities and our limitations, where we could be.
3. Strategic formulation: From the above analysis, we will have to decide the strategy to follow and formulate the main objectives. The result of this formulation will be the strategic plan.
4. Implementation of the strategy: Once formulated, the strategy must be deployed. It will seek to identify actions to develop and align the organization's different objectives with the strategy.
5. Evaluation and control: This will consist of defining management indicators and monitoring compliance with the objectives set, so its effectiveness will depend on the management control systems available to the organization. According to the analysis of the data and the deviations produced, feedback can be generated for future reformulations of the strategy and organizational change. For this reason, the strategic planning process is presented as a circular diagram, because this evaluation and control phase provides feedback to the process again.

Any planning process must begin with a reflection on the starting position of each organization. The first thing to do is to know ourselves well and be sure of our starting point. Therefore, the main thing in this phase will be to reflect on each organization's so-called key strategic concepts:

- The values.
- Mission.
- Vision.

Once we are sure of the key factors that influence our strategic choice, we must analyze the environment around us (external analysis) as well as our own internal capabilities (internal analysis) in order to conclude on what we could do, depending on the environment, and what we can do, based on our own means and possibilities.

Thus, we can talk about:

- Differentiation strategies.
- Low-cost strategies.
- Specialization or niche strategies.

Companies that follow a differentiation strategy tend to emphasize aspects such as quality, service, design, technology, brand, innovation, etc., and they invest a lot of resources and efforts into them.

Companies that follow cost leadership strategies seek to offer customers a good product or service at a low price, which does not mean in any way that because the price is low, they give a bad product or service. For this, they emphasize aspects such as large-scale production, efficiency in assembly, and design of the product or service; sharing activities with other companies, the company stops providing part the service, and the individual takes over.

In the case of IVI, we have clearly opted for a differentiation strategy based on achieving maximum patient satisfaction.

5.3 Organization Principles

In addition of the strategic plan, there are some general quality principles that always must guide our organizing actions which, from our strategic point of view, are:

- Patient satisfaction. To achieve optimum patient satisfaction, only two relevant areas have to be considered: to personalize each treatment and to have the best possible clinical outcome.
- Integrated team. To reach an integrated team, it is needed to select the right personnel and to practice the best possible leadership.
- Scientific activity. To do science, a part of economic resources in which we will have to invest, we need to have projects from our professionals, motivating them and helping them by a good coordination.

  In fact, all three can be considered as only one: *patient satisfaction*, since a true teamwork and scientific production are actually improving the patient experience and clinical outcome.

  After a deep study of each organization or company, it is very convenient to find only one main principle that includes our strategic plan and organization principles. It could be cost control, professional prestige, brand recognition, or any other. For IVI it is *patient satisfaction*.

Then, every time we ask ourselves if a given action or organizational change is adequate, we just have to answer if it will increase, directly or indirectly, the patient satisfaction degree, and this applies for any other main principle like the abovementioned: cost control, prestige, etc.

5.4 Organization and Workflow Consequences

Workflow analysis has often been used with the goal of improving efficiency. In response to financial pressure and incentives driving provider organizations, minimizing slack time has become important. Some of the studies discussed below demonstrated the power of analyzing and changing workflow to improve efficiency [7].

Workflow analysis can be used to redesign existing processes. A classic study of this type is Cendan and Good's [8] analysis of the routine tasks of the various members of the operating room (OR) team. They found that there was a wide variability in functions based on clinical and organizational factors. They designed a new workflow based on the analysis and conducted a pilot study. Part of their recommended solution involved defining functions in a more consistent fashion. They were able to improve turnover and improve the mean number of cases handled in a day. A significant factor in their success was their consideration of workflow from both the physician and the nursing perspectives.

It is also possible to improve efficiency by carrying out processes in parallel, rather than improving the efficiency of existing steps [9]. Friedman and colleagues [10] compared the impact of administering anesthesia in the induction room versus in the OR for hernia repair patients. They found that the OR time used by the surgeon decreased without significant impacts on patient satisfaction or outcomes [11]. Harders and colleagues [12] employed a combination of approaches. They used parallel processing and process redesign to improve workflow in a tertiary care center with multiple OR suites. This combination of approaches allowed for a reduction in nonoperative time. Similarly, in a study of trauma teams, Driscoll and Vincent [8] modified task allocation so that standard tasks performed during a trauma code were conducted in parallel rather than sequentially.

5.5 Strategy Implementation: Organization of the Clinic Activity

Taking into account what has been said, it is not difficult to conclude that a management system that takes into account the company as a whole, that has global reach, and that also takes into account nonfinancial elements at the time of decision-making will be much more effective.

The design of good organizational workflow is not simply about improving efficiency. Workflow processes are maps that direct the care team how to accomplish a goal. A good workflow will help accomplish those goals in a timely manner, leading to care that is delivered more consistently, reliably, safely, and in compliance with standards of practice. An excellent workflow process can accommodate variations that inevitably arise in health care through interaction with other workflow processes, as well as environmental factors such as workload, staff schedules, and patient load [7].

Obviously, in a private organization, there will always be the objective of increasing profitability, which is even necessary to guarantee the continuity of the organization and, therefore, of the service it provides and its continuous improvement through the necessary investments. Nevertheless, the ways to achieve it can be very diverse and that is precisely what the management model consists of: the set of decisions and actions carried out by the leadership to implement the strategic directions. Said management will be based on the fundamental strategic principle of each organization, which in our case is differentiation through patient satisfaction.

Management, in being always subjected to strategy, is dynamic; and its development, evolution, and optimization are performed through management control.

According to V. Serra and colleagues [13], management control is the direction technique that consists of:

- Establishing objectives at all responsibility levels in the company.
- Quantifying said objectives through a budget.
- Periodically controlling and evaluating the degree of their fulfillment.
- Taking the appropriate corrective decisions.

We believe this definition to be the most accurate, since it considers the institution of objectives as part of the strategic plan, not as something isolated that is decided "de novo."

According to this reasoning, the first thing to do is to find out what really satisfies patients and not to assume it due to its apparent obviousness: achieving gestation. To know what satisfies patients and what does not – and act accordingly – all that is needed is to ask them. Logically, it will be asked in an organized manner, with questions involving the degree of satisfaction in all the aspects that the patients have experienced, from the waiting time to be assisted by phone, obtain an appointment, or enter the office to the kindness and professionalism of each of the collectives and departments, as well the amount and quality of received information, and many other details.

Furthermore, the collection of data must be simple, and it must be registered in a way so as to permit its later measurement and the production of statistical reports.

It is surprising to discover that some patients – even having achieved pregnancy on their first attempt – can be found to be dissatisfied because they had a feeling of insecurity after receiving seemingly contradictory sets of information, or due to having been taken care of by a physician, they did not expect without previously being informed. It is possible that these patients will not recommend our clinic or may not speak well of it. On the other hand, on numerous occasions, even if gestation is delayed or is never obtained, patients reveal very positive opinions when they perceive the true implication of the entire team in achieving their goal and they feel that they have been very exclusively and personally treated.

Once we have the patients' opinions, we know what satisfies them the most and what they believe needs improvement; but we will have also asked them to score – and we can now measure – the degree of importance that they place on each of the consulted areas. Thus, it may be that a high percentage of patients convey themselves as dissatisfied by the waiting times to enter the office or the operating room, but that they do not consider this such an important aspect; however, a particular percentage of patients may be dissatisfied because they were not allowed to participate in decision-making regarding their treatment and also mark this aspect as one of great importance. Therefore, at the time of deciding improvement actions to achieve the patient's satisfaction goal, those areas that combine the lowest satisfaction index with the greatest importance will be prioritized, postponing other aspects that may be even significantly dissatisfying, but that are not deemed as important by patients, for further assessment.

Surveys can be designed internally or an external, specialized company can provide the service, but it is necessary not only to carry them out: they must be well designed and offer useful statistical reports.

The management designed for the fulfillment of the company's strategic plan and the patient's satisfaction will begin by defining objectives, which must be few and challenging – but achievable – and the management tool to attain those goals is clinic organization, which will differ depending on whether the practice is public, private, corporate, etc., and on the company's philosophy.

Therefore, on a day-to-day basis, the management of the unit, clinic, or company is really about workflow and how it is organized.

The organization of a services industry can be classified in infinite ways, but if we really ask ourselves what we need to organize, the right classification will be:

- Organization of the *activity*: departments and sections.
- Organization of the *employees*: charts and roles.
- Organization of *time*: schedules and timetables, work hours, etc.

Applying this simple classification to a fertility clinic, we will have:

5.5.1 Organization of the Activity

In the majority of clinics, there are many activities and services around the patient:

- Patient attention services such as general information, telephone assistance, front desk, appointment management, billing, etc.
- Office visits: gynecology, psychology, genetics, andrology, endocrinology, etc.
- Nursery attention, blood sample extraction, explanation, drugs administration, etc.
- Laboratories: hormones, serology, semen analysis and preparation, IVF, PGD, etc.
- Surgery: oocyte retrieval procedures, embryo transfers, and testicular biopsies. In some cases, reproductive surgery like laparoscopy and hysteroscopy, etc.
- Administrative services: financial office, price information, private insurance management, and financing.

All these activities must be distributed in departments in a logical way, paying special attention to the interaction between them. This entire distribution must be fit into a larger design that includes other activities that are not provided directly to patients but that are equally important, such as management, research, teaching, or relationships with other external doctors and institutions (Fig. 5.1).

On the other hand, the different activities of the unit not only have to do with the service they provide but must also be grouped according to the types of professionals or collectives that perform them, the treatment to which they belong, or the department that carries them out, as is observed in the example in Fig. 5.2.

Once the activities have been organized in groups according to the different criteria, the personnel performing said activities must be well dimensioned and organized.

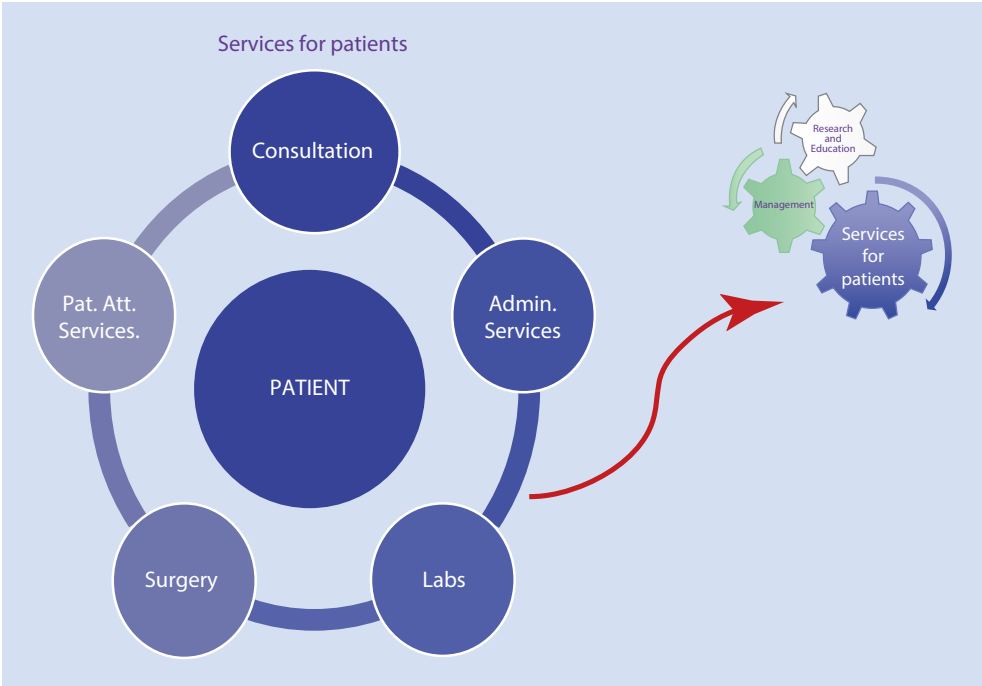

Fig. 5.1 Organization and interaction of activities within different departments

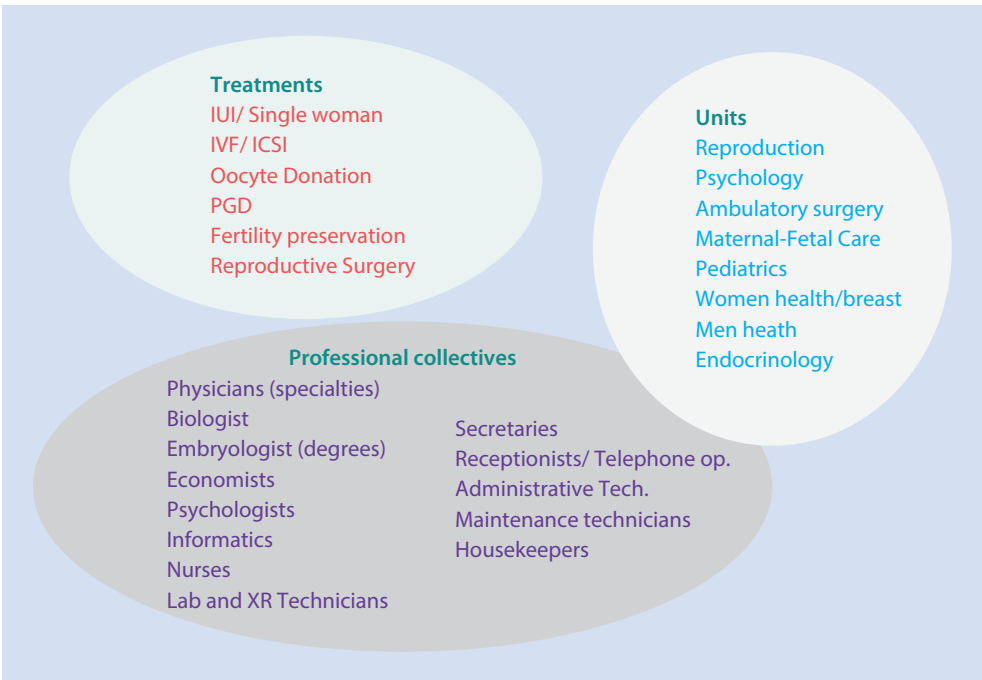

Fig. 5.2 Activities grouped by professional collectives, treatments, and the departments that carry them out

5.5.2 Organization of the Employees

The size of the clinic's staff is a topic of capital importance. If it is scarce, it can result in bad attention to patients and duties, as well as unrest and a bad work environment, which can equally impact productivity and quality. But the staff's dimension is not the topic of this chapter, its organization is.

In any kind of industry with more than one or two departments and more than 15–20 employees, the relations between people within the organization are arranged in an organizational chart. This is a valuable way to enable one to visualize the complete organization, by means of the picture its presents.

By definition, an organizational chart (OC) is a diagram showing graphically the relation of one official to another, or others, of a company.

Frequently, companies use to design an OC adjusted to their actual size and the employees they have at that particular moment, but then, it becomes obsolete when the size, complexity, and number of employees increase, adapting the OC on the fly, resulting in inconsistent perceptions of

reporting lines of the operational teams, as well as confusion in the roles and departments' definition.

In our experience, as a group of numerous different size clinics, it is more convenient to deploy a complete organizational chart – even for small clinics – that could be easily adapted to the growth and increasing complexity in the future. In new or small IVI clinics, one person assumes several roles in the chart and – as the volume and complexity increase – there is already a plan on how to allocate new professionals.

Organizational charts must be designed with vision in the medium or long term, because at the beginning, or in the smallest clinics of a group, one person may assume several roles, but when it grows up, all specific positions are already defined, as well as their hierarchical dependencies. This facilitates maintaining a continuous workflow along the time.

Regarding the hierarchical pyramid, prioritizing the internal communication before than the "command and control," we prefer it to be as flat as possible since this facilitates internal communication and teamwork. In our experience, what works best is a three-hierarchical-level pyramid:

1. Direction level: clinic and medical director, administrative responsible, clinic supervisor, etc.
2. Mid-level management: one manager for each functional unit or department (e.g., IVF Lab, Andrology Lab, Egg Donation, etc.) and one coordinator for each professional collective, even if they belong to different departments (e.g., nurses, technicians, front desk – patient services, international department, etc.).
3. Rest of the employees: every single person in the clinic has a representative in the mid-level management.

This structure allows effective communication and rapid diffusion of novelties or changes, since it facilitates internal communications and teamwork.

5.5.3 Organization of Time

Most clinics organize patient flow according to their doctors' individual plans and very few establish their doctors' and departments' schedules based on patient preferences.

Visiting reproduction units and clinics all over the world, in general, it is observed that in most of them, time organization begins by taking into account the different activities, needs, and preferences of the doctors and other collaborators, to then try to fit the patients around that. For example, there are doctors who can have parallel activities that make them only available at certain hours, or the laboratory requires that all blood samples for the determinations must be in by a particular time of the day, or the follicular development ultrasounds are only performed by one person and must all be grouped into a few-hour shift, or the entire team directly wants to have free afternoons, etc., and taking into consideration all these variables, patient flow, office appointments, and operating room schedules are organized.

In an organization based, for example, on cost control, the mentioned system may make sense, although other factors would have to be considered as well. Certainly, however, if our strategy is differentiation based on patient satisfaction, this approach is frontally opposed to what we need.

Following our plan to manage through clinic organization and placing our focus on time organization, in addition to the regulations and habits of each country, it is important to analyze the preferences and needs of the patients to optimize each activity's efficiency. In this line, we define the number of hours per day for patient attention, the patient distribution, or density along the day, whether it will be convenient to see patients until the late hours because that is what they request in some places (such as Spain) to avoid giving explanations at work, or whether appointments for first visits should be offered on Saturdays (e.g., in Japan).

All the working hours of our laboratories, of our personnel, the establishment of the different shifts, etc., will be based upon this information in order to facilitate a complete service to the patient, at the hour that the patient prefers, and with enough staff to be seen without waiting lists or delays at the clinic.

We also measure precisely the mean duration of each type of procedure to assign it the appropriate time in the schedule. These calculations allow us to design the appointments, since it is necessary to minimize the waiting time for the patients and the bad work distribution for the professionals: the objective is that they do not have to wait for us and we do not have to wait for them.

Finally, although we have focused on the term "patient" because we are devoted to a medical activity, private and corporate IVF units must be viewed as service companies. Therefore, in terms of management, when we speak of patient satisfaction, we should really see it in a broad sense of client – and not only patient – satisfaction, which includes both the external client (the patient) and the internal one (the staff).

The organization and the concepts described are applicable, therefore, to the satisfaction of all the people who integrate the team and to the relationships with providers, affine institutions, and societies in which we play a part, in the sense that satisfying relationships – in the long run – help to achieve goals and to be coherent with our strategic plan.

Last but not least, no matter how deeply rooted an IVF unit's organization is, it must be a totally dynamic thing, always remembering that what we do not ask or we do not measure, we do not know. And what we do not know, we cannot improve.

Review Questions

1. On what should the organization of a clinic be based?
2. What should be defined before developing all the organization and workflow?

3. Five steps of a circular diagram for the development of a strategic plan.

4. What are the three key strategic concepts to start any planning process?

5. What is management control?

6. What are the three main areas to organize in a services industry?

7. Is the organization and workflow a static document or a dynamic process? Why?

Risk and Safety in the IVF Clinic

Julius Hreinsson and Kia Borg

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_6

Learning Objectives

This chapter aims at informing the reader of the following:

- Conceptual information on risk management from a quality control perspective
- Practical information on how to perform a risk assessment
- How to minimize risk and maximize safety in the IVF clinic

6.1 Risk Management: Background

6.1.1 What Is Risk?

All definitions of risk involve concepts of uncertainty and loss or injury. Here, we define risk as a possibility of an activity causing injury or damage to someone's interests. In the context of ART, "someone" is any of the stakeholders in the activities of an ART clinic.

6.1.2 Risk and Conflicts Between Interests

There are inherent conflicts of interest between stakeholders, so that the pursuit of one interest creates risk to another interest, i.e., it increases the probability of injury to another party. For example, the patients (the prospective parents) may desire to have twins, in the belief that they will get "two for the cost of one." However, this is a disadvantage to the offspring, since there is a significant health risk associated with being a twin sibling. The different attitudes to twin pregnancies in Europe [1] and the USA [2] illustrate different ways of solving this conflict and balancing the risks. The community may make a different risk–benefit assessment than scientists when new reproductive technology is about to be introduced. This was demonstrated in Italy, where the legislature severely restricted the practice of reproductive medicine after public reactions to claims of human cloning and egg donation to very old recipients [3]. Finally, there is the conflict between owners and employees, where the two are making demands on the same resource, i.e., a conflict over how the economical surplus from the clinic's operations should be shared between the investors and the employees. If either party receives too little in return for their input, they may decide to withdraw their support for the organization. Risk management is about balancing risks to different stakeholders, i.e., patients, offspring, community, the profession, owners, and staff.

6.1.3 Types of Risk

The severity of the injury may be anything from a minor inconvenience to the loss of life or the closure of a clinic or even the prohibition of the practice of reproductive medicine. The damage can be financial or nonfinancial (human), and damage to a human interest can lead to financial damage and vice versa. The risks that patients face are both financial and human, i.e., they may waste hard-earned money on inappropriate diagnostic or therapeutic measures, and they may suffer physical injury from the treatment in the form of ovarian hyperstimulation syndrome, infections from bowel perforation during oocyte retrieval, etc. The medical adverse events may also have financial consequences for the patient, and for the treating clinic, as they may be sued for damages. As mentioned above, there may also be consequences for the whole ART industry. Conversely, if the clinic is under financial strain, it may choose to increase risk taking with regard to quality of care, and this may in turn cause injury to patients.

6.1.4 Risk and Quality Control from the ISO 9001 Perspective

Risk management has over the years become an ever more central part of continuous improvement of patient safety and is of importance for the clinics' future progress and development. Risk management is now an integral part of the ISO 9001:2015 certification standard. One of the key purposes of a quality management system is to act as a preventive tool. Annual risk analysis of operations and similar analysis of new and planned activities are advised. This could include organizational changes, application of new methods and techniques, suggestions for improvement or experienced risk for nonconformities, as well as adverse events in other operations. Initiation of risk analysis is typically initiated by management or quality control officers.

6.2 Quantifying and Analyzing Risk

6.2.1 Assessing Risk

The risk perspective helps us see opportunities.

Assessing risks is an essential part of the patient safety work. We can try to avoid risks, reduce risks, or sometimes even accept risks that we cannot do anything about. Risk perspective also helps us to see opportunities for improvement.

We can identify our risks in annual risk assessments and, if necessary, in several specific risk analyses. The identification may be of a general nature such as "worst-case scenario" for the business in general or possible specific risks to a particular process.

Prioritizing is important as it helps us to allocate resources to where they are of most utility. This requires us to quantify the different risks (risk scoring) that can be done by using a "Risk matrix" (Table 6.1).

An example of a risk with very low probability but high severity is death after IVF treatment. Although this is a very rare event, probably occurring at a frequency of <1/100,000 [4], it is a very severe event, obviously not only to the patient and relatives but also to the reputation of the clinic and to the industry.

Table 6.1 Risk matrix

Risk matrix					
		Severity			
		Very severe (4)	Serious (3)	Significant (2)	Minor (1)
Probability	Highly probable (4)	16	12	8	4
	Probable (3)	12	9	6	4
	Less probable (2)	8	6	4	2
	Minor (1)	4	3	2	1

Examples of probability and severity

Probability:

Highly probable (4)	May occur every week
Probable (3)	May occur a few times a month
Less probable (2)	May occur a few times a year
Minor (1)	Occurs very rarely

Severity

Very severe (4)	Death after IVF treatment, misidentification of gametes, transmission of infections
Serious (3)	Inadvertent embryo demise, thawing an embryo on the wrong day, bleeding or critical loss of blood pressure during a procedure
Significant (2)	Wrong stimulation protocol, missed diagnosis of a twin or triplet pregnancy
Minor (1)	Discomfort/concern for the patient, prolonged waiting times, patient not treated with respect

Errors in appointments booking represent a common event, but not a severe risk. In a single instance, they do not have a major impact on the clinic, but if they occur too often, they will damage the reputation of the clinic, and patients may make demands for compensation.

When assessing risk, we cannot limit the analysis to one event going wrong. Instead, we must consider how a minor error in one step can increase the likelihood, or compound the effect of an error later in the process.

Of course, all very severe risks must be addressed immediately as they can threaten the continued existence of the clinic or the life of a patient. However, also less significant events that are likely to occur often should be addressed, as they will drain the resources of the clinic. The risk scoring process only indicates the priorities but does not suggest how to address the risk issue.

6.2.2 Managing Risk

In principle, there are three ways of managing risk: elimination, reduction, and transfer. In real-life situations, it is not possible to eliminate the risk of an activity, except by desisting from that activity. That in itself creates other risks, and it can sometimes be useful to evaluate the options using the matrix below:

What will happen if we take this action	What will happen if we do not take this action
What will not happen if we take this action	What will not happen if we do not take this action

For example, a clinic may choose to not do blastocyst culture because of possible negative developmental effects of

extended culture. One adverse consequence would be that the chances of pregnancy in a fresh cycle decreases, so that the patients may have to undergo more treatments and subject themselves to more treatment risks to achieve pregnancy. Another risk is that the clinic may forgo an opportunity to improve its standing in league tables and then suffer a reduced demand for its services.

Risk reduction requires a thorough understanding of the process and a thorough risk analysis. This involves validation, process mapping, and monitoring of performance indicators for the process in question and the application of techniques like FMEA (failure mode and effect analysis) and root cause analysis. The results of these analyses have to be fed back into the process design or review, and they have to be repeated as experience accumulates.

The concept of risk transfer or risk sharing is meaningful only in the context of financial risk. A very common example of risk transfer is insurance, whereby the insurer bears the brunt of the financial burden of an adverse event. An example of risk sharing is the reimbursement policy that many clinics have for situations where a treatment cycle has to be cancelled or is unsuccessful.

6.2.3 Analyzing Factors That Influence Risk

There are a number of tools that can be used to identify factors that increase or decrease risk. In IVF, the actual probabilities of various adverse events are not well known, and therefore, a qualitative approach is required. One such approach is force-field analysis, whereby factors or forces that increase or reduce risk are identified and ranked. The example shown in Fig. 6.1 is by no means comprehensive.

6.2.4 Monitoring

When the procedure is being performed, the operator should certify that all the steps have been carried out according to the SOP. Witnessing should be certified, electronically or by handwritten signatures. The certification should be audited regularly, and all nonconformities, adverse events, and near misses should be recorded in the incident log, both on a process level and an individual operator level. All incidents must be reviewed and analyzed regularly and system improvements initiated. Training and education may also need to be improved.

6.2.5 Implementation

1. Identify risks: Choose the process you want to analyze and describe the subprocesses schematically in a risk analysis spreadsheet (Table 6.2). Identify risks, for each step of the process, by asking yourself the following questions: "What could have gone wrong in this step?"—"What would the consequences be for the patient?"
2. Estimate the magnitude of risk: Risk size is an aggregate of severity and likelihood of occurrence. Multiply the value of the severity with the value of the probability (see Risk matrix, Table 6.1). At risk score ≥8, an action plan should be developed to reduce the risk. After completion, a follow-up and a new risk estimation are done. Action plans can also be initiated for scores under 8, if needed.
3. Identify the underlying causes: Each risk can have one or more causes. At each risk ask "Why?" and answer "Because...." repeatedly. When the cause (one or more) is identified, the answer to the question "If the identified

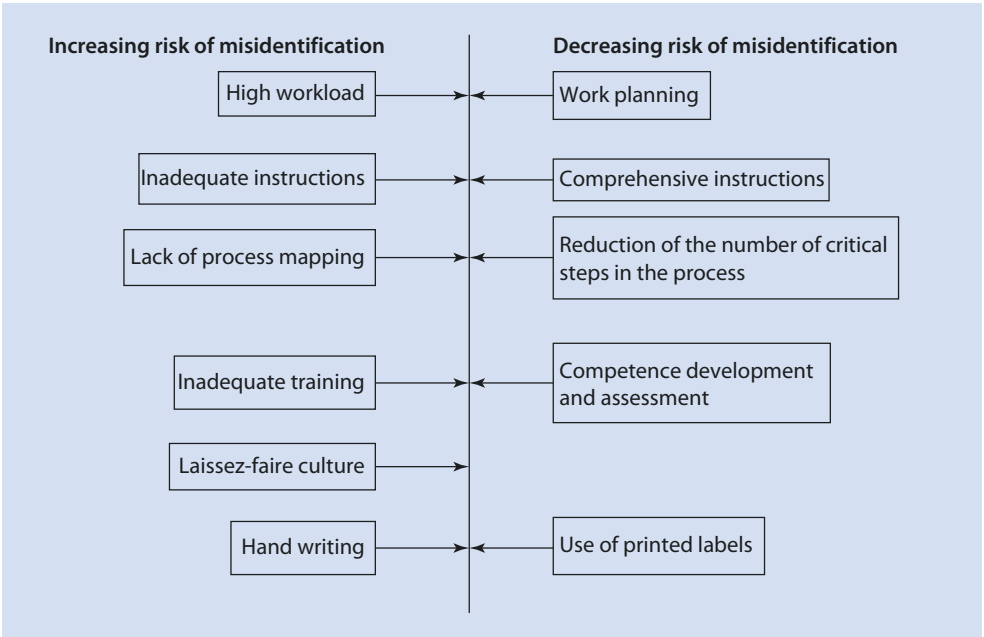

Fig. 6.1 Force-field analysis. One approach to identifying factors that increase or decrease risk is force-field analysis, whereby factors or forces that increase or reduce risk are identified and ranked. The example shown is by no means comprehensive

Table 6.2 Risk analysis spreadsheet

Process:_____

Sub processes	Risk * What happened or could happen? * Where and in what situations it is most likely to happen?	Scoring			Continue the analysis? **Yes or No** If yes, please complete an action list
		Severity	Probability	Risk score	
Description	Description of risk				

Example of a spreadsheet used to identify and evaluate risk in various processes

causes are removed or restricted, will it prevent that the risk may occur again?" should be "Yes."

4. Create action plans and follow-up methods: Give suggestions for actions for each underlying cause to be eliminated, limited, and/or monitored. The suggested action plans should be concrete, realistic, and possible to implement within a reasonable timeframe. Decide a method of follow-up to ensure that the actions have had the intended effect.
5. Prepare a final report: Write a report summarizing the main risks associated with the underlying causes and suggested actions. The report should be objective and based on patient safety.

6.3 Risk Management in the Laboratory

To address a risk, one can follow a four-step method: process analysis with identification of critical steps, identification of how errors can occur in the critical steps and what their consequences could be, possible causes of these errors and their prevention, and determination of how the critical steps should be monitored. This is of course an iterative process. The risk analysis will often lead to the whole process being redesigned, and this then requires a new risk analysis. Also, once the process has been in operation for a while, performance data will be used for a risk analysis to redesign the process.

It is extremely important to focus on the process and not the people. Certainly, individual performance must be monitored and deficiencies addressed, but identifying system weaknesses and opportunities for improvement is the only way to improve by design rather than by chance. It is also important to understand that in a reasonably well-run clinic, improvements happen at a modest rate. The long-term rates of improvement in national live birth rates in Sweden and the UK are in the order of 0.3–0.4% per year. If your clinic improves by 0.6% per year, you are outpacing your average competitors very fast.

Example: Misidentification

Misidentification is one of the most dreaded adverse events. It has a reasonably high probability of occurring and the consequences to the patients, the offspring, the embryologist, the owners, and the profession are dire [5]. Any nonconformity in this area, even if it is discovered before any damage has occurred, must be recorded and treated as a serious incident, analyzed, and acted on.

When designing a process, we start with process mapping. The process map is then used to write instructions for performing the steps of the process, standard operating procedures (SOPs). An SOP should contain background information with scientific references, requirements for performing the procedure (operator competence, materials, equipment, conditions), detailed instructions, requirements for data input and output/reporting, interpretation of results, standards and reference ranges, risks associated with the process, and instructions for nonconformance events. Figure 6.2 is an example of a simple process map for ovum pick-up (OPU) (each step requires elaboration) to assist in risk management of the process.

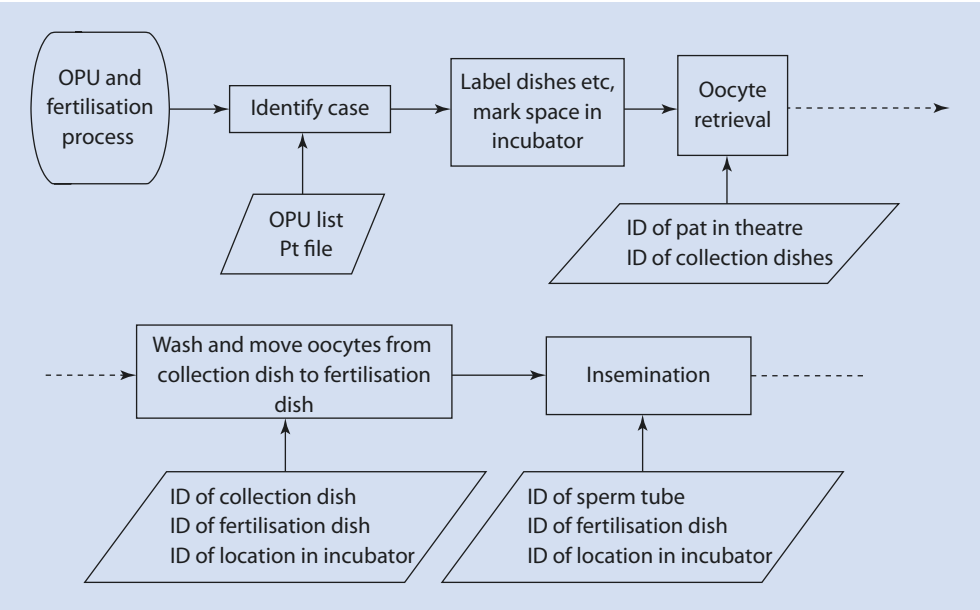

Fig. 6.2 Process map. An example of a simple process map for OPU (each step requires elaboration) to assist in risk management of the process. OPU, ovum pick-up

6.3.1 Where Can It Go Wrong and How Can It Go Wrong?

It is obvious that there is a risk of misidentification in each step. We can misread the OPU list and get information from the wrong patient files. If data for the wrong patients are entered, all ID steps down the line will be incorrect. At another step, the dishes can be incorrectly labeled, because we are working with the wrong information or because we misread the information or because we accidentally labeled the dishes wrongly or in a way that allows misinterpretation. We can put the dishes in the wrong location in the incubator, we can get the wrong set of dishes out, and we can inseminate with the wrong sperm. In short, every time we read something, write something, or move something, we can make an error. If the errors are discovered at an early stage, injury may be limited, although trust is always damaged in these events.

6.3.2 What Is the Cause of the Error?

In this example, the root causes are failure or mistake in reading or writing and misplacing things. A system-level action to reduce errors should therefore focus on these issues. Thus, we should reduce the number of instances where reading and writing is performed, e.g., by transferring information electronically from a patient file onto labels for dishes. By using clear labels and by working with material from only one patient at a time in a workstation, we reduce the risk of misreading and misplacing. When it is necessary to work on material from several patients in parallel, like in sperm preparation, separate workstations for each patient can be used. This increases time cost and equipment cost, thus hurting other interests, so an informed decision has to be made about what level of risk is acceptable and at what cost. Today, RFID (Radio Frequency Identification) and barcode systems for IVF laboratories are available to reduce the risk of misidentification, misreading, and misplacing. Double witnessing may also reduce the risk of misreading and misplacing and is mandatory in IVF in the UK. It is also required in the many processes in the pharmaceutical industry.

6.3.3 Risk Tolerance

Since we cannot eliminate risk but only reduce it, we have to decide how far we want to reduce the risk, i.e., what risk level we can tolerate. There is a cost associated with risk reduction, and some kind of cost–benefit analysis is required for informed decision-making. It is important to estimate the cost of failure, not just catastrophic failure where the cost is infinite but also the cost of minor failures, in terms of time, money, and mental energy. This process is not an exact science, but it is often possible to determine whether a particular action increases or decreases a particular risk or cost. As pointed out above, any action or lack of action involves risk to more than one stakeholder, so the risks to the different stakeholders must be arbitrated, and acceptable risk levels defined, i.e., optimized.

6.4 Critical Decisions Made in the IVF Laboratory

Examples of two decisions, critical to the outcome of the treatment, which are made in the IVF laboratory, are (1) choice of fertilization method and (2) selection of embryos for transfer and cryopreservation. The consideration in the first case is the risk of fertilization failure versus the less known risks of using a more invasive technique as well as the increased costs of ICSI. In the second case, the embryologist must balance the risk of treatment failure against the risks

associated with multiple pregnancy. Each clinic has to develop their own policies based on own data and published information, as well as the risk tolerance in their setting.

6.4.1 Fertilization Method

The use of ICSI varies tremendously between countries. According to the EIM results [6], the frequency of ICSI in European countries in 2011 varies between 36% and 96% with an average of 68%. Certainly, the choice between IVF and ICSI is not always easy for the IVF laboratory, and in many cases, a drift toward an increasing rate of ICSI can be seen. It is, however, well established that ICSI improves outcomes only in cases of low sperm counts or previous fertilization failure in IVF and is not indicated in cases of female pathologies such as poor ovarian response or in cases of previous implantation failure [7–9]. ICSI is more costly than IVF, so this is an economical issue for the IVF laboratory as well.

Each IVF laboratory must develop criteria for selection of fertilization method based on the clinic's patient population, culture methods, and, of course, the quality of the sperm sample. Common indications for ICSI include reduced sperm sample parameters (concentration, motility, etc.) in the original sample and/or low yield after preparation (<1 million motile sperm). Adhering to set parameters increases reproducibility and allows improvements through experience and data analysis since the lack of selection parameters hinders learning by experience—nonexistent parameters cannot be improved. It is important to realize two aspects of this problem:

- Fertilization failure after ICSI occurs at a rate of about 2%, and in the authors' experience, it need not be much higher in IVF, about 3% (unpublished observations).
- Patients with fertilization failure after IVF in spite of a normal sperm sample have a reduced chance of success with ICSI compared to ICSI for male factor patients [10].

The problem is one of informing the patient of the chances of success and limitations of the methods available, based on robust scientific evidence. The IVF laboratory must continuously monitor its key performance indicators, such as fertilization rate after IVF or ICSI, and benchmark them against leading clinics. Over time, this will assist clinics to improve and fine-tune selection criteria. These aspects are discussed in Chapter 70 in this volume.

6.4.2 Selection of Embryos for Transfer and Cryopreservation

This decision involves determining firstly which embryos can be transferred and frozen and, secondly, how many should be transferred. The criteria used for assessing the developmental capacity of embryos include morphology, developmental rate, and metabolic markers, and these criteria can be assessed at a single stage or at multiple stages. As a rule, the earlier the assessment is made, the poorer the predictive power, but by waiting until later stages, the exposure to the in vitro environment is prolonged.

The embryologist thus has to balance the risk of making a poor assessment against the risk of damage to the embryos due to the suboptimal culture environment. Also, the more thorough the assessment, the greater the exposure of the embryos to the environment outside the incubator. If the embryologist is skilled in assessing embryo developmental capacity, the number of embryos transferred can be decreased, and the risks associated with multiple pregnancy can be accordingly reduced.

6.5 Safety and Health in the IVF Lab

As in any laboratory, there are general risk-reducing measures that must be in place to ensure the safety of IVF laboratory staff. These include fire safety planning, instructions for handling any substances, materials, etc., that may cause injury, reducing the risk of slipping and falling, minimizing the risk of falling equipment, etc., and ensuring manual handling is done in an ergonomically sound way. Guidelines for such measures are published by national or supranational bodies, for example, the European Agency for Occupational Safety and Health. In addition, there are health and safety risks that are specific to particular areas of work, and examples of such risks are given below.

6.5.1 Liquid Nitrogen

In the USA, deaths from liquid nitrogen (LN_2) asphyxiation in a variety of industries occur every year, so this remains one of the most severe health risks to IVF laboratory staff [11]. A review of the health risks associated with LN_2 handling in ART laboratories has been published by Tomlinson [12], and a few of the issues are highlighted below.

Because of the huge temperature differences between LN_2 and the laboratory environment, materials such as plastic containers will contract/expand depending on whether they are being placed in or taken out of LN_2. This stress may cause cracking or, in the case of sealed containers, explosive destruction of the container. Use of appropriate materials and containers intended for use with LN_2 is essential to avoid injury and/or loss of specimens. Safety glasses or face shield must be used at all times when handling LN_2 since splattering may occur in addition to the abovementioned risks. Protective clothing and shoes are warranted, especially when handling LN_2 in pressurized containers such as some variants of controlled-rate freezers.

Liquid nitrogen has no smell, and when it evaporates, it has the same density as air since the atmosphere we breathe is to approximately 78% composed of LN_2. When large volumes of LN_2 evaporate, the oxygen (O_2) concentration in the room may drop from the ambient concentration of approximately 21%. One liter of LN_2 will expand in a ratio of 1:694 to the gas phase, so this effect may be quite dramatic. Only a few percent drop in the oxygen concentration may have an effect

on a person in the room, a drop below 10% O_2 will cause unconsciousness, and an O_2 concentration of less than 6% is lethal. Most alarms for low O_2 concentration are set to go off at a level below 18% O_2.

All facilities where large amounts of LN_2 are stored must be equipped with adequate ventilation and an alarm system for a drop in atmospheric oxygen. Detailed routines for each laboratory will depend on the amount of LN_2 stored as well as local ventilation systems. Laboratory directors should remember, however, that even the best ventilation systems may fail occasionally and the most robust vacuum isolated storage tanks may develop an isolation breach or leakage. Therefore, alarm systems are mandatory unless very small volumes of LN_2 are handled. The risk of asphyxiation from displacement of oxygen is present also in any space where CO_2 or N_2 gas bottles are stored, and the same precautions are mandated there.

6.5.2 Ergonomic Aspects of Laboratory Work

The embryologist has a repetitive job where several hours each day are spent at the microscope or performing repeated movements such as pipetting or micromanipulations. The IVF laboratory invests a large amount of training in each employee, and an optimal work environment is necessary to ensure a healthy and productive working life. This is cost-effective in the long run since ill health and financial liabilities can be avoided. Some important issues to consider are the following:

Adjustable ocular tubes for microscopes (ergotubes) are important to ensure an optimal posture while working with analysis and manipulations. This will reduce the risk of back problems associated with long sessions at the microscope. Readers who are not convinced may test sitting in the driver's seat of a car, which has been adjusted for a person 10–20 cm shorter or taller than themselves and drive for 3 h without adjusting the seat or steering wheel. This is equivalent to an ICSI session at a busy IVF lab or a difficult case of TESA-ICSI.

For the same reasons as above, laminar flow hoods with adjustable stands are preferable in the IVF lab. Producers of modern laminar flow hoods should be able to deliver these with height-adjustable stands. Other ergonomic support items include mechanical pipettes and multi-dispensers to minimize repetitive pipetting and semi-stationary arm supports, which may be used, especially if problems have already occurred. Similar considerations are relevant when choosing the height of incubator supporting tables, etc.

6.5.3 Infected Specimens

The risk of infections from infected specimens is not greater in the IVF lab than in other medical laboratories. Patients are screened for hepatitis A, B, HIV, etc., but nevertheless, the use of protective gloves is mandatory when working with samples such as sperm and follicular fluid. Hospital and/or cleanroom clothing should be worn at all times. The use of protective gloves, when performing micromanipulations and handling of oocytes and embryos, may be considered a risk in itself and is not mandatory when working with material from screened patients. Samples from patients with known contagious diseases, on the other hand, must be processed with special caution, using a face mask, single-use protective clothing, and gloves. This type of work must be conducted in designated biohazard facilities, which can be easily and thoroughly cleaned.

Care must be taken when handling sharp instruments such as needles and micromanipulation pipettes as well as breakable items such as glass. Routines should be developed for handling any situation that involves injury to patient or personnel. The routines should include blood testing to check for development of infection and reporting to authorities according to local regulations. It is strongly recommended that the infection status of staff is checked at the start of employment and that vaccination is offered as appropriate.

Acknowledgment A previous version of this chapter was written in collaboration with the late Dr. Peter Sjöblom. We owe a debt of gratitude to him for his knowledge and his generous input from years of experience in the field of assisted reproduction.

Review Questions

1. How can a risk evaluation be performed using a risk matrix where values of probability and severity are taken into account?
2. Why is an O_2 alarm mandatory in storage facilities for liquid nitrogen? Explain.
3. Why is it important to focus on systematic causes of errors in any given process instead of conferring blame to individuals?
4. What are the different kinds of burden conferred on a clinic by infrequent and serious errors vs. frequent and minor errors, respectively? Explain.

Control of Variables

Cecilia Sjoblom and Georgios Liperis

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_7

Learning Objectives

- To provide an update on core variables within the embryology laboratory
- To discuss and determine ways of improving monitoring to allow for detection of fluctuations
- To provide knowledge and tools to enable action to be taken against the root cause of fluctuations, allowing for quality control process development
- To apply these approaches to implement efficient control of variables

7.1 Introduction

7

Success of assisted reproductive technology (ART) is influenced by a number of different factors. The aetiology and age of the patient seeking treatment, ovarian reserve, response to ovarian hyperstimulation and receptivity of the uterus affect the outcome. The embryology laboratory itself has a leading role, with treatment results being highly dependent on the quality of the laboratory environment, culture protocols and media used, the equipment, disposables and supplies as well as the individual skills and performance of the embryologists [1, 2]. All of these factors can be considered as variables, and while each patient is different to the next, we must strive towards keeping these factors constant in order to increase the success of ART.

The female reproductive tract provides an optimal environment for the gametes and developing embryo. From the point of ovulation, to fertilisation and then as the embryo transverses the oviduct towards the uterus, it is exposed to an environment evolved to support and promote its growth at every stage. The physical aspects of this environment are perfectly controlled with a precise temperature, pH and absence of light. This stands in stark contrast to the in vitro environment of the embryology laboratory, where the main purpose is to maintain the quality of gametes and embryos by mimicking the highly stable environment of the female reproductive tract [3, 4]. The human pre-implantation embryo does not possess mechanisms to respond to changes and stress as adult cells do. Most notably, embryos cannot control changes in physical parameters such as temperature, pH and osmolarity. As a consequence, when embryos are exposed to minute changes in physical and chemical conditions such as media composition and pH, temperature and osmolarity, they are unable to develop optimally [5–7].

7.2 Variables

7.2.1 Temperature

Temperature is a significant variable that affects the outcome of an ART cycle. The concept of temperature control goes beyond the culture dish, encompassing laboratory room temperature and temperature of refrigerators and freezers. During culture, temperature is a key determinant of gamete viability and embryonic growth [8]. Maintaining a constant temperature in vitro close to the human body temperature of 37.0 ± 0.2 °C is crucial during all in vitro manipulation and culture [9, 10]. Modern IVF laboratories control temperature by using incubators with precise temperature and heated stages to allow for temperature control during manipulations outside the incubator.

Both cooling and overheating during routine in vitro manipulation of oocytes and embryos can result in short- or long-term temperature shock [11]. The severity of these temperature shifts depends on the type of dish used, the accuracy and function of the warming device, volume of culture media and the presence of an oil overlay [12]. The negative consequences depend on both the duration and severity of suboptimal temperature exposure, as well as the developmental stage of the embryo [13]. Cells respond to changes in temperature by changing their metabolism. Cooling results in a slower metabolism [14].

A cellular structure highly susceptible to temperature fluctuations is the spindle apparatus. Microtubules represent the major component of the meiotic spindle, and these structures assemble and disassemble in response to changes in temperature [15–17]. Cooling and overheating of oocytes have been shown to affect the morphology of the meiotic spindle in a number of species, and even miniscule changes as small as 0.3 °C for very short times can cause irreversible damage [17, 18]. The meiotic spindle is a determinant of oocyte viability, responsible for correct chromosome alignment and segregation during metaphase I and metaphase II, genomic stability and consequently fertilisation and post-fertilisation events [19, 20]. More than 80% of aneuploidies originating from fragmented human embryos following ART originate from the oocyte [12, 21]. The correlation between meiotic spindle and oocyte quality is important to remember, as poor spindle architecture can result in high levels of aneuploidy, which in turn could result in embryo degeneration, spontaneous abortion and disease [19, 20, 22]. A recent study showed oocytes with normal spindle morphology were more likely to generate a euploid embryo, compared to oocytes with an abnormal spindle when viewed by polarised light microscopy [23]. The morphology of the meiotic spindle has also been associated with improved fertilisation rate, pronuclear formation, early cleavage, embryo developmental competence and blastulation rates, although using spindle morphology alone cannot predict the success of an ART cycle [24, 25].

Changes in temperature during oocyte and embryo development can influence pre-implantation developmental processes causing alterations in methylation patterns of imprinted genes resulting in developmental failure and mortality [26–28]. Moreover, heat shock in embryos can disrupt protein synthesis, cytoskeleton organisation and zona pellucida architecture resulting in developmental delays and embryo arrest [27]. Considering all the above-mentioned outcomes, stringent control of temperature throughout the in vitro period is an absolute necessity.

7.2.1.1 Control of Temperature as a Variable

Incubation Temperature

The incubator and culture system act as a substitute reproductive tract during the in vitro period. Controlling temperature for this period is dependent on the incubator. Historically, cell culture incubators were used for embryo culture; however, over time, incubator technology has been refined to meet the precise demands of a constant environment. A shortfall of traditional 'big-box' incubators has been having one large door, with frequent openings causing fluctuations in temperature. The modern big-box incubators are now fitted with multiple smaller doors, minimising the impact of openings. More refined design of 'benchtop' incubators, including multiple smaller chambers, has led to an even greater control over temperature. Comparison of these two types of incubators has shown the benchtop incubator to have a decreased recovery time of temperature resulting in a significantly higher blastocyst yield [29, 30]. A major shortcoming of benchtop incubators is that temperature sensors are located in few parts of the incubator, leading to an uneven distribution of heat (hot spots and cold spots) in contrast to big-box incubators that have the sensor inside the chamber and use a fan for even heat distribution. Another important consideration is minimisation of incubator door openings. Using working incubators for intermediate holding of dishes during processes that require frequent access to the sample can achieve optimal chamber temperature stability.

Whichever incubator system is used, controlling incubator temperature first requires comprehensive temperature mapping. Using an accurate thermometer (±0.2 °C) mapping should be done in all compartments of the incubator by measuring temperature within the culture system and the chamber air at each mapping point. The validation report should contain the culture temperature for each mapping position, together with the corresponding air temperature (±SD). Temperature is thereafter monitored daily using an independent accurate device (±0.2 °C). Noting the display temperature daily does not provide any control over culture temperature. Modern laboratories are equipped with continuous temperature monitoring systems allowing computer-logged 24-h monitoring with built-in alarm systems. Established processes are needed to include the appropriate action to be taken if the temperature falls outside the set range (i.e. ±0.2 °C).

Temperature of Warming Devices

Cooling is more likely to occur when manipulating oocytes and embryos outside the incubator. Warming devices need to be validated through temperature mapping in the same way as incubators to assure a stable temperature of 37 ± 0.2 °C is maintained. For tube warmers, the temperature is validated in a tube containing fluid in each position of the warmer. Testing each culture device separately is important as plasticware have different designs and distance between the actual bottom of the dish and the heated stage. There are dishes available for embryo culture where the plastic is in direct contact with the heated stage (Vitrolife). Surface temperature at each mapping point is also measured. The validation report should contain the culture temperature for each mapping position together with the corresponding surface temperature (±SD). The temperature for the warming device is to be adjusted to assure 37 ± 0.2 °C inside the culture system itself. Through full mapping/validation, the laboratory can identify possible hot/cold spots in order to avoid this affecting gametes and embryos. Based on the validation, the limits for the measurement can also be established. Following mapping, target temperatures are verified by daily measurements using a surface probe for the areas marked as appropriate for use.

When considering controlling temperature variations during manipulations, it is also important that the embryologists understand that the process itself can introduce fluctuations. Insertion and swirling of a glass pipette into the media during the process of denudation for ICSI on a temperature-validated heated stage has been shown to result in rapid cooling with different methodologies also resulting in alternate cooling rates [31]. This highlights the importance of validating different methods.

Room/Laboratory Temperature

Laboratory temperature needs to be controlled and kept constant. Laboratory equipment is designed to operate at the standard laboratory temperature of 22–24 ± 2 °C, and fluctuations in room temperature (RT) will affect equipment performance and results [32]. A dish taken out of the incubator and placed on a heated stage at RT of 20 °C will experience different cooling rates than a laboratory where the temperature is held at 30 °C. As a result, core processes such as ICSI and vitrification will be indirectly influenced. Although high laboratory temperatures >26 °C could be considered beneficial for reducing cooling rates when embryos are handled outside the incubator, high temperatures may result in increased risks for incubator overheating, staff discomfort and bacterial and fungal contamination.

Laboratory temperature needs to be monitored daily, preferably at more than one point of measurement in the room. All storage areas need to be included in the monitoring scheme, as extreme temperatures will affect the toxicity and cause plasticiser built-up in plasticware and other plastic devices. Monitoring should be done using a thermometer with an accuracy of ±2 °C and a process in place for appropriate action if temperature falls outside the set range of 22–24 ± 2 °C.

Refrigerator/Freezer Temperatures

The temperature of stored culture media and reagents is important for product stability and quality. The manufacturer specifies the accurate storage temperature range on the package insert. Similarly, the model of refrigerator needs to comply with storage requirements stipulated by the manufacturer. For storing culture media, pharmaceutical refrigerators fitted with a circulation fan and wire shelves to allow for even distribution of temperature throughout the chamber are used. It is important to not over-stack shelves and to place the

products in a manner that does not disturb the flow of cold air in the refrigerator. Many laboratories store culture media in a standard kitchen refrigerator. This risks compromising the quality and stability of the media as these refrigerators do not maintain accurate temperature throughout the chamber and would normally have a 2–3 °C difference between the top and the bottom shelves.

The temperature inside the refrigerator/freezer is set according to the manufacturer's specifications and needs to be monitored at least once daily using a thermometer with an accuracy agreeing with the limitations (i.e. ±1 °C) accompanied with recording and actions to take if a reading is found to be outside the set range. As for incubators, continuous 24-h monitoring of refrigerator temperature is recommended.

7

7.2.2 pH

Maintaining a constant pH in the culture environment is a critical aspect of an IVF laboratory and has significant effects on the outcomes [2, 33]. The regulation of intracellular pH (pHi) is essential for maintaining cell homeostasis in oocytes and embryos [34]. Controlling the pHi is crucial for a range of cellular processes such as metabolism, DNA and protein synthesis, respiration, enzyme activity, cell differentiation, growth and proliferation, membrane transport, cell-cell communication, calcium level modulation and cytoskeletal dynamics [5, 35, 36].

The pHi of human embryos ranges between 7.1 and 7.2 [37]. While most cells have a wide range of mechanisms to regulate pHi, early embryos have relatively little homeostatic capability [38]. In early embryos, pHi is regulated using three transporters: Na^+/H^+ antiporter, $Na^+/ HCO3^-/Cl^-$ transporter and the $HCO3^-/Cl^-$ transporter [39]. The Na^+/H^+ antiporter is functional under acidic conditions (pH 6.8), actively removing protons from the cytosol in exchange for extracellular sodium ions. The $Na^+/ HCO3^-/Cl^-$ transporter becomes active at more neutral pH ranging from 6.8 to 7.1 and uses bicarbonate ions to increase pHi during an acidic load. The $HCO3^-/Cl^-$ exchanger is active at slightly more alkaline conditions of 7.2–7.3 and transports bicarbonate ions from the cytosol in exchange for chloride ions. With changing pHi, the transporter system exponentially increases in activity until the pHi returns to normal [35].

The sequential changes of the reproductive tract, with alkaline milieu of the oviduct to the more acidic conditions of the uterus along with the differential activity and expression of transporters across pre-implantation development, underline the susceptibility of embryos to changes in pH in vitro where conditions are not comparable to those in vivo. Although cleavage embryos grown in vivo can effectively regulate small pH changes, in vitro culture exposes embryos to rapid fluctuation patterns of pH by incubator door openings and observations of embryos that result in reduced development potential [40].

In somatic cells, minute alterations in pHi can result in disruption of a number of crucial processes such as respiration, protein synthesis and nucleic acid synthesis [35]. In comparison, somatic cells are relatively stable, while embryos are dynamic, undergoing several rounds of cleavage, genome activation, compaction and blastulation over 120 h. Taking this into account, it is unsurprising that even the smallest fluctuations in pH can be catastrophic.

Exposing murine embryos to the weak acids, such as pyruvate and lactate, has been shown to decrease the pHi to sub-physiological levels that results in developmental arrest at the two-cell stage and blastulation inhibition [41]. In the same study, it was also shown that acidic conditions perturb metabolism, another sign of embryo stress [41]. In a subsequent study conducted using hamster embryos, exposure to weak acids and bases resulted in the disruption of mitochondrial organisation within the cytoplasm with the effect being greater after intracellular alkalinisation [42]. It is evident therefore that embryos are extremely susceptible to pH changes, and this can cause irreversible damage. Other than the pHi, embryos are exposed to the endogenous external media pH (pHe). While it has been suggested that embryos can tolerate some fluctuation in pHe, recovery of pHi is mostly irreversible [7, 42, 43].

7.2.2.1 Control of pH as a Variable

Control of Incubator pH

The pHe is regulated in vivo by a bicarbonate-buffered system via carbonic anhydrase and circulating CO_2, whilst in vitro, the pH of culture media (pHe) is regulated by the level of CO_2 in the gassed atmosphere and the use of buffers in culture media. These buffers are used to accommodate the minute pH fluctuations caused by the accumulation and depletion of other alkaline and acidic substances in the media such as amino acids. Commonly the pH of embryo culture media ranges from pH 7.2 to 7.4, allowing the embryo to maintain a pHi of 7.1–7.2. Bicarbonate, HEPES and MOPS buffers all have buffer capacity in these ranges and are commonly used in embryo culture and handling medium.

The pH scale is logarithmic; a 0.2 variation in pHe represents a 60% change in H^+ concentration. It is therefore crucial to minimise pHe fluctuations in order to reduce variability in the culture system. Factors including temperature, humidity, altitude, incubator gas concentration as well as handling will affect the pHe [39]. The bicarbonate buffering system is the most physiological and commonly used system in embryo culture. However, this system is dependent on the concentration of CO_2 in the surrounding atmosphere. Most commercial embryo culture media have a bicarbonate concentration requiring a CO_2 concentration between 5 and 6% to maintain a pH range of 7.2–7.4. If a bicarbonate-buffered medium is taken out of the gassed incubator and is exposed to ambient CO_2 concentrations (0.04%), the pH begins to rise dramatically within minutes and can take up to 30 min for the pH to decrease to the desired levels when returned to the incubator [5].

The pH inside the incubator needs to be monitored with specialised pH meters using the same conditions including

volume of media and/or oil overlay, which gametes and embryos are exposed to during culture. Alternatively, employing a blood gas analyser will result in more accurate measurements. The manufacturer sets the pH, and its accuracy should be within ±0.2 units. The pH measurements need to be undertaken on a weekly basis and all measurements recorded in a logbook with actions outlined if measurements fall outside the specified range. In addition, pH measurements are considered essential every time a new lot of culture media is introduced and also when a new gas cylinder is installed.

Control of pH Outside the Incubator

Since exposure of embryos to alkaline conditions is unacceptable for culturing embryos, handling procedures outside the incubator requires appropriate buffering systems. HEPES buffer (4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid) is a highly stable zwitterion with a midpoint buffering range (pKa) of 7.31 at 37 °C, highly soluble in water, with low permeability through plasma membranes making it ideal for use in cell culture [44]. MOPS buffer (3-(*N*-morpholino)propanesulfonic acid) is another zwitterion with similar properties to HEPES and a 7.04 pKa at 37 °C [44]. The main advantage of these buffers is that they are not dependent on CO_2 to maintain a stable pH making them suitable as buffers in handling media for benchtop procedures such as oocyte collection, ICSI and embryo biopsy.

Several reports have found that HEPES may be negatively impacting embryo development [45–47]. Consequently, some manufacturers have replaced HEPES with MOPS in handling media. Despite this, there is limited data on the effects of MOPS on embryo growth development [48]. MOPS has been shown to support in vitro maturation of murine oocytes and bovine embryo development just as well as HEPES [49, 50]. Furthermore, even though gene expression of environmentally sensitive genes differs from in vivo derived embryos, the two buffers showed no significant difference between them [50].

Buffer capacity can have a significant impact on gamete and embryo quality [51]. Nonetheless, it is important to critically assess the literature and scrutinise culture conditions. Some studies, for example, have used HEPES or MOPS as fertilisation media to assess developmental competence of embryos [47, 49]. However, the time and duration of exposure to HEPES or MOPS used in these studies do not replicate the processes in a clinical setting where the time in HEPES- and MOPS-buffered medium is kept at a minimum [45, 50]. With the exception of ICSI, which can take a few minutes, there are no long-term cultures.

An alternative approach to HEPES or MOPS is to handle gametes and embryos in bicarbonate-buffered media supplemented with phenol red as a pH indicator. This compound can be used in concentrations from 0.003 to 0.010 g/L, and when the pH falls outside the range of 7.15–7.35, its pink-rose colour changes. In particular, at a pH <7.15, the colour becomes yellow, and at pH >7.45, the colour becomes red-purple. Some reports however have shown that phenol red has a mild oestrogenic effect and can be toxic [52, 53]. In a different study, it was shown that at such low concentrations, it is impossible for phenol red to induce estrogenic effects [54]. Nevertheless, the possible toxicity and the inability to quantify pH changes when using it make phenol red not ideal for use.

Closed Workstations

The use of closed workstations that control temperature and gas can also be an alternative to the use of HEPES- and MOPS-buffered media. There is a range of workstation options with portable models, models with the possibility of O_2 control and models with fittings for stereomicroscope and inverted microscopes. The shortcoming of using such workstations is that the aseptic conditions are somehow lost, because of the turbulent flow inside the workstation. Furthermore, there is an increased risk of bacterial and fungal growth and the matter of decontamination and cleaning in situations of spillage where fumes from methanol would be re-circulating inside the workstation.

In the past few years, introduction of time-lapse incubators has enabled the continuous surveillance for the morphological evaluation of in vitro–derived embryos. This offers the benefits of uninterrupted culture, flexible workflow and improved embryo selection since more information is gained for the relationship between development and timing [55]. Furthermore, correlation has been drawn between time-lapse parameters and developmental competence, aneuploidy and pregnancy [56–58]. Nonetheless, it is well documented that good morphology embryos may well be aneuploidy, and therefore aneuploidy screening is still considered as the major selection tool.

7.2.3 Osmolarity

The osmolarity of culture media is critical when considering the optimum media for culture of pre-implantation embryos. The osmolarity of the female reproductive tract ranges between 310 and 370 mOsmol/kg for most species [43, 59]. The osmolarity of the human uterine fluid is in the range of 276–307 mOsmol/kg in unstimulated women and 305 mOsmol/kg in stimulated cycles [60]. Original attempts to culture embryos at osmolarity levels of over 300 mOsmol/kg have proven fruitless, with studies showing that mouse zygotes fail to develop in vitro at these levels. Specific amino acids have been suggested to serve as protective osmolytes allowing survival of in vivo embryos at high physiological osmolarity [61–63]. The optimal osmolarity supporting the growth and development of embryos in vitro varies among species with most modern culture media having an osmolarity of 260 mOsmol/kg [64–66].

Embryo culture at suboptimal osmolarity has been shown to affect embryo developmental competence and increase expression of apoptosis-related genes [59]. The effect of suboptimal osmolarity is suggested to be stage specific with mouse oocytes and one-cell embryos being more susceptible

to osmotic stress than cleavage stage and post compaction embryos [67]. Mammalian pre-implantation embryos employ a range of mechanisms to adjust cell volume in response to osmolarity changes [64]. When adjusting to changes in osmolarity, most cells will alter their volume by regulating osmotic pressure across their membranes and alter the concentration of osmotically active osmolytes in the cytoplasm [68]. Solute releasing reverses cell swelling, while shrinkage is counteracted by the active import of solutes [62]. In hypertonic conditions, the embryo increases its intracellular concentration of inorganic ions (Na^+, K^+ and Cl^+) resulting in an increased osmotic pressure. This leads to cellular proteins being destabilised and a disruption in metabolism [69]. The presence of organic osmolytes in media with high osmolarity is therefore necessary to maintain cell volume and counteract for the deleterious effects of intracellular inorganic ions. Modern culture media utilise organic osmolytes such as methyl ammonium compounds (e.g. betaine), small zwitterionic amino acids (e.g. glycine and taurine) or sugars and polyols (e.g. myo-inositol) [62].

7.2.3.1 Control of Osmolarity

Studies of evaporation in culture media have shown that the surface area can affect osmolarity [70]. A large dish surface with a small volume of media can increase the osmolarity value, whilst an increase in volume leads to osmolarity stabilisation [71]. The volume of culture media with proper ratio to surface area is necessary to achieve a stable osmolarity. As it has been shown previously, when a dish containing 3.0 ml of culture media is left at RT for 30 min, it causes an osmolarity rise of 5%, whilst when the dish is left at RT for an hour, osmolarity rises by 14% [72]. Dishes that are left for extended time without oil overlay should be checked for possible evaporation and increase of osmolarity.

When culture dishes are placed in a gassed incubator, airflow on the liquid will cause an increase of evaporation even in a humidified incubator, and that will inevitably cause an increase in osmolarity. An effective way to reduce evaporation of the culture media and osmolarity changes is to overlay culture drops with mineral oil. Making culture dishes should be done at room temperature with medium that is taken out of the refrigerator just before dish preparation. Dish preparation is done on a non-heated surface area of the laminar airflow hood, and under no circumstances should the heated surface be used. Having dishes with a volume of <20 μl culture media when using oil overlay should be avoided. A further factor to be considered is the humidity of the incubator. It is vital to maintain the optimum humidity in the incubator in order to keep evaporation of the media to a minimum and maintain a stable osmolarity.

7.2.4 Culture Media

Although the necessities of embryos during pre-implantation development have not been fully described, ongoing research has been able to establish the complexity of needs during different stages of development [73]. As an outcome, media formulations have become more composite [74]. The success of an IVF program relies on an optimal culture system that reduces stress and ensures gamete and embryo viability and development. Up to the stage of embryonic genome activation, embryos are more susceptible to damage, since they have not developed their own mechanisms and solely rely on mRNA from the oocyte [75]. Even after embryonic genome activation, the culture environment can have a significant effect on embryonic transcription and translation affecting birth weight and infant health following IVF treatment [76, 77]. In addition, commercially supplied culture media and buffers can result in spontaneous formation of reactive oxygen species (ROS), as in the case of HEPES buffer, which can result in formation of hydrogen peroxide and disruption of signalling pathways associated with fertilisation [78]. In addition, the culture conditions have been shown to affect imprinting [79].

7.2.4.1 Control of Culture Media

Culture media is not a variable that can be controlled; however, selection is vital when it comes to the success of an IVF program. When commercial media are used, it is important to track batch numbers and composition of each batch. Other than the certificates of analyses that companies provide with information regarding their testing (mouse embryo assay, endotoxin testing, etc.), it is important to consider the manufacturer's quality control systems during production. Dataloggers can also be utilised to record temperatures of the culture media during transportation.

If homemade media are used, then the appropriate bioassays for testing have to be performed as defined by national and international regulations, whilst sperm survival toxicity tests can be employed for validation of media batches. Whatever the source of media, it is important to keep records of dates of use for each batch to allow for key performance indicators to be used effectively. When media are aliquoted in smaller volumes, it is vital that the aliquot containers are deemed appropriate for embryo culture and off-gassed for at least 24 h before use. Plasticware may contain Bisphenol-A, which has been shown to affect reproductive function [80]. Recording lot number of media versus aliquoting media in smaller volumes is preferable because it will minimise variability and provide better control of potential issues with other variables that might affect the success of the IVF program. All culture dishes should be pre-equilibrated for temperature and pH by being placed into the incubators a few hours before being used. Dish making has to be done in a sterile and efficient way. When making culture dishes by overlaying micro-drops by oil, no more than one dish can be made at a time to avoid changes in evaporation and osmolarity.

7.2.5 Oxygen Tension and Gas Supply

Oxygen is one of the most characterised elements that controls embryo function with its concentration in the female tract around 5% and atmospheric oxygen around 21% [81].

Oxygen can be converted to superoxide radicals that are deleterious to cells, and culture in atmospheric oxygen has been shown to affect transcription, translation, metabolism as well as cause epigenetic changes [82–85]. In addition, embryos cultured in atmospheric oxygen have been shown to be susceptible to ammonium build-up in the surrounding media [86].

In light of the stressors associated with the use of atmospheric oxygen, concerns have been raised about the rationale behind culturing embryos to the blastocyst stage [87]. On the other hand, the benefits of low oxygen culture (5–7%) have been documented in terms of embryo development and live birth rates, suggesting that utilising a low incubator oxygen tension is a more rational approach [88, 89]. Nevertheless, a number of clinics and countries still utilise atmospheric oxygen tension regardless of its negative effects. Instead of considering extended culture as a potentially harmful procedure, the birth rates derived following blastocyst transfers and vitrification need to be interpreted based on the culture conditions, with 20% oxygen levels considered unacceptable [90].

7.2.5.1 Control of Gas Supply

Embryo culture requires a reliable and consistent quality supply of gases and gas mixtures. All gases utilised in gamete and embryo culture have to be attained from suppliers that comply with international standards in terms of purity and specification. In all the gases for the 'atmospheric' mixture of 6% CO_2 in air or the 'physiological' mixture of 6% CO_2, 5–7% O_2 in N_2 have to be of high purity. The low oxygen environment can be created either by supplying the incubator with pre-mixed gas or by suppressing the atmospheric O_2 using N_2. Auto-changeover manifolds have to be in place to ensure constant supply of gas into the incubator systems. Gas cylinders are supplied with certificate of analysis and the incubator CO_2 and O_2 levels monitored daily and actions taken if readings fall outside the range.

The pH can be disturbed by the gas quality. Therefore, each time a new cylinder is installed, the pH has to be measured. This is particularly important in certain countries, where either gas cylinders are not certified or the gas levels can vary even with certification. A blood gas analyser is a good tool to be employed for verification of CO_2 and O_2 levels along with pH readings. When the pH of an incubator falls out of the specified range, the CO_2 level is adjusted accordingly. Specifically, due to the inverse relationship of CO_2 and pH, lowering CO_2 levels can be used to raise pH, while raising CO_2 levels can be used to lower pH until the levels reach the pre-determined acceptable range. There is a range of gas-measuring devices including devices with thermal conductivity sensors, devices with infrared sensors and portable devices that can simultaneously measure CO_2, O_2, relative humidity and temperature. Before using such a device, calibration against a standard certified gas is essential.

7.2.6 Air Quality

In order to achieve stable results, the laboratory environment needs to be tightly controlled and a vital component is air cleanliness. In relation to the air quality, the presence and concentration of volatile organic compounds (VOCs), airborne particles and growth of any contaminants such as bacteria and fungus will impact both the safety and success of embryo culture [91, 92]. The environment inside the IVF laboratory can contain a number of microorganisms that are indigenous to humans [93]. Airborne particles vary in size, and their concentration can increase with personnel movement, operation of equipment as well as infection. VOCs are synthetic chemicals that can be vaporised; these include paints, pesticides, glue, alcohol and cleaning products. Exposure of human embryos to aldehydes and motor vehicle emissions has been shown to reduce pregnancy rates [94].

7.2.6.1 Control of Air Quality

Clean air means control of ventilation, filtration and adoption of aseptic processes, along with cleaning, disinfection and maintenance of equipment [95]. The position and number of air exchanges of the heating, ventilation and air conditioning (HVAC) system are important in order to reduce the number of particle counts. Air quality can be maintained by having positive pressure in the laboratory with a differential of 10–15 Pascals from the adjacent areas. In the embryology laboratory, when the gametes and embryos are exposed to environmental conditions outside the incubator, laminar airflow hoods and biological safety cabinets are used. The use of such flow hoods and cabinets are essential since they clean the air by the use of high-efficiency particulate air (HEPA) filters that capture particles of 5 μm or bigger, while UV light or heat can also be used. On the other hand, HEPA filters cannot trap VOCs that are smaller in size [96].

When gametes and embryos are placed in the incubator, the use of VOC filters in the incubator instead of HEPA filters has been shown to produce higher blastocyst rates [2]. Furthermore, the use of solid carbon and potassium permanganate filters has also been shown effective in removing VOCs [91]. These systems are available for gas bottle inlets or are installed within the incubator while they can also be integrated in the central air conditioning system of the laboratory or purchased as standalone units. The efficiency of these filters should be monitored on a regular basis.

Active measures need to be taken to minimise particle counts and VOCs. Particular attention should be given to the embryology laboratory design. Furnishings such as Formica, pressed wood or fireboard release formaldehyde, and hence, their use is prohibited. Flooring should also be carefully considered and the use of glue avoided. As it concerns paint, water-based paints with low VOC potential should be selected with the use of large industrial construction fans and venting of the exhaust to the exterior. All plasticware should be out-gassed by being unpacked from the plastic wrapping in order to release accumulated VOCs before use. All cotton

and other high-lint materials should be banned from the laboratory with preference towards low-lint laboratory clothing. To ensure standardised air quality, monitoring should include the measurement of VOCs and particle counts in operation and at rest. To achieve clean room standards, these parameters need to be measured daily and recorded with appropriate action described should a measurement fall outside the safe range.

Anything that enters the embryology laboratory including consumables, equipment and fresh, frozen and imported gametes and embryos can be a source of contamination. Even when embryologists apply stringent aseptic techniques, there are still contamination risks if the environment is not controlled. To reduce chances of infection, the laboratory should always be tidy and clean with the personnel maintaining high hygiene standards and good waste disposal management. Furthermore, access to the laboratory should only be permitted to authorised personnel and a routine for daily cleaning and decontamination should be established. All surfaces must be cleaned with 70% ethanol or commercially available embryo-tested spray, followed by rinsing with sterile water to remove any toxic overdue from the disinfectants.

In order to detect environmental microorganisms such as bacteria and fungi, Sabouraud dextrose agar (SDA) and tryptic soy agar (TSA) settle plates can be used and placed on work surfaces [97]. In addition, swabs should be used for hard-to-reach and non-flat surfaces. Active air sampling of viable particles is also necessary for microbiological monitoring of the IVF laboratory [95]. Active sampling is done by drawing air with the syringe and expelling it over the SDA and TSA plates. The selection and use of the sampling method should be validated in terms of its compatibility in the recovery and incubation conditions to allow growth and identification of microorganisms. These culture conditions vary, with bacteria requiring 2–5 days at 30–35 °C, while fungi and moulds require culture for 5–7 days at 20–25 °C [97]. The tests for the detection of microorganisms should be conducted every 3 months.

7.2.7 Light

Although it is generally assumed that light has no effect on gametes and embryos, in media containing HEPES buffer, it has been shown that ROS are produced with exposure to light [98]. Furthermore, cool white fluorescent light has been shown to produce more ROS in mouse zygotes, and embryos have been shown to have better developmental potential in the absence of light [99]. Light damages the embryos either directly by activating stress genes and damaging DNA by ionisation or indirectly by oxidation of components of culture media or oil [100].

7.2.7.1 Control of Light

The effect of light on zygotes and embryos therefore should not be ignored. Embryology laboratories should not be exposed to direct sunlight. Low-wavelength light energy (<500 nm) can be avoided by selecting appropriate light sources (avoiding fluorescent lighting) and/or use of filtration systems. Additionally, the exposure of gametes and embryos to light should be minimised by reducing the time they spent outside the incubator. Using a green filter when viewing and manipulating gametes and embryos under the microscope can be a practical solution. Caution is required when using hood lights and headlamps. Switching off the lights is the only way to minimise stress to the embryos.

7.2.8 Air Humidity

If the conditions in the laboratory vary between seasons or days of the week, then outcomes can be affected. This includes the humidity of the laboratory that should be set and maintained at levels below 50%. This is because contaminants such as fungi increase when humidity levels are high, with humidity levels between 40 and 60% shown to minimise fungal growth [101]. In addition, microorganism inactivation by UV radiation has been shown to be dependent upon relative air humidity [102]. The humidity in the ambient air can also cause formation of ice and frost on the stored cryopreserved samples located in vapour tanks, increasing the risk for contamination and also affecting the readability of labels and barcodes [103]. Air humidity levels should be checked and recorded on a daily basis.

7.2.9 Sound/Music Vibrations

One of the variables in the IVF laboratory that has not been extensively researched is the effect of sound and music vibrations on gamete and embryo development. The first study that conducted monitoring of early embryonic development of chicken eggs using acoustic resonance frequency analysis showed that fertile eggs decrease their resonant frequency at a certain stage of incubation [104]. A follow-up study monitoring the course of vibration parameters during early incubation of chicken eggs showed that the point of vibration alteration was correlated with the diameter of the eggs and prediction of hatching time [105]. In humans, application of a tilting embryo culture system was shown to improve embryo development to the blastocyst stage [106]. Similarly, micro-funnel culture conditions have shown improvement in embryo development and pregnancy rates [107]. The use of mechanical micro-vibrations to the culture system also showed improvement in pregnancy rates [108]. In a recent study, the effect of music as a source of mechanical vibrations was explored, and results showed that any type of music (pop, heavy metal, classical) played in the laboratory environment improved the fertilisation rates, but did not have an impact on embryo development as assessed on day 2 [109]. From the above-mentioned studies, it appears that dynamisation during culture can be beneficial in assisted reproduction; however, additional research is required.

7.2.10 Equipment Performance

The success of any IVF program relies heavily on the performance of the equipment it possesses. All equipment must operate within tolerable limits that are pre-set based on the values that are biologically optimal having in mind the instrument variability. For example, a type-K micro-probe will not be as accurate as using a Platinum Sensor PT100 for temperature monitoring because the type-K micro-probe can be affected by electromagnetic fields and lacks precision to detect differences of ±0.1 °C at 37 °C. Furthermore, newer technology equipment have built-in sensors and readings that can be reviewed on a daily basis.

An often-neglected task in the IVF laboratory is the performance of daily quality control for monitoring of equipment. To ensure that all equipment function within acceptable limits, daily readings are conducted either manually or through continuous monitoring systems. The data are either recorded in logbooks or transferred by a wireless system to the base if continuous monitoring systems are in place. The monitoring logbook should include measurement value, acceptable range and action taken if a measurement falls outside the given range, with each entry requiring a staff signature. The data are checked daily in comparison to the instrument display and weekly to verify that there are no fluctuations over time. In addition, alarm options can provide external control, where SMS messages, phone calls and alarm relays can be programmed if an instrument falls outside the specified acceptable limits.

A user's manual is required for all operational equipment alongside the appropriate validations. These validations include documentation that the equipment has been installed according to the requirements in a safe manner, along with documentation of its functionality according to specifications. Performance of the equipment must also be validated and documented by testing that equipment function within appropriate ranges and generate reproducible results. Equipment failure or underperformance can be minimised by preventative maintenance. Records for the calibration are kept together with maintenance records. Backup solutions must be in place for critical pieces of equipment such as incubators, aspiration pumps and inverted microscopes. The use of consumables and supplies should also be tightly monitored and controlled. All disposable items must be non-embryo-toxic with quality assurance certificates. Similarly to the culture media, lot numbers for plasticware need to be recorded when in use.

7.2.11 Staff Performance

The sophisticated process of ART requires coordinated teamwork and collaboration of a team of individuals with different personalities and characteristics working towards a common purpose. Like domino pieces, the success of an IVF program relies on the interdependence between the members of the team to deliver the end result. The ideal IVF laboratory will have a safe workplace with staff sufficiently trained with regular review of their performance. All staff should have training logbooks to provide records for the tasks that have demonstrated competency as assessed by senior staff.

Thereafter, competence assessments are recorded for all trained embryologists twice a year. Competency can also be obtained by the use of online quality assessment schedules such as UKNEQAS (► http://www.ukneqas.org.uk) and FertAid (► http://www.fertaid.com). Monitoring individual staff performance can be beneficial for individual embryologists, the embryology team and the results of the IVF centre. When the records show a lower key performance indicator (KPI) for a certain task, the individual can be assessed performing the task to be assessed and re-trained if this is deemed necessary. In that way, individual embryologists can improve their performance and effectiveness. It is important that this exercise is performed without criticism. In addition, members of the team can observe and learn from embryologists who perform well in certain tasks. In that way, all members of the team can entrust in each of their colleague's efficiency and professionalism in the pursuit of delivering the best treatment to patients. Ultimately, all members of the team are critical to success; therefore, even if one team member fails to proficiently complete a certain task, it can be reflected on the results of the IVF centre.

7.3 Final Summary

There are a number of variables influencing the successful outcome of an IVF cycle. The knowledge obtained over the years has led to a standardisation of processes that has allowed for the increase of embryo utilisation interwoven with a reduction in embryos transferred and superior pregnancy and live birth rates. Due to the multifactorial nature of ART, not everything falls under the control of the laboratory. Stimulation variables and patient dissimilarity in medication response can also directly affect results. However, the lack of rigorous control over variables will undoubtedly lead to failures with answers and solutions to problems not easily found. Controlling variables is therefore the key to success.

Review Questions

1. How can temperature variations be controlled during embryo culture?
2. How can temperature variations be minimised during manipulations outside the incubator?
3. What type of refrigerator is required for correct storage of culture medium?

4. What are the pros and cons of having a warm laboratory?
5. What is the optimal pH range for embryo culture?
6. How can fluctuations in pH be avoided?
7. How can the embryologist minimise changes to culture medium osmolarity?
8. What important environmental controls and tests are necessary to safeguard a constant environment of the laboratory?
9. How can traceability be achieved with regard to devices used in the laboratory?
10. What are the important components of equipment quality control?
11. What are the benefits of monitoring individual staff performance…?
    1. For the individual embryologist
    2. For the embryology team
    3. For the results of the IVF centre

Daily, Weekly, and Regular Preparations for the IVF Laboratory

Klaus E. Wiemer

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_8

Learning Objectives

- Provide an overview of how to establish standards of performance for various aspects of the embryology laboratory.
- Recognize that different aspects within the laboratory require different levels of measurements.
- Provide suggestions for daily, weekly, and regular measurements for important parameters as they pertain to different aspects of the IVF laboratory.

8.1 Introduction

In order to establish and maintain the highest standards of performance in an embryology laboratory, it is recommended that certain preparatory measures occur on a daily, weekly, and regular interval basis. Standards for variables that can impact embryonic development should be determined for each laboratory, recorded, and verified that values are acceptable. This would include taking and recording measurements of important variables such as heated surface temperatures, pH values of culture media, and liquid nitrogen levels in cryostorage tanks. In addition, standards should be established for the proper maintenance of equipment and normal ranges of variation permitted within the laboratory. These standards should be established by determining the ideal ranges of acceptable variability through empirical tests designed to optimize the laboratory environment for growing healthy embryos.

In an effort to optimize use of laboratory space, increase efficiency of workflow, and accommodate staff effectively within the laboratory, the laboratory should be designed so that different embryology procedures are performed in different areas that are designated for those particular procedures [1]. For example, the laboratory can be divided into three to four separate rooms based upon primary function, such as cryopreservation/cryostorage room, main embryology laboratory, a room for performing embryo biopsies as well as cell preparation, and a room for embryo culture dish preparation. A separate room for andrology-related procedures is a viable option if space permits. Having a separate room for semen analysis and sperm preparations is ideal since this lab space is often much busier and the potential for contamination from sperm samples is greater. The andrology laboratory also houses all the equipment used for various types of diagnostic testing, so traffic and probability of introducing potentially infectious material from a variety of sources are higher.

The main laboratory should serve as designated space where all general embryology procedures take place and would house the majority of lab equipment. With increasing use of embryo biopsy, having a room or space that is not located in the main traffic of the embryology lab is ideal. This allows a quiet space for embryo biopsy and processing cells resulting from the biopsy procedure. Embryo biopsy and cell preparation require high levels of concentration and constant communication with the witness who is helping with the cases. Less interruptions and distractions are an ideal setting and reduce the potential for errors. The media preparation room is designed specifically for refrigeration of media, preparation of culture media, the weighing of chemicals, and general laboratory preparations. In the media preparation room, having a sterile hood to prepare dishes and material for embryo culture is ideal as well. The cryopreservation/cryostorage room is utilized for gamete/embryo freezing, as well as short- or long-term cryostorage of embryos and oocytes. Having bench or hood space to house dissecting microscopes is optimal for freezing and thawing. With the different thawing protocols now used for vitrified samples, having a dissecting scope with a heated stage adjacent to a scope with a non-heated surface is ideal because thaw protocols often call for initial thawing at 37 °C with the subsequent steps being performed at room temperature.

In addition to these three to four main areas of the embryology laboratory, two other areas of high importance are the gas manifold room and HVAC room. This chapter is organized based on the daily, weekly, and regular preparations required in these different sections of the clinical embryology laboratory. Establishment of standards will be discussed as well.

8.2 Cryopreservation/Cryostorage Room

The advantage of having a separate cryopreservation room is that oocyte and/or embryo cryopreservation procedures can be performed concurrently, while general embryology procedures are performed in the main embryology laboratory. Therefore, general workflow is not interrupted by any cryopreservation procedures. This allows cryopreservation to occur without having to allow hoods designated for general embryology to cool down, for example. The cryopreservation room also provides a designated area for cryostorage tanks for short- and/or long-term cryostorage of embryos and oocytes. The cryopreservation/cryostorage room should be designed so that it contains a liquid nitrogen outlet, space for cryostorage tanks, and a laminar flow hood for performing cryopreservation-related functions such as dish preparation for vitrification and/or thawing.

As mentioned in the introduction, vitrification has become the cryopreservation method of choice. For many thawing protocols, dissecting microscopes with heated stages and ovens to house warming solutions are now required for the initial thawing step. If this is the case, then temperatures of these heated devices should be checked every day. Temperature values should be established to ensure the media is at the proper thaw temperature. For convenience purposes, the placement of incubators to house specimens for cryopreservation is becoming more commonplace. If this is the case, then incubator temperatures, gas levels, and water levels should be checked on a regular basis as well.

It is advantageous to have liquid nitrogen access in the cryopreservation lab for various reasons. Some of these reasons include the ease with which cryostorage tanks can be

refilled, liquid nitrogen can be procured for use during freezing/thawing procedures, and liquid nitrogen can easily be obtained for temporary removal of cryostorage canes from storage tanks during cryotank inventory. Having liquid nitrogen access in the freezing lab can also prove to be invaluable during emergencies as samples are trying to be saved or moved to other tanks. Having access to liquid nitrogen in the lab also reduces the risk of introducing contaminants in the lab by not having to leave the clean area to enter an often more dirty room like the tank room where liquid nitrogen is often stored.

A number of measurements should be performed in the cryopreservation/cryostorage room on a daily, weekly, and regular interval basis. The following items should be checked and recorded on a daily basis: room temperature and temperatures of any refrigerators or freezers if applicable. In addition, liquid nitrogen levels in cryotanks, local alarms on cryotanks, and visual inspection of wires and temperature probes should also be performed on a daily basis. If any frozen material on the temperature probes is observed, the probes should be thawed and cleaned. We have found that checking the cryotanks on a daily basis helps us determine the integrity of the tank and rate of liquid nitrogen evaporation. Our experience is that self-contained rolling cryotanks typically lose about 1–2 cm per day in our lab environment along with normal tank openings. We have noticed that tanks that begin to lose more than that might be on the verge of losing their integrity. For example, tanks that all of a sudden start to drop 4–5 cm per day either have a faulty lid or the seal on the tank is in danger of breaking. Samples should be moved immediately until the source of the problem is located.

On a weekly basis, cryotanks should be refilled to their established levels. On a regular basis, integrity of all alarms hooked up to the cryotanks should be tested in order to ensure that the alarm will alert all lab personnel in case of a tank failure or drop in liquid nitrogen levels below established minimums. The call-back system on the alarm should be tested on a regular basis as well.

Standards should be established for filling cryotanks. If individual rolling cryotanks are used, minimum standards for liquid nitrogen levels in cryotanks must be developed in order to ensure that all cryopreserved embryos remain submerged [1]. Based upon the average amount of liquid nitrogen used by the laboratory, a regular schedule of liquid nitrogen delivery should be established. Clinics should determine if having a backup liquid nitrogen tank is warranted. A brief summary of recommended variables that should be measured with suggested time intervals is found in Table 8.1.

Table 8.1 Schedule of measurements performed within the cryopreservation/cryostorage lab

	Variable frequency	
Daily	**Weekly**	**Regularly**
Room temps	Fill tanks	Clean alarm probes
LN_2 levels	Check alarm integrity	Test alarm
Refrig-freezer temp		
Incubators/oven		
Heated surfaces		

A variable that can affect establishment of standards and requirements within the cryopreservation/cryostorage area is the type of cryostorage tanks used for holding cryopreserved specimens. IVF clinics that prefer to have their patients' embryos and oocytes shipped out for long-term storage after some period of time will most likely find that individual cryotanks are most appropriate for this course of action. A disadvantage of having individual rolling cryotanks is the frequency with which they must be filled in order to keep the liquid nitrogen levels in the tank at the proper level. Individual cryotanks also store fewer specimens than large auto-fill cryotanks. However, these tanks on a whole are very efficient at conserving liquid nitrogen and are considerably less expensive than auto-fill systems.

Clinics that elect to hold their patients' cryopreserved specimens in long-term storage "in house" will most likely find that large auto-fill cryotanks are most appropriate. Large auto-fill tanks can hold hundreds of specimens and are equipped with sensors that will automatically fill the tank with liquid nitrogen when it is necessary. Possible disadvantages of large auto-fill cryotanks include their cost and amount of space they occupy in the laboratory. Another potential disadvantage is that maintenance and repairs can be costly. If a lab decides to use these types of cryotanks, it is important that the lab purchase a tank that is designed to open frequently so that the seal on the lid will not wear out prematurely. Many of these tanks are not designed to be open on a daily basis.

It is important to establish a policy regarding shipper tanks as well. Standards should be established to ensure that transport tanks are filled to capacity with liquid nitrogen for 2 days prior to use. In most instances, the specifications on a particular brand of shipper tanks will state the weight of a tank when it is fully charged. Once a transport tank is charged, all liquid nitrogen can be poured out of the tank, and the canes containing the specimens can be placed into the charged tank and will be kept safely for 7–10 days.

8.3 Main Lab

The advantage of having a designated area for performing general embryology procedures is that it allows increased efficiency and speed of workflow within the laboratory. The close proximity of incubators, microscopes, and heated laminar flow hoods (or isolettes) is ideal for performing all

embryology procedures at optimal speed. In addition, the main laboratory should be designed so that the highest air pressure exists in this main room [2]. The main laboratory houses the majority of equipment found in an embryology laboratory. This includes laminar flow hoods, dissecting microscopes, isolettes, anti-vibration tables, inverted light microscopes with and without micromanipulation capabilities, audiovisual equipment, and incubators. As previously mentioned in the introduction, embryo biopsy cases might be performed in a separate room or alcoves within the main embryology lab.

A number of checks should be performed in the main laboratory on a daily, weekly, and regular interval basis. On a daily basis, the surface temperatures of heated microscope stages and hood surfaces should be checked and recorded, as well as room temperature and humidity. Surface temperatures of heated hood surfaces or isolettes should be taken in places where gametes are commonly kept. Temperature of block heaters should be noted as well on a daily basis. Incubator settings that should be measured on a daily basis include temperatures and gas levels within the incubators, pH of culture media, and status of water pan if applicable. With commonly used benchtop incubators, surface temperatures in both chambers, gas flow rates, and visualization/confirmation of humidification system should be noted on a daily basis. Ensuring good seals and proper gas flow is of paramount importance with these new benchtop incubators to confirm proper pH values for the embryo culture conditions.

Also on a daily basis, one should be certain that the values of the aforementioned items are within the laboratory's established range and adjustments are made as necessary. All temperature readings should be taken with a calibrated thermometer or thermocouple to ensure accuracy. If applicable, gas levels associated with the anti-vibration tables should be checked as well. Biohazardous materials and regular trash should be removed. Daily removal of all biohazardous materials reduces the risk of transmission of blood-borne pathogens and any possible airborne pathogens arising from the biohazardous material.

An important daily practice is unpacking new plasticware at the end of the day after all embryos are properly put away into incubators. Newly unpackaged plasticware should remain on shelving inside the back of a laminar flow hood to "off-gas" for a minimum of 48–72 h prior to use for any embryology procedure. The reason for this practice is to reduce potential exposure of gametes to VOCs from freshly unwrapped plasticware [3].

The following miscellaneous tasks should be performed on a weekly basis: refill liquid dispensers, change water in incubator pans, change water in humidification flasks used for benchtop incubators, check the water level of the circulating water baths that heat the surface of laminar flow hoods as well as the water level in heated isolettes, check the level of water in the tubes that thermometers sit in within incubators, change out glassware and hood accessories, remove discarded material from incubators, dispose of filled sharps containers, and restock all disposable materials in the laboratory.

It is highly recommended to evaluate the pH of the embryo culture media at least every week if not daily. The pH of the culture media should be evaluated in order to compare it with the CO_2 level readings obtained using a gas analyzer as well as on the incubator readout. CO_2 levels of the culture incubators should then be adjusted based on the pH values obtained using a high-quality pH meter. In addition to weekly pH evaluation of culture media, it is also recommended that a pH evaluation be performed on every new lot number of culture media that is received by the laboratory [1]. Weekly evaluation of the pH of culture media serves to elucidate the true levels of gases within the incubator as well as test the pH of new media before embryos are introduced to the new lot of culture media. For benchtop incubators, pH testing should be performed several times a week to ensure the seals on the incubators are intact. Often, the only way to tell that the seal on these incubators is starting to fail is by pH testing. If applicable, O_2 levels should also be determined and adjusted if outside of the established laboratory ranges.

A number of other tasks should be performed on a regular basis within the main area of the laboratory. These tasks include confirming that the uninterrupted power source (UPS) modules are working properly, checking the alarms and call-back system on all incubators, having maintenance performed on all microscopes, cleaning of all incubators, and changing all gas lines or incubator carbon filters if applicable. Water reservoirs in isolettes should be checked and cleaned as these reservoirs can be a major source of contamination. Laboratory floors and surface areas should be cleaned on a regular basis as well. A summary of items that should be checked on a regular basis can be found in Table 8.2.

Standards should be established and applied to equipment as well as procedures performed within the main area of the embryology laboratory. A regular cleaning schedule for incubators should be established. It is recommended that a thorough incubator cleaning occur at least quarterly. Also, standards for acceptable ranges should be established for CO_2 and O_2 levels in incubators based upon values obtained

Table 8.2 Schedule of parameters measured within the main IVF lab including embryo biopsy alcove

	Variable frequency	
Daily	**Weekly**	**Regularly**
Room temp and humidity	pH	pH new media lots
Hood surface temps	Refill dispensaries	Test UPS
Stage temps	Change water pans	Test alarms
Block heaters	Circulating water baths	Water in isolettes
Incubators	Isolettes	Clean incubators
pH		

from either a gas analyzer or preferably from obtaining actual pH values of culture media. These ranges should be based upon the laboratory's experience as well as the optimum pH level recommended by culture media manufacturers.

Protocols should be established for acceptable temperature ranges for all heated work surfaces, microscope stage warmers, tube warmers, ovens, and within all incubators [2]. It is important to check the temperatures of any surface that the culture dishes will come into contact with during Day 0–Day 6 in order to ensure that the embryos are not exposed to temperatures outside of the optimal range for embryonic development. Ranges of temperatures for each piece of laboratory equipment should be established based upon the actual temperature values obtained using a very sensitive temperature measurement device such as a thermocouple. The thermocouple probe should be placed into micro droplets for oocyte and embryo culture at various time intervals that mirror the time intervals that oocytes and embryos are kept in contact with those particular surfaces under normal conditions during embryology procedures. For benchtop incubators, a fine-wire thermocouple probe should be used to confirm temperature within micro droplets of culture dishes. This integral aspect of quality assurance helps to ensure that the embryos are never exposed to temperatures that could induce spindle defects and poor developmental rates or have other deleterious effects.

8.4 Embryo Biopsy Room or Alcove

As previously mentioned, the incidence of embryo biopsy at the blastocyst stage has increased dramatically in recent years. As a result of these changes, providing a more conducive environment for performing these procedures has become increasingly important. The reason for this is that embryo biopsy requires the use of inverted microscopy equipped with cameras and monitors situated in a quiet/non-distracting setting. A quiet setting is preferable because there needs to be constant communication between the person performing the biopsies and the person witnessing the procedures. The witness is responsible for confirming that embryos are being placed in their appropriate drops and that subsequent tissue samples are loaded in their properly labeled tubes for processing. The ability to communicate in a non-distracting environment with minimal to no distractions will likely reduce the potential for errors.

As a result of these increasing needs for specialized microscopy skills and corresponding identification of material, more laboratories are constructing either separate rooms for embryo biopsy or alcoves within the main lab to create quiet spaces to perform these delicate tasks. These rooms require the use of same building materials as found in the main embryology lab as well as clean air in a positive pressure room. The general equipment needs for these rooms usually consist of the following: laminar flow hood with a heated surface, gassing capabilities to maintain dishes outside the incubator, and a dissecting microscope. In addition, a good inverted light microscope with micromanipulators equipped with a camera and monitors is required. The need for a good anti-vibration table is of paramount importance, since the removal of tissue requires a very steady platform. Having an incubator or two for holding patient's dishes that are undergoing biopsy is ideal as well for convenience.

Tasks that should be performed on a daily basis include monitoring of temperature of the room, temperatures of headed surfaces including the hood and microscope stage, as well as gas levels for the anti-vibration table if applicable. If the lab is equipped with either benchtop or box incubators, the aforementioned QC measures should be taken on a daily basis. The laser used for embryo biopsy should be calibrated prior to use each day. Since this section of the lab contains many of the same equipment as found in the main embryology lab, the same protocols and procedures should be performed here in order to ensure that all biopsy procedures are performed in an optimum manner that does not reduce embryo viability and potential.

8.5 Media Preparation Room

The media preparation room provides a designated clean area for preparation of media solutions and weighing out chemicals used in preparing various solutions. Having a separate area for these procedures also ensures that embryos are kept away from any potentially hazardous chemicals. For those labs that do not make any media solutions, a media preparation lab provides a clean environment for preparing dishes for embryo culture, vitrification, and thawing. Some typical items that could be housed within the media preparation room include a laminar flow hood in which media or dishes can be prepared, a sterilization oven for heat sterilizing glassware, storage space for glassware, and a refrigerator/freezer used to store culture media and other items at proper temperatures. Other items commonly found in this room include a pH meter, an osmometer, and supplies. Ideally, the media preparation lab should be in a centralized portion of the lab. First aid items and an eyewash station are best located here as well. In many laboratories, media preparation rooms also house a purified water system. The media preparation room is also a good location to house all inventory records of materials used in the lab, including culture media, freezing/thawing solutions, and plasticware.

A number of tasks should be performed in the media preparation room on a daily, weekly, and regular interval basis. On a daily basis, it is recommended to check the room temperature, check the performance of the clean water system if applicable, and check the temperature of the refrigerator containing media as well as the freezer. Electronic thermometers that display the high and low range of temperatures inside the refrigerator and freezer should be used. This will ascertain that temperatures were never outside the established ranges in the refrigerator and freezer.

On a weekly basis, the eyewash station should be tested. On a regular interval basis, the water system parameters should be checked, including levels of silica and chlorine [3].

Table 8.3 Measurement of parameters within the media preparation lab

	Variable frequency	
Daily	**Weekly**	**Regularly**
Room temp	Eye wash	Media
Water system	Media inventory	Chemicals
Refrig-freezer temp	Test water system	QC sterilization oven

The water system should be cleaned according to the manufacturer's recommendations. If the lab uses a heat sterilization oven to sterilize its glassware, a contamination test should be run on a regular basis to ensure that the heat sterilization oven is working properly.

Standards that should be put into place in the media preparation room include establishment of maximum and minimum acceptable temperature ranges for the refrigerator/freezer. A diary of media preparations is recommended that should include staff that prepared and/or aliquoted the media, the date media were prepared, and expiration dates for both aliquoted and prepared media with protein. A diary or record keeping system of staff that prepared culture dishes should be kept as well. An inventory system for all chemicals used as well as a system of safe disposal of all expired chemicals should be created. A list of suggested variables that should be measured in a media preparation lab is found in Table 8.3.

8.6 Gas Room

Gas or manifold rooms, as they are commonly referred to, are usually located in a different area away from the lab. This allows the delivery of gases and liquid nitrogen by the delivery company to occur without interrupting workflow or risk of contamination of the lab. Gases and liquid nitrogen are then plumbed to the various parts of the lab.

Gas and liquid nitrogen levels should be noted and recorded on a daily basis. Based upon daily consumptions, a delivery schedule should then be put into place. On a weekly basis, delivery of liquid nitrogen and gas tanks should be confirmed as well. On regular intervals, the alarms and callback system should be checked, and the gas manifold system should be checked for gas leaks.

The standards that must be established in the gas manifold room include the minimum acceptable levels of gas and liquid nitrogen, a system to record lot numbers of gas tanks in use as well as lot numbers of tanks not yet in use and the number of tanks held in reserve at all times. Some clinics may find that a gas manifold system is safer for their laboratory as opposed to individual tanks. The manifold system provides the laboratory with the opportunity to establish settings in which the manifold system will switch the intake to a backup tank when a certain gas tank is depleted to an established minimum level. An automatic safety system serves to ensure that the incubators will always receive gas from a properly filled gas tank. In addition, standards for testing should be established to confirm that tanks will switch within the manifold system when tank pressures fall to a preset level. Today, many state regulations require that carbon dioxide levels are measured. If this is the case, then labs should have carbon dioxide detectors in their gas/manifold room and should establish testing intervals.

8.7 HVAC Room

The HVAC system is an integral component of an embryology laboratory. The HVAC system filters out the vast majority of airborne pollutants and volatile organic compounds that could enter the laboratory [3]. A well-designed clean air system is now considered an essential part of an embryology laboratory [4–6]. Most IVF centers that have been built recently use two types of filter beds in addition to HEPA filters. To physically scrub the air of volatile organic compounds, beds of carbon filters in combination with beds of potassium permanganate are often used. To remove particulate matter, a series of prefilters as well as HEPA filtration are used. On a weekly basis, pressure gradients across filter beds should be checked, and an inspection of motors and all moving parts be should be performed as well.

A number of standards must be established within the HVAC room to ensure optimum performance. A schedule for changing air filters must be established. This schedule will vary by region and depends heavily on local outside air quality. In regions with higher quality outside air, the carbon/permanganate filters can be changed approximately every 6–8 months based upon testing of the activated carbon and permanganate substrate. In areas with poor outside air quality, it is advisable to change the carbon/permanganate filters more often. It is also advisable to perform an annual check of air quality and pressurization in individual rooms within the lab. Finally, preventative maintenance should be performed on each individual component of the HVAC system based on the manufacturer's recommendation. The entire system should have preventative maintenance performed semi-annually.

8.8 Conclusion

In conclusion, daily, weekly, and regular preparations as well as establishment of standards are essential for the maintenance of ideal conditions within the embryology laboratory. Establishment of these standards should facilitate the elimination of internal laboratory factors affecting embryo quality. In other words, a rigorous assessment of internal variables allows the laboratory to focus on potential negative influences originating from outside of the laboratory. This allows the embryologist to focus on the biological variability inherent to the patients being treated at the time.

Review Questions

1. How often should surface temperatures be measured for heated surfaces in the laboratory?
2. Describe how regular measurements between benchtop incubators and big box incubators are different?
3. Why is measurement of liquid nitrogen tanks on a regular basis an important task?
4. How often should pH measurements be taken?
5. How often should chemical beds in an HVAC system be changed?

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_9

Learning Objectives

- Understand the importance of having a well-designed laboratory space.
- Understand the importance of incubator, type, and number present within the lab.
- Review pH values and frequency of testing based upon patient volume and incubator type.
- Review the differences between workstations and isolettes.
- Review the importance of video imaging equipment in an IVF lab.
- Review the importance of uninterrupted power sources.
- Review the importance and role of all the miscellaneous equipment found within an IVF lab.
- Discuss the types, uses, precautions, and limitations associated with most plasticware found in today's lab.

Prior to selecting the type and placement of any major equipment within an IVF laboratory, the space allotted for the laboratory within the clinic must be examined thoroughly and planned with forethought. The expected patient volume, type and complexity of embryology procedures offered, and expected number of embryologists working within the space should be taken into account prior to planning the physical layout of the lab. Creating task-specific rooms within the main embryology laboratory can reduce congestion. It is important to have good workflow, allowing multiple people to work simultaneously on different procedures, safely and efficiently. For example, anticipation of traffic flow reduces congestion around incubators and microscopes. In addition, the location of air vents should also be anticipated. Airflow from air-handling systems can have a large impact on the performance of many heated pieces of equipment such as incubators, heated stages on microscopes, and heated surfaces of laminar flow hoods. The location of airflow vents is especially important in laboratories that will be using or are using benchtop incubators. If possible, a layout of equipment prior to placing air exhaust vents can help reduce potentially deleterious airflow around microscopes and incubators. The lab design should also include potential space to add additional incubators and other necessary equipment, as required.

9.1 Equipment

9.1.1 Microscopes

The following types of microscopes are essential to the operation of every IVF lab: a dissecting microscope, an upright light microscope, and an inverted microscope equipped with micromanipulators and a laser. Ideally, the dissecting microscopes are located in either a modified laminar flow hood for optimal temperature and pH control or a heated isolette with proper gas and temperature control. The dissecting microscope is used for the majority of all oocyte and embryo manipulations. With PGS and PGD becoming routine procedures performed on a daily basis in the laboratory, it is probably prudent to have multiple dissecting microscopes available. An upright microscope, which is mainly used for semen analysis and sperm preparation, can be located on a workbench outside the laminar flow hood. The inverted microscope is used for all oocyte, zygote, and embryo evaluation as well as micromanipulation procedures of oocytes and embryos. These microscopes should include differential interference contrast or modulation contrast systems and a temperature-controlled stage [1, 2]. As previously stated, an important consideration for all microscopes is the location in the laboratory relative to ventilation air ducts and air purification devices. Surface temperatures on the heated surfaces will fluctuate dramatically if cool air is allowed to vent directly onto them. It is also recommended to place micromanipulation equipment against an interior wall, well away from elevators and heavily traveled areas that may cause vibration. If possible, the use of an antivibration table for micromanipulation procedures is advised. Some laboratories perform micromanipulation procedures with their equipment on a bench top, but unexpected vibration may cause a higher degeneration rate during intracytoplasmic sperm injection (ICSI) or reduce implantation potential of embryos following biopsy.

9.1.2 Incubators

The incubator is perhaps the most important piece of equipment in the laboratory, and the selection of the style and type requires forethought as far as the initial design of the lab as a whole. Management of patient volume and workflow is crucial to optimize the recovery and stabilization of the temperature, gas concentration, and humidity [2–4]. The primary incubator still in use in most IVF laboratories is the box-type CO_2 incubator, both large and small sizes. However, benchtop incubators have started to become more popular in choice. Since it has become standard practice to culture in a reduced oxygen environment of 5% O_2, these models are available in many forms from various manufacturers. These CO_2 incubators use nitrogen gas to reduce the oxygen level. There are also multiple manufacturers offering compact benchtop incubators that use a heated chamber base plate and lid, thereby providing a more consistent thermal environment for embryo culture. The gas source is premixed and customizable by the user. The unique design of these incubators allows rapid equilibration and stabilization of temperature and pH due to the compact chamber, unlike the large upright chambers of traditional water- and air-jacketed incubators. Recently, time-lapse incubators (Embryoscope®, Esco Miri®, Geri®) are gaining in popularity despite their high price tag. There have been a few publications that have suggested that by monitoring embryo morphokinetics, it may be possible to select embryos that may be less likely to carry chromosomal abnormalities, thus improving clinical outcomes [5].

If designing a new lab, it is ideal to select the type of incubators that will be used in the lab early in the design process in order to place the appropriate gas lines in the proper location for present and future use. Depending on the culture system, a combination of incubator styles may be a practical choice. It is important when designing a new lab to be sure to include gas outlets for future incubators as well.

A gas analyzer is used to monitor the actual gas content within an incubator, and these measurements should be taken as part of the daily quality control program. The measured value is compared to the digital value displayed for each individual gas, and adjustments are made as required. A pH meter is used in conjunction with the gas analyzer to determine the appropriate settings for each incubator. The commercially prepared media that are available from most manufacturers generally measure at a pH of 7.2–7.4 post-equilibration. Each incubator should be checked on a regular basis with a control lot of medium to confirm that the pH of medium cultured within that incubator measures within the laboratory's established acceptable range. It is suggested that each new lot of bicarbonate-buffered medium received be pH checked prior to use. These pH values should be the main determinant of the CO_2 set point of each incubator. pH values should be taken as well when the water humidification systems in benchtop incubators are replaced to ensure the systems are functioning correctly.

9.1.3 Workstations

It is recommended that all IVF procedures are performed within a controlled environment. One method used to accomplish this is to use modified laminar flow hoods. These workstations provide protection against particulate and microbiological contamination while also providing a temperature-regulated surface for embryo/oocyte manipulation. Typically, these hoods are fitted with a heated surface that uses either a heated circulating water bath or electrical circuitry. They also are fitted with gassing and humidification devices that enable the embryologist to maintain the pH of culture media while dishes are outside of the incubator. An additional benefit of these systems is they allow the embryologist to sit at the workstation and work in an unencumbered environment. However, these hoods require calibration of the heated surfaces and a source of gas for the gassing devices.

Some laboratories choose to use a modified isolette that provides temperature and pH regulation within a closed system. These isolettes are modified in such a manner to allow a dissecting microscope to be placed within the isolette. The advantage of the systems is that the chamber is completely enclosed so there is less chance of pH drift and temperature fluctuation. These systems also allow embryologists to work without the use of HEPES-buffered media since the chambers are typically flooded with 5–7% CO_2 gas. Isolettes are also available in portable models and are useful when the procedure room is not adjacent to the laboratory. The main disadvantage of these systems is that they are cumbersome to use, can be quite restrictive as far as hand movements, and require the embryologist to stand throughout the tasks at hand. The heated surfaces should be checked as well, as temperature fluctuations have been noticed in these isolettes.

9.1.4 Video Equipment

Due to the nature of this field, it is advisable to have video monitoring equipment at each IVF workstation. In this way, a witness can watch procedures as required and confirm patient identity as necessary. This establishes a visual chain of custody for such procedures as insemination of oocytes, change of oocytes/embryos to new dishes, and embryo biopsy. It is recommended that visual conformation of all steps associated with embryo biopsy and the processing of the cells be performed.

If this equipment is also included in the patient procedure room, the patient can be included in the identification procedure for retrievals and transfers. It is also customary to provide each patient with an embryo photo at the time of embryo replacement. A camera and/or digital video recorder (DVR) may also be used to record other procedures in the laboratory.

9.1.5 Cryopreservation and Storage

Cryopreservation technology in human IVF and the trend toward extended culture have changed the emphasis from cryopreservation of early-stage embryos using controlled-rate freezing to vitrification of all stages of oocytes and embryos. The equipment needed for most vitrification protocols is minimal but varies depending on the protocol used. In order to ensure clear and legible writing on cryostraws and devices, a label maker should be used. Marking pens eventually wear or rub off, jeopardizing the correct identification of patient specimens. This is a huge risk, and the cost of a labeling machine is less compared to the cost involved if a sample is misidentified! Other commonly used supplies for cryopreservation include a heat sealer for cryostraws, plastic dewar for liquid nitrogen, protective gloves, and a thermocouple thermometer. It is recommended that a small warming oven be placed in close proximity of the dissecting microscope used for thawing of vitrified samples to reduce the possibility of the thaw solutions cooling prematurely.

There are many variables to take into consideration when choosing cryostorage tanks including patient volume and whether the clinic plans to offer short- or long-term storage for their patients. If long-term storage is planned, an investment should be made in large tanks with autofill capability. For smaller programs, individual tanks on roller bases can be used but should be monitored individually for temperature or nitrogen level by alarms. It is also a good idea to have a vapor tank on hand to transport specimens. The vapor tank can also be used for certain types of embryo and oocyte vitrification procedures. All equipment housing gametes or

embryos should be monitored 24/7 by an alarm system, which automatically calls out in the event of an equipment malfunction.

9.1.6 Power Related

An uninterrupted power source (UPS) is traditionally used as a short-term power supply in the event of a power failure. They are most beneficial in protecting sensitive electronic equipment from power fluctuations, brownouts, and line noise. A well-planned laboratory will have all incubators and tissue-freezing equipment running through UPS power. A UPS is very effective at "cleaning up" electricity and, in doing so, extends the lifespan of electronics. IVF laboratories should have backup electrical generators that provide electricity in the event of a power outage. UPS batteries should be checked annually and replaced accordingly. Generator output should be determined after the total amount of equipment that needs to be functional when power outages have been established. Whenever possible, equipment needs should be determined during the construction phase of the lab so that the equipment can be wired and placed on emergency breakers. This way, when the generators turn on, the essential equipment will be on emergency power. In addition, the UPS systems will hold the incubators and other crucial equipment until emergency power is available. The generator should be tested on a monthly basis, and at least once a year, the lab should be run exclusively on emergency power.

9.1.7 Miscellaneous Equipment

It is generally accepted today that contaminant-free air is an integral part of an IVF laboratory in order to consistently produce high-quality embryos. Therefore, an HVAC system is an essential part of today's IVF center. HVAC systems used in IVF laboratories remove volatile organic compounds (VOCs) and chemical air contaminants (CACs) as well as particulate matter. If an HVAC system is not an option, mobile air purification devices (including carbon and HEPA filters) are available. Some of CO_2 units available today remove VOCs, CACs, odors, mold, and particulates.

There are three common pieces of equipment used for oocyte retrieval in most IVF clinics: a dry bath incubator, an aspiration pump, and a warming oven. Dry bath incubators provide uniform dry heating for test tubes. Interchangeable modular heating blocks provide the flexibility of accommodating various test tube sizes and quantities. A dry bath is useful for many purposes, and it is practical to have multiple dry baths in different areas of the lab. They can be used to warm media and oil used for micromanipulation procedures, as well as test tubes used during oocyte retrievals. A forced-air incubator with microprocessor control is ideal to warm media, test tubes, and modular warming blocks used during oocyte retrievals and embryo transfers. An aspiration pump with foot control is used with either a single- or double-lumen needle to puncture follicles and collect oocytes during the oocyte retrieval. The pump should ideally provide smooth, low-volume suction at a predetermined negative pressure. This pump may also be used in other procedures such as endometrial sampling or cyst aspiration.

A high-speed multipurpose centrifuge is used during semen processing for IVF, IUI, or diagnostic procedures. A high-end centrifuge with an internal microprocessor simplifies operation, ensures repeatable results for continued success, and alerts operators when periodic maintenance is due. Do not place the centrifuge in an area where vibration would cause problems for other pieces of equipment.

Oocytes and early embryos (particularly in the pre-compacted stage) are extremely sensitive to their environment and fluctuations in temperature (among other factors) may alter their cellular physiology and compromise viability [2]. Therefore, a thermocouple thermometer is essential for checking surface temperatures of microscope stages and heated work surfaces. This instrument is important for initial calibration and daily quality control (QC). It is also handy for checking temperatures of media that are warmed to certain temperatures prior to use and the temperature in microdrops of culture media under oil when calibrating equipment or performing QC procedures. A mercury or spirit-filled thermometer is necessary to monitor the temperature of each incubator, dry bath, warming oven, water bath, refrigerator, and freezer. Digital thermometers are also available and can be used for some of these items. A certified thermometer is required for annual calibration of all thermometers that are not sent to outside facilities for calibration.

The size and type of refrigerator and freezer needed should be based upon patient volume, kind of materials stored, and type of tests/procedures offered. However, refrigerators that can keep culture media and other important materials within their ranges of temperature for storage should be selected. The storage temperature range recommended for most commercial media is 2–8 °C. In many instances, a refrigerator for only culture media and related products is warranted. The type of freezer selected should be based on type of materials to be stored, sensitivity to temperature changes, and anticipated length of storage. Given the increasing popularity of PGD and PGS and the need to store particularly sensitive tissue specimens, a specialized lab freezer may be a practical investment.

The following pieces of equipment may not be necessary but can be useful. A water purification system is convenient as a supplier of unlimited ultrapure water for incubator humidification pans. It is a significant investment and may not be necessary for most IVF programs. An osmometer is used to measure the osmolality of any given solution. The osmolality of commercially prepared media generally falls between 260 and 290. Osmolality is not a commonly performed test in most labs; however, some of the proficiency testing services include this as a test for culture media. An analytical balance might be useful to weigh out chemicals used for making media for various procedures.

9.2 Disposable Supplies

9.2.1 Plasticware

Disposable plasticware (Petri dishes, culture/centrifuge tubes, flasks, serological pipettes) is utilized extensively throughout the IVF laboratory for everything from oocyte/embryo culture to storage of various solutions. Too often, when designing a new laboratory, inadequate space is allotted for storage of plasticware and other disposable supplies. It is beneficial to have a sizeable storage room adjacent to the lab. When supplies are received, they should be removed from any brown cardboard packaging. Brown cardboard is frowned upon in most any hospital/medical storage areas due to its "dirty" connotation. Ideally, the individual packages of plasticware are slightly opened to begin the off-gassing process in the storage area. The amount of each item to stock is a function of the budget, the number of patients cycling, and the amount of storage space available. If possible, it is practical to purchase multiple boxes of the same lot number as it will save time and money as far as the QC required for each new item.

Each lab should develop an inventory database in order to ensure an adequate supply of all necessary materials are on hand and to create a rotational system where older stock is used first. As new lots are received, they are logged into the database with the date of receipt, specific lot number, product expiration date (if applicable), and testing status. As each new lot is put into use, the start date is also logged into the database. Used in this manner, the database may be a useful tool if a negative trend in the lab is noticed, such as poor embryo development.

There are many products manufactured specifically for IVF that are marketed as "tested," meaning that they have passed some sort of bioassay. However, the assays themselves and their criteria for passing should be reviewed. They may not meet the guidelines established in a particular laboratory as acceptable for use. In addition, these same "pre-tested" materials may become toxic if stored or shipped in suboptimal conditions [3].

Most companies and IVF laboratories use either the mouse embryo assay or the 24-h sperm survival assay (or a combination of the two) to test media and lab disposables. While the two-cell mouse assay used to be the standard, it has become evident that the one-cell assay is much more sensitive in detecting a problem [6, 7]. The strain of mouse used can also impact the test sensitivity. Other factors that can affect the test include the presence of amino acids and the concentration of protein in the culture medium. Both are able to chelate toxins and possibly ameliorate their effect [8].

An important aspect concerning plasticware is that it should be removed from its packaging to allow for the off-gassing of VOCs for at least 24 h and preferably longer, prior to use. VOCs such as styrene and toluene are present in Petri dishes [9] for a period of time after removing from packaging. These compounds are highly soluble in oil and can affect embryo development. The levels in any incubator are directly proportional to the number of dishes currently housed in the incubator [10]. In the case of certain Petri dishes, tubes, and flasks, there also may be residues from ethylene oxides used in the sterilization process [11]. In addition to off-gassing, rinsing of dishes or material used to store products such as media or protein for embryo culture is recommended to remove debris and contaminants (mostly from the manufacturing process). Disposable syringes used for embryo transfer may benefit from being "leached" in culture medium for a short time prior to use.

Plasticware for embryo culture is available from many large manufacturers (BD Falcon™, Nunc™, and Corning™) and more recently from some specialty companies (LifeGlobal and Vitrolife) and is a matter of personal choice based on the type of culture system the laboratory director elects to use. The majority of oocyte and embryo culture systems currently in use are oil and microdroplet systems. Many types of dishes or multiwell plates can be used for this type of culture system. Plasticware can be classified into categories based upon function and purpose. For example, plasticware used for oocyte identification tends to have a larger surface area in order to expedite the identification of the cumulus-oocyte masses. These dishes range in size from 60 to 100 mm in diameter.

Dishes for oocyte culture tend to be approximately 60 mm in size. This size dish allows for larger drops to accommodate the cumulus-oocyte masses prior to and after insemination using either conventional means or ICSI. A 60 mm dish can easily accommodate most, if not all, of a patient's oocytes. The main issue to consider when selecting a dish manufacturer for microdroplet culture is how the droplet shape will present itself. Many times, the drops will flatten out with time. This is mainly determined by the presence or absence of an electrical charge on the dish. The type of oil used also may have an effect on droplet integrity.

Dishes for embryo culture tend to be smaller and range in size from 35 to 60 mm. Multiwell and microdrop dishes are used for embryo culture as well and there are many new designs available.

9.2.2 Oocyte Retrieval Needles

The type (single or double lumen) and size (16 g or 17 g) of oocyte retrieval needles in use today are a matter of choice and that decision will probably be made after consulting with the physician. All work very well, and the incidence of damage to oocytes caused by needles is remote when properly used. The pressure used to evacuate the follicles is critical, and damage to the cumulus-oocyte complex is more likely to occur with increased pressure.

9.2.3 Miscellaneous Disposables

One of the most important decisions to be made as far as disposables is what tool will be used for oocyte and embryo manipulations. Pulled glass pipettes were very popular for a

long time. If the physician is able to sanitize and sterilize them on-site, they are an extremely cost-effective tool; however, their preparation is labor intensive and has its own cost as far as the ultrapure water required for preparation. They can be purchased pre-prepped and sterilized. Their one drawback is that there is a rather steep learning curve as far as pulling the size desired for the procedure the physician is performing.

There are many other tools offered on the market today (Stripper® Tips, Flexipets®, EZ-Tips®), but they also bear a large price tag. The use of a mix of materials may be a wise choice. Other materials required for a lab to run efficiently are items such as catheters for embryo replacement, micropipets for ICSI and embryo biopsy, serological pipettes, filters for solutions, and supplies for cryopreservation such as canes and goblets. The choice of which of these materials are used is very dependent on how the lab director manages the lab, the caseload, the number of staff available to perform the procedures, as well as budget.

9

9.3 Conclusion

This chapter is an overview of the essential materials required to set up a clinical human IVF laboratory. If a new lab is being built, it very important to select the major pieces of equipment at the outset of the design phase so that the floor plan can accommodate them in an efficient and well-thought-out manner. This will also help with designing casework as well as budgetary requirements. The type of equipment selected should be a process that involves both the physician and the laboratory director so that the center can maximize usage of the equipment and space.

The selection of disposables is almost an arbitrary selection that should be based upon the needs of the director and staff. An efficient inventory system and QC program will ensure that proper quantity and quality of materials are on hand at all times.

Review Questions

1. What impact can airflow have on heated surfaces?
2. What is the most important piece of equipment in an IVF lab?
3. How often should pH measurements be taken?
4. What are some of the advantages and disadvantages of workstations as compared to isolettes?
5. Why is it important to have video equipment in today's IVF lab?
6. What role(s) do uninterrupted power sources serve in an IVF lab?
7. How should plasticware in the lab be inventoried and managed in the lab?

CO_2 and Low-O_2 Incubators

Marius Meintjes

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_10

Learning Objectives

- To review and to compare the physical characteristics of traditional and second- and third-generation incubators for the IVF laboratory
- To assess benefits of low-O_2 concentration incubators relative to "traditional" CO_2 incubators
- To evaluate the need for different embryology laboratories for certain types of incubators to best serve their functions
- To review how to perform maintenance on the incubators and what quality control measurements are important

Embryo incubators can be considered the heart of any in vitro fertilization (IVF) laboratory. Understanding the strengths and weaknesses of our incubators is invaluable as a tool and essential to optimize clinical IVF outcomes. Whether we consider using our existing incubators to their full potential or trying to decide if we have ample incubators for our current needs, it is imperative to have current knowledge of what is available in the marketplace and to make some sense from the myriad of specifications and claims on the various product brochures. When we are fortunate to consider the purchase of a new incubator or, even more so, when constructing a new IVF laboratory facility, it is critical to review potential costly infrastructure demands, depending on the type of incubator under consideration. The historical standard is the conventional thermoconductivity (TC) sensor, water-jacketed CO_2-only incubators. With some level of blastocyst culture becoming an industry standard and more publications in favor of reduced-O_2 culture, reduced-O_2 incubators with their requirements for premix or N_2 infrastructure should be considered. With second- and third-generation top-load benchtop incubators now available from multiple vendors, we are challenged with a paradigm shift away from larger conventional incubators. Should we choose to go this route, the laboratory design must be able to accommodate altered floor space configurations, additional bench space, dedicated premix or N_2 gas supply lines, and, in some cases, supply gas pressures higher than those we are accustomed to. Knowing that more than one sound approach to IVF can yield excellent results, the goal is not to recommend specific products or solutions but rather to suggest principles and general guidelines useful to everyday decision-making.

10.1 Do We Need Low O_2?

The embryos of various mammalian species, including the human, are not exposed to O_2 concentrations in excess of 8% in vivo [1–3]. Not unexpectedly, numerous studies in animals have consistently demonstrated that embryo cultures in low-O_2 concentrations markedly improve in vitro embryo development and subsequent pregnancy outcomes when compared with similar cultures in atmospheric O_2 concentrations [4–8]. However, when culturing human embryos in lower-O_2 concentrations, the expected improvement in measured laboratory parameters [9, 10] or clinical outcomes [11] is frequently not observed. The human studies that found no benefit in early clinical outcomes with a lowered-O_2 tension in the incubators were mostly associated with embryo transfers on day 2 or on day 3 [10]. When transferring blastocysts and, specifically, when observing live births, a clear beneficial effect of lowered-O_2 embryo culture is consistently observed [12] with an increase in live-birth rate of almost 15% [13]. Stated in another way, the embryos of only seven patients have to be cultured in a reduced-O_2 culture environment to result in one additional live birth.

Numerous animal studies have found that even a brief exposure of pronuclear or cleavage-stage embryos to atmospheric O_2 can be detrimental even though it may only be manifested at the morula or blastocyst stage [14, 15]. It becomes apparent that even embryos transferred on day 2–3 might benefit from culture in reduced O_2. Selective later-stage reduced-O_2 culture may be an ill-advised approach, since the damaging effects of atmospheric O_2 may already be present in early embryos but only manifested at later stages of development and expressed as altered metabolism or gene expression [16] with reduced viability. Furthermore, low-O_2 culture appears to improve the frequently observed skewed live-birth sex ratio (more boys than girls) when culturing blastocysts [17]. Available live-birth data clearly suggest that human embryos should be cultured in a low-O_2 environment through all in vitro stages of development to ensure the highest live-birth rate and the most appropriate gene expression. Using modular chambers inside existing conventional CO_2-only incubators provides one way to culture embryos in a low-O_2 environment. With the clear clinical indications for low-O_2 culture, only incubators capable of reducing the O_2 concentration will be reviewed in this chapter.

10.2 Benchtop (Top-Load) Incubators

It was reported that the implantation rate was increased from 10% to 14% and the pregnancy rate from 19% to 32% when culturing human embryos in MINC (Cook IVF) incubators in an atmosphere of 6% CO_2, 5% O_2, and 89% N_2 instead of in standard water-jacketed incubators in an atmosphere of 5% CO_2 in air [18]. It is likely that the beneficial effect seen in this study was due to the faster recovery rate demonstrated by the MINC incubators rather than by the lowered O_2 concentration or the higher CO_2 concentration. The benchtop incubator design allows for the direct transfer of heat through contact surfaces to the embryo culture dish unlike the indirect convective transfer of heat through surrounding air in a conventional incubator [19]. This helps to explain why the temperature recovered within 5 min in an MINC incubator compared with roughly 30 min for a standard, water-jacketed incubator after a single door opening [20]. With premixed gases immediately purging the microchambers of the MINC and Planer BT37 incubators, or the constant recirculation of custom-mixed gases through the microchambers of the

Table 10.1 A comparison of some features of common top-load benchtop incubators

Benchtop incubator	Gas supply	Humidity control	List price	Capacity (patient units)	Digital recording	Alarms
Cook MINC	Premixed	Yes	$13,500	2 × 4	+	+
Planer BT37	Premixed	Yes	$11,900	2 × 4	+	+
FIV-6	Premixed	Yes	$4600	1 × 2, 1 × 4	–	–
K-Systems G-185	Built-in gas mixer	No	$32,000	10 × 2	+	+

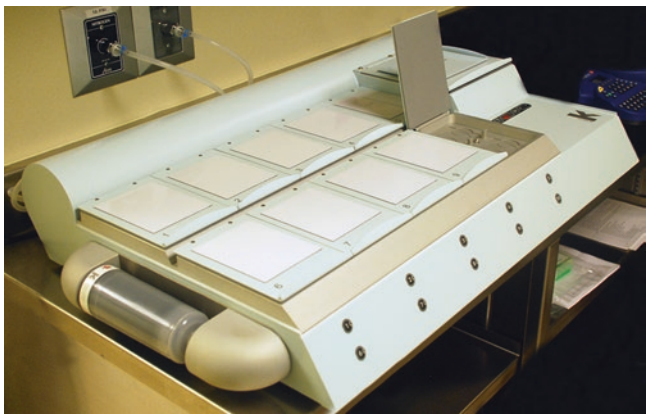

Fig. 10.1 An example of a benchtop, top-load incubator, allowing for direct heat transfer to culture dishes from all sides, fast gas-phase recovery, and in-line N_2 and CO_2 filtration

K-Systems G-185 (Table 10.1) incubator, it is understandable that the targeted O_2 and CO_2 concentrations are reached much faster in benchtop incubators. The smaller footprint size of benchtop incubators and patient-specific chambers allows for use in confined spaces with minimal disturbance of the culture environment when accessing multiple culture dishes (Fig. 10.1). The minute amounts of gas needed to stabilize a benchtop microchamber and the relative lack of moving parts result in significant savings in maintenance and gas supply, estimated to be in excess of $1000 per incubator per year. With a single gas source now lasting longer, the gas supply becomes a lesser source of variation over time. Benchtop incubators are very easy to clean and maintain and are less prone to fungal and bacterial contamination compared with bulky conventional incubators with multiple moving parts, exposed sensors, and abundant internal insulation material.

Benchtop incubators do pose significant quality control and quality management challenges, unique to their size and design. In the event of a sustained power failure or unexpected loss of gas supply, limited opportunities exist to redeem patient material, even with a timely alarm signal. Unlike conventional water-jacketed incubators that gradually lose temperature (~1 °C/h) and gas content over time, the destabilizing effect of an untoward event in a microchamber of a benchtop incubator is immediate. The BT37 benchtop incubator has a standard 2-h battery backup capability, reducing some risk in the event of a power failure. Periodic temperature, gas concentration, and pH checks are more difficult in benchtop incubators due to the small chamber size and relative inaccessibility of the microchambers. The temperature can be verified without much trouble by feeding an appropriate K-type wire thermocouple into the chamber. The Planer BT37 is equipped with specific thermocouple measuring ports in the lid and the chamber to assist with temperature verification efforts. Gas supply quality control is less relevant in models using a premix gas (MINC and Planer BT37). Once the purity and accuracy of the source gas has been verified, no need should exist to continuously test the gas supply. However, periodic CO_2 and O_2 concentration measurements are essential for the K-Systems G-185 to verify the consistency of the built-in gas mixer. The G-185 is equipped with a customized sampling lid and sample ports, which allow for convenient measurement of CO_2 and O_2 gas concentrations. Conventional CO_2 and O_2 fyrite solutions are not usable in benchtop incubators, since the sample size required for a measurement is larger than the capacity of the incubation chamber. Capnometers and in-line continuous-read CO_2 and O_2 sensors have been proposed as more expensive alternatives. pH measurements of culture media in benchtop incubators are more challenging. The pH can be measured in situ with a micro-pH probe through the sampling lid of the G-185, or, alternatively, an immediate on-site blood-gas analysis and pH reading can be obtained.

The MINC, FIV6, and Planer BT37 incubators use premixed gas only, which makes it difficult to incorporate these incubators into existing laboratories without previously installed premix gas lines. Options are to bring dirty premixed gas cylinders into the laboratory or to install an additional premix gas delivery manifold and pipeline. The recommended supply pressure of premixed gas is ~22 psi, which is significantly higher than the ~10 psi used for conventional incubators. The K-Systems G-185, with its own gas mixer, can be incorporated more easily into existing laboratories with standard-pressure (10 psi) CO_2 and N_2 supply lines. When using premixed gas, the CO_2 concentration can be adjusted for specific batches of media or different stages of embryo culture only by replacing the supply tank with a new one. The G-185 allows instant customization of the CO_2 concentration by simply adjusting the CO_2 set point. The MINC and BT37 pass the premixed gas through a water reservoir to provide chamber humidification. The G-185 does not have a similar feature and humidification, and if desired, it can only be obtained with an open

water-filled petri dish in each chamber. The lack of humidity is not important for media kept under oil since there is no detectable change in osmolarity for at least 48 h. Medium changes every 48 h render humidity control effectively irrelevant in the G-185. However, culturing or warming media in the G-185 without an oil overlay should be avoided. The FIV6 is representative of the first generation of benchtop incubators with less accurate temperature control and higher premix gas flow rates and, therefore, should not be used for prolonged embryo culture. All premixed gas delivered to the MINC or BT37 should be of the highest quality with HEPA- and broad-spectrum gas filtration. The K-Systems G-185 recirculates the chamber atmosphere to conserve gas but increases the risk for VOC build up on the inside. The G-185 incorporates a HEPA and activated carbon filter, but filtration of alcohols, ketones, aldehydes, and other common polluting gases is compromised by the lack of permanganate in these filters.

10.3 Water-Jacketed and Direct-Heat (Air-Jacketed) Incubators

The ability of a water-jacketed incubator to preserve chamber temperature after a power failure is superior, allowing more time to rescue embryos. Thermo Scientific Inc. reported, that during a power failure simulation of the Forma Series II water-jacketed incubators in an 18 °C ambient environment, the drop of the chamber temperature was only 1 °C per hour (from 37 to 36 °C) and approximately 7.6 °C in 10 h. Under the same conditions, a similar air-jacketed incubator lost 3 °C during the first hour (from 37 to 34 °C) and 17 °C in 10 h. Decontamination cycles are only possible with direct-heat, air-jacketed incubators. Water-jacketed incubators are unable to be heated to the levels (> 90 °C) necessary to achieve chamber sterilization. Water-jacketed incubators are heavy and large, gas-phase recovery may be compromised, and maintenance of the water jacket can be challenging. The typical elaborate chamber insulation in these incubators can become moist over time and serve as a continuous source of fungal contamination.

10.4 Size of Incubator

As a rule, the smaller the incubator, the faster the gas-phase recovery with the fastest recovery to be expected from the top-load, benchtop incubators such as the MINC and K-Systems G-185. This is not always true, as a larger incubator with an infrared (IR) CO_2 sensor (Fig. 10.2) can have a faster CO_2 recovery time than a smaller incubator with a thermoconductivity CO_2 sensor, e.g., the 170 L Sanyo 18 M has a faster recovery time than the 49 L Sanyo 5 M (Table 10.2). Smaller air-jacketed incubators have a smaller footprint and, due to their light weight, can be stacked and incorporated into integrated workstations. Most of the larger incubators (>150 L) were originally designed for bulk cell-

Fig. 10.2 A 170 L infrared CO_2 sensor, conventional air-jacketed incubator. Faster CO_2 recovery can be expected with a large infrared sensor-equipped incubator than with a smaller incubator with a thermoconductivity CO_2 sensor

culture and microbiology applications with limited door openings anticipated per day. When culturing human embryos, these same conditions are rarely observed with multiple door openings per day common and a strong incentive to limit the number of patients per incubator. In human IVF applications, the number of patients per incubator should be limited to reduce risk in the case of incubator malfunction, to decrease the likelihood of sample confusion, and to maintain the most optimum culture conditions by reducing the number of door openings per day [21]. The number of cases to be cultured in a single incubator should be determined not only by the mere size of the incubator but also by the recovery time for the specific incubator as a function of the size of the chamber, the type of CO_2 sensor, the method of humidification, and the clinic-specific culture protocols. As an example, a large 184 L Forma incubator with a thermoconductivity CO_2 sensor and passive humidification will have trouble maintaining stable culture conditions with more than 3–4 sets of embryos at any given time. Keeping this in mind, much of the space of a large, conventional, water-jacketed incubator is unusable.

Table 10.2 A comparison of characteristics of common, conventional low-O_2 incubators

Model	CO_2 sensor	O_2 sensor	Humidity control	Jacket	Size (L)	Decon cycle	HEPA filtration	UV	Copper

10.5 Carbon Dioxide Measurement and Control

Two main CO_2 sensor types are commonly found in modern-day incubators: thermoconductivity (TC) and infrared (IR) sensors. TC sensor-equipped incubators are less expensive; however, CO_2 recovery is dependent on the chamber's relative humidity (RH). When opening and closing an incubator set at 6% CO_2 and equipped with a TC sensor, the digital display will show a recovery of the CO_2 concentration within 5 min. However, when measuring the CO_2 concentration with an independent device, the actual CO_2 concentration will be closer to 2% and only approach the 6% original setting once the RH move toward 90%. Depending on the chamber size and humidification system, it may take 1 h or more to reach a 90% RH. When culturing embryos under oil, the RH level per se is less important, except that it directly affects the CO_2 recovery time in a TC-equipped incubator. Some manufacturers, such as NuAire, Galaxy, and Heraeus, improve the CO_2 recovery time for their TC sensor models with active-spray humidification systems to significantly reduce the humidity recovery time. Interestingly, the smaller 49 L Sanyo MCO 5 M incubator, only available with a TC sensor, has a longer CO_2 recovery time than the larger 170 L, IR sensor-equipped MCO 18 M (Table 2). Sanyo improved the CO_2 recovery time of the MCO 5 M model significantly over that of conventional TC sensor incubators by housing the TC CO_2 sensor in a smaller side chamber. The RH recovers much faster in the small side chamber than in the main MCO 5 M incubation chamber with the CO_2 recovery time now reduced to less than 15 min. The CO_2 recovery of IR sensor-equipped incubators is humidity independent and takes only minutes. Therefore, a larger IR sensor-equipped incubator can be used for more patients at a time compared with the conventional TC sensor-equipped incubator while maintaining stable culture conditions. With a much faster

CO_2 recovery, even after multiple door openings, IR sensor-equipped incubators are the incubators of choice for today's IVF applications.

10.6 Oxygen Measurement and Control

There are several different ways of measuring O_2 using technologies such as zirconium dioxide ceramic, electrochemical (also known as electrogalvanic fuel cell), infrared, ultrasonic, and, more recently, laser technology. The two commonly used methods in today's IVF incubator applications are zirconium dioxide (ZrO_2) sensors and electrogalvanic fuel cells. The zirconium sensor is also referred to as the "high-temperature" electrochemical sensor, using a solid-state electrolyte (ZrO_2) to generate a current directly related to the O_2 concentration. Zirconium sensors do have a faster response time compared with fuel-cell sensors and, typically, are more expensive. Due to the high temperatures of operation, the life of the sensor can be shortened by on/off operation causing sensor fatigue. The lifetime of a zirconium sensor, generally, is much longer than that of the fuel-cell sensor.

The fuel-cell sensor is an ambient temperature sensor and functions very much like a battery, making use of a chemical reaction between KOH and O_2 to create a current directly proportional to the O_2 concentration. Unlike the solid-state zirconium sensor, a fuel-cell sensor typically presents as a small, partially sealed, cylinder that contains two dissimilar electrodes immersed in an aqueous electrolyte such as KOH. Electrogalvanic fuel cells have a limited lifetime, similar to a battery, which is reduced by exposure to high concentrations of O_2 (higher rate of chemical reaction consuming the fuel cell). The lifetime of the sensor can be increased by leaving it in open circuit when not in use, but unlike the zirconium sensor, it takes about 20 min to become functional after reconnection. With the advance in mechanical designs, refinements in the electrode materials, and enhanced electrolyte formulations, the life of the fuel-cell sensor is significantly extended over earlier versions and similar to the zirconium sensor is recognized for its accuracy over a wide range of O_2 ranges. Both zirconium and fuel-cell O_2 sensors are well suited for IVF applications.

10.7 Quality Control

10.7.1 Temperature

Incubator temperature drives the metabolic rate of the embryos in culture. Some authors believe that the incubation temperature should be kept safely below 37 °C at 36.7 °C [22]. Another way of thinking is to set the incubator at 37.1 °C to prevent the temperature from dropping below 37 °C for prolonged periods when opening and closing the incubator door. Regardless of the target temperature, fluctuations in temperature should be avoided. As discussed above, the direct transfer of heat from below and from above in top-load incubators allows for a much faster recovery of heat compared with conventional incubators [19, 20]. Heat stability in conventional incubator chambers can be improved with the use of passive heat reservoirs such as the Incuplate (Cook). It has been demonstrated that the temperature recovery time for conventional incubators with Incuplate devices approaches that of top-load incubators and significantly outperforms conventional incubators without Incuplate [19]. The volume of the culture medium, the volume of the oil overlay, and the use of a culture dish lid significantly affect heat retention and heat recovery time, regardless of the incubator type. In general, heat is conserved when using a lid and when culturing in larger volumes of medium and oil [23]. The tolerance range for temperature variation in the stabilized incubator chamber should be very small (±0.1 °C). The chamber temperature should be monitored daily with an independent device, preferably with a certified thermometer. Perforated shelves are essential to prevent a temperature gradient within the incubator, especially for brands without fan-mediated air circulation such as Galaxy (Table 10.2). Even with perforated shelves, the temperature may be different on different shelves. Therefore, the incubator chamber temperature should be calibrated and verified specifically in the same location destined for embryo cultures.

10.7.2 pH

Incubators should not be set for a specific CO_2 concentration but rather with the goal to achieve a target pH such as that recommended by the media company for a specific medium. The pH of the culture medium is not necessarily a function of the percentage of CO_2 in the incubator chamber but rather of the partial pressure of the CO_2 in the embryo culture environment. The partial pressure of CO_2 is affected by the height above sea level, and therefore, the set CO_2 concentration required to achieve the target pH in a batch of medium may be different for laboratories in different sites. Since different batches of medium may differ slightly in buffering capacity, the actual pH at a specific CO_2 setting should be verified for each new batch of medium. In addition, consistency in pH values at a given setting between incubators should be confirmed periodically. As a guideline, the target pH should never exceed 7.4, even when moving or evaluating embryos outside the incubator. The repeatability and dependability of pH measurements are critical and, sometimes, challenging. The pH probe should always be calibrated with buffers that bracket the target pH, and importantly, calibration should take place at the target temperature (37 °C). In situ pH measurements of the culture medium, as used for IVF inside the incubator after overnight equilibration, consistently yield reliable results. An instant pH measurement with a calibrated blood-gas analyzer of appropriately sampled, equilibrated culture medium is a dependable alternative. A blood-gas analyzer has the added benefit of also measuring the partial pressure of O_2 (PO_2) in the culture medium.

10.7.3 Carbon Dioxide

CO_2 is usually delivered in the liquid form in H-size, medical gas cylinders. The CO_2 then evaporates from the pressurized CO_2 liquid, yielding a very clean supply of CO_2 for use in IVF incubators. All particulate and gaseous impurities mostly stay behind in the liquid phase. When the cylinder runs empty (no more liquid), these impurities are released at once with the potential to saturate and bypass any in-line gas-phase filters. It is, therefore, good practice to prevent CO_2 supply cylinders from running completely empty before switching to the reserve. Because of the liquid state of the CO_2 supply and a constant pressure in the air space of the tank, one will not see a notable drop in manifold pressure until shortly before the cylinder runs empty (Fig. 10.3). To prevent the CO_2 cylinder from running empty and to ensure a timely switch to the reserve cylinder, one must set the changeover pressure on the manifold above 50% (~500 psi) of the original tank pressure (~850 psi). Alternatively, the active supply cylinder can be secured on a scale and then a manual switch can be made to the reserve cylinder as soon as a predetermined weight is reached. In the event that a CO_2 cylinder does run empty, the in-line gas-phase filters should be replaced.

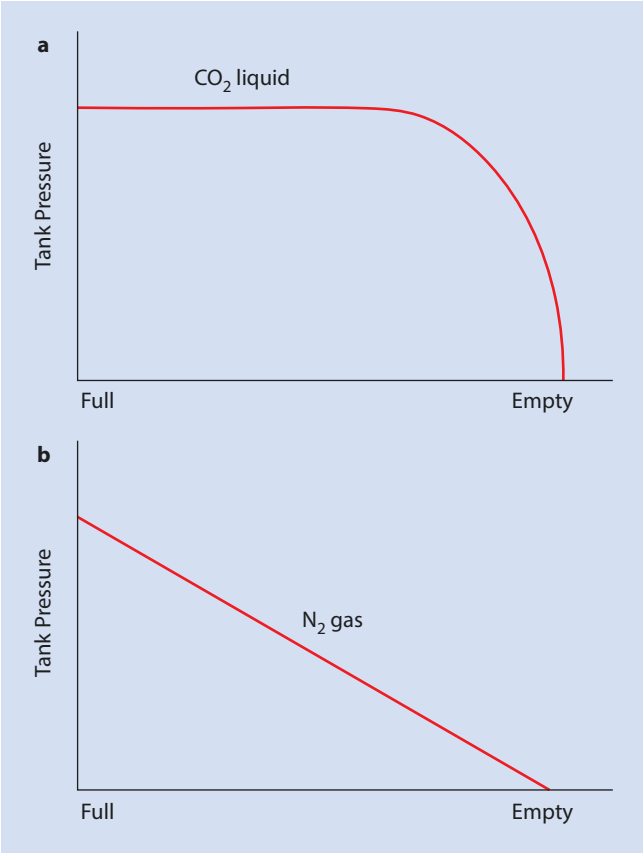

Fig. 10.3 **a** Because of the liquid state of the CO_2 supply and a constant pressure in the air space in the container above the liquid, one will not see a notable drop in manifold pressure until shortly before the cylinder runs empty. Liquid N_2 dewars will behave in the same manner. The manifold pressure is not an accurate reflection of the amount of gas left in the container. **b** In contrast, the pressure of compressed N_2 supplied in H-size metal cylinders is directly related to the amount of N_2 gas left in the cylinder, and the pressure in the tank is a reliable indication of the N_2 reserve

10.7.4 Oxygen

It is agreed that precise CO_2 control is essential for optimum IVF outcomes. However, the question must be posed if the same is true for O_2. It is possible that a slight variation in O_2 concentrations over time or a slightly elevated O_2 concentration can yield the same clinical results. Operating an incubator at 7% O_2 instead of 5% O_2 has significant implications on the amount of N_2 used, chamber humidity control, and the overall cost of operating reduced-O_2 incubators. Running out of N_2 may not have any direct short-term detrimental effect on the contents of the incubator, but depending on the brand of incubator and the type of CO_2 sensor, this may indirectly affect the CO_2 concentration and, therefore, the pH of the culture medium. Even though reduced O_2 in incubators have been correlated with improved clinical outcomes [13], concerns have been expressed regarding the detrimental effects of a possible too low O_2 concentration [2]. Similarly as for CO_2, the partial pressure of O_2 in the culture environment determines the amount of dissolved O_2 in the culture medium. Consequently, one should consider allowing higher concentrations of O_2 (6–10%) at higher elevations to ensure appropriate levels of dissolved O_2 in the embryo culture environment. Supplying N_2 to conventional incubators to lower the O_2 concentration can be expensive, cumbersome, and challenging. The cost savings, shortcomings, and benefits related to the gas supply of top-load, benchtop incubators have already been discussed. The N_2 needed for O_2 reduction can be provided as a compressed gas in H-size, medical gas cylinders, it can be siphoned off from larger liquid nitrogen supply tanks, or it can be generated continuously on-site by a N_2 generator.

Using compressed N_2 gas as the main source is the most inefficient and expensive, usually requiring daily tank changes. Changing tanks so frequently is labor intensive, demands significant space for an adequate supply of spare cylinders, and introduces daily variation to the IVF culture environment. Compressed N_2 gas is only as clean as the industrial manufacturing site. Considering that considerable effort and expense are generally invested in laboratory air quality and that approximately one-fifth (15% N_2, 5% CO_2) of the air in the actual incubator enters from the medical gas room, bypassing the laboratory air supply system, one should be diligent to apply the same standards of air filtration as for the laboratory room air. Nitrogen supplied to the incubators should be filtered for particles (HEPA filtration) and for gaseous contaminants (Fig. 10.4). The gas-phase filter should contain both activated carbon and permanganate (sodium or potassium salt) to ensure the filtration of both volatile organic compounds (e.g., hydrocarbons, aldehydes) as well as other common air pollutants (e.g., HS_2, SO_2).

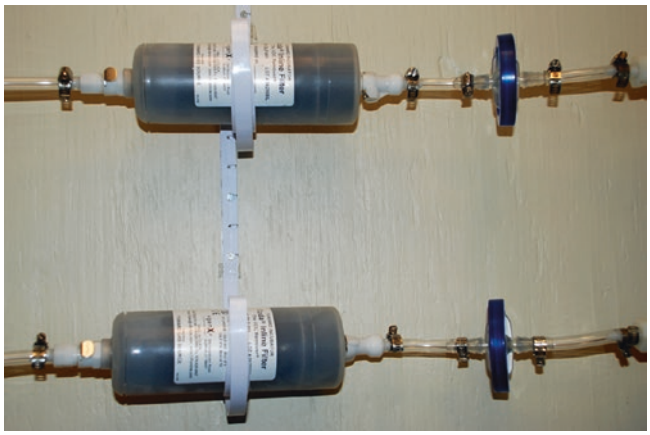

Fig. 10.4 All incubator supply gases should pass through a HEPA filter (particles) as well as a filter containing sufficient activated carbon/permanganate to remove gaseous contaminants

Siphoning pure N_2 gas off of 150 psi liquid nitrogen dewars instead appears to be a much more viable approach with changing of dewars required only every 2–4 weeks. In the liquid form, a typical dewar holds ~20 times more N_2 than an H-size cylinder filled with compressed N_2. A dewar can simultaneously serve as a liquid nitrogen source for IVF cryopreservation applications. As in the case with CO_2, the N_2 gas delivered from the evaporation of liquid nitrogen is pure and clean, provided that the dewar is not drawn from until empty. An ideal setup consists of a 150 psi primary and secondary dewar on a low-pressure manifold with high-pressure compressed N_2 gas cylinders as a tertiary backup.

Nitrogen can be supplied continuously to IVF incubators with the use of an on-site gaseous N_2 generator. With the atmospheric air consisting of roughly 78% N_2 gas, a N_2 generator only has to remove the other gases (O_2, Argon, CO_2, and others) to increase the percentage of N_2 to >99%. Atmospheric N_2 can be purified by membrane filtration (N_2 stays behind and the other smaller gas molecules pass through) or, alternatively, by pressure swing adsorption (PSA; smaller molecules are adsorbed on a pressurized adsorption bed and the N_2 passes through). PSA is the better technology yielding up to 99.999% pure N_2 gas. Not considering the investment cost of the N_2 generator, it is the most cost-efficient and least labor-intensive way to supply N_2 to IVF incubators. N_2 gas from compressed cylinders currently costs upward of \$4/100 ft^3; when from liquid N_2 dewars, upward of \$2/100 ft^3; and when generated on-site by an N_2 generator, roughly \$0.06/100 ft^3.

10.7.5 Humidity

After closing an incubator door, a significant volume of non-humidified N_2 is injected into the incubator to reinstate the lower O_2 concentration. This inadvertently will lower the RH in the incubator chamber for an hour or more after closing the door, especially for incubators with standard humidification pans. Therefore, the loss of RH after opening will be more pronounced in low-O_2 incubators compared with standard CO_2 incubators. As discussed under "Carbon Dioxide Measurement and Control" above, RH directly affects the CO_2 concentration in incubators equipped with TC CO_2 sensors, while the CO_2 concentration of incubators with IR CO_2 sensors is not affected. When using incubators with TC CO_2 sensors, it is, therefore, imperative to monitor and verify the RH on a frequent basis using an independent RH measuring device. It is not uncommon for inner doors or access ports to become less impervious over time with significant drops in incubator chamber RH.

10.7.6 Cleaning, Commissioning, and Decontamination

Incubators should only be cleaned when necessary without disabling the gas supply or switching off the power. Once completely switched off, it may take days, and sometimes weeks, to reach the same level of steady state as experienced before the shutdown. The CO_2 and O_2 sensors are particularly vulnerable when cleaning if the manufacturer's recommendations are not followed. The inside of the incubator can be washed with a soft, odorless soap solution to remove any culture medium and protein residue, followed by distilled water to remove the soap. Next, a 70% methanol solution is applied to remove oils and to assist with disinfection, followed by a second round of distilled water. Methanol is preferred over ethanol as a general IVF laboratory disinfectant because of its lower volatility index, typically releasing fewer fumes into the laboratory environment. The use of halogens such as bleach solutions (chlorine) or Betadine (iodine) is contraindicated as caustic agents to the incubator interior. Furthermore, halogen residues can persist in the incubator for an extended period to potentially affect future embryo cultures. Sterile, surgical gauze sponges are optimal for use when cleaning incubators. Shelves and water pans may be autoclaved; however, autoclaving glass inner doors is not recommended, since, over time, autoclaving tends to leave irremovable stains on the glass doors.

Starting up a new laboratory or introducing a new incubator into the laboratory, without compromising IVF outcomes, presents a special challenge. The concentration of gaseous contaminants found in a new incubator can be 100 times higher than that found in a seasoned incubator [24]. Off-gassing of new incubators can be enhanced by preheating the incubator chamber above normal operating temperatures for an extended period (days to weeks) before final commissioning for use. A thorough rinse of the inside of the incubator with a solution of household baking soda ($NaHCO_3$), followed by the standard cleaning protocol described above, further reduces odors from plastics, gaskets, and glues used during manufacturing. An intraincubator-activated carbon filter device may further improve incubator chamber air quality [25]. A new incubator should be at steady state for some days in all areas of interest (temperature,

humidity, CO_2, and O_2). Confirming a safe environment for IVF culture with a sensitive mouse-embryo bioassay is helpful. Even when passing all these quality control measures, some incubators may outperform others for no apparent reason [22]. Therefore, one should entrust only a few cultures to a new incubator over time and diligently and prospectively compare it with culture outcomes from an older proven incubator before commissioning the new incubator without reservation.

With good cleaning practices, attention to laboratory and incubator air quality, and sterile technique, contamination should be rare. Most of the new-generation air-jacketed incubators have sterilization cycles that can be incorporated into the regular maintenance routine or applied as needed. Sanyo and Galaxy incubators have an optional intrachamber ultraviolet lamp to complement chamber sterilization. Some incubators are manufactured with copper-stainless steel alloy interiors (standard for Sanyo) or with 100% copper linings, water pans, and shelves (options: Heracell, Binder, Galaxy) with inherent antifungal properties. Any observed or suspected contamination should be submitted for a culture and antibiogram. Knowing the identity and sensitivity of the organism can be crucial in identifying the source of contamination and to implement the appropriate corrective action. Contamination has been traced to room air, incubator air, incubator insulation, culture products, patient specimens (sperm or oocytes), and a lack of aseptic technique. Strategically placed bacterial and/or fungal culture plates can be helpful to identify the origin of contamination when air is suspected as a mode of transmission. Fungal contamination is by far the most common laboratory encounter, with *Aspergillus fumigatus* or *Aspergillus nigricans* a frequent isolate. When faced with fungal contamination and not equipped with high-heat decontamination capabilities, the chamber should be disinfected with 2% hydrogen peroxide, which is a proven fungicidal. Seventy percent methanol is not fungicidal. Some manufacturers provide decontamination kits (door seals, fans, filters) that should be installed after sterilization of the incubator chamber. A common source of fungal contamination is the interior insulation of older incubators. Insulation as the source can be verified by inspecting and culturing a small sample of the interior insulation. If confirmed, a contaminated incubator is best discarded. Furthermore, a review should be done of the general laboratory air conditioning system and concurrent humidity control as common contributors to fungal contamination. Daily inspection of the water pans can serve as an early warning sign of impending contamination. Water pans in the incubator function as a trap and reservoir for gaseous and particulate impurities and, therefore, should be changed at regular intervals. If changed too often, a continuous stable incubator environment will be harder to maintain. If not changed regularly, water pans themselves can become a source of contamination. Water pans should be autoclaved at a recommended interval of ~4 weeks and filled with distilled water or better to ensure chamber sterility and air quality.

10.7.7 Safety

Guidelines and requirements by most regulatory agencies with jurisdiction over IVF laboratories mandate that there should always be a backup incubator (minimum of two incubators per laboratory). Incubators should be monitored and the alarm system connected to an instant notification system 24-h per day when specimens are cultured. The number of incubators available should be adequate for the number of patients undergoing IVF at any given time. This will depend on the type of incubator used, the type of CO_2 sensor in the incubator, passive or active humidification, whether patients are grouped together for treatment, and other factors specific to each laboratory.

10.8 Discussion and Conclusion

Every laboratory operates under unique circumstances, and, in addition, personal preferences in equipment and in laboratory protocols should be considered. However, understanding the principles of incubator operation, realizing the shortcomings and strengths of various models, and being cognizant of available technologies are imperative for optimized IVF outcomes. With these in mind, the following guidelines should be considered:

- Culture in a reduced-O_2 environment.
- Consider top-load mini-incubators or the use of passive heat reservoirs for fastest temperature recovery.
- When using top-load incubators, be aware of the unique safety and quality control challenges posed.
- Conventional incubators equipped with IR CO_2 sensors are preferred. When having to use incubators with TC CO_2 sensors, humidity conservation is essential with thought given to the number of patients per incubator and incubator door openings.
- All supply gases (CO_2, N_2, premix) to the incubators should pass through a HEPA, activated carbon, and permanganate filter. Compressed N_2 should not be used as a primary source. When totally depleting the CO_2 or N_2 cylinders before switching to the backup source, the carbon and permanganate filters should be changed.
- Direct-heat air-jacketed incubators are preferred over water-jacketed incubators.
- As a rule, smaller incubators perform better than large incubators due to faster temperature and gas-phase recovery times.
- Calibrated, independent measuring devices should be used daily to monitor incubator chamber temperature, CO_2 and O_2 concentrations, and relative humidity levels. A case can be made to monitor O_2 and relative humidity only periodically.
- CO_2 settings should be determined based on pH measurements of the culture media guided by the pH target recommended by the medium manufacturer. Partial pressures of CO_2 differ with height above sea level, and therefore, different settings should be expected to achieve the same pH at different facility locations.

- A major preventative cleaning of incubators should be minimized and incubators switched off only if essential.
- Never use halogens for cleaning (bleach, iodine).
- New incubators should be burned in before use, according to a predetermined protocol, and appropriately commissioned through several quality control-guided steps.
- Refrain from allowing plastics, plastic test-tube racks, Styrofoam, glues, ink, and other aromatic substances in the incubator.
- Contamination should be rare and dealt with aggressively when observed. Fungal contamination is most common. Hydrogen peroxide can be used as a disinfectant for fungal contamination. Alcohols are not fungicidal.
- There should be ample backup incubators with a minimum of two incubators in any laboratory, regardless of type of incubator. Incubators should be connected to a 24-h alarm and notification system, monitoring all critical incubator parameters.

Review Questions

10

1. Please describe the different types of incubators available.
2. Please define what the major functions of the incubators in the embryology laboratory are.
3. Please explain why low-O_2 concentration incubators are recommended for embryo culture.
4. Please describe how to perform quality control correctly on the incubators.

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_11

Learning Objectives

- To provide a quick overview of the products on the market
- To describe what you need to look for when selecting the best product
- To describe what products to buy that meet all requirements for gametes and embryos

11.1 Introduction

In order to construct and establish a high-quality assisted reproduction technology (ART) clinic, a multidisciplinary skilled task force needs to be formed that guarantees that all aspects concerning the design and building of the clinic, selection of equipments and disposables, as well as logistic treatment procedures are taken into consideration.

The clinic needs to be built in accordance with country-specific standards and legislations and perhaps also to international legislations, if cross-border treatments are also to be performed. The newly updated EU GMP guidelines and revised Annex 1 (tentatively published in early 2018) seem to suggest that ART clinics in the future might need an EU C-Class work environment (ISO 7), whereas an EU D-Class (ISO 8) is demanded currently. There will also be an evaluation of the effectiveness of the clinic's ventilation system (air change effectiveness index, ACE, and contamination reduction effectiveness, CRE), where perforated diffusers ensure an effective mixing of the inlet air and a cleaner environment.

In addition, the clinic must proactively prevent the exposure of oocytes and embryos to environmental embryotoxic pollutants from within the clinic (building materials, ventilation, laboratory furniture, light and gas source, disposables, detergents and cleaning agents, clothing materials, and bio-burden of staff and therefore restricted access to the laboratory [1–8]) and ensure that the couple's gametes and embryos are given an optimal chance to develop into top-quality embryos with high implantation and low miscarriage rates [9, 15].

This chapter tries to give information and guidance in the selection of a suitable unidirectional airflow (UDAF) bench, Class II-III Cabinets, multipurpose workstations, or isolettes that meet your needs in terms of quality and costs, operational features and options, service and support expected by the companies, legislation within your country, expectations from the couples for optimal handling of oocytes and embryos, identification, and safety. This chapter focuses on the most frequently used brands on the market, but there are both regional differences in preference of brands and availability of additional products. (Tables 11.1 and 11.2).

The building materials of the workstations should be of the highest quality, preferably antibacterial, easy to keep clean, resistant to cleaning detergents and disinfectants, impervious, seamless, and non-embryo-toxic, and must be given time for outgassing and function tests (particle and microbial count) before it is taken into usage.

Built-in incubator	Yes	Yes	Yes	Yes	?

All laboratory staff must also be educated and their competency tested in the operation of these equipments (technical standard operational procedures), treatment procedures (SOPs), and quality controls [10, 11]. Each piece of equipment should be labeled with a chronological identification number, and repairs, annual services, and action taken must be registered. The most sensitive and vital equipments must be connected to uninterrupted power supply (UPS) to avoid disruption of work, recalibration, and damage to the equipments or gametes and embryos.

11.2 Principles of Different Types of Workstations

11.2.1 LAF (Laminar Flow) or UDAF (Unidirectional Airflow) Benches

IVF-Tech – ► www.ivftech.dk; Origio and K-System – ► www.coopersurgical.com; Astec – ► www.astec.com; Kojair.- ► www.kojair.com; ESCO – ► www.escoglobal.com; Telstar – ► www.telstar.com; EuroClonegroup – ► www.euroclonegroup.it; LAFTech – ► www.laftech.com.au; Gelman – ► www.gelmansingapore.com

The vertical laminar flow UDAFs are the most commonly used workstations within ART. Unfortunately, and due to the cooling effect of the airflow over the content of the culture dishes, the clinics run the UDAFs at half ventilation speed, which corresponds to only 15% of their efficiency. Thus there is no guarantee that the work area is kept at the needed standards for ensuring that the patient's culture dishes are not contaminated during different procedures.

The benches should run continuously since this also will contribute to the cleanliness of the laboratory. The personnel must know that if a bench is switched off and started up again, it will initially (15 min) release a substantial amount of debris that will contaminate everything within the bench. All this can be avoided if programmable benches are bought where turn off and on times can be programmed so that all parameters (temperatures and cleanliness) are at optimum when the work starts in the morning. However, most UDAF benches I have seen in the clinics are overloaded with items that affect the cleaning efficiency of the bench. Behind each object turbulence is induced that is three times the width of the object, where particles are precipitated, which increases the contamination risk.

The benches are usually equipped with a heated surface that might give an equal temperature over the whole surface area, a heated glass stage, and a light source. A high-quality stereomicroscope should be used for search and handling of COCs, evaluation, and selection of embryos for embryo transfer and vitrification. A humidified pre-warmed gas support and oil overlay of the culture dishes ensure that the humidity, osmolality, and pH of the culture media are kept within expected optimal ranges. Another option is to have an integrated incubator at the back wall of the workstation, but be aware that these types of incubators also have a very long recovery time of the culture conditions after one door opening. Thus rather use the built-in mini-incubator with a proven quick recovery of the culture conditions.

In the double LAF benches, each side is equipped with a separate control system for heating, humidity, and light; thus, it can therefore be used for other purposes like vitrification or for testicular biopsies. However, there are also multi-zone benches where the temperature of each zone is individually adjusted and under surveillance.

Benches or workstations can also be used for ICSI, IMSI, and biopsy techniques if an inverted microscope equipped with a laser and micromanipulators is installed on an anti-vibration table. However, be aware that vibrations might affect the outcome of the procedures.

11.2.2 Class II/Safety Cabinets

11.2.2.1 Most Companies Selling LAF Benches Also Sell Class II Cabinets

The safety cabinet protects both the product and operator, which regulatory bodies in some countries require. However, these cabinets are mostly used in a separate laboratory for handling and preparation of semen samples and especially for handling samples from patients with infectious diseases.

The very high airflow within these cabinets affects the temperature of the dishes and can simultaneously also alter the pH. This makes the Class II bench less suitable for handling of oocytes with temperature-sensitive meiotic spindles that might become disrupted, which later affects the embryo quality.

11.2.3 Class III Safety Cabinets (Isolators or RABS (Restricted Access Barrier Systems))

Closed systems (isolators or RABS) are usually used for processing aseptic products, toxins, and biological materials where contaminations and/or cross-contaminations must be avoided. These types of equipments are mostly used in the pharmaceutical manufacturing industry.

There is a physical barrier between the staff and the work area within the isolator. Access into the isolator is via sealed port glove-sleeve assemblies.

11.2.3.1 Mobile Chambers, Isolettes or Smart-Stations

G-603 (K-System, ► www.coopersurgical.com); Cell-Tek 3000 Series (► www.Tekevent.com); SmartStation SS250 (► www.Astec.com); UNICA (► www.IVF-Tech.com), SCE-IVF (► www.escoglobal.com).

These mobile and enclosed workstations, with an incubator-like environment and fitted with a suitable stereomicroscope or TV monitor, are suitable for search of cumulus-oophorous-complexes (COCs) in follicular fluids

during retrieval, evaluation, and selection of embryos for ET, denudation of oocytes, and microtechnologies (ICSI, IMSI, and PGD). The stress on gametes and embryos is minimized since the inner environment is controlled and adjusted for pH, osmolality (humidification of the environment via heated water reservoir), and the temperature of the work area [2]. The heated plate can independently be turned on or off and adjusted to various laboratory procedures.

There are also possibilities of having built-in mini-incubators and pre-warmed dishes, thus less handling of oocytes and embryos outside the workstation.

HEPA, carbon, and VOC filters or UV photocatalytic removal of VOCs provides the workstation with a clean room environment. However, it is still advisable to use MOPS- or HEPES-buffered media, with an oil overlay, during aspiration, handling, and injection of oocytes (ICSI). Such dishes ought to be stored under the lid of a separate heated gas purge inlet hole, when they are not used and for a better control of the pH, since workstations are not leak proof.

The work area is accessed via small holes in the front of the workstation, and side openings are for introduction of dishes, test tubes, heat blocks, and aspirated follicular fluids or removal of waste.

These mobile workstations can be fitted with a motorized height-adjustable stand on which small gas cylinders can be mounted. The content of the gas cylinders can either be mixed by the workstation itself or pre-mixed gas cylinders could be used.

Since these workstations are fitted with lockable large rubber wheels, they can easily be relocated between different rooms, provided that different kinds of contaminations are not also transferred.

There is also the matter of decontamination and cleaning in closed workstations. In open workstations the cleaning of any spillage is straightforward, whereas in closed workstations it is more complicated.

11.3 Basic Constructions and Comments

11.3.1 Steel Frames, Stands, Sloped Fronts, and Side Walls

The benches or cabinets usually come with stands of fixed heights, most commonly 700, 800, or 900 mm; they might have a footrest and perhaps a practical solution for integration of a computer or storage shelves underneath the workspace area.

There are also electrically operated height-adjustable (750–1110 mm) stands so the staff can either be seated or work standing. A good investment, for the electrically height-adjustable stands, is a sensor on top of the bench or cabinet that alarms when it comes too close to the ceiling. Many manufactures do not sell the electrically height-adjustable stands since they can become unstable and cause accidents. If an electrical stand is bought it should have been developed according to EN 61010 and assure full stability at its highest elevation. Most of the benches come with leveling feet and/or wheels and are 900, 1200, 1500, or 1800 mm in width.

A sloped front allows an ergonomic, fatigue-free, and comfortable work environment and has usually a programmable LCD display control system in easy reach for the staff. The side walls can be of stainless steel, glass, or polycarbonate, and they can also be equipped with pre-drilled holes.

A sliding shelf, under the surface of the LAF bench, is an efficient way to store a keyboard and to keep the workspace clear.

11.3.2 Filters, Motors, and Noise Levels

Most benches come with thick HEPA (99.99% efficiency in removing 0.3 um particles) or ULPA (99.999% efficiency in removing 0.1–0.3 um particles) filters of a high quality that do not easily block and can therefore be used for a very long time before the filter must be exchanged. There is therefore no requirement for large strong fans that generate high noise levels and vibrations, thus a good work environment.

Some benches have also built-in dampers that furthermore reduce vibrations and facilitate evaluation of oocyte maturation, fertilization, and embryo quality and other sensitive microscopic work.

The prefilters on top of the benches are easily exchanged, and the large HEPA/ULPA filters should be easily exchanged when the airflow monitoring system indicates it. When a new bench is installed, the distributor must ensure that the filters are not damaged during the transport. Some benches can also be fitted with activated carbon filters for partial removal of volatile organic compounds (VOCs).

11.3.3 Stainless Steel or Corian Table Tops

The most common work zone consists of a single piece of stainless steel but can also be made of Corian (HiMacs). In some benches, the surface has been coated with a silver-ion-impregnated antibacterial/antimicrobial coating (Isocide) that prevents growth of bacteria and reduces the risk of contaminations.

The absence of screws or connectors in work zones and rounded easy clean corners in the bench reduces potential contamination and facilitates the maintenance and cleaning of the surface. Cleaning is performed with special embryo-tested cleaning detergents at the end of the day. However, in between patients and if spillage occur, the spillage should first be removed; the surface washed with water for injection and finally cleaned with a detergent. If the detergent makes the surface sticky or greasy, clean it again with water for injection.

11.3.4 Heated Surface and Glass Stage

Select a heated work area that meets the requirements for the number and types of treatments. Most of the clinics

equip their benches with an electrically controlled heated surface since water-controlled heating needs more attention and might also become a source of contamination of the cultures. In the multi-zone ART workstations, each zone is independently controlled (accuracy: ± 0.2 °C) and surveyed. The surveillance system provides the user with real-time information of the different zones' performance as well as parameters for gas pressure and flow rate. Ensure that there is no crossover heating between the different zones.

Note: Remember that the temperature of all heated surfaces of the bench must be calibrated with a sensitive temperature probe within the most commonly used dish and not against the surface of the bench! [16]

The pre-mixed gas pipelines, embedded in the electrically heated sheet underneath the heated surface, are connected to a heated and pressure-controlled humidifier providing dishes with filtered humidified pre-mixed gas.

The heated glass stage has a dedicated and uninterrupted power supply to further strengthen the temperature control of this very important area where the staff searches for COCs in follicular fluids, performs denudation of oocytes, evaluates fertilization, controls the quality of embryos, and selects embryos for transfer. The glass stage must be in level with the heated surface area to avoid relocation or loss of oocytes or embryos.

There is also a need for an easy access for service staff and laboratory personnel to gas pipelines, electric cables, and light fittings.

11.3.5 Gas Support, Filters, and Humidification

In order to maintain optimal culture conditions within the dishes during egg collection and handling of embryos, the benches are fitted with a pressure-controlled and humidified gas support system. The connecting gas tube must be of nontoxic and VOC-free material, leak proof, and easily fitted to the gas reduction inlet valve. The concentration of CO_2 must be adjusted to that of the clinic's choice of culture media and contain low oxygen (5–6%), which ensures the development of high-quality embryos of high implantation rates.

The compressed gases may contain high levels of organic contamination. It is therefore essential that the gas quality should be of the highest purity (medical grade for both nitrogen and carbon dioxide) and have the lowest concentration of contaminations [3, 12].

The benches can also be fitted with a gas mixer that mixes the CO_2 and the N_2 to recommended concentrations for optimal outcomes.

Many clinics also pre-clean the inlet gas via an inline HEPA, charcoal, and potassium permanganate filter before it is heated and humidified.

Take care to select a bench where the heated surface gas inlet is as close as possible to the stereomicroscope so the work is facilitated. The companies usually also supply glass hoods which are positioned over the gas inlet hole and the culture dishes. Thus, the cultures are kept at an optimal pH via the pre-warmed humidified gas mixture. The humidifier must be regularly cleaned with nontoxic detergents that do not leave any residue behind, sterilized, and filled with water for injection.

11.3.6 Pass-Through Hatches/Tunnels and Built-in Incubator(s)

Some of the benches can be provided with a temperature-controlled and calibrated pass-through hatch or tunnel with direct access to the egg collection room. Test tubes containing aspirated follicular fluid are placed in the heated blocks by staff in the egg collection room and their content evaluated by the embryologist in the laboratory.

Also, single door incubator can be installed in the back wall of the bench. Since the incubator door is frequently opened, the culture conditions are never optimal, which affect the outcomes of the treatments. It is better to use built-in mini-incubators, with individual small doors and a gas inflow purge, for a quicker recovery and better maintenance of the culture conditions. However, also control the lids of the dishes for condensation, since that is an indication of evaporation and problems with the osmolality of the culture media. The latter can easily be avoided by using oil overlay of the culture media in the dishes, which most clinics also practice.

Yet another option is to transfer the dishes, after completed work, from the glass hood to mini-incubators, close to the bench and with a quick recovery of the culture conditions. Only use large incubators for pre-incubation of culture dishes and not for cultures. Very recently, some models of IVF workstations have come out, which provide inbuilt small-bench top incubators integrated to the work surface.

11.3.7 Stereomicroscopes, Light Source, and High-Resolution Screens

There are a lot of different stereomicroscopes that are suitable for the work within the benches. The stereomicroscope needs to be fitted with an adjustable ergonomic tri-ocular tube so also a good camera can be connected to a TV monitor, within or outside the bench [4]. The space between the heated light source and the objective should allow easy handling of dishes, oocytes, 2PNs, and embryos, so I recommend a 0.7× objective.

The combination of a high-quality stereomicroscope, a camera and a light source, where the mirrors can be angled and adjusted (diascope light), and the generated picture evaluated on a high-resolution screen makes it even possible to evaluate pronuclei. For this, it is very important that the bench has dampers so vibrations are avoided. The new light

sources are fitted with LED light, thus longevity and less change of bulbs.

Any cables are led through the pillar of the stereomicroscope.

It is an advantage to have the high-resolution screen on the outside of bench for dual control, evaluation, and teaching purposes. It also makes it much easier to repair a screen that is located on the outside versus a screen mounted within the UDAF bench.

In addition, there are touchscreen monitors available from which you can view, record, and export images of gametes and embryos. A built-in joystick in the bench controls focus, brightness, contrasts, and magnification of the digital and inverted microscope.

11.3.8 Optional UV vs UV-C Sterilization

The detoxification or rather the removal of pollutants is very important in IVF clinics since they could have an enormous impact on embryo quality, embryo survival, and thus the clinical outcome of the treatment.

Many pollutants settle on work surfaces or into tissue culture plastics where they could dissolve in the culture media. Therefore, some UDAF benches but mostly Class II Cabinets can be equipped with time-regulated UV lights for sterilization of the work areas. A built-in controller monitors the effectiveness of the UV light and when it needs to be replaced.

UV light is divided into three different sources: UV-A 315–400-nm, UV-B 280–315-nm, and UV-C 100–280-nm wavelength. The UV-C wavelength of 254 nm effectively destroys bacteria, viruses, and VOCs (volatile organic compounds) and does not produce the very toxic ozone by-product [5, 13]. Ozone in itself is a highly effective decontamination product for the lab surfaces and HVAC system, but not suitable for IVF clinics since it is highly unstable and reactive.

All higher organisms are protected from low exposure to UV radiation by their external skin or cortex. Since gametes and embryos do not have these kinds of protective layers, they are more vulnerable to exposure of ozone.

11.3.9 ID Control

(Matcher, ► www.imtinternational.com; RI Witness, ► www.riwitness.com)

There are at least two electronical witnessing and traceability systems created for IVF clinics and donor banks. The aim is to prevent errors in identification of patients, their gametes and embryos, as well as products used during their treatments. These electronic witnessing systems provide a double control system that ensures that all procedures are performed in a chronological manner with patient-customized name and barcoded lab ware and media products or via radio frequency identification (RFID) technology [6, 14].

The identification system is installed within or on the surface of the UDAF (LAF) benches and Class II Cabinets.

11.3.10 Inverted Microscope

Some companies also provide workstations where an inverted microscope has been integrated on a free-standing antivibration table. The latter prevents vibrations from the UDAF bench reaching the microscope, and hence the staff simultaneously can work aseptically during ICSI, IMSI, and biopsy procedures. This also provides better mobility of gamete−/embryo-containing dishes in lesser time between ICSI and IVF workstations.

11.3.11 Lighting

All light fittings are recommended to be of yellow light with low VOC emittance and made out of top-quality components.

The light tube should be positioned so it can easily and safely be replaced when needed.

11.3.12 Service Agreement and Spare Parts

It is advisable to get at least a 2-year service agreement included in the purchase deal to avoid any unforeseen extra payments due to hidden problems.

If you need service will it be undertaken by educated service staff in a timely manner and do they have spare parts available within your country? Or do you have to pay for expensive repairs from abroad?

Chronologically label all equipments and have a separate register over repairs for each piece of equipment in order to document and detect “hidden” problems.

11.3.13 Daily Routines and Quality Controls

All UDAF benches and Class II Cabinets should continuously work since they also keep the laboratory environment clean. Every time they are turned, there is a release of particles that contaminates all items stored within the benches.

After a day’s work, the surface area is cleaned with approved cleaning detergents following the prescribed cleaning routines. Also control the surface underneath the bench, or the Class II Cabinet, since splashes from waste products (follicular fluids, semen, blood, etc.) might have contaminated it.

The following morning and before any handling of gametes or embryos, perform a routine control of the functionality of the equipments, either via a wireless system or via manual documentation. Also the function and settings of stereomicroscopes (Köhler) and inverted microscopes must be performed and registered.

11.4 Where to Place the UDAF Benches or Class II Cabinets?

The floor to ceiling height of the laboratory, the location of ventilation inlets and outlets, UPS-supported electrical outlets, and pre-mixed gas reduction valve must be considered when you decide where to place the UDAF bench or Class II Cabinet.

It is important to see to that you have enough of electrical outlets so that cords are inserted directly into the outlets without any extension cord. All outlets should be fitted so they reside within the wall, which prevents the collection of dust that potentially over time could contribute to contaminations within the laboratory.

The pre-mixed gas reduction valve is for built-in mini-incubators or mini-incubators next to the UDAF bench or if the UDAF bench is provided with pre-mixed gas inlet hole(s) for gassing of culture dishes.

After extensive cleaning and "burn-off" of toxic volatile organic compounds (VOCs) in another nearby room, it is placed and leveled in its final position in the laboratory. Thereafter, the staff undertakes a comprehensive training program in the handling and maintenance of the bench (Written technical SOP) via the company that you purchased it from.

11.5 Cleaning and Disinfection

Before any measurements of release of particles from the filters within the bench or cabinet and biological contaminations, the equipments must undergo a thorough cleaning and decontamination. All parts are pre-washed with water for injection for removal of potential contaminations and followed by disinfection by approved ART products like Oosafe. Avoid 70% ethanol since it only reduces and does not eliminate the contaminations, and hydrogen peroxide might damage the metal parts of the equipment over time.

The daily cleaning routines are preferably performed at the end of the day (usually in three steps (water, Oosafe, and water)) so you avoid cleaning in the morning and the release of potential toxins from the detergents. Since the bench or cabinet is constantly running, all fumes from the detergents are eliminated overnight, provided the equipment is serviced and controlled yearly. Remember to register all services and repairs for each piece of equipment.

Any spillage in between patients should be immediately cleaned with dry tissue or tissue wetted with water for injection only. Only clean it more thoroughly when no oocytes or embryos are to be evaluated or manipulated.

"Do not forget the effects of personnel bio burden on the environment and the outcome. The dress code must be followed in all aspects and the staff must understand why jewelries, mobiles, long nails, nail polish and scented products (cologne, perfume, deodorant, hairspray, facial foundation, body wash or powder, after shave, etc.) cannot be used. Smoking staff members should only work in the andrology or sperm preparation laboratory, since tar particles within their breath and contaminations of skin and hair are released for a prolonged period of time after smoking." [7, 15]

11.6 Quality Control (QC) and Calibration

Provide the equipment with a specific chronological identity and bar code, which is used to register all parameters (QC), services, yearly recertifications, reasons for malfunctioning, and repairs.

After extensive cleaning and decontamination, the equipment is controlled for the release of particles and biological materials (bacteria), which is more frequently done during the upstart period to reveal malfunctions. The airflow within the bench/cabinet is evaluated with a smoke test, which visualizes airflows.

The heated surface temperature and the heated light source are calibrated within the most frequently used culture dish, at a specific fan speed, with a surface temperature probe. The final surface and light source temperature should be within 36.5–36.9 °C for best outcome, which also causes less damage to the most sensitive stage of the oocyte – the meiotic spindle [8].

As for the surface of the workstations, the heated glass plate, on the inverted microscope, is also calibrated to 36.5–36.9 °C, with a surface temperature probe, in a flat ICSI dish. Ensure that the bench/cabinet does not cause vibrations of the injection pipettes, which potentially could increase lysing rates of injected oocytes.

For all the above, it is better to purchase all equipments from your local dealers since it simplifies communication and service.

11.7 Written Standard Operational Procedures (SOPs)

Standardization in handling of the equipments and ART procedures makes it easier to improve techniques or test new products. It gives traceability of all actions performed, makes the processes and procedures more efficient, and improves service quality, which is beneficial for both customers and staff.

SOPs are upgraded yearly and the latest international technologies and bench mark processes and procedures are incorporated in a never-ending project.

The competency of the staff in different techniques and procedures is tested yearly and saved in their personal file.

The traceability of relevant data related to products and materials (batch number and expiration date) that come in contact with the patient's gametes or embryos during their treatment cycle is recorded in the patient's file and a log book.

By the use of key performance indicators (KPIs), the clinic detects changes in results, performance of staff members, and areas in need of reeducation. Indicators should be internationally defined and recognized, which reduces misinterpretations and facilitates internal as well as international communication and auditing [9, 17].

11.8 Evaluation of the Performance of the Bench/Cabinet

Before any treatments are performed in the new bench or cabinet, all measured parameters should be within the set threshold values. All staff members should also have been properly trained and their competency controlled. Select a number of suitable couples where you expect a high number of oocytes after egg collection, denudation or micro-injection, and embryos for evaluation and embryo transfers. Perform a sibling study against another bench or cabinet and compare the ease of work and outcomes.

11.9 Final Comments

The position of the cabinet can have a major effect on its performance, and it can also affect or become affected by the surrounding equipments, walls, benches, laboratory through traffic, and of course the air handling system. Care must be taken to ensure that the inflow diffusers are positioned so they do not create turbulence across the cabinet inflow area.

Even if the clinic has invested in high-quality UDAF benches or cabinets and controlled their performance, the outcome of the treatments is also very much dependent upon how the treatment is performed. For instance, the disposables selected by the clinic must have shown to consistently give good results in clinics all over the world. The choice of disposables is the preference of the clinic as long as they have been embryo-tested with several different methods and are non-pyrogenic, preferably gamma-irradiated, and of clear plastics, facilitating inspection and evaluation of gametes and embryos. Pipetting of culture media is performed according to best practice and with sterile filter tips of high quality (RNA, DNA, and pyrogen-free). The plastic covers might be toxic so there is a need for fuming off of all particles on the surface of the UDAF bench or Class II Cabinet before they are used. To avoid contaminations, all handling of the culture media is performed with embryo-tested powder-free sterile gloves without chemical additives, accelerants, or emulsifiers.

Review Questions

1. Why is it important to have perfect control of the temperature during egg collection, denudation of oocytes, and evaluation of embryos?

   The meiotic spindle in oocytes is very sensitive to fluctuations in temperatures, which can cause aneuploidies and adverse effects on the embryo development. Variations in temperatures can also cause developmental problems within embryos and lower implantation rates.

2. The engines of the ventilation system must be silent and not cause vibrations! Why?

   Working in benches or a laboratory with equipment's generating high noise levels give discomfort to staff and could also affect the work, if micro-manipulation techniques are implemented in the LAF/Class II.

3. A high-quality light source and a reliable temperature-controlled heated glass is one of many important features of a high-quality UDAF bench! Why?

   Unreliable light source will affect the search for COCs, oocytes, and handling as well evaluation of embryos. Defect temperature control could affect the meiotic spindle, embryo development, and outcomes (IR).

Culture Media in IVF: Decisions for the Laboratory

Jason E. Swain

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_12

Learning Objectives

- Identify key energy substrates included in human embryo culture media and the developmental stages that utilize them
- Discuss macromolecule supplementation and available options in clinical IVF
- Understand pH control of embryo culture media and factors within the laboratory that impact pH

12.1 Introduction

Substantial efforts have been taken in attempts at refining and improving IVF culture media since the initial reports of human embryo culture utilizing somatic cell media, such as Ham's F10 [1, 2]. Through the work of pioneers like Quinn and Menezo, media designed specifically for human embryo culture in vitro initially became available [3, 4]. Extensive studies in the mouse from the lab of John Biggers led to media formulations later adopted for use in clinical IVF [5–8]. Subsequent modifications and refinements to these media ensued, and it is now possible to routinely grow blastocysts in vitro in defined media without the use of serum.

This pursuit has resulted in an extensive body of literature examining various culture media formulations, culture paradigms, supplemental additives, and their impact on embryo development. Because of the breadth of these data, an exhaustive review of all media components is beyond the scope of this chapter. However, certain topics are required for embryologists to gain appreciation for the progression of the field, to understand the rationale for current media formulations, as well as to have the ability to make informed choices when it comes to selection and use of commercially available media within the laboratory. Importantly, certain aspects of IVF culture media, such as selection of media type, pH set point, and macromolecule supplement, are still directly decided or controlled within the IVF laboratory. Furthermore, media characteristics such as pH and osmolality can be inadvertently altered in the laboratory and thus require special attention. Review of these topics is necessary to optimize laboratory efficiency and ultimately IVF outcomes.

12.2 Laboratory Choices and Culture Media

12.2.1 Manufacturing and Consistency

Commercial production and supply of various IVF culture media is one of the primary causes for dramatic improvements in the field. Utilization of ultrapure water, clean facilities, and impeccable quality control during production has helped reduce much of the variability previously encountered within the IVF laboratory.

12.2.2 Media Formulations

Formulations should consider the specific cell types involved. When one mentioned "culture media" in the context of the IVF laboratory, this can actually refer to an entire suite of products that are often formulated based on the specific needs of the cell type for which use is intended. Sperm, oocytes (cumulus enclosed vs. denuded), and embryos of various developmental stages have different nutritional needs and environmental sensitivities. Thus, consideration of these cell types and the associated procedural steps should be considered when selecting media, and the multitude of media used throughout the IVF process should be considered when attempting to discern impacts of "culture media" on embryological or perinatal outcomes.

Most often, focus is placed on the medium used to culture preimplantation embryos.

In the last 15–20 years, there was a dramatic shift toward the use of sequential culture media, where cleavage-stage embryos are cultured in one medium formulation for the first 1–3 days and subsequently placed into a second medium formulation for the next 2–3 days to support morula compaction and blastocyst development. These media vary slightly in their composition, changing the levels of glucose and other energy substrates as well as altering the complement of amino acids, chelators, and other components. The rationale behind this approach is to meet the changing needs of the embryo by attempting to emulate what is observed in vivo, where the composition of oviductal fluid differs from that of uterine fluid [9]. In addition, this approach entails replenishing embryos with fresh culture media, ensuring adequate supply of substrates and removal of potentially harmful by-products, such as ammonia (Fig. 12.1).

In contrast, monoculture systems entail supplying a single medium formulation that is a product of exhaustive experimentation designed for "letting the embryo decide" which components it prefers [10]. These media have received renewed attention, largely due to the increased implementation of time-lapse incubators and the ability to use with uninterrupted culture throughout the culture period in attempts to minimize environmental perturbations. The approach of replenishing media at 2- to 3-day intervals to supply fresh nutrients and remove waste products is also compatible with this approach. Indeed, in a number of laboratories, monoculture systems prove to be as efficient as sequential culture systems in terms of embryo development, morphokinetic timings, and implantation/live birth outcomes [11–18].

Extensive data on the release or depletion of nutrients by both mouse and human embryos led Leese [19] to propose the "quiet embryo hypothesis," which suggests that a reduced metabolic level is consistent with a viable phenotype. Further, environmental stresses are seen as one of the components that elevate metabolic activity resulting in heritable damage to daughter cells

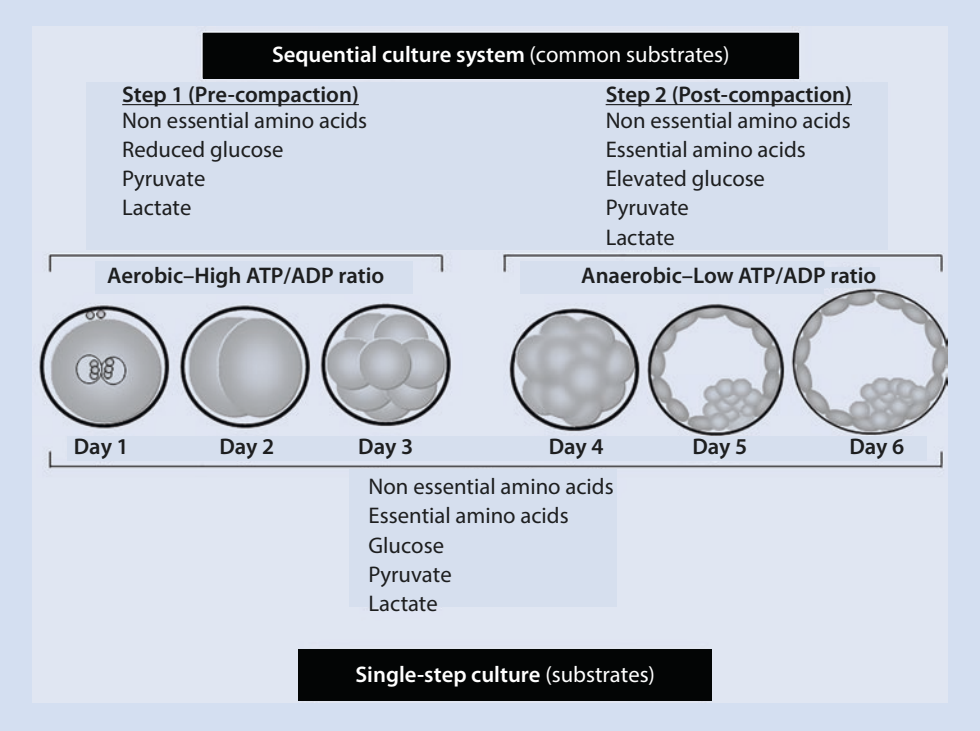

Fig. 12.1 Key energy substrate components of embryo culture media

such as heat shock and nucleic acid damage [19, 20]. The extent to which "noisy metabolism," induced by stresses from the in vitro environment, influences embryonic responses to various metabolite challenges during medium design experiments remains unknown. But it is important to realize that all current media formulations were developed in animal models, not with human embryos, and it is not known that human zygotes respond in the same manner as those from other species to a specific environmental challenge. Medium design should therefore be considered a work in progress.

Regardless of the approach employed, the success of such a wide variety of media underscores the plasticity seen with regard to the embryo's ability to adapt to its environment. Importantly, though many media support embryo development, their efficiency needs to be evaluated in the context of their use within a particular laboratory, in conjunction with the variety of other supplements and processes that make up the complete culture system [21, 22]. To this end, careful attention to detail and development of more sensitive endpoint assessments are needed to truly tease out minor improvements and lab-to-lab variability. Emerging data indicate that "embryo culture media" may impact human embryo gene expression patterns [23, 24] and perhaps even birthweight [25–29], though existing studies have done a poor job in controlling for confounding variables in the culture system that may also impact results (i.e., protein supplement, pH, oxygen tension, etc.) and fail to isolate culture media as the sole variable potentially responsible for observed outcome differences. Others indicate that media have no impact on perinatal outcomes [30, 31]. Independent of which media are utilized, certain themes hold true and are important to understand in order to appreciate intricacies of embryo physiology and to assist in making informed decisions within the lab.

12.2.2.1 Glucose

Glucose has been a wide source of contention within the field of embryology and is one of the primary variables in sequential culture media. Though cleavage-stage human embryos can use glucose, it is in minimal amounts compared to oxidative substrates like pyruvate [32–35]. Indeed, sequential systems utilize reduced levels of glucose (0–0.5 mM) in the first step of their system, also often include EDTA, which further suppresses glycolysis [36]. Furthermore, culture media devoid of glucose support high rates of human embryo development and pregnancy during the first 3 days of culture [37–40]. Thus, any minimal initial requirement for glucose may likely be obtained through initial exposure and carryover from handling media containing glucose or from internal stores of glycogen. Metabolic studies indicate that mammalian embryos primarily utilize glucose during compaction and blastocyst development. Therefore, the second media employed in sequential systems raise the concentration of glucose (>2.0 mM). Single-step media supply glucose at intermediate levels and also contain EDTA. This would seem to contradict the rationale used to rationalize the need of sequential media but, in the context of other nutrients, is able to support embryo development to the blastocyst stage.

12.2.2.2 Lactate/Pyruvate

Though extensive focus has been placed on glucose and its role in supporting blastocyst development, perhaps more important are the roles of energy substrates that permit the prerequisite cleavage-stage embryo development. The addition of lactate to early salt solution media was instrumental in supporting development from the two-cell stage of mouse embryos [41]. Furthermore, pyruvate was discovered to be imperative for cleavage of one-cell mouse zygotes and is the

primary energy substrate for cleavage-stage embryos [42, 43], including human, where it is used throughout development to the blastocyst stage [34, 35, 46]. Importantly, low levels of lactate can affect pyruvate metabolism [47, 48] and can also acidify internal pH [50, 51]. It has been suggested that only the metabolizable L-lactate isomer be included in culture media formulations to avoid excess suppression of internal pH that may exist with the use of D/L-isomers [47, 48].

12.2.2.3 Amino Acids

Amino acids can serve as energy sources to developing embryos but also serve to maintain intracellular homeostasis by acting as zwitterions to buffer pH and antioxidants and as organic osmolytes to control cell volume [52]. As a result, amino acids are now an essential component to successful embryo culture media. Tedious sets of experiments were conducted examining effects of individual amino acids on hamster embryo development [53]. These studies demonstrated that three amino acids in particular improved development in the context of the utilized base medium: glutamine, taurine, and glycine. Additional experiments conducted by Lane and Gardner utilized commercially available mixtures of amino acids known as Eagle's "essential" and "nonessential amino acids" in a sequential culture system. These studies determined a preferential exposure sequence that improved embryo development and viability following transfer, which entailed addition of nonessential amino acids with glutamine during the first 3 days of culture, followed by inclusion of all 20 amino acids during the following 2–3 days [54]. Benefits of amino acids are also evident when included in a monoculture system, such as KSOM, yielding improved blastocyst development, cell number, and hatching rates [6, 8, 55]. Indeed, even brief exposure of mouse zygotes to media lacking amino acids can impair development [56]. Therefore, it is imperative that all media contain some source of amino acids, especially handling media utilized for oocyte retrieval and ICSI.

One potential concern with amino acids in culture, especially during cleavage-stage development, is their breakdown and production of ammonia, which may impact subsequent development and health of the resulting offspring [57–61]. Of particular interest is glutamine, which is the most labile of the amino acids [62, 63]. Fortunately, dipeptide forms of glutamine, such as alanyl-glutamine [59]) or glycyl-glutamine [62–64], are stable at 37 °C and help alleviate this concern. Therefore, the use of media utilizing these stabile forms of glutamine is highly recommended. With modern embryo culture media, utilizing minimal amino acid concentrations and inclusion of dipeptide glutamine, ammonium production is minimal. Of note, while dipeptides may reduce ammonia production, they may not be as readily used by embryos as the individual component amino acids [65, 66].

12.2.2.4 Salts (Osmolality)

An important concept in regard to culture media is osmolality and its resulting effect on cell volume and ultimately embryo development. High osmolality can compromise embryo development and was one of the underlying causes of the "two-cell block" observed in early embryo culture media studies (see review [67]. Osmolality of commercial culture media vary (Table 12.1). Fortunately, active mechanisms exist in oocytes and embryos to regulate cell volume, and these mechanisms depend on media ingredients. Therefore, selection of appropriate culture media is paramount. Studies demonstrate various amino acids provide protection against high osmolality [76–78] and are thus recommended in all media to aid in this regulation [67]. Special concern exists in changing from one media to another, such as between handling media and culture media with differing ion composition, which can impact cell volume regulation. In addition, choice of culture volume can impact media osmolality due to evaporation while on heated working surfaces as well as due to air movement over culture dishes within flow hoods during dish preparation and use [79] (Fig. 12.2). Use of larger volumes of media helps combat resulting osmolality rise, and adequate oil overlay is essential, especially if using non-humidified incubators to prevent evaporation and resulting in dramatic increases in osmolality [80]. Culture in dry incubators, even under oil, can still result in evaporation and harmful osmolality increase (Fig. 12.3). This is of special concern if using an uninterrupted culture approach with a single-step medium [81]. It is useful to confirm that media osmolality is still within specific ranges following standard dish prep, especially in busy labs that may prepare numerous dishes at one time. It is also useful to confirm media osmolality following standard culture practices (drop size/time). If media osmolality is higher than acceptable ranges, dish preparation methods or culture practices can be adjusted (limit number of dishes made at one time, replenish media more frequently, increase drop size or oil overlay, etc.).

12.2.2.5 Phenol Red

Phenol red is a common media component added to media to help visually monitor pH. This may be useful to gauge media age or incubator function. Some media have chosen to exclude this indicator due to possible negative impact on embryo development. It has been suggested that possible estrogenic effects of phenol red could be detrimental. However, estrogenic activity appears to be due to the con-

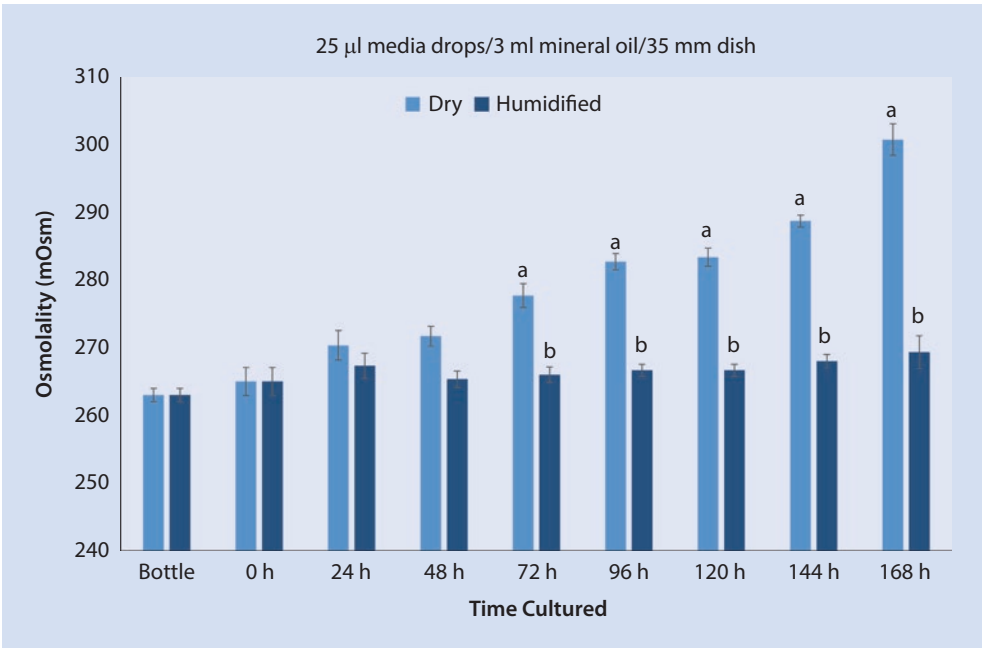

Fig. 12.3 Culture conditions can impact media evaporation during incubation, even under mineral oil. Special precautions need to be taken when culturing in non-humidified benchtop incubators, especially if using a single-step media with uninterrupted culture over 5–7 days. Different superscripts within a time point indicated a significant difference in osmolality between humidified and non-humidified culture

taminants in certain preparations not due to the phenol red itself [82]. Additionally, it has been suggested that phenol red use may lead to generation of reactive oxygen species (ROS) following light exposure [83], though this has not been shown using modern human embryo culture media. Therefore, it cannot be concluded that phenol red conveys a negative impact and its use in media may be useful.

12.2.2.6 Antibiotics

Though not required, an antibiotic of some sort should likely be included in embryo culture media. If an antibiotic is included, gentamicin, rather than penicillin/streptomycin (Pen-Strep) should be utilized. Ninety-one percent of contamination cases in IVF were Pen-Strep resistant [84], and Pen-Strep was detrimental to human and hamster embryo development [85, 86], possibly via damage to embryo chromatin, gene expression, and increased apoptosis [87]. Additionally, gentamicin is heat and pH stable, and of 70 bacterial strains in contaminated embryo media, all were sensitive to gentamicin [84].

12.2.3 Macromolecules

Macromolecules are an especially important consideration in discussions of IVF culture medium since their source, composition, and concentration are still largely decided within individual laboratories (Table 12.2). Therefore, diligence and familiarity with their components and effects are critical.

As IVF culture media advanced, the field moved toward the use of a fully defined media, and the use of maternal serum was largely abandoned. However, protein and other

Osmolarity can be inadvertently changed through common laboratory practices, and measures should be taken to avoid evaporation and harmful osmolarity increases

macromolecules still prove beneficial by improving embryo development, increasing cryo-tolerance, also acting as surfactants, and increasing colloidal osmotic pressure [88]. Some labs began to use commercially available serum substitute products such as Plasmanate or Plasmatein. A common protein source utilized for in vitro embryo culture is serum albumin, though lot-to-lot variation can be a concern [89], as well as the presence of various contaminants. Therefore, recombinant albumin is also used and has been found to be as effective or superior to albumin in animal models [68, 69]. Importantly, "contaminants," found in serum-derived macromolecules, may include beneficial growth factors [90]. A growing trend in human embryo culture is the use of more complex macromolecules. Inclusion of alpha and beta globulins with human serum albumin (HSA) improved human embryo development [71] and live birth outcomes [70] and may be concentration dependent [91]. Additionally, macromolecules such as hyaluronan are advantageous when included in culture media [73–75]. In vivo, embryos are surrounded by various proteins and macromolecules. Thus, they likely play a physiologic role in supporting embryo growth. Potential benefit of these macromolecules may stem from nutritional roles but may also be tied to improvement of the physical environment stemming interactions with water as suggested by Pool and Martin [71]. These authors postulated that the more pronounced interaction of water with glycoproteins, compared to albumin, might be beneficial in the in vitro environment. As a test of this, dextran, a linear polymer of glucose and a molecule known to interact strongly with water, was added to albumin as a medium supplement [72]. This combination supported embryonic developmental rates equivalent to albumin with alpha and beta globulins and produced clinical pregnancy [71, 72]. It should also be mentioned that macromolecules might be advantageous with respect to embryo transfer media. Hyaluronan has been suggested as being advantageous for transfer and embryo implantation, though conflicting data exist [92–100]. The potential for benefit is unclear as the compound cannot penetrate the zona pellucida to access the embryo and no receptors are present on the zona pellucida, though one cannot rule out direct uterine effects. Another potential rationale is that increased viscosity of transfer media may be advantageous to promote adherence of embryos to the uterine wall and can be accomplished through the use of increased protein concentrations. Another important factor to consider and monitor when utilizing macromolecules is their effect on media pH.

12.2.4 pH

While a large amount of attention in regard to IVF culture media has focused on concentrations of energy substrates or supplemental additives, the very basic principle of acid-base balance is often overlooked. Though this parameter is routinely indirectly measured during daily laboratory quality control assessments of the atmospheric CO_2 content of our incubators, it is often not appreciated that we are in fact attempting to monitor medium pH (external pH, pHe). This is a very important consideration because, though commercial

media companies now control many aspects of media production and quality, the laboratory itself directly controls this aspect of culture media.

The pHe of culture media is the measure of hydrogen ion concentration. This is set primarily as the result of the equilibrium between dissolved bicarbonate supplied in the media and CO_2 in the incubator, which dissolves in solution to yield carbonic acid. The importance of this parameter becomes more apparent when one stops to think about proper lab procedures, such as the rationale for limiting patient numbers in a single incubator, reducing incubator openings/closings, installation of inner incubator doors, minimizing dish time out of the incubator, and the use of oil overlay. All of these practices serve to limit the amount of external stress imposed upon gametes and embryos in an attempt to optimize the in vitro culture environment by stabilizing the CO_2 environment and ultimately pHe. Though mammalian embryos have various mechanisms to regulate their intracellular pH (pH_i) [101], including the Na^+/H^+ antiporter and HCO_3^-/Cl^- transporter, excursions in pHe are readily converted to variances in intracellular pH (pH_i), at least initially [102]. Additionally, denuded mature oocytes, as well as cryopreserved/thawed embryos, have a greatly reduced ability to regulate pH_i [103–106]. Ability to regulate pH_i in the oocytes is normally controlled by surrounding cumulus cells and does not become inherent to the egg until 3 h after fertilization. Similarly, following warming, pH_i regulatory capacity does not return around 6 h.

The need to establish a target pHe and adopt procedures to limit drift is clear when one considers pH controls several intracellular processes that can impact embryo development. Deviations in pH_i for only a few hours can have dramatic impacts. Raising (~7.4) or lowering (~6.8) pH_i in mouse embryos for only 3 h disrupts localization of mitochondrial and actin microfilaments compared to controls (~7.2) [107]. Minor rises in pH_i can dramatically impact embryo metabolism through the regulation of various enzymes, such as phosphofructokinase (PFK). Raising pH_i ~0.1–0.15 units for just a few hours significantly increased embryo glycolysis and lowered oxidative metabolism [50, 105], which can dramatically impact developmental competence. Considering pH_i regulatory capacity can be impaired for several hours after denuding eggs or warming embryos, the need for tight pHe control becomes more apparent. Finally, more recent evidence suggests that pH cannot only affect embryo development but resulting fetal development as well. Lowering the pHi of one-cell mouse embryos from 7.25 to 7.1 for 19 h resulted in significantly fewer blastocyst cell numbers, higher levels of apoptosis, and reduced fetal size/weight compared to controls [108].

12.2.4.1 Optimal pHe?

The ability of embryos to regulate pH_i is evidenced by various studies that show embryos can develop over a pHe range of ~7.0–7.4 without any discernible effect on pH_i or development [109, 110], while excursions of pHe outside this range have deleterious effects on embryo developmental competence [111–115]. However, just because blastocysts can be formed over these pHe ranges does not indicate that resulting embryo quality is equivalent. Drifting too far away from the pH_i of around 7.1 likely stresses the embryo, as more resources are required to maintain the proper pH_i. Conventional wisdom tells us that the pHe of culture media should be slightly higher than pH_i to help offset the acidification that occurs as a result of intracellular metabolic processes. Thus, many laboratories culture their embryos in the range of 7.2–7.4. However, considering that pH scale is logarithmic, a range of 7.2–7.4 encompasses a >60% change in the molar $[H^+]$, and a tighter range is likely prudent.

Unfortunately, there is likely no "optimum" pHe for oocytes and embryos, as this will vary from medium to medium based on specific ingredients [116, 117]. The amount of monocarboxylic acids, such as lactate and pyruvate, in culture media can lower pH_i [50, 51]. Additionally, amino acids, particularly glycine, taurine, and glutamine, act as zwitterions and help in buffering pH_i [50]. Thus, though pHe may be the same, embryos grown in different media with different amounts of monocarboxylic acids may have different pH_i. Along with potential species or strain-specific requirements associated with various animal models, this likely explains variations in the literature regarding acceptable and optimal pHe [43, 44, 118, 119]. Regardless, it would be insightful to see a properly controlled clinical trial to determine if culturing human embryos at a pH closer to 7.2 offers any benefit on embryo development, implantation, or live birth compared to culturing embryos in the same media at a pH closer to 7.3–7.35. The lack of consensus as to an "ideal" pHe at which to culture embryos is reflected in the wide ranges of acceptable pHe given by various commercial media companies (Table 12.3) [116, 117].

Furthermore, despite the growing trend, it remains unknown whether early cleavage-stage embryos prefer a slightly lower pHe than later stages of embryo development. A preliminary study using sibling oocyte splits and a single-step media adjusted pH by altering CO_2 levels suggests that perhaps a lower pHe (higher CO_2) during cleavage stages and a higher pH (lower CO_2) during later developmental stages may be advantageous [120]. Similar results have been reported for mouse embryos, though pH was adjusted in sequential media by changing bicarbonate concentrations [121]. However, it should be noted that adjusting pH by changing CO_2 may not yield the same outcomes as changing pH through adjusting bicarbonate levels (as is done with some sequential media by the commercial manufacturer) [122]. It is known that later stages of embryos with tight junctions, like the morula and blastocysts, can regulate their pH_i more rigorously than early cleavage-stage embryos and can thus tolerate a wider range of pHe [50]. Additionally, later stage embryos may have different requirements for bicarbonate or CO_2, as these serve roles in membrane-bound transporters and biosynthetic pathways. Interestingly, there are data to suggest a slightly more alkaline pHe may benefit fer-

Table 12.3 Recommended pH ranges for various commercial IVF culture media

Media	Recommended pH range
Irvine	
P1	7.27–7.32

Sydney IVF Blastocyst	7.3–7.5

CO_2 will need to be adjusted by the laboratory to obtain the recommend pH range. Some companies recommend tighter ranges than others. (Data in parentheses indicate tighter recommended ranges from the manufacturer that may not be indicated in product literature)

tilization. Dale et al. [102] found higher rates of sperm binding to empty zonae pellucidae at pHe 7.5 compared to lower pHe. This has led to the common practice of fertilizing oocytes in a slightly higher pH, culturing day 1–3 embryos in a slightly lower pH and culturing day 4–6 embryos in a slightly higher pH (high-low-high paradigm).

12.2.5 Handling Media and Buffers

Due to the crucial nature of pH in gamete and embryo physiology, the importance of IVF handling media used for manipulations outside the incubator is also an important consideration [116, 117, 123–126]. These media are formulated to maintain appropriate pHe in room atmosphere, outside the elevated CO_2 concentrations of the incubator. Though techniques such as oil overlay can combat this pH rise, dishes of bicarbonate-buffered culture media kept out of the incubator with oil for even brief periods can result in pH rising above 7.4 [124, 125, 127]. Thus, for procedures such as oocyte retrieval, sperm processing, oocyte denuding, ICSI, and embryo transfer, it is often recommended that special handling media be utilized that resists changes in pHe. In the past, handling media included phosphate-buffered saline solutions (PBS), and some laboratories continue to use this medium for oocyte retrieval. However, PBS lacks essential components, such as bicarbonate and metabolic substrates. These inadequacies, coupled with elevated levels of phosphate, may compromise gamete and embryo metabolic activity, disrupt organelle distribution, and interfere with intracellular ionic homeostasis, including intracellular pH [128–130]. Indeed, even brief exposure to PBS as a handling media has been shown to compromise hamster and rabbit embryo development [131, 132] and results in aberrant gene expression in bovine embryos when compared to other buffers [133]. Therefore, a better choice, and an approach that has benefited IVF, entails adoption of handling media that contain appropriate energy substrates, bicarbonate (though at reduced levels to help maintain pHe), and synthetic organic buffers to maintain media pH within a desired range at room atmosphere. These buffers, commonly referred to as Good's buffers, are organic compounds derived from zwitterionic amino acids that provide supplemental buffering capacity over physiologic pH range of approximately 6.1–8.3 [134–136] (Fig. 12.4a). However, different cell types display varying sensitivity to individual zwitterionic buffers [134]. Thus, determining the suitability of specific buffers for use with mammalian gametes and embryos in IVF is crucial. Two of these commonly used in commercially available handling media for ART are 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES) and 3-(N-morpholino)-propanesulfonic acid (MOPS) and are selected based on their pKa values, an indication of their optimal buffering capacity.

a

Buffer	pH range	pKa 25 °C	pKa 37 °C
MOPS	6.5–7.9	7.20	7.02
TES	6.8–8.2	7.40	7.16
HEPES	6.8–8.2	7.48	7.31
DIPSO	7.0–8.2	7.60	7.35
MOBS	6.9–8.3	7.60	n/a
TAPSO	7.0–8.2	7.60	7.39

b

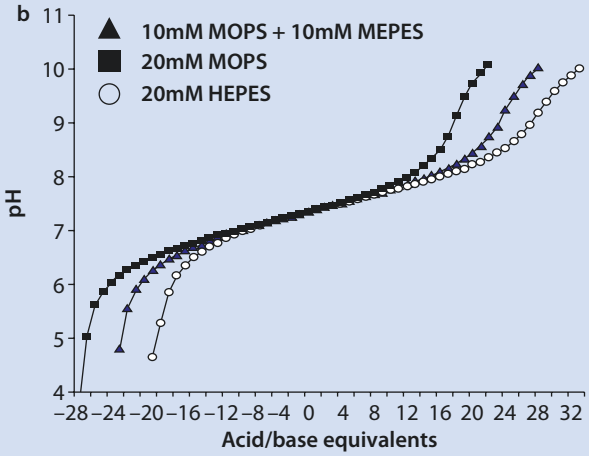

Fig. 12.4 **a** Common zwitterionic (Good's) buffers and their pKa values (optimal buffering) in relation to temperature. **b** Combining buffers allows for adjustment of pKa at specific temperatures

Historically, HEPES at ~21 mM has been a standard for IVF handling media, though commercial companies may also include MOPS or a mixture of the two compounds [124–126]. Both buffers are efficient, and laboratories using media containing these buffers yield high success rates. However, though HEPES has been widely used in IVF for years, its suitability for procedures has been questioned [137, 138]. Importantly, many of the conclusions drawn concerning toxicity of HEPES are often derived from a progenitor literature that has been cited incorrectly and the conclusions are not fully supported by the studies performed. In considering these pharmacologic effects, it is essential to note that many are largely dependent on interactions with other compounds in the media, not due to toxicity of the buffers themselves. Thus, it is important to examine the use of these buffers in the context of specific base medium. Early somatic cell studies citing HEPES toxicity stemmed from light exposure and interactions with riboflavin [139, 140]. This may have also been a factor in the observations of Butler et al. [141]. Though no data were presented, the authors commented that inclusion of HEPES in the medium resulted in increased oocyte degeneration; however, the medium contained riboflavin. Several studies actually indicate HEPES is able to support oocyte maturation [142–144], fertilization [144–148], and embryo culture [137, 144, 147, 149–152]. Those studies indicating lower fertilization rates in the presence of HEPES are likely due to the simultaneous reduction in bicarbonate concentrations [148]. Embryo development is supported in the presence of HEPES when bicarbonate is present, but not when bicarbonate is absent [151]. Furthermore, when embryos are cultured at room atmosphere and compared to controls cultured in 5% CO_2, differences in development cannot be attributed to HEPES alone. Elevated CO_2 of the laboratory incubator is utilized by embryos for various biochemical processes as a carbon source [153–155] and is likely beneficial over culture at room atmosphere. It has been demonstrated that 25 mM HEPES has no adverse effect on mouse embryo development and that there are no adverse effects of up to 50 mM HEPES when cultured with 25 mM $NaHCO_3$ in ~5% CO_2 [124, 125]. Though there may be species-specific sensitivities to HEPES, or other buffer systems, data indicate that when adequately controlling for other factors such as osmolality, bicarbonate levels, gas levels, and pH, these buffers are able to successfully support mammalian embryo development.

Temperature is another variable to be aware of regarding the use of zwitterionic buffers in IVF handling media [124–126]. Though it is known that temperature can affect pH probe readings and should be accounted for when measuring pH in this respect, it is often not appreciated that the pKa of synthetic organic buffers, as well as the actual pH of the media, changes as temperature changes [124, 125]. As an example, MOPS was presumably selected as an alternative to HEPES for IVF media not only due to toxicity concerns but also because its pKa of 7.2 is the closest of the 20 zwitterionic buffers to the pH_i of embryos of 7.12 [156]. Thus MOPS would seemingly offer the best pH buffering of available options. However, the pKa of 7.2 for MOPS is at 25 °C. Many laboratories warm their handling media to around 37 °C, a temperature at which the pKa for MOPS is actually 7.02. This is low, considering many labs set their media pH between 7.2 and 7.4. Thus, utilization of MOPS alone, or any other single buffer for that matter, may not offer ideal pH buffering of IVF.

12.3 Future Directions

12.3.1 Improved Handling Media

A novel concept to address concerns with buffer toxicity in handling media, as well as the issue of temperature and optimal pH stability, is the combination of several organic buffers into a single solution [157]. Combining buffers allows for selection of an exact pKa value at a given temperature, which may be more appropriate and offer better buffering than a single buffer (Fig. 12.4b). Additionally, superior buffering and combination of buffers allows for the use of lower individual buffer concentrations, thus lowering possible toxicity concerns and may be superior to current handling media with commonly utilized 21 mM of buffer. Indeed, this approach is a valid substitute for current mono-buffered handling media. Swain and Pool [124, 125] verified that bi- and

tri-buffered media with combinations of zwitterionic buffers support mouse embryo development. Preliminary data suggest these buffers may be beneficial for ICSI over mono-buffered media [124, 125]. With further testing and verification, additional buffers such as DIPSO or TES or their combinations with HEPES and MOPS could be explored and added to further refine media. In addition, specialized handling media for varying cell types may offer an avenue for further improvement. Just as sequential media have been developed to meet the differing needs of the embryos, formulating handling media to meet the differing needs of sperm, oocytes, and varying stages of embryos may be beneficial.

12.3.2 Improved Media Stability

12.3.2.1 Stable Additives

Supplementation of media with various additives has proven to be a major source of IVF culture improvement. Use of the dipeptide form of glutamine has proven to be beneficial due to its increased stability in culture and resulting decrease in ammonia production [62–64, 158]. A similar approach could be explored with other amino acids such as glycine [65] or other ingredients, such as pyruvate. In addition to its role as a metabolic substrate, pyruvate also acts as a powerful antioxidant [159] and can protect embryos from harmful reactive oxygen species (ROS) [160–162]. However, sodium pyruvate, the form of pyruvate added to all current embryo culture media formulations, is labile in solution [163]. By-products of pyruvate breakdown interfere with key steps in the TCA cycle, thereby compromising metabolic activity [163, 164] and are not able to scavenge ROS. Preparations of sodium pyruvate stored in media at 5 °C for 1 month may produce enough by-product to inhibit embryo metabolism [165]. A potential improvement over current use of sodium pyruvate in embryo culture media entails the use of esterified forms of pyruvate, such as ethyl- or methyl-pyruvate. These esterified forms of pyruvate have proven superior to sodium pyruvate in various experiments in somatic cells examining their protective effects against various stress paradigms [166–176]. Interestingly, in preliminary studies, both ethyl and methyl pyruvate were superior to sodium pyruvate in supporting mouse embryo development when pyruvate was the sole energy source [177] and appeared superior for embryos from mice of advanced maternal age [178]. Thus, these esterified forms of pyruvate may lend added benefit due to increased stability in solution or increased membrane permeability, factors that could have an impact on both or embryo metabolism or ability to scavenge ROS.

12.3.2.2 Progressive Media and Microfluidics

An intriguing possibility to improve upon current IVF culture media lies in its use in conjunction with another technological development known as microfluidics [179–184]. Media could be flowed over or around embryos in an occasional or continuous fashion to replenish nutrient, remove by-products, or change media composition. Through the use of automated microfluidic devices, one could potentially integrate in-line, real-time assays to monitor growth conditions. Nanosensors could theoretically detect changes in the growth environment or sense other cues from the developing cells and subsequently modify the culture environment seamlessly, without the need for removing dishes from the incubator or manually moving embryos. In essence, this would improve upon current monoculture or sequential culture systems and on practices such as splitting all cases between two media [185], by providing a customized growth environment of endless compositional possibilities suited to the specific needs of particular embryos, rather than expecting all embryos to adapt to a predetermined environment of just one or two media formulations.

12.3.2.3 Lyophilized Media/Dishes

Another approach to improve the stability of media components is through the use of lyophilized media. Lyophilized media avoids component degradation from being in aqueous solution for extended periods. This permits storage for longer periods of time, with reconstitution at the time of use. While reconstituting lyophilized media in bottles in not overly novel, one could envision having spots/drops of lyophilized media adhered to specialized culture dishes. Water could be added immediately prior to use at a time sufficient enough for equilibration, but not for extended periods where media components can degrade and harmful by-products produced. Coupled with a microfluidic system, one could envision an automated pipette system or media flow within the incubator to a discrete area of lyophilized media to rehydrate and equilibrate the media and then move the embryo to the new media. This would avoid degradation over time and would be compatible with uninterrupted culture approaches without the need to remove the dish from the incubator, thus permitting a sequential or multistep media system in an uninterrupted fashion.

Review Questions

1. There are two main approaches to embryo culture media. Regardless of the approach utilized, one energy substrate is required to permit cleavage-stage embryos to undergo the first cell division. This energy substrate is:
   (a) Glucose
   (b) Amino acids
   (c) Lactate
   (d) **Pyruvate**
   (e) Glutamine

2. The laboratory is trialing a new culture media that is presupplemented with protein. This is a departure from their normal medium, where protein is supplemented within the laboratory. Upon initial use and following overnight

equilibration in the same incubators they used with their old medium, it is noted that the color of the culture media appears more yellow than that previously observed. What would likely correct this?

(a) Raise incubator CO_2 levels
(b) **Lower incubator CO_2 levels**
(c) Raise incubator O_2 levels
(d) Lower incubator O_2 levels

3. What is the closest approximate internal pH of embryos that helps establish the recommended pH range of embryo culture media?

(a) 6.9
(b) **7.1**
(c) 7.3
(d) 7.5
(e) 7.7.

4. The best way to decrease the pH of culture is to:

(a) Increase CO_2 and increase bicarbonate concentration
(b) Increase CO_2 and decrease protein supplementation
(c) **Increase CO_2 and increase protein concentration**
(d) Decrease CO_2 and increase bicarbonate concentration

5. Perhaps one of the most researched substrates, this carbohydrate is not required for early cleavage and can inhibit early embryo development. It is used primarily by morula and blastocysts.

(a) Pyruvate
(b) Lactate
(c) Amino acids
(d) **Glucose**
(e) Glutamine

6. High levels of ammonium in culture media can impair embryo metabolism and development and possibly affect offspring. The most appropriate method to reduce ammonium production in culture media is to:

(a) Lower media pH
(b) Use a single-step medium
(c) Utilize a sequential medium
(d) Supplement with complex protein supplements
(e) **Utilize a medium containing a dipeptide**

7. This amino acid is primarily responsible for ammonium build-up in culture media.

(a) Glycine
(b) Taurine
(c) **Glutamine**
(d) Alanine
(e) Methionine

Assessment of Oocyte Quality

Basak Balaban

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_13

Learning Objectives

- The maturity stage of the oocyte is of major importance for the successful fertilization outcome after in vitro fertilization (IVF) or intracytoplasmic sperm injection (ICSI). Visualization of the morphological appearance of mature metaphase II stage (MII) oocyte may also play an important role on the clinical outcome specifically for ICSI cycles at which the cumulus-corona cells are removed before the fertilization procedure.
- The objective of this chapter is to provide an overview of the effect of morphological deviations of MII oocytes on the clinical success in assisted reproduction.

Key Points

The deviations that should be examined with high priority are in the following order:

- Oocytes that are large in size (giant oocytes) and oocytes that have a large first polar body should not be used for insemination because of the high risk of chromosomal abnormalities. If the patient has only such oocytes, preimplantation genetic screening of the derived embryo can be recommended.
- Oocytes should be observed for the presence of smooth endoplasmic reticulum cluster/s within the cytoplasm. The patient should be informed that embryos derived from such oocytes may have significantly reduced rates of healthy offspring.
- Oocytes should be observed for the presence of vacuole/s within the cytoplasm. Patients should be informed that MII oocytes with vacuole(s) ≥14 μm have a significantly lower chance of getting fertilized when compared with oocytes with a normal morphological appearance.
- Oocytes should be observed for the presence of organelle clustering/centrally located condensed granulation within the cytoplasm. The patient should be informed that embryos derived from such oocytes may have a higher risk of chromosomal abnormalities.
- Oocytes defined with other cytoplasmic deviations such as refractile bodies/cytoplasmic inclusions or with dark cytoplasm/dark cytoplasm-granular cytoplasm/dark cytoplasm with slight granulation/dark granular appearance of the cytoplasm/diffused cytoplasmic granularity should be documented.
- Ovoid oocytes with ovoid zona and normally shaped oolemma or ovoid zona and ovoid oolemma should be observed as the blastocyst formation rate of embryos derived from such oocytes may be detrimentally affected and delayed.
- Oocytes with extremely large perivitelline space (PVS) may result in reduced fertilization rates and higher degeneration rates following ICSI.
- Dysmorphic zona pellucida, discoloration of the oocyte, first polar body morphology, and debris in PVS should be documented.

13.1 Assessment of Oocyte Quality by Morphology

Assessment of oocyte morphology and determination of its correlation with quality/viability and the clinical outcome are difficult tasks, since the underlying mechanisms that change the appearance are multifactorial and complex. Optimal oocyte morphology is defined as an oocyte with a spherical structure enclosed by a uniform zona pellucida, with a uniform translucent cytoplasm free of inclusions and a size-appropriate polar body [1, 2]. However, metaphase II stage (MII) oocytes retrieved from patients after ovarian stimulation are known to show significant morphological variations that may affect the developmental competence and implantation potential of the derived embryo.

More than half of the oocytes collected can contain at least one morphological abnormality, and this may be correlated with the asynchrony between nuclear and cytoplasmic maturations of the MII oocyte, which plays an important role on its viability and the clinical outcome. Morphological variations of the oocytes may also result from other intrinsic factors such as age and genetic defects or extrinsic factors such as stimulation protocols, culture conditions, and nutrition.

Conflicting results are published in the literature regarding the effect of morphological variations of the oocyte on embryo development and implantation.

This chapter reviews the correlation of morphological abnormalities of the MII oocyte and the clinical outcome and the effect on genetic disorders, discusses the predictive value of specific abnormalities, and examines whether any of these parameters can be utilized in all the scoring systems applied in in vitro fertilization (IVF) laboratories.

Morphological abnormalities of the oocyte will be observed under two different subgroups: extracytoplasmic abnormalities and cytoplasmic abnormalities [1–4].

13.2 Morphological Deviations of Mature Metaphase II Stage Human Oocytes

13.2.1 Cytoplasmic Abnormalities

Cytoplasmic abnormalities of MII oocytes include different types and degrees of cytoplasmic granulations (slightly diffused or excessive whole/centrally located granulation) and appearance of refractile bodies, smooth endoplasmic reticulum clusters (sERCs), or vacuolization in the ooplasm. Detection of cytoplasmic variations was first termed as cytoplasmic dysmorphism by Van Blerkom and Henry in 1992 [5] and since then used as a selection method to assess the viability and implantation potential of the derived embryos.

13.2.1.1 Morphological Appearance of the Cytoplasm

Although the appearance of cytoplasm was considered as a potential predictive factor for the success of clinical outcome, different definitions and groupings of multiple morphologi-

cal features in various published studies make the comparative analysis difficult. The terminologies used in the literature are dark cytoplasm [6–8], dark cytoplasm-granular cytoplasm [9], dark cytoplasm with slight granulation [10], dark granular appearance of the cytoplasm [11], and diffused cytoplasmic granularity [12]. High subjectivity of the definition of these types of granulations in various laboratories provides limited predictive value for the clinical outcome. Despite the fact that the majority of the clinical trials examining the effect of dark granular cytoplasm as an individual feature showed no detrimental effect on the viability of the derived embryo [6, 9–11] and even may be associated with higher fertilization when compared with the group of oocytes with total absence of granularity [13], controversial results were also published by other authors [7, 8, 12]. Variations published in these articles may be correlated with the subjectivity of the definition, as diffused slight cytoplasmic granularity, so-called also as dark cytoplasm, can be ill-defined and could differ by different modulations of the optical path in phase-contrast microscopies in various laboratories. Homogeneity of the cytoplasm is expected; however, biological significance of non-homogeneity is unknown, and based on current evidence, it may only represent variability between oocytes rather than a dysmorphism of developmental significance [1].

Centrally Located Granulation of the Cytoplasm

Condensed granulation that is centrally located within the cytoplasm with a clear border is unlike various degrees of diffused granulation described above, as it is easily distinguishable with a significant darker appearance than normal cytoplasm, which could be clearly visible by any modulation type of the optical path in different phase-contrast microscopies. It had first been defined by Serhal et al. [14] with a detrimental effect on the outcome of intracytoplasmic sperm injection and named as centrally located granular cytoplasm (CLCG) by Kahraman et al. [15] later. It was indicated that CLCG is a rare morphological feature of the oocyte that is diagnosed as a large, dark, spongy granular area in the cytoplasm, and the severity is based on both the diameter of granular area and the depth of the lesion.

Even though fertilization rate and embryo quality were not affected in the study by Kahraman et al., poor ongoing pregnancy chance correlated with high aneuploidy (52.3%), and abortion rates (54.5%) were obtained by the transfer of embryos derived from oocytes with severe CLCG. The study by Meriano et al. [16] defined CLCG oocytes as organelle clustering and found out that this certain abnormality is the only repetitive dysmorphism in consecutive cycles and is a negative predictor of pregnancy and implantation rates in intracytoplasmic injection cycles. Even though more research is needed to define the subcellular and molecular mechanisms of organelle clustering, hypoxia of the follicle was shown to be correlated to oocytes of such poor developmental competence [17]. It has also been demonstrated that MII oocytes that exhibited severe cytoplasmic disorganization had a lower intracytoplasmic pH and ATP content as well as increased incidence of aneuploidy and chromosomal scattering [18, 19], which was later confirmed by Kahraman et al. as well [15]. A more recent study by Yakin et al. [20] had also shown that the embryos that were derived from oocytes with severe cytoplasmic abnormalities where CLCG oocytes were included had a higher rate of aneuploidy rate (60.0%) when compared with group of embryos derived from oocytes with a normal morphological appearance (41.9%). However, the results were not statistically different most likely based on insufficient number of embryos included in the comparison. The same group demonstrated that cryopreserved day 3 cleavage stage embryos derived from oocytes with severe cytoplasmic abnormalities, where CLCG oocytes consisted the majority of the experimental group, had a significantly lower cryosurvival rate, and even if they survived, they had lower rates of blastocyst formation, and none of the blastocysts obtained were of good quality, and none were able to successfully complete the hatching process [10]. Based on the evidence proof, it is important to inform patients about such morphological defect of the MII oocyte and the reduced implantation outcome, as well as increased risk of aneuploidy with the resultant embryos [1].

Refractile Bodies

Refractile bodies are so called as cytoplasmic inclusions, which can be dark incorporations, fragments, spots, and dense granules: lipid droplets and lipofuscin. Transmission electron microscopy studies and Schmorl staining had shown that refractile bodies over 5 μm showed the conventional morphology of lipofuscin inclusions consisted of a mixture of lipids and dense granule materials [21]. Lipofuscin bodies in human oocytes can be detected throughout meiotic maturation (GV, germinal vesicle; MI, metaphase I; and MII, metaphase II stage), which is different from other cytoplasmic abnormalities in humans, such as smooth endoplasmic reticulum clusters, which appear only in mature MII oocytes.

The average diameter of a recognizable refractile body under bright-field microscopy is approximately 10 μm [22]. As in the majority of the published articles, cytoplasmic abnormalities are examined jointly, whereas data on the individual predictive value of refractile bodies on clinical outcome are limited. According to some investigators, cytoplasmic inclusions did not appear to affect fertilization, embryo quality, and implantation rates [5, 8]. A more recent study by Rienzi et al. [12] has also shown that refractile bodies do not detrimentally affect fertilization and normal pronuclear morphology rates. In contrast, Xia [23] and Otsuki et al. [21] reported a decreased fertilization rate and embryo development. It is most likely that controversial results might be correlated to the factors that are still unknown, and one possible confounding factor could be the differing diameters of refractile bodies. Only one study in the literature had examined precisely the relationship between the sizes of the refractile bodies and developmental competence of oocytes and had found that lipofuscin inclusions were associated with reduced fertilization and unfavorable blastocyst development only when their diameter is over 5 μm. This study

had also shown that the size of refractile bodies is not correlated with the age of women, or different stimulation protocols, and the embryo developmental outcome was not significantly affected by stimulation regimes [21]. According to the outcome found by Otsuki et al. [21], the aging of oocytes during inactive phases of oogenesis may not be involved with lipofuscinogenesis; instead, the accumulation of lipofuscin may occur during the growth phase of the oocytes when dominant follicles are being recruited into the preovulatory pathway. The occurrence of large lipofuscin bodies in normal aging may also be related to conditions of the developing ovarian follicles, such as perifollicular blood circulation and follicular fluid composition. Other explanations can be related to oxidative stress [24], proteolytic degradation [25], or lipid metabolism as a source of energy supply [26]. Further research will be needed to investigate whether any of these possibilities are involved in refractile bodies mainly, which are mainly correlated with lipofuscinogenesis in human oocytes.

Vacuoles

Vacuoles are membrane-bound cytoplasmic inclusions filled with fluid that is virtually identical with perivitelline space liquid [27]. Their sizes and numbers may vary, and it is assumed that vacuoles arise either spontaneously [27] or by fusion of pre-existing vesicles derived from smooth endoplasmic reticulum and/or Golgi apparatus [28].

The incidence of vacuoles in MII oocytes varies from 3.1% [11] to 12.4% [29]. However, multiple vacuolization is a less likely seen phenomenon with approximately 1%–1.5% [6, 7, 30]. The study by De Sutter et al. [6] reported a severely reduced fertilization rate in vacuolated oocytes (40%) compared with oocytes without any vacuoles. Ebner et al. [30] had also reported a significantly decreased fertilization rate for oocytes containing single vacuoles (51.6%) and multiple vacuoles (43.8%) compared to oocytes without vacuoles (65.3%). A more recent study by Rienzi et al. [12] demonstrated a significantly reduced fertilization rate for vacuolated oocytes; however, pronuclear morphology and embryo quality were not detrimentally affected. Only one study [30] had a subgroup analysis examining the effect of the size of the vacuoles on fertilization rates and in fact found out that the group of oocytes that fertilized normally in between vacuolated oocytes contained vacuoles with less than 9.8 ± 3.7 μm diameter, which was significantly smaller than the diameter of vacuoles that the unfertilized oocytes contained (17.6 ± 9.0 μm). A cutoff value of 14 μm for vacuole diameter was noted, above which fertilization did not occur. This study had shown that a larger vacuole or multiple vacuoles may cause a much more detrimental effect to the oocyte than a small vacuole, since a larger portion of the cytoskeleton (e.g., microtubules) cannot function as it is supposed to. The study by Van Blerkom et al. [27] also suggested that large vacuoles might displace the metaphase II stage spindle from its polar position, which in turn can result in fertilization failure, cleavage abnormalities, and/or an abnormal cytokinesis pattern. Even though the presence of few small vacuoles (5–10 μm in diameter) that are fluid filled but transparent is unlikely to be of biological consequence, observation of large vacuoles bigger than 14 μm should be noted [1]. Besides the deficiency on fertilization rates, it has also been shown that blastocyst formation, good quality, and hatching blastocyst rates can significantly decrease after intracytoplasmic sperm injection of vacuolated oocytes. The percentage of aneuploid embryos can also be affected by the utilization of vacuolated oocytes (41.9%) when compared with embryos that are derived from oocytes with a normal morphology (60.0%) [20]. Vacuolization in MII oocytes can also decrease cryosurvival rates and subsequent embryonic development of the derived cryopreserved embryos [10].

Smooth Endoplasmic Reticulum Clusters (sERCs)

The presence of sERCs in the cytoplasm of MII oocytes is one of the most important cytoplasmic defects that need to be carefully examined. Correlation between the presence of sERCs in MII oocytes and the clinical outcome was first published by Otsuki et al. [31]. Otsuki reported that in approximately 10% of the cycles, cytoplasmic localization of translucent vacuoles similarly sized as pronuclei exists at the metaphase II stage of human oocytes after the denuding procedure for intracytoplasmic sperm injection. This incidence was 5% in the study of Mateizel et al. [32], whereas it was 7% in the study of Braga et al. [33]. However, it is most likely that the number of oocytes with sERCs can be underestimated, as it has been shown by transmission electron microscopic analysis that there are at least three forms of sERCs: large (18 μm); medium (10–17 μm), which can be classified by light microscopy; and small (2–9 μm), which are not visible under the conditions used in clinical embryology laboratories for examination. sERCs can easily be distinguished from fluid-filled vacuoles since they are not separated from the rest of the ooplasmic volume by a membrane and seen as translucent vacuoles. Even though the mechanism responsible for sERCs is still unknown, there are some human and animal studies assuming that it could be correlated to some functional and structural alterations of ER during oocyte maturation such as an increase in the sensitivity of the IP3 receptor for Ca^{2+} [34]; increased storage of Ca^{2+}, which is released during oscillation [35]; changes in the structure from a sheet-like form to a spherical form in starfish oocytes [36]; and distribution of the ER in mouse oocytes [37]. In the human oocytes, the localization of mobilizable Ca^{2+} was detected in the small vesicles beneath the plasma membrane of sER. Otsuki et al. [31] compared the clinical outcome of patients with oocytes containing sERCs and patients with retrieved oocytes without sERCs and examined whether any confounding parameters such as stimulation methods and hormonal levels can affect the outcome. Fertilization rate and embryo quality were not detrimentally affected; however, significantly lower clinical pregnancy and implantation rate and significantly higher biochemical pregnancy were observed for sERC-positive cycles. Due to the limited number of sam-

ples tested, no significant differences were found between the study groups when stimulation protocols were compared. However, the number of sERC-positive oocytes obtained by the short protocol was about three times larger than that by the long protocol. Serum estradiol levels on the day of hCG administration were significantly higher in sERC-positive cycles. This study had clearly shown that the viability of an embryo is significantly reduced with the presence of sERCs. Even though the embryo is derived from an oocyte without any clusters, its implantation potential is detrimentally affected if the oocyte is from the cohort of oocytes where at least one oocyte is with clusters. Besides the viability of the derived embryos, the most important issue with the presence of sERCs had been the neonatal safety based on evidence proof in the literature. In the study by Otsuki [31], only one pregnancy derived from gametes with an sER defect has been reported, in which the baby was diagnosed with Beckwith-Wiedemann syndrome.

The study by Ebner et al. [38] had shown that the occurrence of sERCs is significantly related to longer duration and higher dosage of the stimulation. Fertilization and blastocyst formation rate were significantly lower for oocytes with sERCs when compared with oocytes without sERCs. Take-home baby rate was significantly lower in the group with sERCs, and miscarriage rate was significantly higher in the same group of patients. Pregnancies in women with affected gametes had a significantly higher incidence of obstetric problems. Birth weight of babies born in the group with sERCs was significantly lower, and there were two unexplained neonatal deaths reported in the group with affected gametes, whereas there were no deaths reported in the group without sERCs. The malformation rate was similar in both groups, with one case of diaphragmatic hernia reported in the group with sERCs. Similar findings reported by Ebner [38] and Otsuki et al. [31] support the idea that this phenomenon is the manifestation of an intrinsic oocyte defect caused by a suboptimal ovarian stimulation [27] and perhaps as a result of overstimulation. Following other studies reporting multiple malformations [39] and ventricular septal defects [39] after the transfer of embryos originated from oocytes with sERCs, it was strongly recommended that oocytes with this feature should not be inseminated and even the sibling oocytes should be carefully examined [40]. However, a very recent study [32] in which 394 sERC-positive cycles and 6845 sERC-negative cycles were retrospectively analyzed should lead the investigators to further research as this study reported that there was no difference in the rate of major malformations between sERC-positive cycles (5.3%) and sERC-negative cycles (82.1%). In addition, no major malformations were reported from the live born definitely originating from embryos originated from oocytes with sERCs positive. Three newborns, from single-embryo transfer with frozen-thawed embryos originating from sERC-positive oocytes, were delivered and presented no major malformations. Taking into account these recent controversial data on neonatal outcome, the fate of babies born from oocytes with this feature should be very carefully evaluated and reported.

13.2.2 Extracytoplasmic Abnormalities

A variety of extracytoplasmic anomalies exist, which in part negatively influence fertilization (consistency and thickness of the zona, polar body (Pb)1 decay, and debris within the PVS), blastulation (thickness of zona, Pb1 fragmentation), and pregnancy (thickness of zona, Pb1 morphology, debris in PVS). Characteristics of the zona pellucida and the PVS are most probably associated with the health of the developing follicle, e.g., its vascularization and oxygen content. Any disturbance during growth might severely alter oocyte morphology resulting in a pool of gametes with different prognoses.

13.2.2.1 Dysmorphic Zona Pellucida

As a result of the mutual dependence between somatic cells (e.g., cumulus cells) and the egg, it is likely that any disturbance negatively affecting the follicle will have a comparable impact on the oocyte itself. Among the conceivable changes in oocyte performance, it is possible that the secretion/patterning of the zona pellucida (ZP) from the secondary follicle onward could be altered or interrupted [41, 42]. This could result either in dysmorphism that can be seen under a light microscope or more subtle changes of the three-dimensional structure of the ZP.

Definitely the most severe form of impaired growth of the zona pellucida is its complete absence. Normally, up to four zona proteins [43, 44] build up the three-dimensional matrix of the outer protective shell. Filaments are constructed of repeating zona protein (ZP) 2 and 3 units, which are cross-linked by ZP 1 [45], thus contributing to the structural integrity of the ZP. Experiments in mice lacking the ZP1 gene showed that secreting only ZP2 and ZP3 results in a thinner, more loosely organized zona pellucida [46]. On the other hand, disruption of ZP 2 and 3 led to complete absence of the acellular coat resulting in infertility [47].

In humans, a defect in gene expression was shown to cause a failure in glycoprotein matrix, even though the ovum itself showed intact corona cells [48]. In such rare cases, the ova fail to fertilize in conventional IVF. In ICSI, there is a considerable risk of exposing the gametes to mechanical stress during the denudation process. Stanger et al. and others [48, 49] showed that in patients with zona-free eggs, pregnancies can be achieved by simply leaving the coronal cell layer attached, as it acts as a supporting structure keeping the oocyte in shape during injection.

From conventional IVF, it is known that thicker zonae (e.g., >20 μm) are associated with lower fertilization rates [50]. This has been linked to patient and stimulation parameters [51]. In ICSI, however, a thicker zona interferes with neither subsequent fertilization nor implantation since assisted hatching can be applied.

Recently, it has been published that the multilaminar structure of the ZP can also be analyzed quantitatively using polarized light microscopy [52]. Though variation exists in the thickness of zona layers around individual eggs and between members of a cohort, it is evident that the inner zona layer is the most dominant part of the zona [42, 52]. It

has been reported that the birefringence of the inner zona is directly proportional to its thickness [42, 53, 54].

Shen et al. [42] found an almost 30% higher mean light retardance in conception cycles compared to non-conception cycles, indicating that stimulated cycles may yield oocytes of affected quality. There are two retrospective studies that have suggested a relationship between ZP birefringence (inner layer) and preimplantation development. Montag et al. [54] noted a higher rate of good-quality embryos on day 3 (but not on day 2) in an oocyte group with high zona birefringence (41.7%) as compared to a cohort with low birefringence (24.4%). Others [53] observed a difference in progression to the blastocyst stage. The lower the measured retardance, the lower the blastocyst formation.

13.2.2.2 Discoloration

Irrespective of the actual thickness of the ZP, ovarian stimulation sometimes generates gametes showing a zona pellucida that appears dark or brownish under a light microscope. Mostly, the egg itself is affected as well. In the literature, it is reported that the presence of discolored ZP is a common phenomenon, e.g., 9.5–25.7% [6, 9, 29, 55].

It has to be kept in mind that it is not completely clear that dark or brown zonae/oocytes occur for the same reasons. Recently, these oocytes were termed "brown eggs" since they were found to be dark with a thick ZP, a rather small perivitelline space (sometimes filled with debris), and granular cytoplasm [11]. Esfandiari and coworkers [11] prospectively compared the outcome of brown gametes with that of gametes of normal appearance. Although the zona in discolored eggs were thicker than that of control gametes, in conventional IVF, the fertilization rate was similar. The same was true for the fertilization after ICSI, embryo quality, implantation rate, and clinical pregnancy rate. However, it has to be mentioned that because of the thick zonae, brown oocytes were subjected to laser-assisted hatching significantly more often than the control group.

13.2.2.3 Shape Anomalies

Even if the thickness or color of the zona pellucida is inconspicuous, it is not automatic that the shape of the gametes is spherical. Indeed, there is evidence that extremely ovoid eggs exist [56]. Such gametes have been shown to be fertilizable and may lead to the birth of a healthy baby. However, a major problem with these reports is that the degree of the shape anomaly was not quantified, and rather more imprecise descriptions have been given (e.g., cucumber shaped).

Recently, our group successfully measured ovoid oocytes [57] and calculated a roundness index (RI, length divided by width). Actually, two indices were determined to assess whether the whole oocyte was affected (showing an ovoid ooplasm and zona) or only the zona pellucida was of ovoid shape (with the ooplasm being perfectly round). Special care was taken to detect splitting of the innermost zona layer that might keep ooplasm in round shape (while zona is ovoid). The latter dysmorphism was shown to be associated with implantation failure [42].

The degree of shape anomaly was correlated to neither fertilization nor embryo quality [58], which is in line with previous data [56]. Interestingly, two types of cleavage patterns were observed on day 2. Either ovoid gametes cleaved normally like a tetrahedron (a crosswise arrangement of four cells with three blastomeres lying side by side) or, if the ovoid zona failed to exert its shaping function, resulted in a rather flat array of four blastomeres. Since the abnormal pattern reduces the number of cell-to-cell contact points from 6 to 5 or 4, compaction and blastulation of the corresponding embryos may be delayed [57, 59].

Two possible mechanisms may account for the occurrence of ovoid oocytes. First, mechanical stress during oocyte puncture and/or denudation processes could deform the egg. This unwanted occurrence would create ovoid gametes with both ooplasm and zona being affected. In these artificially damaged gametes, a tendency toward recovery within a day has been suggested [57]. Thus, for the vast majority of ovoid ova, it can be assumed that the deformation is a preexisting anomaly generated during maturation within the follicle.

13.2.2.4 Perivitelline Space

The size of the perivitelline space (PVS) is closely related to the maturational phase of the oocyte. While at germinal vesicle stage (prophase I) expansion of PVS is minimal, it begins to increase after the resumption of meiosis. In detail, at metaphase I, PVS can clearly be detected, and after completion of maturation (metaphase II stage), its full size is reached.

Several authors have noted that up to 50% of all ova show a large PVS [12, 23]. In oocytes with a larger PVS, a lower fertilization rate was observed (67%) as compared to gametes with a normally sized (85%) gap [23]. This is more or less in line with the results of an Italian group [12], which showed that a large PVS is detrimental to fertilization and zygote morphology. Interestingly, patient parameters such as female age and indication did not seem to influence PVS performance [23], but the ratio of estradiol to testosterone (and to progesterone) did [58].

Data from in vitro and in vivo matured oocytes indicate that a large PVS may be ascribed to over-mature eggs [60, 61]. In other words, such eggs have shrunk in relation to the zona pellucida presenting a large gap between them. A large PVS would also occur if a larger portion of cytoplasm is extruded together with the haploid chromosomal set during first polar body formation. This would result in a large first polar body and a large PVS.

13.2.2.5 First Polar Body Morphology

For a long time, it was thought that first polar body (Pb1) extrusion marks the completion of nuclear maturation ending in a metaphase II stage oocyte. Recently, using polarized light microscopy, it has been demonstrated that some oocytes showing a Pb1 were actually in telophase I and not in metaphase II stage [62, 64]. Otsuki et al. [65] found a chromosome aggregation phase, which occurred not only from germinal vesicle breakdown to metaphase I but also from

telophase I to metaphase II stage. In case that ICSI is performed, although chromosomes are unaligned, it may result in failed fertilization or three pronuclear zygotes due to abnormal chromosomal segregation.

The impact of 1Pb morphology on outcome is still discussed controversially. Though some 1Pbs in humans remain intact for more than 20 h after ovulation, they generally have a shorter lifetime [66]. Taking this time dependency into consideration, it might be hypothesized that 1Pb morphology provides adequate information on the actual postovulatory age of the corresponding egg [61].

Ebner et al. [55] tried to focus exclusively on the status of the Pb1. Ova showing an intact Pb1 gave rise to higher rates of implantation and pregnancy [67] probably due to an increase in blastocyst formation [68]. However, these data are still a matter of debate [12, 55, 63, 68–71].

Apparently, the benefit of selecting oocytes according to the morphology of the Pb1 is somewhat reduced with increasing time span between ovulation induction and ICSI, since studies with different schedules could not find a relationship between constitution of the Pb1 and subsequent ICSI outcome [63, 70, 71]. In these data sets, the percentage of oocytes with fragmented polar bodies was higher [23, 63, 70, 71] than that reported in the work of Ebner et al. [55] in which polar bodies were scored 2 h after collection. This is in line with the finding that of all intact Pb1, 13% were already fragmented at a second inspection 3 hours later [71].

For practical reasons and in order to minimize the risk of ovarian aging in vitro [33], ICSI should be finished within 42 h post ICSI [72].

Data from Hungary [70] suggest that a large Pb1 is the worst case. When large Pb1s were extruded, embryos with multinucleated blastomeres were significantly ($P < 0.001$) more frequent (26.7%) than in all other Pb1 classes (ca. 8%). It has been postulated that the extrusion of an abnormally large Pb1 is due to dislocation of the meiotic spindle [73]. This would in part explain the observed impact on fertilization and embryo development [12, 55, 63].

13.2.2.6 Debris in the Perivitelline Space

Sometimes it is difficult to distinguish between heavily fragmented Pb1s and debris within the PVS. Two hypotheses have been proposed in order to explain the origin of the latter dysmorphism. One hypothesis is derived from ultrastructural data indicating the presence of an extracellular matrix comprised of granules and filaments in the space between oolemma and ZP since the matrix is identical to that found between cumulus cells and the corona radiata [74, 75].

The second hypothesis is based on the existence of coronal cell processes passing the zona pellucida and reaching the egg early in maturation. It is suggested that after withdrawal of these processes, some remnants remain within the PVS [76].

The findings of Hassan-Ali et al. [77] support the latter theory since they found a close relationship between the frequency of PVS granularity and maturation. In detail, they never detected debris in prophase I eggs but found debris in 4% of the metaphase I and in 34.3% of metaphase II stage gametes. They were also able to show that the presence of PVS granules was gonadotropin dose-dependent. If less than 30 ampoules were used to stimulate the patient, 17.4% of the eggs were positive for this anomaly compared to 45.4% in high-dose patients (>45 ampoules). Fertilization rate, cleavage rate, and embryo quality were found to be unaffected by the presence of coarse granules in the PVS [77, 78]; however, rates of implantation and pregnancy seem to be affected [78], since transfer of embryos derived from PVS granule-free oocytes increased implantation rate by 5% and pregnancy rate by 21%.

13.3 Conclusions

The final endpoint for evaluating morphological abnormalities of MII oocytes is to be able to correlate it with oocyte quality and viability and in correlation increase the overall efficiency of human-assisted reproduction in terms of clinical success and safety of offspring. High heterogeneity of the published material and subjectivity of the evaluation of morphological deviations of MII oocytes may only provide limited take-home messages on the predictive value of outcome parameters for successful results. It is of major importance to use the evidence-based definitions and visualizations (e.g., normal mature oocyte, extracytoplasmic deviations like zona pellucida, shape, perivitelline space and first polar body differentiations, dense cytoplasmic granularities, refractile bodies, vacuolization, and presence of sERCs for morphological deviations) to minimize the subjectivity [79]. A recent meta-analysis [80] examining the clinical results of 40 relevant articles on previously described extracytoplasmic and cytoplasmic abnormalities showed that there was no clear tendency to a general increase in predictive value of morphological features and that these contradicting evidence proof underline the importance of more intensive and coordinated research that would lead to more objective criteria with better predictive value to determine the viability of derived embryos. Rapidly developing continuous research on new biomarkers of oocyte quality may perhaps be utilized in addition or as an alternative to morphological assessment in the future; however, current limited predictive value of morphology should not be underestimated considering that they still remain to be the sole method of choice for selection until a more effective technology can substitute its utilization in routine practice in various clinical in vitro fertilization laboratories worldwide. Beyond the predictive value of oocyte morphology, it must not be forgotten that information linking dysmorphism with genetic disorders is of great value and scarce as these disorders are directly correlated with the health of the offspring in ART applications. According to a common hypothesis [5], the vast majority of extracytoplasmic anomalies occur late in maturation since they are associated with fertilization and developmental failure rather than with aneuploidy (e.g., giant eggs). However, evidence-based data clearly demonstrate that some specific severe cytoplas-

mic defects are correlated with chromosomal aneuploidy and genetic disorders as described above. It is obvious that some anomalies, e.g., so-called giant eggs [81, 82] with an almost double-sized diameter, show a diploid chromosomal set, which contributes to digynic triploidy. Other authors [83] analyzed embryos genetically according to their polar body classes. No correlation was observed between polar body shape and genetic constitution; however, the only polar body group bearing a theoretical risk of chromosomal disorder, considering the larger volume of ooplasm in large polar bodies, was not analyzed.

Review Questions

1. How can the normal morphology be defined for mature MII human oocytes?
2. Which type of morphological deviations can a mature MII oocyte have?
3. What are the cytoplasmic abnormalities a MII oocyte may consist of?
4. Which type of cytoplasmic abnormalities is shown to affect the clinical outcome?
5. What are the extracytoplasmic abnormalities of the MII oocyte defined in the literature?
6. Can any type of extracytoplasmic abnormality affect the clinical outcome?

Oocyte Denuding

Laura Francesca Rienzi, Roberta Maggiulli, and Filippo Maria Ubaldi

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_14

Learning Objectives

- Indication to oocyte denudation
- Laboratory routine procedures to perform oocyte denudation
- Noninvasive assessment of oocyte quality biomarkers
- Expedients to minimize any potential damage to oocyte viability
- Future directions and improvements about oocyte denuding

14.1 Overview

Mammalian folliculogenesis is a complex, fine-regulated process during which oocytes complete their growth and meiotic maturation. Throughout the preovulatory growth, within the follicle, two different cell layers surround the oocyte, *granulosa cells (GC) and thecal cells*, which support oocyte nourishment and maturation, providing essential metabolites, hormones, and growth factors [1–4].

Whereas a passive role of the oocytes in folliculogenesis was previously assumed, at the beginning of the 2000s, it became undeniable as an oocentric perspective of folliculogenesis that highlights the central role of the oocyte itself in directing its own development, as well as follicle differentiation [5–9]. In this regard, the oocyte is deemed capable of modulating the follicular environment in order to guarantee to itself a correct preantral, antral, and preovulatory development.

During follicular antrum formation, granulosa cells differentiate in two different specialized subpopulations: the cumulus oophorus (CC), whose innermost layer, immediately adjacent to the zona pellucida, is called corona radiata, and the parietal granulosa cells. Cells of the corona radiata extend their cytoplasm toward the oocyte through the zona pellucida, creating gap junctions with oocyte microvilli. Communications (either paracrine interaction or gap junction) occur between the oocyte and the cumulus–corona cells, allowing oocyte nutrition and maturation from the diplotene to the MII stage [10, 11]. During ovulation and resumption of meiosis (induced by the preovulatory peak of LH in natural cycles), a definitive retraction of corona cell process and changes in the organization of corona radiata are observed. In parallel, the LH surge stimulates a considerable active secretion of hyaluronic acid, causing further expansion of cumulus corona mass that appears finally as an expanded and mucified layer. This organized structure is referred to as cumulus–oocyte complex (COC). Cumulus expansion is essential for ovulation and fertilization as well as capacitation and selection of sperm.

An unexpanded cumulus with multilayers of compact GCs is a typical feature of immature COCs (for instance, those that are retrieved from small follicles during in vitro maturation cycles).

While in natural spontaneous cycles, oocyte nuclear maturation runs parallel to an increased FSH-dependent expansion and mucification of the cumulus layer [12], in stimulated cycles, an asynchrony of these two processes may be observed [13]. This may be caused by a different sensitivity of the oocyte and the cumulus–corona mass to the stimulants [13, 14].

Besides their well-established role in supporting oocyte maturation, cumulus–corona cells might also be involved later on in embryonic development. These cells are supposed to be involved in embryonic metabolism, either stimulating gene expression [15] or reducing oxidative stress [16].

During assisted reproductive treatments, oocytes are removed from the follicular microenvironment and exposed for a variable amount of time to artificial culture conditions without the protection of cumulus layers and prior activation induced by the sperm entry at fertilization. The effect of this is unknown and still unexplored.

14.2 Ovum Pickup and Cumulus–Corona–Oocyte Complex Harvesting

Once maturity of the follicles is accomplished, human chorionic gonadotropin administration is used to trigger ovulation, and oocyte pickup is performed approximately 36 h later, by ultrasound-guided transvaginal aspiration.

The technical details of oocyte retrieval can differ between centers, but basically the harvesting is carried out using an aspiration unit composed of a vacuum pump, a collection tube connected to a 17-gauge needle, and a collecting test tube. Today, several sophisticated vacuum pumps with adjustable aspiration pressures are available commercially.

During the collection, a maximum pressure of about 120 mmHg is recommended to avoid the risk to damage the oocytes, such as stripping of the cumulus cells or fracturing the zona pellucida [17].

Once the ovaries are visualized, ovarian follicles are aspirated in a systematic way. Immediately after the collection, the adjoining laboratory examines the follicular fluid. COCs are identified in sterile plastic dishes, rinsed, transferred in pre-equilibrated IVF medium tube, and incubated at 37 °C in an adequate atmosphere.

During the entire procedure, efforts should be made to minimize the oocyte exposure to even transient temperature and pH fluctuations that may have a detrimental effect on oocyte competence to develop. Redding and colleagues have investigated the variation in temperature, pH, and dissolved oxygen levels associated with oocyte retrieval, in a bovine model [18]. The authors reported a significant drop (7.7 ± 1.3 °C) in temperature, a pH increase of 0.04 ± 0.01, and substantial rises in the dissolved oxygen content of follicular fluid during follicular aspiration. Therefore, in order to minimize any potential impairment, the collection tubes should be kept in a tube warmer before being connected to the collection system.

14.3 Indication

Typically, a mature preovulatory COC is characterized by the presence of radiating corona cells surrounded by the expanded mass of CCs. The quality and the degree of expansion of these cells do not always represent a reliable index of oocyte maturity and are mostly dependent on the type of ovarian stimulation protocol used [12, 13, 19–21].

About 34–38 h after triggering ovulation, oocytes are supposed to be mature at the metaphase II stage, although it is possible to run into an immature oocyte at the germinal vesicle or metaphase I stage even in an expanded and mucified cumulus. Therefore, during ART procedures, cumulus cells surrounding the oocyte are removed to improve oocyte evaluation and manipulation.

Since the introduction of assisted fertilization techniques such as PZD (partial zona dissection), SUZI (subzonal insemination), and finally ICSI (intracytoplasmic sperm injection) [22], the removal of the surrounding cumulus and corona cells became a crucial step before fertilization. It allowed an unequivocal evaluation of oocyte nuclear maturity and identification of the first polar body in the perivitelline space that indicates a successful completion of meiosis I with arrest at the MII stage of development. Moreover, direct observation of oocyte morphology, including the extracytoplasmic components, is feasible only after denudation of its cumulus and corona layers.

In order to avoid sperm DNA contamination, ICSI has been indicated as the preferred insemination method when preimplantation genetic diagnosis is required. To this end, complete and meticulous removal of somatic cells is similarly of crucial importance, since extraneous DNA from maternal cumulus cells may also represent a potential source of contamination if a PCR-based technology is used [23].

14.4 Equipment and Procedure

The cumulus and corona cells are removed prior to any micromanipulation procedure by exposure of the COCs to a combined enzymatic and mechanical treatment that causes the breakdown of the hyaluronan-based matrix surrounding COCs and disperses the cumulus cells from oocytes [24]. Since hyaluronic acid is a major component of the mucified cumulus mass that surrounds the mature oocyte, hyaluronidase is employed for enzymatic removal of these cells. The type and concentration of this enzyme will be discussed later.

The procedure is usually performed under a stereomicroscope in different wells or microdrops containing buffered medium, usually covered by oil, on a warmed thermo plate.

A limited number of COCs are normally placed into the first well/droplet containing the enzyme to disperse the cumulus cells (Fig. 14.1a). To enhance enzymatic removal of the cumulus and corona cells, the stripping of cumulus cells is performed by pipetting repeatedly the oocytes through a glass/plastic pipette with an inner diameter of approximately 250 μm for up to 30–40 s.

Once initial cell dissociation is observed (Fig. 14.1b), oocytes are moved to the second well/droplet containing buffered medium, taking care to carry over a minimum amount of enzyme. Further denudation is then carried out to remove the corona cells by glass or plastic denuding pipettes with decreasing inner diameters (170–130 μm) (Fig. 14.1c). An accurate washing of denuded oocytes is then required to finally wash out the enzyme.

It has been proposed that a two-step denuding procedure involving an incubation period after oocyte exposure to the enzyme and before the mechanical step [25] may expedite the removal of cumulus cells while minimizing mechanical-induced oocyte damage. After partial removal of the cumulus cells by a short exposition to buffered medium containing the enzyme, the oocytes are rinsed in pre-equilibrated culture medium and placed back into the incubator for 30 min. This further step leads to a weakening of the hyaluronan matrix allowing an easier cumulus cell removal by gently pipetting oocytes with a 150-μm-inner-diameter stripper.

After denudation, the oocytes can be examined under an inverted microscope to assess integrity and the stage of maturation.

14.5 Timing

The oocyte denudation is usually performed between 37 and 40 h post-hCG administration and immediately before the insemination. Already in 1982, Trounson et al. [26] postulated that preincubation of cumulus–corona–oocyte complexes before conventional insemination was beneficial to the accomplishment of complete oocyte maturation and assured high rates of fertilization and embryo development in vitro.

However, no differences were reported between the effect of early (1–2 h after retrieval) and late (5–6 h after retrieval) denudation and injection on early embryo development [27]. The authors assumed that the stimulation protocol involved in the study allowed a well-synchronized nuclear–cytoplasmic maturation hiding the potential contribution of the cumulus–corona complex preincubation.

To evaluate whether the timing of ICSI has an effect on ICSI outcome, we analyzed the possible effects of preincubation of CCOC on fertilization and embryo development rates after ICSI [28]. In agreement with Ho and coauthors [29], we observed that a preincubation period of at least 3 h between oocyte retrieval and ICSI could improve the fertilization rate and embryo quality. This time might be necessary for some oocytes to reach full cytoplasmic maturity, leading to a higher activation rate upon microinjection.

Our observations have been challenged by Yanagida et al. [30], who showed that oocytes retained sufficient potential for fertilization between 1 and 9 h after oocyte collection. On the other hand, they observed that an extended preincubation time might be responsible for impaired embryo viability.

14

14.6 Oocyte Evaluation

In stimulated cycles, sibling oocytes belonging to the same cohort may differ greatly in their developmental potential. While morphological assessment of preimplantation-stage embryos is a basic element of the laboratory routine, the evaluation of the retrieved oocytes is rather rough and superficial. However, oocyte quality is a key limiting factor, holding a crucial role in fertilization, but affecting also the following embryo development [31]. Therefore, a proper selection of the most developmentally competent oocytes to inseminate would be valuable to improve the efficiency of ART treatment. However, due to the complexity of the oocyte maturation process, a comprehensive assessment of oocyte quality would require a detailed and noninvasive analysis of different key markers.

14.6.1 COC Morphological Assessment

Several scoring systems for cumulus–corona–oocyte complex evaluation have been introduced aiming to predict the nuclear maturity of the overshadowed oocytes and identify the proper timing for insemination [20, 32–37].

Early studies from Rattanachaiyanont et al. [20], performed on oocytes scheduled for denudation and insemination by ICSI, reported no correlation between oocyte–corona–cumulus complex morphology and nuclear maturity, fertilization rate, and embryo cleavage. On the other hand, other authors reported that COC scoring is related to fertilization and pregnancy rates [36] as well as to blastocyst quality and development [37].

According to the Alpha-ESHRE consensus document, there is not enough validated evidence to support the existence of a correlation between the appearance of the COC and embryo developmental competence; however, a binary score (0 or 1) with a "good" COC (score 1) defined as having an expanded cumulus and a radiating corona can be used as reference (38).

It has also been suggested that the presence of COC anomalies such as blood clots or amorphous clumps may be an index of a suboptimal follicular maturation and may impair embryo ability to develop to blastocyst stage [39, 40]. When these oocytes are denuded of their cumulus cells, a significant alteration in cytoplasmic texture has been highlighted that may be related to the reduced fertilization rate obtained when those oocytes are used for insemination [40]. Variations in temperature and pH as well, as reactive oxygen species induced by the presence of blood clots, are pointed to be at the origin of the compromised competence of those oocytes [34].

14.6.2 Oocyte Cytoplasmic and Extracytoplasmic Evaluation

It is generally recognized that a typical human metaphase II oocyte should have a round, clear zona pellucida; a small perivitelline space containing a single not fragmented polar body; and a pale, moderately granular cytoplasm not containing inclusions [41–48].

However, the majority of the oocytes retrieved after ovarian hyperstimulation exhibit one or more deviations from the described "ideal" morphological criteria [41, 44–50]. This is true also for oocytes obtained from proven fertile donors [51].

14.6.3 Nuclear Maturity

During oocyte development within the follicle, the nucleus is arrested at the prophase of the first meiotic division. Oocyte nuclear maturation consists in the resumption of the first meiosis, going through the germinal vesicle (GV) breakdown, first meiotic spindle (MS) formation, chromosomal segregation, and IPB extrusion. At this stage, the maturation process is not ended yet, and the oocyte has still to enter the second meiotic division where a second arrest occurs at metaphase II (MII) stage. This stage is characterized by the presence of the MS of the second meiotic division located at the oocyte periphery with one pole attached to the cell

cortex. This highly dynamic structure is formed by microtubule, with the chromosomes condensed and aligned at the equatorial region [52–56]. After insemination, this structure plays a crucial role in chromosomal disjunction and segregation and in the correct completion of meiosis and fertilization. MS alteration and dysfunction lead to unbalanced disjunction and/or non-disjunction of chromatids, chromosome scattering, and the formation of aneuploid embryos [54, 57, 58].

The presence of IPB in the perivitelline space is a marker of oocyte meiosis resumption, but not an evidence of MII stage achievement. It is only observing the presence of the MS of the second meiotic division that the oocyte nuclear maturation can be definitely assessed. Additional information on oocyte nuclear status can be acquired through the use of polarized light microscopy combined with software for image processing for the noninvasive visualization of the MS and other oocyte birefringent structures [59–62]. These systems consist of a microscope equipped with a green filter and a polarizer generating circularly polarized light. Highly ordinate and well-organized structures, such as the parallel-aligned microtubules composed of the oocyte MS, are able to shift the vibration plane and retard the polarized light. The induced retardance can be measured (nm), and this parameter is directly related to the microtubule density [60, 63, 64].

These systems allow to assess the position and appearance of the spindle and to recognize those oocytes that have not completed the first meiotic division and are still in telophase I [65–67]. At this time of the cell cycle, the oocyte cytoplasm and the cytoplasm of the forming IPB are not yet completely separated by cytokinesis. The MS appears to be interposed between the two separating cells, with its long axis corresponding to the axis connecting the center of the two cells. An oocyte at this stage is usually classified as a "mature MII" when observed with the conventional light microscopy. Although at this stage the presence of the IPB is evident in the perivitelline space, chromosome segregation is not completed. This condition normally takes 75–90 min. The MS then disappears in late telophase I, reappearing only 40–60 min later [68]. Therefore, at least in some cases, the absence of MS signal is due to the oocyte maturation process. However, oocyte exposure to suboptimal culture conditions during micromanipulation can contribute to MS disassembly [69]. Finally, the percentage of oocytes with detectable MS is also related to the time elapsed from hCG administration and is higher after 38 h [70]. In general, it is expected that at least 80% of oocytes recovered following ovarian stimulation are MS positive when viewed by polarized light microscopy.

When studying the MS, some factors must be taken carefully into account in order to keep under control those that may interfere with the visualization of the spindle (▶ Box 14.1). First is temperature control during oocyte handling [71, 72]. Second, the absence of MS may be due to unfavorable culture conditions and environmental changes [73]. Third is the MS orientation [74–76]: oocyte rotation by using a micropipette allows the correct orientation of the MS making it visible at the polarized light, with the long axis oriented perpendicular to the viewer's 66 axis [64, 74, 77].

Box 14.1 Parameters that should be considered during MS visualization with polarized light microscopy

1. Presence/absence of MS, which may be due to:
   1. Laboratory factors
      1. Temperature instability
      2. Chemical and physical stress during handling and culturing
      3. Correct oocyte rotation during visualization
   2. Oocyte maturation, which is related to:
      1. Time elapsed from hCG administration
      2. Interval between the first and second meiotic divisions
   3. Maternal factors (i.e., age)
2. Position and appearance of MS:
   1. Allow identification of immature oocytes (late telophase I)
   2. Allow assessment of IPB/MS relative position, which affects oocyte fertilization rate and the orientation of the first cleavage plane
   3. Allow the correct orientation of MS during ICSI

14.6.4 Cytoplasmic Aspect

To acquire full competence for subsequent fertilization and development, the oocyte has to undergo nuclear and cytoplasmic maturation in a coordinated manner. Disturbances or asynchrony of these two maturation processes is believed to result in a variety of oocyte morphological abnormalities [78–80]. The presence of cytoplasmic (vacuoles, refractile bodies, increased cytoplasmic granularity, smooth endoplasmic reticulum clusters) and extracytoplasmic (abnormal zona pellucida, large perivitelline space, or abnormal, fragmented, or degenerated IPB) defects may potentially reflect oocyte developmental impairments [41, 42, 48, 50, 81, 82].

However, a systematic analysis of 50 papers aimed to evaluate the predictive value of morphological assessment of MII phase oocytes has produced contradicting results [83]. None of the investigated features were found to have prognostic value in terms of oocyte viability and developmental competence.

This outcome may be due to the heterogeneity of the grading systems employed for oocyte morphological assessment and to the different outcome parameters assessed.

According to the Istanbul consensus workshop on embryo assessment [38], oocytes displaying cytoplasmic smooth endoplasmic reticulum (SER) aggregates should be managed with caution, because of an increased risk of an abnormal outcome. This conclusion was based on previously reported cases of Beckwith–Wiedemann syndrome [84], diaphragmatic hernia [85], multiple malformations [86], and ventricular septal defect [87] after transfer of embryos originated from SER-positive oocytes.

However, few years later, deliveries of normal healthy babies after the transfer of embryos derived from MII oocytes with visible SER [88] have been reported. Afterward, a systematic review analyzing the clinical outcomes for SER-positive oocytes could not demonstrate the existence of a clear association between SERs and fetal malformations. The birth of healthy babies from SER-positive embryos is encouraging and might lead to a revision of the current consensus in the future. In the meanwhile, oocytes displaying these abnormalities should be approached with caution, and the deriving embryos should be transferred only when no alternative viable embryos are available [89].

14.6.5 Extracytoplasmic Structure Evaluation

Extracytoplasmic peculiarities are classified as fragmented I polar body, abnormal I polar body (large and/or degenerated), abnormal zona pellucida (with sets and/or thick and/or dark), large perivitelline space, and abnormal oocyte shape (oval).

The Alpha-ESHRE consensus document stated that there is insufficient evidence to support any specific prognosis associated with these morphological abnormalities, with the exception of large polar body and giant oocytes [38].

The consensus suggested that oocytes with a remarkably large first polar body should not be considered for insemination, due to an increased risk of oocyte aneuploidy. In our setting, the presence of an abnormal first polar body in the metaphase II oocytes analyzed was relatively rare (4.4%). According to animal experiments [90], it has been postulated that the emission of an abnormally large polar body is due to the inability of the meiotic spindle to migrate correctly at the very periphery of the cell. It is, in fact, the position of the main axis of the meiotic spindle that dictates the orientation of the cleavage furrow. A centrally located meiotic spindle would lead to the formation of enlarged polar body [91]. The polar body morphology, and in particular large polar bodies, may be thus considered a marker of oocyte maturation disturbances [90, 91].

Special attention should also be focused on giant oocytes. Although the occurrence of these oocytes is relatively rare after ovarian hyperstimulation, the use of these cells for in vitro fertilization is potentially dangerous. It has been described that all embryos generated from giant oocytes are chromosomally abnormal, but they may have a normal cleavage and development to blastocyst stage [92]. The transfer of these embryos could thus increase the risk of undesired miscarriages [92].

14.6.6 Noninvasive Analysis of CCs

Efforts to date are directed to the identification of new reliable biomarkers of oocyte quality in order to compensate for the inadequacy of the COC morphological assessment [93, 94].

Follicular fluid, granulosa, and cumulus oophorus cells may offer novel biomarkers due to their close relationship to the oocyte. The bidirectional communication between the oocyte and CCs, essential for the acquirement of oocyte competence [31], can be investigated through noninvasive analysis of CCs (pattern of gene expression or protein synthesis). Given the complexity of the follicular differentiation process, a comprehensive evaluation of oocyte quality may involve the use of a combination of multiple markers.

Several authors have focused their attention to CC gene expression analysis as a noninvasive tool in predicting oocyte competence [95–103]. The main approach used to study CC gene expression is microarray analysis, to simultaneously evaluate the different expression of a large number of genes, followed by quantitative real-time polymerase chain reaction confirmation of CC transcriptome.

Although these results offer a set of potential biomarkers that could be useful for oocyte selection, the final end points of the studies in literature are quite different, generating some discrepancies in the results. To date, more evidence is needed in order to define a CC gene expression pattern that can be considered as noninvasive marker of oocyte quality.

14.7 Possible Damage to the Oocyte

14.7.1 Oocyte Parthenogenetic Activation

In mouse and human oocytes, chemical agents such as ethanol and Ca^{2+} ionophore as well as electrical field stimulation may initiate a series of events leading to the release of the meiotic arrest at metaphase II and consequent cell divisions of the activated oocyte. Although human oocytes seem to be less susceptible to artificial activation in comparison to other mammalian oocytes, several factors related to IVF procedures, such as the high vacuum pressures used for follicle aspiration, the high concentration of hyaluronidase used for cumulus cell stripping, as well as oocyte pipetting, may activate mature oocytes and induce parthenogenetic activation [104, 105].

When ICSI has been introduced, a concentration of 760 IU/ml of hyaluronidase was used to denude oocytes, but high parthenogenetic activation rates (17%) were observed [105]. Van Steirteghem et al. [106] were able to reduce the activation rate to 3% by employing lower concentration (78 IU/ml) of enzyme. Moreover, Joris et al. [107] investigated whether a further reduction of hyaluronidase concentration might influence oocyte intactness and its ability to fertilize and support embryo development. Although no significant effect on ICSI outcome was observed, a significant lower degeneration rate was registered when a concentration of 10 IU of enzyme per ml was used. This finding would justify the use of lower concentration of enzyme.

14.7.2 Meiotic Spindle

A less perceptible effect but likewise harmful to the oocyte is represented by the potential displacement of the polar body

following the denuding procedure. Notwithstanding the intrinsic ability of the polar body to move along the plasma membrane of the oocyte, the mechanical stripping of cumulus cells may impair the frame of microtubules and the actin filament organization, causing the break of the cellular bridges that connect the polar body to the oocyte. This would result in an IPB displacement from its original extrusion site [74].

The use of polarized light microscopy may be helpful in the assessment of the position of the MS in regard to the IPB. MS position at the very periphery of the cell, attached to the oolemma cortex [108], dictates the orientation of the cleavage furrow and thus the site of IPB extrusion. According to different studies, moderate degrees of IPB/MS deviation do not seem to affect ICSI outcome, in terms of fertilization and embryo development rates [74, 109]. However, in our laboratory, we found that a mechanical stress able to induce a dislocation of the IPB ≥90° with respect of the MS position is related to a lower fertilization rate [74]. MS dislocation has also been reported to affect embryo development since its position determines the correct orientation of the first cleavage plane and therefore of the animal vegetal pole [77]. It is thus advisable to perform oocyte denudation in a gentle manner.

Besides the hypothetical effect on ICSI outcome, a possible drawback of IPB displacement is the potential injury to the MS during microinsemination. In fact, when performing ICSI, the oocyte is maintained in a fixed position where the IPB is placed at 90° from the injection pipette entry site. Displaced IPB may thus expose the MS to the pipette passage during sperm injection and hence to mechanical damage. In view of this fact, the use of polarized microscopy was considered helpful during ICSI to allow the correct orientation of the MS (and not of the IPB). However, the usefulness of this technology for routine ICSI, together with the additional time and expense, is still questionable, since some studies have shown comparable fertilization and development rate of human oocytes subjected to ICSI regardless of the position of the spindle relative to PB1 [109, 110].

Moreover, it has been widely shown that oocyte exposure to even slight temperature variations dramatically injures the MS structure by inducing microtubule disassembly [73, 111–114]. In fact, MS microtubules are highly sensitive to chemical and physical stress that may occur during oocyte retrieval and handling. Thermal stability is therefore necessary during oocyte denudation, observation, and manipulation.

14.7.3 Mechanical Stress

In order to avoid damage to the oocytes, meticulous care should be taken during the mechanical removal of cumulus cells. In fact, excessive or vigorous pipetting of the oocyte may result in zona pellucida fracture and even oocyte degeneration. The stripping of the cumulus cells should be performed gradually by employing decreasing inner diameter denuding pipettes. The use of a stripper with a diameter smaller than 140 μm should be avoided since it may induce oocyte deformation and damage the oocyte cytoskeleton impairing its ability to sustain correct pronuclear formation.

14.8 Enzyme Type and Concentration

14.8.1 Hyaluronidase or Coronase

Traditionally, the denuding procedure involves a bovine-derived hyaluronidase. Bovine testicular hyaluronidase is an endo-β-*N*-acetyl-D-hexosaminidase that catalyzes the hydrolysis of hexosaminidic linkage contained in hyaluronic acid. Although purified preparations of the enzyme are commercially available, the possibility of animal-derived pathogens or contaminant transmission cannot be excluded [115]. The use of a plant enzyme preparation containing citric acid and pagane as well as NaCl and phosphate (coronase) has been proposed as an alternative to animal-extracted hyaluronidase. Because of the different action mechanisms of coronase that acts by chelating Ca^{++} ions and inducing a degradation of glycoprotein granules of the hyaluronic matrix, a longer exposure time to the enzyme is required [116]. However, coronase exhibited similar performance in terms of oocyte integrity and competence preservation when compared to conventional hyaluronidase. Moreover, because of the absence of any human or animal compounds, it may be more suitable for the clinical practice [116].

14.8.2 Enzyme Concentration

In order to minimize any potential toxic effect on oocytes, a reduced enzyme concentration as well as shorter exposure time is advisable. As already mentioned, lower concentrations of the enzyme such as 80 IU/ml, which is generally used in the clinical practice, significantly decrease the rate of parthenogenesis. A concentration as low as 10 IU/ml in combination with a denuding pipette of 1000 μm diameter has also been shown to be able to denude mature oocytes efficiently [25].

14.8.3 Animal-Derived or Recombinant Human Hyaluronidase

Several concerns arose from the clinical application of the animal origin enzyme that may be affected by a reduced purity and standardization. Human recombinant hyaluronidase (Cumulase) has been proposed to bypass problems and concerns associated with the animal-derived enzyme. De Vos et al. [117] have conducted a randomized sibling-oocyte study in order to validate the effectiveness of recombinant human hyaluronidase versus bovine-derived hyaluronidase, observing comparable results in terms of oocyte survival and fertilization. A following study [118] confirmed these findings with a significantly increased fertilization rate and decreased oocyte damage rate when the recombinant form of the enzyme was involved.

Therefore, the human recombinant form of the enzyme may represent a safer, quality-controlled, but likewise effective alternative.

14.9 Influence of Microenvironmental Conditions

A general principle for the physical environment is to keep it free of any insults. The handling of oocytes during the entire IVF procedure should be carried out under conditions of constant pH and stable temperature.

In order to prevent the evaporation of the medium and minimize the fluctuations of pH and temperature, 4-(2-hydroxyethyl)-1-piperazine ethane sulfonic acid (HEPES)-buffered media and temperature-controlled humidified chambers are employed to maintain these parameters in a physiological range.

14.9.1 Temperature

We have already affirmed that temperature fluctuations likely associated with the handling of oocytes may impair the microtubular system. Changes in spindle organization have been observed in human mature oocytes exposed to room temperature even for only few minutes [112]. Notwithstanding the ability of the meiotic spindle to reassemble when the temperature is reestablished, the risk of aneuploidy occurrence is increased after a temperature-induced depolymerization [112].

Because of this extreme meiotic spindle sensitivity to temperature changes, all the equipment in use (Petri dishes and Pasteur pipette) should be prewarmed at 37^0 C. In order to maintain a constant temperature in the droplets, the working areas (hood and microscope) and the thermo plate must be calibrated regularly. However, it is very difficult to maintain constant temperature without the use of specific chambers.

14.9.2 CO_2 Concentration

Dale et al. demonstrated that the baseline intracellular pH (pHi) of human egg is 7.4 ± 0.1 [119]. Unlike germinal vesicle that is endowed with a robust mechanism of pH regulation, denuded metaphase II oocytes are deficient of HCO_3^-/Cl^- and Na^+/H^+ functioning exchangers and do not have the ability to control and regulate intracellular pH [120]. It is only 2–3 h after fertilization that the oocyte begins to recover the exchanger activity and the consequent ability to regulate its pH. HEPES-buffered media are usually employed during oocyte handling outside the incubator in order to preserve oocyte homeostasis and avoid pHi fluctuations that may impair developmental competence. However, media containing bicarbonate/CO_2 buffers would be preferable, since requiring controlled chambers to maintain a 5–7% CO_2 atmosphere avoids the use of HEPES and thus the increased risk of toxicity to the oocyte. In fact, the low percentage of CO_2 entails a low percentage of HCO_3^- in the media, essential to the functionality of HCO_3^-/Cl^- exchanger and thus the HCO_3^--dependent mechanism that oocytes utilize to defend against acidosis. The use of combined multiple buffers, such as HEPES, MOPS, and DIPSO, into a single medium has been proposed to enhance the buffering capacity over a range of temperatures while simultaneously reducing the absolute concentration of individual buffers and then related toxicity concerns [121].

14.9.3 O_2 Concentration

Several IVF procedures entail an increase in oxidative stress that may be detrimental to the embryo. Although several physiological events, such as ovulation, fertilization, as well as the implantation process, are modulated by a reactive oxygen species (ROS) formation [122–124], a considerable increase in ROS concentration exceeding the oocyte antioxidant defenses may result in cellular structural and functional alterations. It has already been shown that during their journey along the female reproductive tract, embryos encountered a decreasing oxygen gradient. Moreover, oxygen levels in the oviduct and uterus of several species are considerably lower than in the atmosphere (1.5–6% vs. 21%). However, historically, most IVF laboratories have cultured embryos under atmospheric oxygen concentrations, probably because of the additional expenses required to perform culture at a lower oxygen concentration.

There are enough validated evidence for recommending the use of low oxygen tension (5%) within the incubation atmosphere to improve embryo development and potential to implant [126–148]. However, this benefit was observed only for embryos cultured and transferred at the blastocyst stage, and not for those at the cleavage stage. Even if the precise O_2 level may be developmental stage-dependent, the low oxygen level should be a principle for all mammalian embryo culture systems including humans.

14.10 Incomplete Denudation

In support of a positive effect of cumulus–corona cells on oocyte development, it was proposed that incomplete denudation of oocytes prior to ICSI improves embryo quality and development since it may assist embryonic metabolism, either stimulating gene expression [15] or reducing oxidative stress [16]. A study involving sibling oocytes investigated the actual effect of homologous adhering cumulus cells, resulting in improvement in terms of preimplantation development when oocytes were cultured with attached cumulus cells [149].

Similar findings were obtained in previous studies suggesting that the presence of cumulus cells allows better nuclear as well cytoplasmic in vitro maturation, particularly in oocytes that were immature at the time of denudation [150, 151].

14.11 Future Direction and Improvement

The involvement of automated systems in IVF procedures is attracting increasing attention. A micro-fluidic device has been proposed to remove cumulus cells automatically, aiming to minimize physical stresses related to this procedure [152]. The system entails pressure-driven flow to obtain a correct positioning and transit of COC into a micro channel that allows yielding predictable cumulus removal. Although further studies are required to assess the impact of these procedures on embryo health, several efforts are focusing on the development of a single integrated automated system skilled to perform all the steps from oocyte retrieval to insemination and embryo culture.

Review Questions

1. What are the indications to perform oocyte denuding?
2. What is the best timing to perform oocyte denudation?
3. Which morphological features should an "ideal" human metaphase II oocyte show?
4. What are the typical enzymes used to perform oocyte denudation in clinical practice?
5. Which microenvironment conditions should be properly and finely controlled during oocyte handling?
6. What are the most promising forthcoming devices that could be introduced in the near future to perform oocyte denudation?

Interrupted or Uninterrupted Culture to the Blastocyst Stage in a Single Medium

Don Rieger and Klaus E. Wiemer

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_15

Learning Objectives

- To understand the history of the development of culture media for human embryos
- To understand the characteristics and advantages of interrupted or uninterrupted culture in a single medium
- To understand the importance of laboratory air quality and other aspects of the culture conditions to the use of uninterrupted culture
- To know that each laboratory must make a careful comparison between interrupted and uninterrupted culture before adopting uninterrupted culture as routine practice

15.1 Introduction

The objective of embryo culture, as part of human-assisted reproduction, is to provide a suitable environment for the embryo to grow and develop from fertilization through to the appropriate stage for transfer into the uterus or cryopreservation. Although embryo transfer was originally done at the cleavage stage (Day 2 to Day 3), it has become clear that it is preferable to transfer at the blastocyst stage (Day 5 or 6), for a number of reasons. First, in spontaneous conception, the human embryo does not normally pass into the uterus until the morula to early blastocyst stage, and the uterus is likely not well equipped to support the cleavage-stage embryo. Second, gonadotrophin stimulation of the ovary to provide an increased number of oocytes results in very high circulating concentrations of estrogen that lead to abnormal development and functional activity of the uterus. Delaying transfer until the blastocyst stage allows the uterus to return, at least partially, to a more normal condition. Third, culture to the blastocyst stage allows for more extensive evaluations of the embryos, for the purposes of selection (and to a certain extent, self-selection) of the best one(s) for transfer. Before the major onset of expression of the embryonic genome, on Day 3, the development of the embryo is largely driven by the proteins and messenger RNA present in the oocyte. Evaluation of the cleavage-stage embryo provides little or no opportunity to evaluate the morphological, metabolic, or functional activity arising from the embryonic genome. Most notably, the de-selection of aneuploid embryos by preimplantation genetic screening (PGS) is much more effective at the blastocyst stage (trophectoderm biopsy) than at the cleavage stage (single blastomere biopsy).

Without question, the implantation rate for blastocyst transfer is superior to that for cleavage-stage transfer, so much so that high pregnancy rates can be achieved with the transfer of single blastocyst, with a very low incidence of multiple births. When combined with vitrification and single transfer in a subsequent unstimulated cycle, and 24-chromosome trophectoderm biopsy PGS, clinical pregnancy rates of greater than 60% are achievable, with almost no multiple births [1–3]. This must be considered as the future of human-assisted reproduction treatment (ART).

15.2 A Brief History of the Development of Embryo Culture Media

Defined tissue culture media began with Ringer's [4] simple salt solution containing NaCl, KCl, $CaCl_2$, and a low concentration of sodium bicarbonate ($NaHCO_3$), based on the constituents of blood serum, for the study of the beating frog heart, in vitro. Various modifications were made for the study of specific tissues (e.g., [5, 6]). Most notably, Krebs and Henseleit [7] increased the concentration of sodium bicarbonate to 25 mM (Krebs-Ringers bicarbonate, KRB). This 25 mM bicarbonate concentration is conventionally used with 5% CO_2 in many tissue culture media to produce a physiological pH.

Defined culture of mammalian embryos began with Whitten [8], who used KRB supplemented with 5.55 mM glucose and showed that eight-cell mouse embryos would develop to the blastocyst stage. In a landmark study, McLaren and Biggers [9] cultured eight-cell mouse embryos to the blastocyst stage in Whitten's medium and produced live young when they were transferred to recipient mothers. Whitten [10] added lactate and could culture outbred two-cell mouse embryos, but not zygotes, to the blastocyst stage, which led to the concept of the "two-cell block" to mouse embryo culture. Subsequent modifications of the concentrations of energy substrates by Brinster [11] and Whittingham [12] resulted in BMOC2 and M16, respectively. These media were widely used for mouse embryo culture, but, except for inbred strains of mice, they could not overcome the two-cell block. Blocks to development in vitro were similarly found for hamster (2 cells), cattle (8–16 cells), pig (4–8 cells), and human (4–8 cells) embryos, all approximately coincident with the major onset of expression of the embryonic genome (see [13]). Chatot et al. [14] were able to culture mouse embryos through the two-cell block with CZB medium, a modified version of BMOC2 with no glucose, 1.0 mM glutamine, and 0.1 mM EDTA. Although a significant step forward, it led to the mistaken idea that glucose was inhibitory to early embryo development (see [15]).

Embryo culture media based on simple salt solutions were followed by the "back to nature" approach to the formulation of media using the measured concentrations of the components of oviduct and uterine fluids: SOF, based on sheep oviduct fluid [16]; B2, based on cattle oviduct and uterine fluids [17]; HTF, based on human oviduct fluid [18]; MTF, based on mouse oviduct fluid [19]; and G1/G2, based on human oviduct and uterine fluids [20].

As a result of the measured differences in the composition of oviduct and uterine fluids and measured changes in the metabolic activity of embryos during early development, Gardner and Lane [21] suggested that "in order to optimize mammalian embryo development in culture, sequential media are required, each designed to meet the changing requirements of the developing embryo." In this scheme,

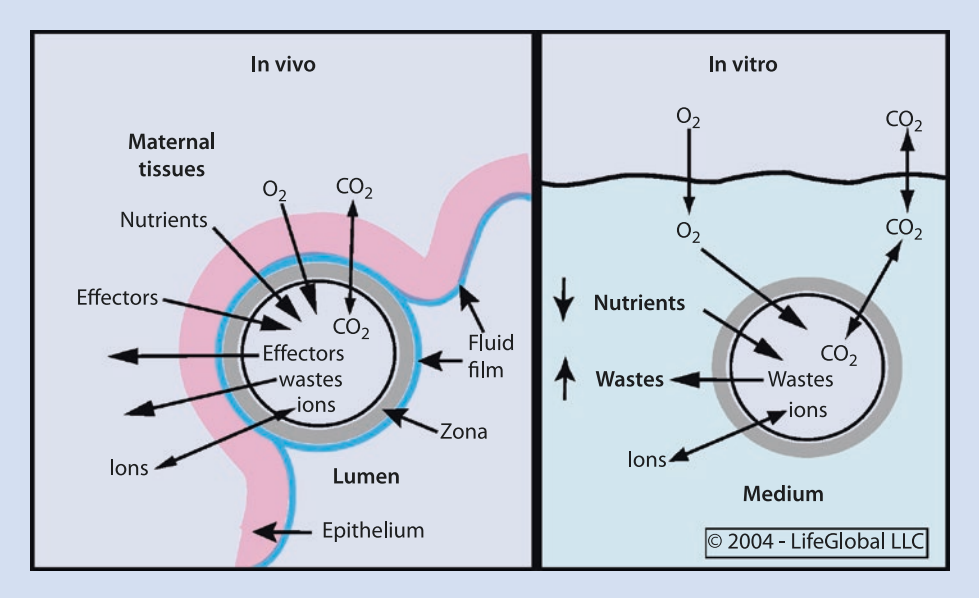

Fig. 15.1 A comparison of the interaction of an embryo with its environment, in vivo and in vitro. (Reproduced with the permission of Life Global LLC)

embryos are cultured from the zygote to the eight-cell stage (Day 1 to Day 3) in a medium based on the oviduct fluid and then in a second medium, based on the uterine fluid, for culture onward to the blastocyst stage (Day 3 to Day 5 or 6). Although this seems logical, this "back to nature" approach relies on several questionable assumptions.

First, the measurements of the components of the oviduct and uterine fluids are highly variable [22] and almost certainly subject to physiological inductance. Second, such measurements are of the overall composition of the tract fluids and not the microenvironment around the embryo. Third, as shown in Fig. 15.1, the physical and chemical environment of the embryo in vivo is completely different from its environment in vitro. In vivo, the embryo is surrounded by a thin layer of fluid and is in close contact with the maternal tissues, allowing rapid exchange of nutrients, gases, wastes, and effectors between the embryo and the mother. In contrast, in vitro, the embryo is bathed in a relatively large pool of fluid in which the nutrients are continually decreasing and the waste products are continually increasing during culture. Clearly, the stresses on the embryo in vitro are very different from those in vivo, and culture media must be designed to optimize embryo development under in vitro conditions.

Using a very different approach to the development of embryo culture media, Lawitts and Biggers [23, 24] applied the principles of simplex optimization to determine the optimal concentration of each component. They began with a medium based on M16 and CZB, containing NaCl, KCl, KH_2PO_4, $MgSO_4$, lactate, pyruvate, glucose, bovine serum albumin (BSA), ethylenediaminetetraacetic acid (EDTA), and glutamine. In a series of test cycles, they varied the concentration of each component and evaluated each combination for the ability to support the development of mouse zygotes through the two-cell block. The component concentrations in each cycle were based on the effectiveness of the medium in the previous cycle. In essence, the embryo defined the formulation of the successive test media, and this is often referred to as the "Let the Embryo Choose" approach to medium development.

A total of 20 such cycles resulted in the formulation of simplex optimization medium (SOM), which was marked by a low NaCl concentration and was able to overcome the mouse two-cell block [24]. Subsequent modifications included increasing the concentration of KCl to produce KSOM medium [25], and addition of all 20 common amino acids to produce KSOMaa [26–28]. Biggers et al. [29] and Summers et al. [30] subsequently showed that the development of mouse embryos were better when the medium included the glycyl-glutamine dipeptide, compared to either glutamine or alanyl-glutamine.

In addition to many studies on mouse embryos, KSOM, with or without amino acids, has been shown to support the development of cattle [31], rabbit [32], rhesus monkey [33], pig [34], and rat [35] embryos from the zygote to the blastocyst stage. For more detailed and extensive reviews of the history of the development of embryo culture media, see Biggers [36], Hammer [37], Summers and Biggers [22], and Cohen and Rieger [38].

15.3 Culture of Human Embryos in a Single Medium from the Zygote to the Blastocyst Stage

Based on the success of KSOMaa, as a single medium, for culture of mouse embryos and embryos of other species, Biggers and Racowsky [39] compared the development of human embryos in KSOMaa (Days 1–5) with the development in the sequential pair of P1 (Days 1–3) and CCM (Days 3–5). The

Table 15.1 Characteristics of approaches to embryo culture from zygote to blastocyst

Characteristic	Sequential media interrupted	Single medium interrupted	Single medium uninterrupted
Leaves embryos undisturbed	No	No	Yes
Accumulated endogenous growth factors	Lost	Lost	Left in place
Replacement of essential nutrients	Yes	Yes	No
Accumulated toxins	Removed	Removed	Left in place
Relative stress to embryos	High	Moderate	Low
Required quality control	Two media	One medium	One medium
Relative labor intensity	High	Moderate	Low
Relative cost	High	Low	Low

Adapted from Biggers and Summers [47]

development to the expanded blastocyst stage was not different between KSOMaa and the P1/CCM sequential media pair. Transfer of nine blastocysts from KSOMaa culture resulted in the birth of five babies.

Macklon et al. [40] compared the development of human embryos in their Rotterdam medium (17:3 mixture of Earle's salts and Ham's F-10) either uninterrupted or with a change to fresh medium on Day 3, against the G1/G2 sequential media pair. The development to blastocyst and implantation rate were not different among the three treatment groups.

Many subsequent studies have shown a single medium (based on KSOMaa) to be as effective as, or more effective than, various sequential media pairs, for the development of human embryos to the blastocyst stage and for implantation. Examples include Nanassy et al. [41], Sepulveda et al. [42], Carrillo and Yalcinkaya [43], Wirleitner et al. [44], Summers et al. [45], and Sfontouris et al. [46]. In these studies, the single medium was used in two steps, with a change to fresh medium on Day 3, in parallel with the change from the cleavage medium to the blastocyst medium in the sequential media.

Biggers and Summers [47] have suggested that a single-step (uninterrupted) culture may be preferable to both sequential culture and two-step (interrupted) culture in a single medium, for culture of human embryos from the zygote to the blastocyst stage (Table 15.1). Practical advantages of uninterrupted culture include reduced quality control procedures, labor, and cost. Physiological advantages of uninterrupted culture include the possibility of accumulation of endogenous growth factors and a decrease in stress to the embryo. Direct comparisons have shown that uninterrupted culture in a single medium can be as effective as interrupted culture in the same single medium, or culture in sequential media [48–53]. Uninterrupted culture is of particular interest for time-lapse evaluation of embryo development, and this too has been shown to be effective with a single medium [54–57].

It must be noted that uninterrupted culture increases the risk of accumulation of embryo-toxic volatile organic compounds (VOCs) from the culture dishes, laboratory gases, and the environmental air into the culture oil and then the culture medium. Studies have shown that laboratory air quality is a critical aspect of embryo culture and that common VOCs such as benzene and aldehydes can accumulate in the oil and medium used for embryo culture [58–62]. Uninterrupted culture increases the time for potential accumulation of VOC and hence the possibility of deleterious effects on the embryos. Consequently, the laboratory air quality should be critically evaluated, and a careful comparison of the effectiveness of uninterrupted vs. interrupted culture should be made before introducing uninterrupted culture as general practice in any ART laboratory.

15.4 Procedures for Interrupted or Uninterrupted Embryo Culture in a Single Medium

The following describes the materials and methods used for uninterrupted culture in a single medium at POMA Fertility.

15.4.1 Culture Media

For embryo culture, we use washed oil, GPS® dishes, and either Global HP® or Global Total®. In general, embryos are cultured in Global Total. Global HP is used for thawed zygotes and embryos from patients that are over 35 years of age. We feel that the thawed zygotes benefit from the higher protein and lipid content following thawing. Similarly, we feel that embryos from older patients benefit from the increased factors found in the increased protein content in Global HP. In our laboratory, we do not aliquot culture media into other containers or vessels for storage because we feel the exposure to plastic introduces an additional variable.

15.4.2 Oil Preparation

All oils are washed before use because oil is one of the least defined products used in embryo culture, despite great improvements in manufacturing and testing. Oil quality can be affected by shipping, storage, and light, which are out of the manufacturer's control, and can impact embryo

development [63]. Our center felt that it would be a good practice and would not harm the oil if we washed the oil with culture media that did not contain protein. Therefore, the rationale for washing oil in our center is to remove any potential oil contaminants [64] that might not be detectable with currently used testing methods and to equilibrate the oil with beneficial components found in the media that are also be oil soluble [65].

15.4.3 Preparation of the Culture Dishes

GPS dishes that had been previously off-gassed for at least 48 h are labeled and filled with 11.5–12.5 ml of washed oil. The dishes are allowed to sit for 10–30 min in the laminar hood without the fan on to allow the oil to stabilize in the dish.

The culture medium is placed into a 35 or 60 mm pre-rinsed Nunc® holding dish (depending on the total volume required). The holding dish is rinsed 4–5 times with protein-free HTF medium to remove any potential contaminants that may be present as a result of the dish manufacturing process. Fire-polished, sterile, 9-inch glass Pasteur pipettes are similarly rinsed 4–5 times with HTF. These pipettes are used to underlay the culture droplets with the appropriate Global medium.

Microdrops of approximately 20–30 μl of the medium are used for embryo culture. It is important to note that the oil depth should be at least 1–2 mm over the top of the micro droplets. Culture media can evaporate even in humidified incubators, and culture dishes should be made no later than 1:00–2:00 P.M. on the day prior to the anticipated embryo culture. These steps must be taken to ensure culture media do not evaporate during the culture interval and that the dishes have sufficient time to reach optimum pH prior to use [66].

15.4.4 Incubator Concentrations of CO_2 and O_2

The regulation of pH in the culture medium depends on the bicarbonate concentration in the medium and the CO_2 partial pressure in the incubator. Unfortunately, it is not possible to define an appropriate CO_2 concentration for all circumstances, for at least two reasons. First, for any given CO_2 concentration, the partial pressure decreases with increasing geographical elevation. For example, a 6% CO_2 concentration is required to produce the same CO_2 partial pressure in Denver, as a 5% CO_2 concentration in Boston. Second, measurements of CO_2 concentration are notoriously unreliable. Consequently, the only reliable way to produce the required pH is to adjust the CO_2 concentration until the desired pH is measured in the medium [67]. The manufacturer recommends a pH of 7.27–7.32 for Global Total and Global HP. However, in our experience, embryo development is improved at a pH of approximately 7.23–7.28, and we have increased the CO_2 concentration accordingly.

As noted by Wale and Gardner [68], the atmospheric concentration of oxygen (20%) has been shown to have a wide variety of deleterious effects on the development and function of preimplantation embryos, and this is of particular concern for extended culture to the blastocyst stage [69]. Consequently, we use 5% oxygen for all embryo cultures.

15.4.5 Interrupted and Uninterrupted Embryo Culture

In our laboratory, we use both interrupted and uninterrupted culture. Interrupted culture is used for embryos that are to undergo blastocyst biopsy for preimplantation genetic screening. On Day 3, the embryos are removed from culture, and a small opening is made in the zona pellucida with a laser. The embryos are then moved to fresh dishes for culture through to the blastocyst stage. We move the embryos out of concern for what impact the laser and the elevated temperature might have on the embryo or the culture media. Uninterrupted culture is used for embryos that are not scheduled for biopsy and will undergo a fresh transfer or cryopreservation. These embryos are cultured in the same dish and droplet from Day 1 through to Day 5/6.

It is important to note that we did several sibling trials in our lab before we went to uninterrupted culture. Development to blastocyst was excellent and not different between interrupted (122/200, 61.0%) and uninterrupted (131/220, 59.5%) culture. In addition, we took air samples to ensure the levels of VOCs were as low as possible for our lab. We culture embryos in groups of four to six in some instances but mostly perform single embryo culture so we can be sure of the embryonic history when we are selecting embryos for replacement and/or vitrification.

15.5 Conclusions

- A single medium can support the development of human embryos from the zygote to the blastocyst.
- Interrupted or uninterrupted culture in a single medium from Day 1 onward reduces the possibility of stress associated with changing the medium composition at Day 3.
- Uninterrupted culture may offer some additional advantages over interrupted culture. However, a careful comparison of uninterrupted vs. interrupted culture should be made before introducing uninterrupted culture as general practice in any ART laboratory.

Review Questions

1. What are the advantages of uninterrupted embryo culture?
2. What is the significance of air quality to uninterrupted embryo culture?

3. What precaution should be taken before introducing uninterrupted embryo culture as general practice in the ART laboratory?

4. Are there any precautions that should be taken with plastic materials that come in contact with the embryos while in culture?

5. What precautions should be taken when using oil in embryo culture?

Sequential Media for Human Blastocyst Culture

David K. Gardner and Michelle Lane

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_16

Learning Objectives

- Benefits of single embryo transfer.
- Negative implications for asynchronous transfer.
- Dynamics of embryo metabolism during the preimplantation period.
- Physiological foundations of sequential media.
- Nutrient gradients exist within the oviduct and uterus.
- Amino acids act as key regulators of development.
- Damaging effects of atmospheric oxygen and ammonium accumulation.
- Blastocyst transfer results in an increase in implantation.
- Sequential media development was among the most rigorously tested procedures in human IVF.

16.1 Introduction

The ultimate goal of human IVF is the birth of a healthy singleton child conceived through the transfer of a single embryo. The benefits that single embryo transfer (SET) brings have been well documented [1]. However, it has taken considerable time and research effort to come close to making this a reality for the majority of patients. The initial success of clinical IVF was limited by a lack of understanding regarding key aspects of embryo physiology resulting in suboptimal culture conditions, impaired embryo development, and all too frequently complete developmental arrest around the eight-cell stage [2–5]. Consequently, it became the paradigm to transfer human embryos to the uterus soon after fertilization on day 1, 2, or 3 resulting in asynchronous development of the embryo within the female tract. Indeed, it was promoted that if the laboratory conditions were not optimal, then embryos should be transferred as soon as possible back to the uterus to avoid the compromised in vitro environment [6]. Ironically, this in vivo environment was also a hostile environment for the cleavage-stage embryo. As a result, implantation rates following the transfer of cleavage-stage embryos to the uterus were very low, and this in turn resulted in the transfer of multiple embryos in order to attain acceptable pregnancy rates. So much so that during the mid-1990s, the average number of embryos transferred in IVF clinics within the USA across all age groups, and oocyte donors, was 4 [7]. With this in mind, in the 1990s, efforts were made worldwide to advance our understanding of the metabolism and physiology of the preimplantation embryo to facilitate improvements in in vitro culture conditions with the goal of increasing the implantation rate of the human embryo, thereby alleviating the need to transfer multiple embryos.

Importantly, in all mammalian species studied to date, including nonhuman primates, the transfer of the cleavage-stage embryo asynchronously to the uterus impairs implantation and fetal development. Rather, in order to ensure high transfer success and good live birth rates, it is important in all mammalian species to transfer the embryo at the blastocyst stage, i.e., replace the embryo in the uterus at the stage in which it resides there [8, 9]. Therefore, we set out to develop a culture system that could support the development of viable human blastocysts at a high rate. Our work led us to analyze the environment of the human embryo in vivo and to determine the effects of medium components on the physiology and metabolism of the preimplantation embryo. This approach led to the development of sequential media, with which it became possible to grow the human embryo to the viable blastocyst stage as a matter of routine. The resultant blastocysts were shown to have significantly higher implantation rates than cleavage-stage embryos and facilitated the elimination of high-order multiple gestations almost overnight and hence helped to pave the way for single embryo transfer while ensuring high pregnancy and live birth rates. Here we describe in detail the journey that led us to formulate sequential media and discuss the potential benefits of blastocyst transfer and how improvements in embryo culture can also impact on embryo selection.

16.2 Physiology of the Preimplantation Human Embryo

If one is to culture any cell type, in order to be successful, it is a prerequisite to understand the physiology of the cell in question. What makes culture of the preimplantation human embryo so interesting (and challenging) is that the physiology of the embryo changes with each successive stage of development. Indeed, the starting point of development, the fertilized oocyte, exhibits a completely different physiology from the blastocyst prior to implantation. The fertilized oocyte and the cleavage-stage embryo are dependent upon pyruvate, lactate, and aspartate to facilitate energy production through low levels of oxidative metabolism [10, 11]. In contrast, the blastocyst has a considerable capacity to utilize glucose as its primary energy source, and does so not only through oxidative metabolism (~50% of the glucose consumed), but also produces considerable lactate through aerobic glycolysis, which is a trait cancers have adopted from blastocysts to support their proliferative and invasive phenotype [12, 13]. The detailed specifics of human embryo metabolism at successive stages of preimplantation development have recently been reviewed elsewhere [14–16]. In order to facilitate the development of a viable preimplantation embryo that will result in the birth of a healthy child, one needs to ensure that the embryo is able to maintain its stage-specific metabolic functions. Aberrations in metabolic function at any stage throughout the preimplantation period not only compromise development prior to transfer but can influence the fetal growth trajectory and in animal models the resultant disease risk of the adult [13, 16, 17]. Hence, analysis of metabolic control during preimplantation embryo development in culture has proven to be an invaluable tool in establishing the suitability of culture media to support normal embryo development and one we have utilized extensively in the development of sequential media [13, 18–21]. Further, with an increased understanding of how metabolic control directly

influences gene expression, through an epigenetic axis [22, 23], the significance of analyzing embryo metabolism has never been more important.

16.3 Development of Sequential Culture Media to Support Development of the Human Blastocyst

Early culture media used in human IVF tended to be rather simplistic, containing just a few salts and carbohydrates. Alternatively, some clinics chose to use tissue culture media, which contained a mixture of nutrients appropriate for somatic cells, some of which are now known to be supraphysiological for embryos, leading to compromised development. The "simple" media, i.e., those lacking amino acids (reviewed in detail in Gardner and Lane [24, 25]) such as those developed initially for the mouse, and adapted for the human, e.g., human tubal fluid medium (HTF) [26], were not effective in supporting human embryos past the eight-cell stage in culture. Indeed, it was not that long ago when it was considered "normal" for the majority of human embryos to arrest around the eight-cell stage in vitro (hence the adoption of cleavage-stage embryo transfers). Consequently, other systems have been tried in attempts to nurture the human embryo to the blastocyst stage in culture. One such system made popular in the 1990s was co-culture, in which human embryos were cultured with oviduct or uterine epithelial cells [27] or specific cell lines [28]. Although the development of blastocysts was facilitated by such technology, co-culture was not widely adopted, likely in part to its complexity and risk profiles associated with cell culture and use of serum. Further, its efficacy was never established in randomized controlled trials. Subsequently, co-culture was replaced with the current approach of the use of more physiological culture media [29].

A key stepping-stone on the path to the development of physiologically based media was the analysis of the in vivo environment of both oviduct and uterine fluids from women at different times during their cycle. Not only were there cycle-dependent differences in the levels of nutrients (as previously determined in an animal model [30]), but crucially there were also significant differences in nutrient concentrations between the oviduct and uterus at the times when the embryo would reside there (Table 16.1) [31]. In essence, the human oviduct is characterized by relatively high levels of pyruvate and lactate and low levels of glucose, while in the uterus, the opposite is true. These findings parallel the known changes in nutrient uptakes and metabolism as the embryo develops and differentiates from a fertilized oocyte to the blastocyst [32–34]. The concentrations of nutrients present in the human oviduct and uterus therefore formed the backbone of the media G1 and G2, the first sequential media designed specifically to support the human embryo.

Evidently, in vivo, the human embryo is exposed to gradients of nutrients as it develops to the blastocyst. The significance of these nutrient gradients is reflected in data from the mouse that show gradients in vitro impact embryo viability following transfer. For example, when the mouse zygote is cultured to the eight-cell stage and then transferred, embryo viability is highest after exposure of the embryo to a high lactate concentration (>20 mM D/L lactate), while when the embryo is cultured post compaction to the blastocyst stage, viability is highest after exposure to lower levels of lactate (<5 mM D/L lactate) [18]. These data support the hypothesis that the physiology of the developing conceptus is temporally regulated by the concentration of nutrients available [35]. Furthermore, the regulation of metabolism of these carboxylic acids changes with development, further highlighting the physiological differences between the zygote and blastocyst stages [16, 35, 36]. The significance of these early observations is further heightened by our more recent understanding that the relative ratio of pyruvate to lactate, which affects the intracellular ratio of NAD^+ to NADH and alters gene expression through ADP ribosylation and acetylation [12, 23]. Hence, the impact of nutrient gradients takes on renewed significance, in that making an embryo adapt to one concentration of nutrients throughout the preimplantation period could feasibly modify its epigenome.

Table 16.1 Concentration (mM) of nutrients in human oviduct and uterine fluids

	Pyruvate	Lactate	Glucose
Oviduct[a]	0.32 ± 0.06*	10.50 ± 1.48*	0.50 ± 0.21**
Uterus	0.10 ± 0.05	5.87 ± 1.19	3.15 ± 0.31

The values of nutrients present in the oviduct and uterus are those present in the media G1 and G2, respectively
Significantly different from uterine values: *, $P < 0.05$; **, $P < 0.01$
[a]Samples taken mid-cycle. Data from Ref [31]

A further major advance in the formulation of embryo culture media came from the determination that amino acids have a significant role to play during embryo development [37–41]. Oviduct and uterine fluids are characterized by high concentrations of the amino acids such as alanine, aspartate, glutamate, glycine, serine, and taurine [42–45]. With the exception of taurine, the amino acids at high concentrations in the oviduct fluid bear a striking homology to those amino acids present in Eagle's nonessential group, i.e., those not required to support somatic cells in culture [46]. Analyses of human and mouse oviduct fluids have also demonstrated that there are significant levels of glutamine present. The functions of such amino acids are listed in Table 16.2. Studies on the embryos of several mammalian species, such as the mouse [40, 47–49], hamster [50–53], sheep [54–56], and cow [19, 57], have all demonstrated that the inclusion of specific amino acids in the culture medium enhances embryo development to the blastocyst stage. In the mouse embryo, it has been determined that inclusion of Eagle's nonessential amino acids and glutamine in the medium significantly increases the rate of zygote development to the blastocyst in

culture and indeed can alleviate the two-cell block [48]. Nonessential amino acids and glutamine stimulate cleavage rates [40, 41, 58], blastocyst formation, and hatching of cultured mouse embryos [40, 41, 59]. After compaction, nonessential amino acids and glutamine stimulate cleavage of the trophectoderm and increase blastocoel formation and hatching [59]. In contrast, Eagle's essential amino acids, i.e., those required for somatic cell function, which are at lower concentrations in the oviduct, reduce the cell number of blastocysts from cultured zygotes [40, 59]. Interestingly however, after the eight-cell stage, essential amino acids stimulate cleavage rates and increase the development of the inner cell mass in the blastocyst [59]. Studies on the effects of single amino acids on hamster embryos by Bavister and coworkers [39, 51, 53] found that asparagine, aspartate, glycine, histidine, serine, and taurine stimulated hamster zygote development to the blastocyst in culture, while cysteine, isoleucine, leucine, phenylalanine, threonine, and valine were inhibitory. All the inhibitory amino acids are present in Eagle's essential amino acids, while the stimulatory amino acids to hamster embryo development other than histidine are found in Eagle's nonessential amino acids. A similar stage-specific effect for amino acids was also determined for the embryos of the cow [60].

So, in summary, embryo development in culture is improved in the presence of amino acids, and there exists stage-specific preferences for amino acids. When amino acids are present, more cells are allocated to the inner cell mass of the resultant blastocysts, stage-specific energy metabolism is better supported, there is reduced apoptosis, and most importantly, embryo viability, as assessed by implantation and fetal development, is higher. One could therefore put forward a very strong case that there is no longer a place in clinical IVF for the use of media that lack these key regulators of embryonic function and viability, and that media such as HTF will significantly compromise embryonic developmental potential. Indeed, even a transient exposure of the early embryo to an environment lacking amino acids has downstream consequences for the developing embryo (Fig. 16.1).

When working in vitro, in a system that cannot mimic many of the physical roles of the uterine epithelium, one must be mindful of in vitro artifacts, induced by working outside of the female reproductive tract. For example, amino acids are metabolized by embryos, which subsequently release ammonium [40]. In vivo, one anticipates that this ammonium is subsequently removed by the epithelial cells of the female reproductive tract and then passes through the circulation and is subsequently detoxified by the urea cycle in the liver. However, in a static culture system, i.e., a dish in an incubator, any ammonium produced by embryonic metabolism simply builds up in the medium [40]. To add insult to injury, the amino acids themselves (especially glutamine) are labile at 37 °C and spontaneously deaminate to release ammonium [40]. The significance of spontaneous ammonium buildup is that it not only retards mouse and human blastocyst development in culture [61] but is also associated with subsequent fetal retardation and neural tube defects in mice [41]. Furthermore, it has been shown that ammonium affects embryo metabolism, pHi regulation, and gene expression in both the mouse and human [62–64] and that perturbations induced by ammonium are further compromised by its interaction with atmospheric oxygen (discussed in more detail later) [65]. Interestingly, there appears to be a link between the concentration of ammonium in serum and the induction of fetal oversize in sheep [66, 67].

Even though data are available on the generation of ammonium in the culture medium over time [40, 61, 68, 69], there remains debate concerning the amount of concern one should place on ammonium toxicity in culture medium [70, 71]. Of relevance to this discussion is the reported impact of culture media composition on the live birth rates and subsequent development of the children conceived [72, 73]. In these reports, the effects of two media were analyzed in a day 2 transfer program, and differences in embryo growth kinetics and subsequent birth weight (which persisted through the first 2 years of life) were described. One of the two media employed contained free glutamine, and hence, embryos in this group (which exhibited the growth delay) were exposed to a level of ammonium known to adversely affect human blastocyst development, gene expression, and physiology [63]. As such, it could be hypothesized that the early exposure of embryos to ammonium may explain the effects of the two different media on subsequent birth rate and fetal and neonatal growth trajectory.

The main culprit with regard to amino acid deamination and ammonium release is glutamine. However, this amino acid can be replaced with the dipeptide alanyl-glutamine, which is stable at 37 °C, and its inclusion significantly reduces ammonium release into the culture medium. However, when ammonium production by human blastocysts was quantitated, it was found that the embryo produced significant amounts of ammonium, presumably through amino acid metabolism and transamination [74]. Therefore, it would appear judicious to renew the culture medium used at least every 48 hours in order to circumvent the toxicity of ammonium. From a practical point of view, the amount of work, cost, and embryo manipulations required are the same whether one is working with sequential media or a monophasic system (i.e., one medium formulation for the entire preimplantation period), unless the medium was specifically designed to generate only very low levels of ammonium over extended culture [75]. Even then however, such media cannot account for physiological changes in nutrient gradients, which leads us onto the next section; just how many media do we really need?

16.4 One Medium or Two?

As detailed above, sequential media were developed based on the changing environment within the human female reproductive tract and to accommodate the changes in nutrient requirements, as well as ensuring normal stage-specific metabolism and physiology of the developing embryo [13, 76, 77]. In contrast, the approach of monoculture (one medium for all stages of development) is based on the principle of letting the embryo choose what it wants during development and differentiation. Clearly, such approaches have fundamental differences, and it has been questioned whether the former, more physiological approach, is really required [78]. One such medium is the simplex-derived medium KSOM^{AA}, available for clinical use as Global medium. Simplex medium (SOM) was developed using a computer program to generate successive media formulations based on the response of mouse embryos in culture to form blastocysts [79, 80]. Once a specific medium was formulated, it was tested and blastocyst formation recorded as the sole parameter. There was no assessment of physiology, cell allocation, etc. The program then generated new formulations for use in the next series of cultures. This procedure was performed several times to generate several media that supported high rates of blastocyst development of embryos derived from the oocytes of outbred mice (CF1) crossed with the sperm of an F1 hybrid male [81] and was later empirically modified to KSOM (which contains around 10 times more potassium than SOM) [82]. Such media were subsequently further modified by another laboratory to include amino acids (KSOM^{AA}) [83]. However, this last phase of medium development was based on independent studies on the mouse embryo [40] and did not involve the simplex procedure. This single medium formulation, KSOM^{AA}, was subsequently used to produce human blastocysts in culture [84]. In such types of media, the embryo therefore has to adapt to its surrounding as it develops and differentiates.

We, therefore, decided to perform an analysis of the efficacy of media types on the development of mouse pronucleate oocytes in vitro and to compare their rates of development to in vivo developed embryos [85]. The media chosen were Whitten's (one of the very first mouse embryo culture media) [86], HTF (one of the first simple media developed for human embryos) [26], P1/blastocyst (a glucose- and phosphate-free modification of HTF for 48 h, after which the embryos are transferred to Ham's F10) [87], KSOM (a computer-optimized monophasic medium lacking amino acids) [79], KSOM^{AA} (a computer-optimized monophasic medium with amino acids) [83], and G1/G2 (a sequential media system based on the composition of the human female reproductive tract) [88]. All media were made with the same chemicals and water, and all embryos were transferred to fresh media after 48 h. There was no difference in cleavage time from one- to two-cell stages between any media (Fig. 16.2a). From two- to four-cell stages, embryos cultured in KSOM^{AA}, HTF, and Whitten's media were significantly slower than those in medium G1 (Fig. 16.2b). From four- to eight-cell stages, embryos cultured in all media were significantly slower than in medium G1 (Fig. 16.2c). Rates of compaction were significantly greater in embryos cultured in G1 (74.4%) compared to all other treatments: KSOM^{AA} (60.2%), KSOM (65.9%), P1 (66.0%), HTF (26.4%), and Whitten's (0.0%). Rates of blastocyst development were similar to in vivo developed embryos in media G1/G2 (Fig. 16.3). Blastocyst development in all media was significantly slower than that obtained in vivo and in media G1/G2. Total blastocyst cell number was similar to in vivo blastocysts in media G1/G2, KSOM^{AA}, and KSOM (Fig. 16.4). However, only the ICM development in G1/G2 blastocysts was equivalent to in vivo developed blastocysts (Fig. 16.4). The data obtained demonstrate that embryos cultured in sequential media develop quicker than those in a monophasic system and that

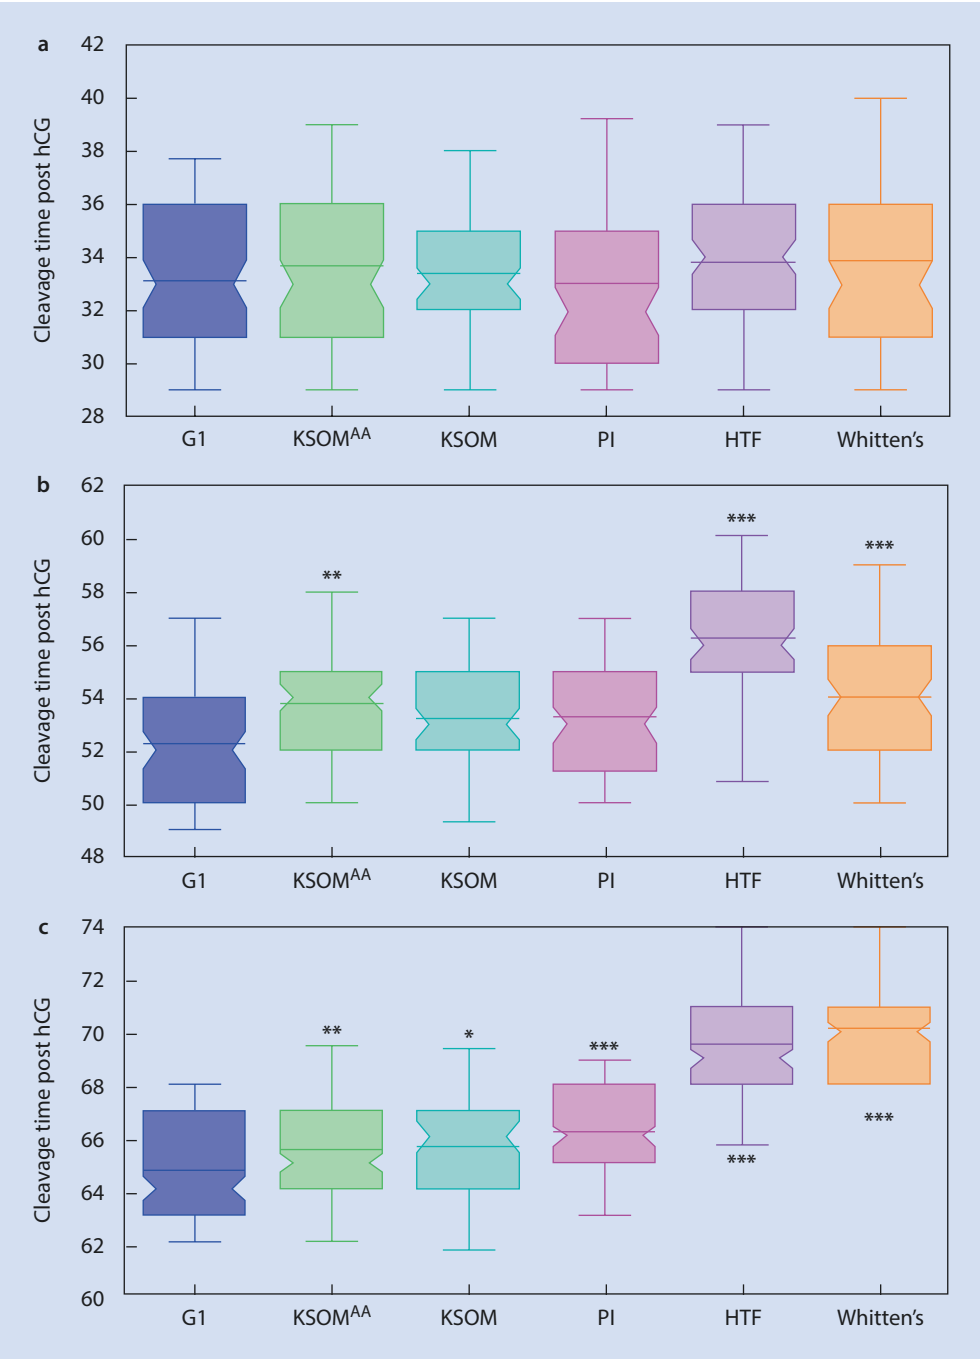

Fig. 16.2 Effect of culture media on cleavage times from the zygote to the eight-cell stage. **a** Cleavage from the one- to two-cell stage. **b** Cleavage from the two- to four-cell stage. **c** Cleavage from the four- to eight-cell stage. Notches represent the interquartile range (50% of the data), and whiskers represent the 5% and 95% quartiles. The line across the box is the mean cleavage time. $n = 100$ embryos per treatment. the subsequent blastocysts have the same cell number as those embryos developed in vivo. Subsequent transfers also revealed higher implantation rates of mouse embryos cultured in sequential media compared to their siblings cultured in a monophasic medium [77].

Sequential media have now proven themselves to be highly effective in clinical settings [89–91]. However, with the clinical introduction of time-lapse, there has been a resurgence of interest in uninterrupted culture. Therefore, a new single-phase medium (GTL) has been specifically designed to cope with the extended buildup of ammonium from amino acid breakdown and metabolism [75]. While available for use clinically, the literature regarding the efficacy of these media through preclinical and clinical implementation is limited compared to the extensive animal- and human-based literature for other types of media. When consideration is given to the potential metabolic and epigenetic impact nutrient gradients could be having on human embryo physiology, and that physiologically based sequential media have been proven to be highly successful clinically, we still consider sequential media to represent a less stressful and plausibly safer environment for embryo development. Research on the impact of nutrient gradients on the human embryo epigenome is therefore required.

16.5 The Holistic Approach to Embryo Culture

It is important to emphasize that the successful culture of viable human embryos entails far more than purchasing the appropriate culture media. Rather, the media is just one aspect of the overall embryo culture system, which itself is just one aspect of the overall laboratory (reviewed in detail; [77]) and that there are likely interactions between media and other aspects of the culture system. Furthermore, it is imperative that sufficient resources be made available for quality control [92] and quality management [93], without which the laboratory is like a plane with no artificial horizon.

One key aspect of the laboratory that is worth reiterating, due to its significant impact on embryo development and viability, is that of oxygen concentration. The fact that both human and F1 mouse embryos can grow at atmospheric oxygen concentration (~20%) has led to some confusion regarding the optimal concentration for embryo culture. The concentration of oxygen in the lumen of the rabbit oviduct is reported to be 2–6% [94, 95], whereas the oxygen concentration in the oviduct of hamster and rhesus monkey is ~8% [96]. Interestingly, the oxygen concentration in the uterus is significantly lower than in the oviduct, ranging from 5% in the hamster and rabbit to 1.5% in the rhesus monkey [96].

Importantly, it has been demonstrated that optimum embryo development of other mammalian species occurs at an oxygen concentration at or below 10% [97–99]. Furthermore, it has been documented that mouse embryos cultured to the blastocyst stage in the presence of 20% oxygen have altered gene expression and perturbed proteome compared to embryos developed in vivo [100–102]. In contrast, culture in 5% oxygen had significantly less effect on both embryonic gene expression and proteome. Further, atmospheric oxygen can affect histone remodeling and methylation patterns in the embryo [103–105]. Recent clinical data in the form of both RCTs and systematic reviews all support the move to the routine culture of human embryos in a reduced oxygen environment [106, 107]. Furthermore, data obtained using time-lapse incubation strongly support the notion that at no time during the preimplantation period should the embryos be exposed to 20% oxygen [108, 109].

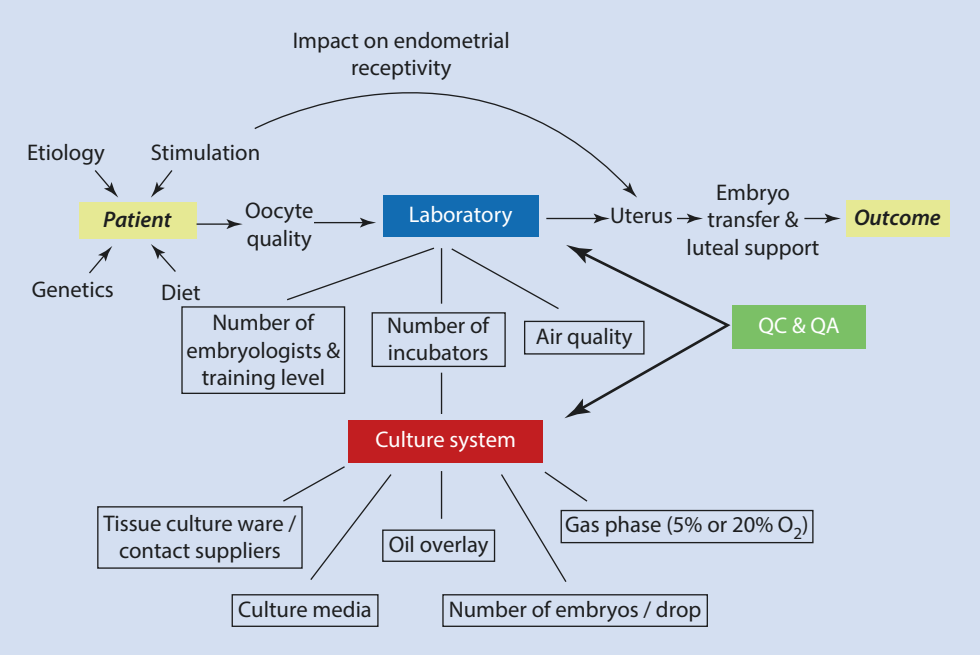

Fig. 16.5 An holistic analysis of human IVF. This figure serves to illustrate the complex and interdependent nature of human IVF treatment. For example, the stimulation regimen used not only impacts oocyte quality (hence embryo physiology and viability [166]) but can also affect subsequent endometrial receptivity [114, 115, 167]. Furthermore, the health and dietary status of the patient can have a profound effect on the subsequent developmental capacity of the oocyte and embryo [168]. The dietary status of patients attending IVF is typically not considered as a compounding variable, but growing data would indicate otherwise. In this schematic, the laboratory has been broken down into its core components, only one of which is the culture system. The culture system has in turn been broken down into its components, only one of which is the culture media. Therefore, it would appear rather simplistic to assume that by changing only one part of the culture system (i.e., culture media), one is going to mimic the results of a given laboratory or clinic. A major determinant of the success of a laboratory and culture system is the level of quality control and quality assurance in place. For example, one should never assume that anything coming into the laboratory that has not been pretested with a relevant bioassay (e.g., mouse embryo assay) is safe merely because a previous lot has performed satisfactorily. Only a small percentage of the contact supplies and tissue culture ware used in IVF comes suitably tested. Therefore, it is essential to assume that everything entering the IVF laboratory without a suitable pretest is embryo toxic until proven otherwise. In our program, the one-cell mouse embryo assay (MEA) is employed to prescreen every lot of tissue culture ware that enters the program, i.e., plastics that are approved for tissue culture. Around 25% of all such material fails the one-cell MEA (in a simple medium lacking protein after the first 24 h) [92]. Therefore, if one does not perform QC to this level, one in four of all contact supplies used clinically could compromise embryo development. In reality, many programs cannot allocate the resources required for this level of QC; when embryo quality is compromised in the laboratory, it is the media that are held responsible, while in fact the tissue culture ware is more often the culprit. (Modified from [77] with permission from Reproductive Healthcare Ltd.)

The holistic approach to looking at embryo culture and transfer is presented in Fig. 16.5.

16.6 Clinical Advantages of Blastocyst Transfer

Some of the inherent advantages of blastocyst culture and transfer are summarized in Box 16.1. For example, not all sperm or oocytes will give rise to a viable embryo [110]. By growing the human embryo beyond the cleavage stages, i.e., past embryonic genome activation [111], one is able to consider the embryo proper, as opposed to an eight-cell embryo, which for the most part can be considered as a cleaving egg. Synchronization of embryonic stage with its relative position in the female reproductive tract is essential for the successful transfer of animal embryos. In all mammalian species studied to date, including nonhuman primates [112], the transfer of cleavage-stage embryos to the uterus (i.e., prior to compaction and therefore before the generation of the first transporting epithelium) results in compromised pregnancy rates compared to the transfer of morulae or blastocysts [9]. Although the human cleavage-stage embryo can develop in the uterus in vivo, the cleavage-stage embryo normally resides in the fallopian tube until day 4 [113]. Consequently, asynchronous transfers are being performed in cleavage-stage IVF cases.

Furthermore, it has been documented in animal models that the environment within the female tract following gonadotropin treatment of the female is not as supportive to embryonic development as a nonstimulated environment [114, 115]. These data question the suitability of the uterine environment following a patient's exposure to exogenous gonadotropins. Clinical data also support the hypothesis that the uterine milieu is compromised following hyperstimulation [116]. Therefore, it may be preferable to expose embryos to such an altered uterine environment for as short a period as possible, which can be achieved through blastocyst trans-

Box 16.1 Advantages of Blastocyst Transfer in Human IVF

- Identification of those embryos with limited, as well as those with the highest, developmental potential through morphological assessment and grading
- Assessment of the embryo post genome activation
- Synchronization of embryo development within the female tract to reduce cellular stress on the embryo
- Minimizing exposure of the embryo to a uterine environment that has been exposed to exogenous gonadotropins
- Fewer uterine contractions by day 5, thereby reducing the chance of embryo being expelled
- Demonstrated higher implantation rates, leading to a reduction in the number of embryos transferred
- Ability to undertake cleavage-stage embryo biopsy without the need for cryopreservation when the biopsied blastomere has to be sent to a different locale for analysis
- Ability to undertake trophectoderm biopsy rather than cleavage-stage biopsy, thereby increasing the number of cells analyzed (typically six to ten) and overcoming ethical/religious concerns of sampling embryonic tissue
- Excellent cryosurvival
- Increase in overall efficiency of IVF

fer. Subsequently, the transfer of human embryos at the blastocyst stage has a sound physiological basis. Several of these advantages were perceived many years ago [27, 28, 117], but it has not been until the last 15 years that culture systems have become practical enough to use as a standard procedure in the IVF laboratory.

16.7 Implementation of Blastocyst Culture

Blastocyst transfer has now been used successfully to treat patients with poor-quality embryos [118, 119], patients with multiple IVF failures [120–122], patients with low numbers of oocytes and embryos [123], and oocyte donors [91]. Although in the examples listed above extended embryo culture has been associated with an increase in IVF success rates, there are a number of reports that question the merits of extended culture [124–126].

Parental factors also affect blastocyst formation and pregnancy-implantation rates. As maternal age increases, both the number and quality of the oocytes retrieved are reduced, thus affecting the outcome of blastocyst transfer [127, 128]. The success of blastocyst culture has also been shown to be under paternal influence [129]. Blastocyst formation is affected by the source of spermatozoa utilized for intracytoplasmic sperm injection, and in close relation to this, clinical pregnancy and implantation rates with blastocyst transfers decrease with the increase in severity of the spermatogenic disorder [130].

Gardner and Balaban [131] reviewed 16 prospective randomized trials using sequential media examining the effect of the day of transfer on IVF cycle outcome [90, 121, 125, 126, 132–143]. Of these 16 trials, 7 reported a significant benefit in the outcome as defined by either increased implantation rate or pregnancy rates (1 study only reported pregnancy rates), when embryos were transferred at the blastocyst stage on day 5 rather than at the cleavage stage. In contrast, only one study found a significant advantage in transferring embryos at the cleavage stage [135]. The remaining eight trials reported no difference in implantation rate with respect to the day of transfer.

The move to blastocyst transfer has had a significant impact on reducing the number of embryos required for transfer, thereby greatly reducing the incidence of high-order multiple gestations. However, although triplets can be confined to the archives of IVF, the overall multiple rate of many programs has not decreased dramatically, as the incidence of twins is typically around 50% when two blastocysts are transferred. The only means to avoid this problem is, therefore, to consider single blastocyst transfer. In the first prospective randomized trial of single versus two blastocyst transfers, in a population of patients with a day 3 FSH $\leq$ 10 mIU/mL and at least 10 follicles >12 mm in diameter on the day of hCG administration (age range 26–43 years), it was possible to establish an ongoing pregnancy rate of 60.9% without any incidence of twins [144]. Significantly, when two blastocysts were transferred, the pregnancy rate rose to 76%, but with a 47.4% incidence of twins.

Therefore, the move to single blastocyst transfer (SBT) appears a more viable alternative to SET on day 3 in good prognosis patients. Papanikolaou and colleagues showed in a prospective randomized trial on SET that not only were higher ongoing pregnancy rates established with blastocyst transfer but that pregnancy loss was lower and birth rate was higher than that obtained with the transfer of cleavage-stage embryos [143, 145, 146].

16.8 Blastocyst Selection for Transfer

As the embryo develops and differentiates into the blastocyst, with its distinct cell types (the inner cell mass and trophectoderm), it becomes feasible to give a more detailed grading to the human embryo. An alphanumeric system [147] has been widely adopted and has proven valuable in assessing blastocyst viability prior to transfer [148–150]. Figure 16.6 shows a human blastocyst that has formed a well-defined ICM surrounded by a cohesive multicellular epithelium, the trophectoderm. Such an embryo from a patient <38 years old, or an oocyte donor, should ideally be transferred alone.

As discussed previously, at the blastocyst stage, one has the ability to examine the embryo proper, and using both proteomic and metabolic analyses, it is evident that even blastocysts with the same morphology have different physiologies [74, 151]. Subsequently, the analysis of embryo metabolism and its secretome will be of great value in quantitating embryonic viability prior to transfer and supporting decisions for single embryo transfer [16].

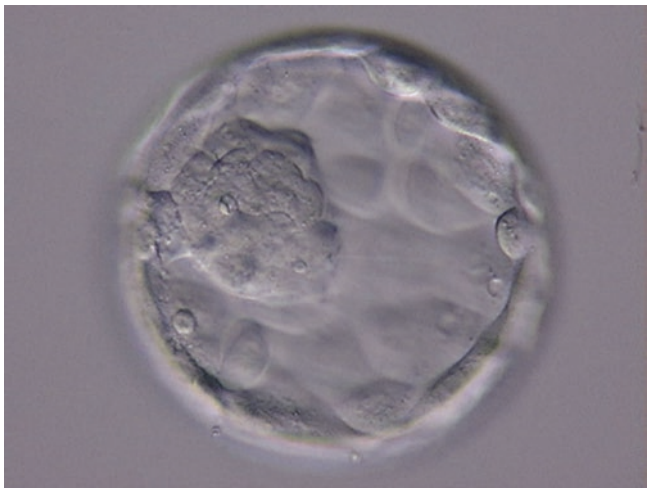

Fig. 16.6 Photomicrograph of a human blastocyst on day 5 of development. Such a blastocyst scores grade 4AA

Box 16.2 Pathway for the Development and Clinical Introduction of the Sequential Media G1/G2

1. Analysis of the nutrient levels within the human oviduct and uterus
2. Use of in vivo developed animal embryos and blastocysts as a "gold standard"
3. Use of several markers of embryo development in vitro including timing of development, gross morphology, blastocyst formation rates, blastocyst cell numbers and cell allocation, and metabolic function (all parameters compared to in vivo controls where possible)
4. Animal embryo transfers (over 5000 embryos transferred in the development of G1/G2)
5. Use of several animal models: hybrid mice, outbred mice, sheep, and cows
6. Preclinical testing on donated human pronucleate oocytes
7. Pilot patient study to ensure safety and efficacy
8. Prospective randomized trial of blastocyst transfer
9. Routine introduction of sequential media in clinical IVF, with monitoring of children born

16.9 Conclusions

With the advent of more physiological culture media, together with better laboratory conditions and management, it is now feasible to culture the human embryo to the blastocyst as a matter of routine. The potential advantages of extended culture go beyond increases in implantation and pregnancy rates and include lower miscarriage rates and the ability to perform comprehensive genetic and physiological analysis of the embryo proper prior to transfer. This in turn has led to a dramatic reduction in the numbers of embryos transferred; we stated earlier that during the mid-1990s, the average number of embryos transferred in IVF clinics within the USA across all age groups, and oocyte donors, was 4. Two decades later, this number has been reduced to 1.7 in patients <35 years old and oocyte donors and to 1.9 for patients <38 years old. In many countries, single blastocyst transfer has become the standard of care [152].

Criticism has been made toward the way in which media for human embryo culture have been developed and introduced [153, 154]. We contend that the sequential media G1 and G2 underwent the most appropriate and extensive development prior to their clinical evaluation and finally their introduction as a routine clinical procedure (Box 16.2). Sequential media have their origins in discovery-based research on the mammalian embryo, including the human, during the early 1990s. Our formulations passed through preclinical phases on multiple animal species, including embryo transfers and live births, extensive trials in the human on donated 2PN embryos, and phase 1 trials and RCTs, and have subsequently been assessed in post-market surveillance by two systematic reviews indicating that optimal blastocyst transfer efficacy is dependent on the use of sequential media.

The capacity to better select a viable embryo will continue to improve the safety of IVF for the mother and child without a compromise in efficacy. The ability of blastocysts to undergo successful cryopreservation with vitrification will culminate in the transfer of genetically analyzed embryos to a naturally cycling uterus. Furthermore, more suitable culture conditions produce embryos more able to survive cryopreservation [155]. The transfer of vitrified blastocysts in a nonstimulated cycle may ultimately be the way all future IVF is performed [156].

Review Questions

1. What are the negative implications of cleavage-stage embryo transfer to the uterus?
2. Can we readily ignore the fact that in vivo the embryos are exposed to nutrient gradients?
3. What is the significance of having amino acids present in human culture media?
4. Does oxygen concentration really matter?
5. How does the detailed development of sequential media compare to that of a monophasic system?
6. What advantages does blastocyst transfer convey?

In Vitro Maturation of Human Oocytes

Zhi-Yong Yang, Ling Wang, and Ri-Cheng Chian

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_17

Learning Objectives

- Describe the source of immature oocytes derived from.
- Prepare medium for IVM procedure.
- Collect and identify immature oocytes.
- Assess the maturity of immature oocytes.
- Inseminate IVM oocytes and culture fertilized zygotes.
- Determine the timing of embryo transfer for IVM.

17.1 Introduction

Today, pregnancy rates achieved with in vitro fertilization (IVF) treatment have exceeded that achieved in natural cycles [1–3]. These figures are achieved with simultaneous transfer of multiple embryos in a given treatment cycle. Traditionally, production of multiple embryos has been only possible after development of controlled ovarian stimulation (COS) protocols.

In a natural menstrual cycle, several antral follicles are present in the human ovary. The interactions between the growing follicles, the pituitary gland, and the hypothalamus prevent multifollicular growth and allow only one follicle complete maturation and reach ovulation in the majority of cycles. COS with exogenous gonadotropins and gonadotropin-releasing releasing hormone analogs enables overriding this natural selection process and collection of multiple mature oocytes, which are amenable to fertilization. COS has been an integral part of conventional IVF treatment for over 20 years.

COS requires multiple daily injections and frequent monitoring scans creating direct and indirect costs, loss of working time, and inconvenience. Unfortunately, the cost of drugs used for COS poses a substantial financial burden and at times prevents a couple's access to treatment. The most important medical problem associated with COS is the risk of ovarian hyperstimulation syndrome (OHSS). OHSS is a potentially lethal condition, most commonly occurring as an iatrogenic complication of COS [4]. It is characterized by ovarian enlargement and increased capillary permeability, causing fluid shift to the third space. This results in ascites formation, hypovolemia, hemoconcentration, and hypercoagulability. OHSS may be further complicated by acute renal failure, hypovolemic shock, thromboembolic episodes, and adult respiratory distress syndrome (ARDS), and in extreme cases, it can be fatal. The risk of OHSS can be as high as 6% in young women with polycystic ovarian syndrome (PCOS) [5]. More recently, the altered hormonal milieu during COS has been suggested to have detrimental effects on developing oocytes, embryos derived from these oocytes, and/or endometrial receptivity [6, 7].

Collection and in vitro maturation (IVM) of the already existing immature oocytes in the smaller antral follicles can provide multiple mature oocytes that can be fertilized or cryopreserved for future use. The technique has been named IVM. Using immature oocytes collected in a nonstimulated cycle to produce multiple embryos avoids the costs, inconvenience, and risks associated with conventional IVF.

Research on immature oocytes dates as far back as the 1930s [8]. These oocytes are shown to resume meiosis upon removal from the follicle, have the capacity to complete meiotic division, and can be fertilized in vitro. More than 80% of oocytes were reported to resume meiosis independent of the menstrual cycle day and gonadotropin support in IVM medium [9]. The first pregnancy and live birth from in vitro matured oocytes in humans were only reported by Veeck and colleagues in 1983 in the context of a stimulated IVF cycle [10]. They reported two pregnancies resulting from IVM of immature oocytes collected alongside mature oocytes in gonadotropin-stimulated IVF cycles. However, IVF with COS had already become the norm, and it was not until 1991 when Cha and colleagues first reported intentional collection of immature oocytes from women undergoing gynecological surgery that IVM began to gain momentum [11]. The immature oocytes donated by these women were matured in vitro, and the resulting embryos were transferred to a recipient with premature ovarian failure [11]. The recipient delivered healthy triplet girls.

Three years later, Trounson and colleagues reported the collection of immature oocytes from women with PCOS for their own use [12]. The immature oocytes collected were matured in vitro with gonadotropin-enriched medium, then fertilized, and a healthy live birth following transfer of resultant embryos was reported. Unfortunately, the initial pregnancy rates were low, and it took another 5 years to allow success rates to exceed 35% per cycle in appropriately selected patient groups [13–24].

17.2 Indications for IVM Treatment

17.2.1 Infertility with PCO or PCOS

Young women with high antral-follicle counts achieve the highest pregnancy rates with IVM [25]. IVM has become an established treatment option for women with PCO or PCOS who need ART. However, the clinical application of IVM technology can be expanded to benefit other patient populations.

17.2.2 High Responders to Gonadotropin Stimulation

IVM combined with IVF can be a valid option for patients who demonstrate an overresponse to COS and are considered to be at risk of OHSS during an already started IVF cycle. The only method proven to prevent OHSS completely is to avoid the injection of human chorionic gonadotropin (HCG) for final oocyte maturation [4]. However, this strategy requires cancelation of the treatment cycle, leading to frustration in both the patient and the physician. Giving the HCG injection when the leading follicle size is 12–14 mm, before the conventional HCG criteria for IVF is met, followed by oocyte collection 36–38 h later may prove to be an effective strategy. Lim et al. reported a 36.6% clinical pregnancy rate using a similar strategy in 123 women who had

≥20 follicles with a mean diameter ≥ 10 mm after ≥5 days of gonadotropin stimulation [26]. None of the women in this cohort developed OHSS. As a further note, 18.9% of 1554 oocytes collected were in vivo matured.

17.2.3 Poor Responders to Gonadotropin Stimulation

Unfortunately, all women do not respond similarly to COS, and some fail to develop a reasonable number of mature follicles in stimulated IVF cycles. The most common cause of poor response seems to be the age-related decline in ovarian reserve, but it also occurs in some younger women.

For women in whom poor ovarian response does not seem to be due to a rectifiable cause inherent to the particular treatment cycle, i.e., inappropriate choice of stimulation protocol, skipped medication, etc., trying further stimulated cycles can prove useless. IVM may provide a viable option in such cases. In two studies involving women with a history of poor ovarian response in a stimulated IVF cycle, pregnancy rates of 31.6 and 40.4% were achieved with IVM [27, 28]. In eight women with a poor response, defined as ≤4 follicles growing or oocytes collected in a previous stimulated IVF cycle, we achieved a similar number of embryos available for transfer in the subsequent IVM cycle [29]. Six women reached embryo transfer (75%), and one achieved a live birth, yielding a 16.7% live birth rate per transfer in this small sample.

17.2.4 Oocyte Donation

Young women who have high ovarian reserve are preferred as oocyte donors. Unfortunately, such women comprise a high risk population for early OHSS in stimulated IVF cycles. Besides the risk of OHSS, the inconvenience of the numerous injections required and the theoretical risk of cancer associated with repeated use of ovulation induction drugs cause reluctance on the part of some potential oocyte donors. IVM can be an appropriate method for oocyte donation cycles as young women with high antral-follicle counts comprise the best candidates for IVM and yield good pregnancy rates.

We reported collection of an average of 12.8 immature oocytes from 12 oocyte donors with a mean age of 29 years. Sixty-eight percent of the oocytes matured in vitro and 62 embryos were available for transfer to 12 recipients with a mean age of 37.7 years [30]. On average, four embryos were transferred (range 2–6), and a clinical pregnancy rate of 50% was achieved. Two women had first-trimester miscarriages while four had healthy live births, yielding a live birth rate of 33%.

17.2.5 Fertility Preservation

The American Society of Clinical Oncology and American Society of Reproductive Medicine have endorsed IVF and embryo cryopreservation (EC) as the only method of female fertility preservation [31, 32]. IVM expands the fertility preservation options for women who are not candidates for IVF–EC for various medical and social reasons. Women with hormone-sensitive tumors may undergo immature oocyte collection and cryopreserve resultant embryos. The advantages of IVM are not limited to eliminating the need for expensive drugs as well as their administration and avoiding hormone-sensitive tumors: IVM enables oocyte retrieval at any phase of the menstrual cycle and completion of the fertility preservation procedure in 2–10 days, preventing a delay in treatment of the primary disease [33, 34]. We reported three women without male partners seeking fertility preservation prior to chemotherapy, who presented for the first time in the luteal phase of their menstrual cycle and were to undergo gonadotoxic treatment immediately [34]. Five to seven immature oocytes were recovered with luteal-phase oocyte retrieval from these patients. Three to five M-II oocytes were vitrified following IVM. Two of these three women later underwent one and two more collections, respectively, in the follicular phase of the next cycle(s), and additional immature oocytes were vitrified following IVM.

Immature oocytes can also be harvested from ovarian biopsy specimens and can be vitrified following IVM [35]. This combination of ovarian-tissue cryobanking and IVM represents a new strategy for fertility preservation. We retrieved 11 immature oocytes from a wedge resection specimen in a 16-year-old patient with mosaic Turner syndrome. Eight of these oocytes were vitrified following IVM [36]. In four women with cancer, we harvested 11 immature and eight mature oocytes from wedge biopsy specimens. Eight of the 11 immature oocytes reached M-II stage following IVM and were vitrified [35].

17.3 Step-by-Step Protocol for IVM Treatment

17.3.1 Monitoring and Management of an IVM Cycle

Monitoring starts with a baseline scan performed in the early follicular phase of the menstrual cycle, preferably between days 2 and 5 of a natural menstrual cycle or a withdrawal bleed, induced with progesterone administration in amenorrheic women. The number and size of the antral follicles and endometrial texture and thickness are recorded. The uterus and ovaries are examined for any abnormalities. A second scan is performed about a week later when it is anticipated that the largest follicle has reached 10–12 mm in diameter and the endometrial thickness is at least 6 mm. The presence of a dominant follicle does not require cancelation of the treatment cycle because smaller follicles are found to contain viable oocytes, even in the presence of a dominant follicle [37, 38].

The role of gonadotropin administration before oocyte collection is still controversial. Randomized controlled trials comparing the outcome of gonadotropin-primed IVM cycles with that of IVM cycles without any priming have yielded

conflicting results [20, 22, 39, 40]. When data from these studies are combined, there is a trend toward higher clinical pregnancy rates with FSH/HMG administration or HCG priming in women with polycystic ovaries (PCO)/PCOS; however, the difference is not statistically significant. Differences in patient characteristics, gonadotropin administration protocols, and the limited total number of patients included in these studies prevent a definitive conclusion, and further research is needed. Based on our own experience and the favorable trend observed in trials of HCG priming, the current routine IVM protocol at the McGill Reproductive Centre (MRC) involves HCG administration priming regardless of cycle regularity.

Our preferred HCG dose is 10,000 IU i.m. 36–38 h before oocyte collection. The decision on dosage is based on failure to observe any improvement in laboratory or clinical outcomes with a higher HCG dose of 20,000 IU in a randomized controlled trial conducted in our unit [41]. On the other hand, in a retrospective analysis, we found an increase in the number of in vivo matured oocytes collected, the rate of oocyte maturation in the first 24 h after collection, and the embryo implantation and clinical pregnancy rates when the interval between HCG administration and oocyte collection was extended to 38 h rather than the traditional 35 h [42]. The relevance of the latter findings is supported by the following studies. Our results suggest that the presence of in vivo matured oocytes can be associated with higher pregnancy rates in HCG-primed IVM cycles [43]. A significantly higher proportion of embryos derived from in vivo matured oocytes attained good morphological characteristics compared with those derived from in vitro matured oocytes in these cycles. Moreover, oocytes that complete IVM in the first 24 h after collection seem to have a higher rate of cleavage, and embryos derived from such oocytes have a higher rate of blastocyst formation compared with their counterparts that complete maturation later [44].

Both the size of the leading follicle and endometrial thickness are taken into consideration regarding the timing of oocyte retrieval. We prefer the size of the dominant follicle to range between 7 and 12 mm at the day of HCG administration, i.e., 36–38 h before oocyte collection, because embryo implantation and clinical pregnancy rates were found to be significantly lower in cycles where the mean diameter of the dominant follicle measured >14 mm compared with cycles that produced smaller dominant follicles with a mean diameter of 10–14 mm or ≤10 mm at the time of oocyte collection [37]. The highest implantation (14.3%) and pregnancy rates (40.3% per transfer) were achieved in cycles with a 10–14-mm-sized dominant follicle.

In a retrospective analysis of 155 unstimulated IVM cycles, we have found mean endometrial thickness to be significantly higher in conception cycles, though the absolute difference was only 0.8 mm (10.2 vs. 9.4 mm in conception and nonconception cycles, respectively, $p = 0.04$). More interestingly, a trend analysis demonstrated a significant increase in pregnancy rates in parallel with endometrial thickness (clinical pregnancy rates were 9.4, 15.9, 27.6, and 28% for endometrial thickness of <8, 8–9.9, 10–11.9, and ≥12 mm, respectively; chi square test for trend, $p = 0.036$) [45]. Interestingly, endometrial texture, categorized as "triple line" or "non-triple line," was not found to be predictive for treatment outcome in the same study.

If the endometrial thickness is <6 mm on the day of the second scan, HCG administration can be delayed if the size of the largest follicle is less than 12 mm. Sometimes, if the largest follicle is close to 10–12 mm but the endometrium is very thin, we would use estradiol alone in a dose of 12 mg/day. This increases the endometrial thickness and delays follicle growth.

For women whose endometrial thickness was less than 6 mm on the day of the second scan, we later adopted an additional strategy of administering HMG in a dose of 150 IU/day and/or starting estradiol earlier. The rationale is increasing endogenous estrogen levels with limited support to the continuing growth of the follicles in the cohort. A retrospective comparison of the two strategies in 48 cycles demonstrated a similar increase in mean endometrial thickness with both methods, from 4.5 to 7.7 mm and from 4.7 to 7.3 mm in HMG and estradiol cycles, respectively [46]. However, compared with oral administration of 17β estradiol, HMG injections were associated with an increase in the number of in vivo matured oocytes collected (cycles with more than one in vivo matured oocyte, 54.5 vs. 34.6%), implantation (15 vs. 8.2%), and pregnancy rates (36.4 vs. 23.1%). The differences were not statistically significant, arguably due to the limited sample size of the study. Currently, we prefer HMG over estradiol for women with a thin endometrium. HMG injections are continued until endometrial thickness reaches 8 mm or the leading follicle reaches a mean diameter of 12 mm.

17.3.2 Oocyte Collection Procedure

The principles of transvaginal ultrasound-guided oocyte retrieval for IVM are the same as those for IVF oocyte collection. There are a few modifications in both the technique and equipment. Most patients easily tolerate the procedure under conscious sedation and with paracervical block achieved with 1% bupivacaine injection. A smaller-gauge needle (19–20G) with a shorter bevel is used. The aspiration pressure is set at 75–80 mmHg, approximately half the conventional IVF aspiration pressure, in order to minimize the risk of oocyte denudation during aspiration. This precaution is carried out because immature oocytes need the presence of surrounding granulosa cells during the nuclear maturation process. The fine-bore needle may be blocked frequently with blood-stained aspirate and ovarian stroma. Therefore, multiple punctures are often needed, and flushing the needle lumen with heparinized saline between punctures is required. Sometimes external abdominal pressure may be required to fix the mobile ovaries during collection. Patients with difficult-to-reach ovaries or poor pain control may do better under limited general anesthesia with propofol.

Fig. 17.1 **a** Labeling on Cell Strainer (Falcon, Becton Dickinson and Company, USA); **b** follicular aspirates are filtered with a Cell Strainer

17.3.3 Laboratory Procedure

Similar to IVF, the follicular aspirate is first examined under a stereomicroscope to identify cumulus-oocyte complexes (COCs). Since identification of small immature oocytes surrounded by scarce granulosa cells, which are not widely dispersed, is more difficult with the conventional technique as they can be overlooked, follicular aspirate is filtered through a nylon mesh strainer (Fig. 17.1) with 70 µm pores after the removal of initially identified COCs. The filtered aspirate can be reexamined after washing with HEPES-buffered human serum albumin (HSA)-containing medium.

In order to determine whether the oocyte is mature or not, a special observation technique called "sliding method" can be employed without denuding cumulus cells from the oocyte.

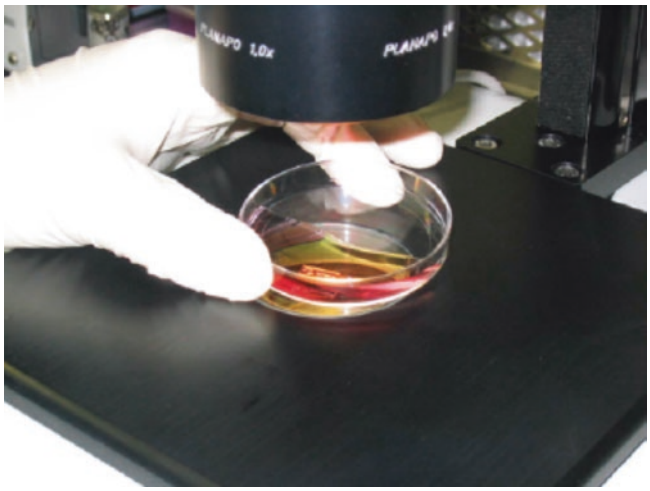

Fig. 17.2 Sliding technique for observation of oocyte maturity. COCs are allowed to slide slowly from one side to the other on the bottom of the Petri dish, while being observed under the stereomicroscope

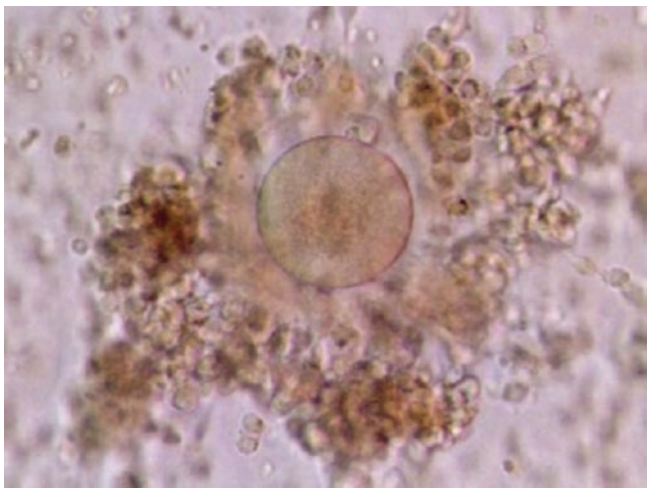

Fig. 17.3 During COC sliding, it is possible to observe clearly whether or not the oocyte has extruded a first polar body (1PB) into perivitelline space (PVS)

Briefly, COC is allowed to slide slowly from one side to the other on the bottom of the Petri dish, while being observed under the stereomicroscope (Fig. 17.2). During COC sliding, it is possible to observe clearly whether or not the oocyte cytoplasm contains a germinal vesicle (GV) or if the oocyte has extruded a first polar body (1PB) into perivitelline space (PVS) (Fig. 17.3). If neither GV is seen in the oocyte cytoplasm nor 1PB found in PVS, the oocyte is defined as germinal vesicle breakdown (GVBD) or metaphase-I (M-I) stage.

The immature COCs (maximum of ten) are incubated in an Organ Tissue Culture Dish (Falcon, 60 × 15 mm) (Fig. 17.4) containing 1 mL oocyte maturation medium supplemented with a final concentration of 75 mIU/mL FSH and 75 mIU/mL LH at 37 °C in an incubator with an atmosphere of 5% CO_2 and 95% air with high humidity (prefer with triple gas mixture, 90% N_2, 5% CO_2, and 5% O_2 with 100% humidity). Oocyte maturation medium should be prepared

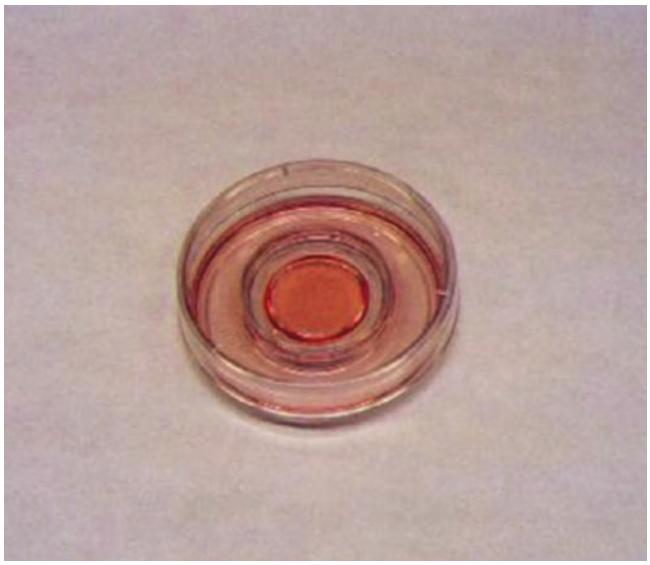

Fig. 17.4 Organ Tissue Culture Dish (Falcon, 60 × 15 mm) containing 1 mL oocyte maturation medium in the inner well and 2 mL of oocyte maturation medium in the outer well

for equilibration at least 2 h before immature oocyte retrieval (particularly, it can be made 1 day before). Some commercially available oocyte maturation media do not contain a protein source. In that case, the oocyte maturation medium needs to be supplemented with some protein source, such as HSA or maternal serum. If maternal serum is going to be used, it is better prepared in advance and inactivated (56 °C 30 min) before using.

Oocytes reaching metaphase-II (M-II) stage on the day of collection are denuded and fertilized together with any in vivo matured oocytes, while immature oocytes are cultured in IVM medium for 24–48 h. Twenty-four hours after maturation in culture (Fig. 17.5), all COCs are stripped for identification of oocyte maturity. COCs are denuded using a finely drawn glass pipette following 1 min of exposure to a commercially available hyaluronidase solution. The mature oocytes are then subjected to insemination by either IVF or intracytoplasmic sperm injection (ICSI) after stripping. The remaining immature oocytes (GV and M-I) will remain in culture for another 24 h. Forty-eight hours after oocyte retrieval, the remaining stripped oocytes are reexamined, and if any have matured at this point, they will be inseminated by either IVF or ICSI.

Since in vivo matured oocytes can be retrieved after HCG priming from leading or dominant follicles, it has been argued that such "IVM treatment" is not genuine. Accordingly, the treatment has been reworded as "natural cycle IVF combined with IVM," simply referred to as natural cycle IVF/M [38, 47–49].

Although similar implantation and pregnancy rates have been reported following fertilization of in vitro matured oocytes with ICSI or IVF, ICSI has been commonly practiced in IVM cycles due to a theoretical risk of zonal hardening during the in vitro culture period [50, 51]. In fact, fertilization rates with ICSI were shown to be higher than with IVF

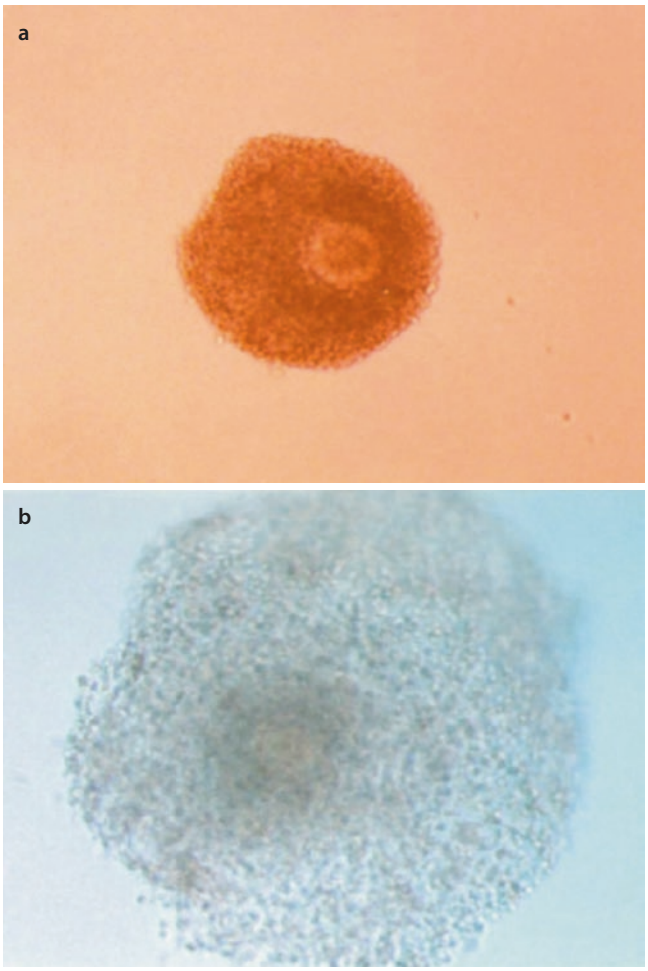

Fig. 17.5 Morphological changes of immature COC before and after culture in the oocyte maturation medium. **a** Immature COC immediately after retrieval from the ovary; **b** the same COC after 24 h of culture in the oocyte maturation medium. Note that the cumulus mass has almost doubled in size compared with its mass before culture (two photos with the same magnification)

in the same study (84.1 vs. 56.3%) [51]. Another reason for preferring ICSI over IVF in IVM cycles is some immature oocytes being denuded for the assessment of polar-body extrusion. Oocytes devoid of cumulus cells may have decreased chemotactic potential for sperm in the medium [52]. ICSI is the fertilization method routinely used in the McGill IVM program. The preferred time for ICSI is 2–4 h after polar-body extrusion [52].

Culture conditions for fertilized oocytes and cleavage-stage embryos derived from in vitro matured oocytes are the same as those in IVF cycles. Embryo development and quality are similarly assessed, based on the number of blastomeres and the amount of nuclear fragments.

17.3.4 Embryo Transfer

The timing of embryo transfer and the number of embryos to be transferred are dictated by the number and quality of available embryos. Embryo transfer is commonly performed on

the third day after oocyte collection. Growth and quality of available embryos are evaluated with regard to fertilization time of each embryo. A group of best embryos for days is transferred using essentially the same technique as that employed in IVF cycles. In general, embryo implantation rates in IVM cycles are lower than in IVF cycles. Therefore, on average, more embryos are transferred in order to maintain similar pregnancy rates. However, as expected, this fact does not seem to increase multiple pregnancy rates after IVM [53, 54].

High implantation and pregnancy rates have been achieved by performing blastocyst transfers in selected IVM patients [55]. A clinical pregnancy rate of 51.9% and an implantation rate of 26.8% have been reported with blastocyst transfer in patients with >7 zygotes and >3 good-quality embryos on the third day postfertilization in IVM cycles [55]. Assisted hatching is routinely employed before embryo transfer in our IVM program due to the abovementioned concerns about zonal hardening [50].

17.3.5 Luteal-Phase Support

The luteal-phase support protocol employed in our IVM program includes 50 mg/day i.m. progesterone injections and 6 mg/day estradiol valerate p.o. in three divided doses. We continue luteal-phase support until completion of the first trimester for pregnant patients.

17.4 Clinical Outcome of IVM Treatment

The most important determinants of pregnancy following an IVM cycle are the female age and the number of oocytes collected. Young women with PCO seem to be the best candidates for IVM treatment. In 2007, we achieved an embryo implantation rate of 15% and a clinical pregnancy rate per embryo transfer (CPR) of 36.7% in women younger than 35 years of age. However, for women aged between 35 and 40 years, implantation and CPR were 10.1 and 29.3%, respectively, in the same period. Similarly, successful results have been reported by different centers around the world [14]. Pregnancy rates seem to be significantly higher when an in vivo matured oocyte has been collected. Recently, we reported a 40% clinical pregnancy rate in such cycles in young women with PCO [43].

Immature oocytes priming with FSH or HCG prior to immature oocyte retrieval improves oocyte maturation rate and embryo quality as well as pregnancy rates when retrieved from infertile women with PCOS and normal ovaries and regular menstrual cycling women. The source of follicles may be important for the subsequent embryonic development, but the developmental competence of immature oocytes derived from the small antral follicles seems to not be adversely affected by the presence of a dominant follicle, which developed a newly named natural cycle IVF combined with IVM, because there will be in vivo matured oocytes and immature oocytes retrieved at the same time and in the same cycle. So far, it has been estimated that there are more than a few thousands of healthy infants born following immature oocyte retrieval and IVM from women with PCOS [56, 57]. In general, the clinical pregnancy and implantation rates per embryo transfer have reached approximately 35–40% and 15–20%, respectively, in infertile women with PCOS following IVM of immature oocytes based upon different reports [56]. If it included the mentioned natural cycle IVF combined with IVM, the clinical outcomes must be higher than those numbers.

Since the introduction of IVF and other assisted reproductive technologies for infertility treatment, the health of infants born from these techniques has been a major concern, including IVM technology, especially for the extra period of culture of immature oocytes in vitro. In fact, IVM of the immature oocytes from GV via M-I to M-II stage normally require 36–48 h of culture in vitro [9, 13]. For clinical IVM of the immature oocytes from M-I to M-II stage, it only needs 6–24 h of culture in vitro [58]. Interestingly, it has been reported that there was no significance in morpho-kinetics of embryos developed from oocytes matured in vivo and in vitro in IVM cycles, indicating that the embryonic developmental potential may not be different between the oocyte matured in vivo and in vitro [59]. There were insignificant differences for zona pellucida birefringence and meiotic spindle between the in vivo and in vitro matured oocytes [60]. Furthermore, it has been indicated that the in vivo and in vitro matured oocytes showed normal ooplasm showing uniform distribution of organelles [61]. Mitochondrial morphology appeared similar between the maturation conditions. Cortical granules were found typically stratified in a single, mostly continuous row just beneath the ooplasm in in vivo and in vitro matured oocytes.

There was a study showing that optimized human IVM procedures have no significant effects on the establishment of maternal DNA methylation patterns at LIT1, SNRPN, PEG3, and GTL2 [62]. There were no differences in terms of oxygen consumption between embryos derived from the in vitro and in vivo matured oocytes, indicating that also there was no imprinting gene disorder founded from IVM babies [63]. No statistically significant impact was found of IVM on chorionic villus and cord-blood DNA methylation at the studied developmentally important genes and interspersed repeats, suggesting that IVM-induced epigenetic changes in offspring, if any, will be relatively small in magnitude and/or infrequent [64]. For human IVM, it seems no definitive conclusion on imprinting establishment can be drawn as well-designed studies are currently not available. Therefore, epigenetic analysis should be performed in children born from pregnancies after IVM to draw definitive conclusions on the epigenetic safety of human IVM [65].

The number of live births from IVM oocytes has been increasing over the past three decades. It has been estimated that more than 5000 IVM infants have been born worldwide [56]. There are many concerns about IVM infants as to obstetric and perinatal outcomes as well as long-term development [66]. Several studies have reported that the mean birth weight

and the incidence of congenital anomalies seem to be comparable with spontaneous conceptions or conceptions of infertile women undergoing IVF treatment [54, 67, 68]. It was reported that 196 infants conceived after IVM of immature oocytes were not associated with an increased risk of adverse obstetric or perinatal outcomes compared with children conceived by in vivo matured oocytes or children conceived by conventional ovarian-stimulated ICSI cycles [69].

17.5 Pregnancy Loss

Biochemical pregnancy loss rates were similar among 1581 women who had a positive pregnancy test following assisted reproduction treatment (ART) with IVM, IVF, or ICSI in our unit during a 5-year period (17.5% for IVM pregnancies, 17% for IVF, and 18% for ICSI pregnancies, $p = 0.08$). However, the clinical miscarriage rate was significantly higher in IVM pregnancies (25.3%) than in IVF (15.7%) and ICSI (12.6%) pregnancies ($p < 0.01$) [70]. However, the incidence of PCOS in the IVM group was 80%, whereas only 8% and <1% of women in the IVF and ICSI groups had PCOS, respectively. Miscarriage rates reaching 25% after ovulation induction, and ranging from 25% to 37% following IVF, have been reported in women with PCOS [71–73]. Arguably, the higher incidence of PCOS in IVM patients in this series can be the reason for the higher miscarriage rates observed in the IVM group. Critically, miscarriage rates were not different between IVM and IVF pregnancies among women with PCOS, 24.5 vs. 22.8%, respectively.

17.6 Obstetric Outcome and Congenital Abnormalities

IVM pregnancies comprised 15.9% of 344 ART pregnancies in a retrospective analysis of all pregnancies delivered at the McGill University Health Centre during a 5-year period from January 1, 1998, to December 31, 2003 [70]. The incidence of multiple or high-order multiple pregnancies was not different among IVM (21 and 5%), IVF (20 and 3%), and ICSI (17 and 3%) pregnancies. Although cesarean delivery rates of ART pregnancies were higher than spontaneous conceptions, the incidence of cesarean delivery was similar among singleton pregnancies conceived with different treatments (IVM 39%, IVF 36%, and ICSI 36%). Likewise, the mean birth weights of all infants conceived with ART were similar among all ART groups, but lower than those of spontaneous conceptions.

In the abovementioned study, the odds ratios (ORs) for any congenital abnormality, calculated with spontaneous conceptions serving as the reference, were 1.42 (95% confidence interval (CI) 0.52–3.91) for IVM, 1.21 (95% CI 0.63–2.32) for IVF, and 1.69 (95% CI 0.88–3.26) for ICSI, respectively [70]. None of these were statistically significant. Interestingly, the odds ratio was lower for IVM than for ICSI, even though ICSI was used for all IVM cases. This suggests that the reported high congenital abnormality rate with ICSI is more likely to be due to poor sperm per se because ICSI with normal sperm used in IVM cycles did not increase the odds of congenital abnormality to the same extent.

Recently it has been reported that 1421 IVM babies born from 1187 pregnancies from 31 IVF clinics located in 22 countries, and the data were collected at the time of birth and include stillbirths but not pregnancy terminations [74]. Of the 1421 IVM infants born, there were 18 major congenital abnormalities (Table 17.1). However, it is comparable with the prevalence of major birth defects (MBDs) with the spontaneous conception per birth ranged to International Clearinghouse for Birth Defects Surveillance and Research (ICBDSR, 2011) [75]. Based on these data, it indicates that IVM procedure may not appear to pose any significantly increased risk of poor obstetric outcomes or congenital abnormalities over those already accepted with IVF or other ARTs.

17.7 Physical and Neuromotor Development

Shu-Chi et al. analyzed the chromosomal constitution and mental development of 21 children born after IVM and compared with 21 spontaneously conceived children. All of the IVM children were found to have normal karyotype and mean developmental index score, similar to controls in this small-sized study [67]. Another study of 46 IVM babies born to 40 women reported similar findings [68]. The neuropsychological development of children was assessed until 24 months and was found to be within population standards. The physical growth of IVM children seems to be similar to that of spontaneously conceived children [67, 68]. Currently available data seem reassuring and do not suggest an increased risk of congenital malformations and physical or neurological developmental delay in IVM children.

17.8 Future Goals

IVM is a relatively old topic and new technology compared to conventional IVF. IVM should be regarded as a complementary assisted reproductive technology that provides unique opportunities rather than merely a competitor of IVF. The source of immature oocytes is an important feature for the subsequent embryonic development and pregnancy, but the developmental competence of oocytes derived from the small antral follicles seems not to be adversely affected by the presence of a dominant follicle. Priming with FSH or HCG prior to immature oocyte retrieval improves oocyte maturation and pregnancy rates. The use of IVM technology can thus be broadened to treat women suffering from all causes of infertility with acceptable pregnancy and live birth rates. Patients who are at high risk of OHSS, those with unexpectedly hyper- or poor responses during controlled ovarian hyperstimulation, those with recurrent unexplained IVF failures, as well as those who are facing imminent gonadotoxic chemotherapy and are in need of fertility preservation can

Table 17.1 Obstetric outcomes and congenital abnormalities in 1421 IVM babies born from 1187 pregnancies

Characteristics from 1187 pregnancies	*Singleton pregnancies (n = 960)*	*Twin gestation pregnancies (n = 221)*	*Triplet gestation pregnancies (n = 5)*	*Quadruplet gestation pregnancies (n = 1)*
Mean gestational age at delivery (weeks + days)	37 + 4	36 + 5	35 + 2	29 + 0
No. of deliveries at >37 weeks (%)	855 (89)	60 (27)	0 (0)	0 (0)
No. of deliveries at 34–37 weeks (%)	82 (9)	132 (60)	5 (100)	0 (0)
No. of deliveries at <34 weeks (%)	23 (2)	29 (13)	0 (0)	1 (100)
Total of 1421 newborns	*Singleton newborns (n = 960)*	*Twin newborns (n = 442)*	*Triplet newborns (n = 15)*	*Quadruplet newborns (n = 4)*
Birth weight (mean ± SD) (g)	2965 ± 532	2434 ± 365	1968 ± 472	1330 ± 84
No. of LBW (%)	35 (4)	59 (13)	12 (80)	0 (0)

VLBW Very low birth weight, <1500 g
SD Standard deviation

benefit from advantages of IVM. Although IVM as an efficient treatment resulted into several thousands of healthy babies born, IVM technology is still considered experimental by the society. Maybe, it is time to reconsider the IVM technology as an efficient clinical treatment.

Essentially, all ART laboratory procedures can be performed with in vitro matured oocytes if the need arises. The first successful IVM cycles combined with preimplantation genetic screening and percutaneous testicular sperm aspiration have already been reported [76, 77]. IVM has enabled successful treatment of patients with empty follicle syndrome in previous stimulated IVF cycles [78]. Patients can undergo several IVM cycles, and we previously reported a series of patients who achieved repeated live births with IVM treatment [79].

As the development of IVM treatment continues, an attractive possibility for increasing the successful outcome rate is combining natural cycle IVF treatment with immature oocyte retrieval followed by IVM of those immature oocytes. If the treatment processes can be simplified, especially for immature oocyte retrieval, more infertile women may be able to take advantage of these treatments. Mild stimulation IVF combined with IVM treatment may represent a viable alternative to standard treatment. As we accumulate more experience and outcome data, mild stimulation IVF combined with IVM may prove to be not just an alternative to standard treatments, but potentially first-line treatment choices [80].

Review Questions

1. LH surge induces the dominant follicle for oocyte maturation and ovulation in vivo. Oocyte maturation refers to the completion of the first meiotic division and is characterized by the extrusion of the first polar body (1PB) and formation of the secondary oocyte, both of which contain a diploid chromosome complement. Although oocyte maturation is defined as the completion of the first meiotic division from GV stage to M-II stage, the clinical definition of IVM should be considered as the procedure of immature oocytes from GV and M-I stages to M-II stage.

2. Many factors affect IVM success rates. Regardless of the different sources of immature oocytes retrieved, the most important factor affecting IVM success rate is the size of follicles.

3. Immature oocytes do not mature at the same time following IVM in culture. Practically, the maturity of IVM oocytes should be evaluated at 24 hours following culture by denuding cumulus and granulosa cells.

4. ICSI may not be required for fertilization of IVM oocytes if sperm parameters are good enough. However, practically, ICSI is recommended for insemination of IVM oocytes, because they may be inseminated two times: on egg retrieval day, 24 hours, and 48 hours following culture. Therefore, the IVM oocytes can be inseminated by ICSI with the sperm sample prepared once and used for the remaining 2 days.

5. IVM procedure seems not appear to pose any significantly increased risk of poor obstetric outcomes or congenital abnormalities over those already accepted with IVF or other ARTs.

Design and Development of Simplified, Low-Cost Technologies for Clinical IVF: Applications in High- and Low-Resource Settings

Jonathan Van Blerkom, Christine Hennigan, and Willem Ombelet

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_18

Learning Objectives

- How the essential principles of clinical IVF, embryo culture, and developmental competence assessment can be significantly and successfully simplified for application in high- and low-resource countries.
- How a relatively simple yet robust time-lapse microscopic imaging capacity can be added at low cost to this simplified IVF system to enable the detection of normal and abnormal embryo morphodynamics during the preimplantation stages.
- How a secure streaming video function allows contemporaneous viewing and discussion online with remote experts to aid in the technical training of embryologists for quality control and developmental competence assessment.

18.1 Introduction

With the birth of the first baby conceived by in vitro fertilization in 1978, the application of IVF technology has increased nearly exponentially for many years thereafter so as to become the worldwide infertility enterprise we witness today. The use of the word enterprise is intentional because in many respects infertility treatment has indeed become a very big business. This is not meant in a pejorative sense about an area of medicine that in reality has a very high "cure" rate for a disease, which is what infertility is considered to be by relevant medical societies and organizations worldwide, but rather one that can be costly given the clinical and technical expertise required, as well as the laboratory infrastructure needed to undertake treatment. In this context, treatment usually begins with the clinical diagnosis of infertility that is best treated by IVF followed by the following sequence of events: (i) endocrine management of the menstrual cycle to achieve some measure of controlled ovarian hyperstimulation that can be anticipated to produce multiple meiotically mature oocytes (i.e., metaphase II, MII) that are likely to be fertilization competent; (ii) fertilization in vitro and embryo culture to the cleavage or blastocyst stages for replacement in the uterus, if estimated to be appropriately synchronized at the cellular and biochemical levels to the developmental stage of the embryo at transfer; (iii) transfer by experienced clinicians, usually under ultrasound guidance; and/or (iv) preservation of embryos by cryopreservation because intrauterine conditions were found to be inconsistent with implantation or supernumerary, stage-appropriate embryos occurred which are cryogenically stored for a subsequent transfer cycle(s). In large measure, these basic elements of infertility treatment using IVF methodology have changed little over the last four decades since the first successful birth. What has changed, however, has been the progressive addition of technologies designed to improve successful outcomes, the birth of a normal baby to an infertile couple, which is the only true measure by which IVF can truly be assessed.

To this end, the progressive increase in the sophistication of the technology employed in clinical IVF laboratories derives from an underlying imperative in the field of reproductive medicine, namely, to continually strive to improve outcome and, indeed, with an increased understanding of molecular, cellular, and genetic aspects of human oocyte and preimplantation embryo biology and physiology and their requirements to function normally under in vitro conditions, this imperative has produced remarkable progress with respect to birth rates. Aside from an increased understanding of how oocytes and embryos "work," in no small measure, increased success with IVF can be directly related to improvements in laboratory design, management, culture media and equipment, and, perhaps of most significance, experienced professional clinical embryologists. But here too, improved outcomes attributable to recognizable and controllable "extrinsic" factors have come at the expense of often unavoidable increases in treatment costs to both program and patient.

In many areas of the world, continued progress in IVF of this nature is of little or no consequence to the vast majority of infertile patients in need of this treatment because even the most basic elements required to provide IVF are either unavailable or unaffordable. As described in numerous studies and reports from various international foundations, private humanitarian agencies, and governmental reports, infertility among young couples of childbearing age in so-called low-resource/developing countries is a significant and growing medical problem with important societal implications that have not been adequately addressed, if at all [1–5], such that the prospects for advanced infertility treatments remain dismal. Yet even in the "high-resource/developed countries," where IVF programs are relatively abundant and IVF births commonplace, many couples are simply excluded or "priced out" out of treatment, including those with some form of medical insurance where coverage for advanced infertility treatments is not included or severely limited for this purpose.

For those familiar with the IVF literature, it has been commonplace to see papers begin with a tribute to the original "pioneers" of clinical IVF, Robert Edwards and Patrick Steptoe. What the authors of these studies that usually come from high-volume, high-cost, high-complexity programs may not realize is that it was the vision of Robert Edwards that the methods and technologies he and his colleagues developed and so freely made available to nascent IVF programs in developed countries, be also be applied in developing countries where there was an urgent need for infertility treatment [6]. However, there are formidable infrastructural, financial, political, and personnel barriers to providing such services in low-resource settings [2]. The following section describes some of the more recent attempts designed to address the issues of affordability and accessibility that may be applicable in such circumstances.

18.2 Models for Delivering Low-Cost IVF in Low-Resource Developing countries

One approach to providing advanced assisted reproductive technologies in low-resource settings that might seem to be both practical and effective has been to promote the repurposing or donation of laboratory equipment from research or clinical laboratories, including those involved in IVF, in high-resource centers, when replacing or updating equipment. While this may be a viable option for stand-alone instruments such as microscopes, pH meters, or small clinical centrifuges, several critical challenges exist for other essential equipment in order to accomplish IVF at sites where the availability of medical grade gas for cell culture incubators is problematic or where a constant source of "clean" electricity is uncertain. Current incubators used for human IVF and embryo culture are all controlled by circuitry that can be susceptible to voltage fluctuations, which can damage or destroy microprocessors used to continuously monitor and regulate atmosphere and temperature. Frequent fluctuations in voltage (so-called dirty electricity) or interruptions in supply can be chronic in some low-resource settings requiring often costly backup power sources and line filters. This is especially relevant for CO2 and triple gas incubators where each of the abovementioned gases are individually monitored and concentrations continuously adjusted. Should these circuit boards and those controlling humidity and temperature need to be replaced and the settings recalibrated, the downtime can be quite lengthy if parts and technical service expertise are not available in a timely fashion, which is essential for IVF operations that occur under well-controlled incubation.

Another approach to delivering IVF for both high- and low-resource settings is to use the patient simply as an incubator for fertilization and embryogenesis in which gametes and embryos are physically isolated from contact with the reproductive tract in manufactured vessels placed in the uterus or vagina until removal for uterine deposition. One such device originally described by Blockeel et al. [7] was a removable intrauterine device manufactured as a hollow tube composed of a laser-microperforated silicone elastomer in which fertilization and early embryonic development occur after the introduction of gametes. Based on initial positive results from this pilot study with respect to fertilization, embryo development, and live births, a patent was issued for a similar design described as follows in the application: "The Anecova AneVivo intrauterine device which is a porous titanium chamber which allows fertilization and the first day of embryo development to occur in the patient's uterus, exposed to tubal and uterine fluids, rather than in an artificial medium, in an incubator. The device is then removed and the embryos are cultured until day 5 at which point an embryologist can select the blastocyst with the best morphology for transfer." If the device is to be used transiently as described, that is, removed on day 1 to confirm normal fertilization and embryos not reloaded and replaced in utero, development to the blastocyst stage (day 5) occurs in vitro during the subsequent 4 days. In this hybrid of "in vivo/in vitro" IVF, it would seem that the prevailing notion is the assumption that regulatory factors unique to the uterine milieu would be developmentally beneficial or significant throughout preimplantation embryogenesis if exposure occurs on the first day of embryogenesis. Because fertilization and cleavage occur in the Fallopian tube, with the former occurring on day 1 in the upper region of the tube, why uterine placement might be better suited than an artificial culture media is unclear because potential or putative beneficial uterine factors or conditions should normally be absent in this region in vivo. Nevertheless, devices such as these that use the female patient as an incubator, or for possible early exposure to yet be identified developmental regulators or promotors, may have an important role in IVF if unambiguously shown in well-designed and controlled studies to produce live births at frequencies significantly higher than currently obtained with so-called standard embryology, that is, insemination, fertilization, and preimplantation embryogenesis entirely in vitro using contemporary one-step or continuous culture media optimized for human embryo culture. At present, it is unclear whether such a device would be acceptable in a low-cost IVF setting due to cost and need for a basic laboratory if after deposition of gametes the device does not remain in utero with embryo collection on day 3, 5, or 6, but rather after the removal of fertilized eggs, culture is continued in vitro until the time selected for transfer. Alternatively, normally fertilized eggs could be returned to the microperforated tube, replaced in the uterus and subsequently removed on the day of embryo transfer.

The use of the vagina as an incubator for a manufactured vessel in which fertilization and preimplantation embryogenesis occur had been suggested and in some instances utilized during the early years of clinical IVF, but was largely abandoned because of improved commercial tissue culture incubators and culture methods, until recently that is, when a device, the INVO Cell, specifically designed for this purpose (Frydman and Ranoux [8]) was introduced commercially. In this instance, the IVF lab consists of a sterile surround, usually a small HEPA-filtered laminar flow hood, where the culture medium is prepared and pre-equilibrated with an appropriate atmosphere, sperm, and oocytes identified microscopically and for the former quantitated for insemination, and then combined in a small conical tube containing ~1 ml of medium contained within a two-piece, thick plastic chamber. The chamber is sealed with an O-ring and placed within the upper region of the vagina. Embryos are removed on a predetermined day post gamete deposition and those showing apparently normal, stage-appropriate development selected for uterine transfer by conventional means, that is, in microliter volumes bracketed by air bubbles in a catheter and displaced by a syringe.

Clinicians using this method often suggest to patients that it is more natural than IVF and acceptable to certain religions because conception and early embryogenesis occur in the patient's body, albeit within with an artificial vessel containing the same type of culture media that would be used for conventional in vitro fertilization to promote fertilization

and preimplantation embryogenesis. Neither sperm, oocytes, nor newly fertilized eggs/embryos interact with the biochemical and physical (i.e., cellular) milieu of the reproductive tract as would occur naturally in vivo, and as for being "more natural," the actual culture vessel is functionally little different from the culture tubes or culture dishes used in conventional IVF under controlled incubation at 37 °C. In addition, similar to the intrauterine device described above, the INVO Cell needs to be removed from the vagina in order to recover embryos that are then loaded into a catheter for uterine transfer. Because only one device can be placed in the vagina for incubation, the number of potentially fertilizable oocytes deposited in the actual culture compartment may be relatively small, and the corresponding protocol of ovarian stimulation should be one designed to produce a low number of fully grown antral follicles. In conventional IVF, outcome success has long been known to be strongly correlated with maternal age, the number and meiotic maturity of oocytes at follicular aspiration and because of naturally occurring increases in aneuploidy with advancing reproductive age, the extent to which recovered oocytes at metaphase II are euploid. This method may be particularly useful in programs that use natural or mild stimulation protocols to produce relatively low numbers of oocytes and potentially best suited for so-called high prognosis patients identified by age (e.g., <35), infertility diagnosis (e.g., absence of polycystic ovarian syndrome and occurrence of absent or obstructed fallopian tubes), and no medically untreatable male factor that would require ICSI (e.g., severe oligozoospermia, asthenozoospermia, or teratozoospermia). Normal development and births with the INVO Cell also call into question the physiological premise that underlies intrauterine culture in devices such as described above where early post-fertilization exposure to putative bioactive agents present in the reproductive tract are thought to be developmentally beneficial.

On the basis of recent reported outcome results [9], the INVO Cell system could be an alternative to establishing a conventional IVF laboratory that may be applicable in low-resource settings, and its use in high-resource settings in developed countries would seem to have merit if primarily a religious or psychological one for the patient. However, if incubation at 37 °C is the relevant issue for intravaginal culture, it can also be accomplished by placing the device in a low-cost, non-tissue culture incubator where temperature is fixed at 37 °C, or by other, even simpler means such as those discussed below. Potential drawbacks to using the patient as an incubator is that the normality of fertilization and early embryogenesis cannot be determined because such devices are intended to remain in place and intact until removed for embryo transfer. This so-called dark fertilization precludes the detection of certain fertilization (e.g., triploidy from dispermic penetration; maternal isodisomy associated with the occurrence of single, diploid female pronucleus owing to suppression of second polar body formation) and early embryonic abnormalities (e.g., first division from 1 to 3 cells) that would ordinarily dictate against uterine transfer and would likely go unrecognized when embryo selection for transfer occurs at later stages because embryo appearance can appear stage- and morphologically appropriate. Other morphological, morphokinetic, and temporal anomalies of developmental significance that have been identified by time-lapse microscopy and would likely go undetected after "in vivo" culture in intrauterine or intravaginal devices, and which would result in their deselection for transfer despite seemingly normal progression to the blastocyst stage, are described below.

In principle, intrauterine or intravaginal incubation relies on the notion of "self-deselection" whereby abnormally fertilized oocytes or embryos that experience most types of developmentally significant cytoplasmic defects or certain chromosomal segregation disorders fail to implant or progress to term. This is a realistic notion and the INVO Cell approach may be a viable one for clinicians and patients, if both are sufficiently informed of the potential risks of not knowing the normality of fertilization, and whether defects or abnormalities in cleavage that would likely be detected with standard IVF could compromise the likelihood of a successful outcome. At present, whether this or other methods of "in vivo incubation" associated with dark fertilization are also associated with a higher risk of adverse downstream consequences such as benign gestational trophoblast disease, the hydatidform mole (i.e., a so-called molar pregnancy) from a dispermic penetration remains to be determined although outcomes from the relatively few current reports in the literature do not indicate current concerns in this regard. However, as described below, it is our opinion that low-cost IVF can be accomplished in a physiologically defined closed system with simple means of incubation without compromising the ability to visually assess the normality of development from fertilization through the hatched blastocyst stage either by static observations or time-lapse microscopy. We suggest that such a method assures both clinician and patient that critical developmental landmarks of preimplantation embryogenesis have occurred normally and at the appropriate stage.

18.3 The Walking Egg Model

An apparent urgent need for advanced reproductive technologies to treat growing rates of infertility among young women in certain developing/low-resource countries was a central theme advanced by local healthcare providers, reproductive medicine societies, international humanitarian organizations, NGOs, and philanthropic foundations on the basis of women's reproductive rights, social justice, and equality, as noted above. Academic studies describing the abysmal and often violent treatment of infertile women by their husbands, families, and communities added a seeming urgency to bring advanced infertility methods that had become commonplace in developed countries to the most affected societies. It was against a background of formidable challenges in establishing a functional and successful low-cost IVF capacity in developing countries that a nonconventional model that

could provide such a service was developed. Parenthetically, in considering different models, applicability to couples unable to access IVF services in moderate-to-high-resource settings owing to their financial situation or to disqualifying conditions imposed on government-paid treatment was also taken into consideration so that whatever system ultimately evolved, it would have universal appeal, rather than being thought of as "low budget" for resource-poor settings only. Rather than simply duplicating the standard model of IVF laboratories common in the developing world, a significantly different approach to the laboratory aspect of delivering IVF services was devised that addressed issues of infrastructure, availability of clinical and technical expertise, and the well-recognized need to significantly improved patient accessibility and affordability for treatment.

The simplified IVF culture system (SCS) described below was originally designed by Van Blerkom et al. [10] as the laboratory aspect of the Walking Egg Program, which had been established to bring modern reproductive medicine to developing, resource-poor countries [2, 11]. The SCS was the successful culmination of several years of laboratory development and preclinical testing at the University of Colorado, Boulder, prior to results that were published in Van Blerkom et al. [10]. The work that led to the development and clinical implementation of a low-cost IVF system was done without the usual financial participation or support of government research grants, private philanthropic foundations, or public institutions that professed concern for social justice in regard to the "reproductive rights" of women. With few exceptions, such as the European Society of Human Reproduction and Embryology, in reality, the interest of most with respect to reproductive rights and equality seemed to focus primarily on population control and contraception rather than aiding infertile couples to have children. Consequently, this largely precluded from consideration projects such as the Walking Egg as appropriate venues for their support or for that matter, their attention.

18.4 The Need for a Simplified IVF Culture System

The SCS method for human IVF is designed to be a self-contained, closed culture system that is inexpensive to set up, maintain, and operate, and which largely eliminates the complex infrastructure required by the typical IVF laboratory in high-resource settings. By greatly simplifying critical aspects of the IVF culture process once gametes are in the laboratory, personnel with some clinical/medical experience should be able to successfully apply this system after relatively minimal training directed to the accurate performance of several specific steps. The inclusion of a time-lapse and streaming video capacity with coincident audio communication through the internet described below allows real-time interactions with experienced IVF laboratory personnel at remote locations so that program adopting the SCS alone or for use with the Walking Egg model [11], or one similar, can have access to the expertise of IVF specialists on an ongoing basis for purposes of training, quality control and if needed, assistance in selection of embryos for transfer. The addition of a time-lapse capacity developed for use in conjunction with the SCS is a recently added function that may be useful for selected patients, such as those with recurrent pregnancy loss or repeat IVF failure in general and where the possibility of preimplantation genetic screening is currently not an option.

Elements currently recognized as essential for successful human IVF such as culture media, pH, CO2, and O2 concentrations were addressed and solved by having a closed system that generated CO2 from a weak acid-base reaction that could be calibrated so as to produce physical and chemical conditions in a simple, sealed culture tube that are consistent with normal human preimplantation embryogenesis in vitro. Maintenance of 37 °C is a critical component of success in IVF, especially in the context of preventing adverse iatrogenic influences on meiotic and mitotic spindle integrity that could lead to aneuploidy. The use of often costly microprocessor-controlled tissue culture incubators is common practice in IVF clinics for this very reason. However, in developing and testing the SCS, it was found that 37 °C could be accurately and consistently maintained in a variety of formats, from conventional, non-tissue culture incubators to water baths, or even the unconventional, thermal beads or high efficiency thermos bottles. The SCS is intended to permit insemination, fertilization, and preimplantation development to the hatched blastocyst stage to occur undisturbed in the same culture tube until embryo removal for uterine transfer.

The design of a low-cost culture system for resource-poor settings has to consider issues associated with infrastructure that are common in developing countries, which would not be problematic for conventional systems typical of developed countries; for example, these might include (i) a reliable and constant source of "clean" electricity, that is, not subject to frequent changes in voltage; (ii) availability of replacement parts and rapid response of technical expertise to repair microprocessor-controlled instruments; (iii) on-time delivery of culture medium, medical grade gases; and (iv) sufficient clinical and technical expertise needed to maintain an IVF program after setup. The underlying challenge was to design and validate a laboratory system that while appropriate for low-resource settings could nevertheless deliver outcomes similar to those experienced in high-resource IVF settings using high-complexity laboratories.

When the possibility of establishing low-cost IVF centers in developing countries was seriously being considered in the mid-2000s by international organizations such as the World Health Organization and assisted reproductive medical societies such as ESHRE, one prevailing notion was to duplicate established IVF platforms common in the developed world with fully operational equipment donated by high-resource programs during equipment upgrades or scheduled replacements. Typically, prospective programs of this type would be hospital-based and situated in large population centers. It seemed doubtful that such a service would

truly be of sufficiently low cost to accommodate those of limited financial means or be truly assessable to patients at more remote areas. The Walking Egg Program envisaged a network of relatively smaller clinics, or satellite clinics associated with a larger central facility, that could deliver advanced assisted reproduction treatments on a comparatively local rather than singular/centralized basis as an alternative model to provide accessible and affordable IVF. However, to be cost and patient effective, an IVF laboratory needed to be developed that was relatively easy to set up and could function independently with a technical staff that while trained to perform specific tasks did not need advanced degrees in embryology or in related areas in the biological sciences (e.g., cell biology). The simplified system described below accomplishes all of the steps in the IVF process that is completely self-contained and requires no external source of medical grade gases such as CO2 or O2, and where incubation at 37 °C does not need a complex instrument designed specifically for embryo culture.

18.5 A Simplified IVF Culture System

The simplified IVF culture system is composed of two standard plain glass 10 ml stoppered medical grade borosilicate culture tubes connected by 18 gauge needles and polyurethane tubing, as shown in Fig. 18.1. One tube serves as the CO2 generator and the other for medium that is equilibrated to an atmosphere and pH consistent for human IVF. The original system described by Van Blerkom et al. [10] used standard plain glass phlebotomy tubes (e.g., Vacutainer®, BD) that were prewashed with sterile deionized water to remove a silicone coating, if present, but only in the tube containing culture medium. A second tube contained sodium bicarbonate and citric acid, which rapidly effervescences after the addition of sterile water and releases CO2 under sufficient pressure to pass it into the culture tube (Fig. 18.1a). The reader is referred to Van Blerkom et al. [10] for specific details related to reagent values and analytical methods used for the validation of culture conditions prior to clinical application. Under these conditions, the atmosphere created with respect to CO2 and O2 concentrations develops relatively rapidly, but typically the tubes remain connected for several hours at 37 °C, or overnight under refrigeration (10–15 °C). High-quality borosilicate glass tubes with tight-fitting nontoxic stoppers can be substituted for partially evacuated blood collection tubes used in the original study, but the pressure generated during CO2 formation can be sufficient to "pop" the stopper from either generating or receiving (culture) tube, so care must be taken to secure the stoppers and maintain the tubes in an upright position to avoid medium contact with the stopper, even if said to be nontoxic. Once the culture tube is secured and connection to the CO2 generator terminated, the conditions created will remain unchanged with storage at normal refrigeration temperatures, as can be visually determined by the salmon-pink color of culture medium containing phenol red as a pH reporter when returned to 37 °C. In our experience, as long as the stopper seal remains intact, the atmosphere and pH in tubes, even if stored at room temperature, remained unchanged for several years.

Experimental studies with mouse IVF and thawed pronuclear and early cleavage stage human embryos donated for research demonstrated normal preimplantation embryogenesis to the hatched blastocyst stage, with trophectoderm outgrowth after hatching on the glass surface of the culture tube observed for both species. The protocol did not permit the intentional fertilization of oocytes for the sole purpose of creating embryos for experimental rather than procreative purposes. Consequently, early pronuclear (12–14 h post insemination) and cleavage stage embryos (2–4 cells) donated to research by patients who no longer wanted to maintain them in cryostorage were used to examine the normality of development and at the blastocyst stage with respect to the following: (i) hatching frequency; (ii) ICM organization; and (iii) trophectodermal cell numbers on days 5.5 and 6.5 after conventional IVF by nuclear counts using DNA-specific fluorescent reporters.

Once the culture medium is equilibrated with the atmosphere created by introducing CO2, a stable pH between 7.29 and 7.35 exists, and if a pH indicator such as phenol red is in the culture medium, a salmon-pink tint is indicative of a proper pH for human oocyte and embryo culture. Male and female gametes can then be added to sodium bicarbonate-based continuous or "one-step" culture medium, currently available from manufacturers such as Irvine, Sage, LifeGlobal, VitroLife, Origio, and others. For the SCS, one or more COCs are added in ~15–20ul of HEPES-buffered culture medium using an 18-gauge needle (Fig. 18.1b) as originally described by Van Blerkom et al. [10] reported that with buoyant density gradient centrifugation of semen as the as the means of deriving a pelleted fraction enriched with morphologically normal-appearing, progressively motile sperm, monospermic fertilization rates similar to those reported at sperm concentrations noted above for "standard IVF" were obtained in the SCS at approximately ≤1000/ml. The long needle is gently and sterilely inserted through the stopper to a level near the bottom of the culture tube containing 1.0–1.2 ml of culture medium and the contents discharged and deposition visually confirmed under a dissecting microscope.

Typically, insemination in clinical IVF programs with "standard" embryology methodology use progressively motile sperm concentrations in the thousands/ml, often numbers ≥50,000/ml. As described by Van Blerkom et al. [10], normal fertilization rates similar to those obtained with conventional IVF were obtained with concentrations at approximately 1000/ml with sperm showing progressive forward motility characteristic of normospermic men after segregation of the pelleted fraction after buoyant density gradient centrifugation enriched in normal morphological forms. The "swim-up" method of sperm preparation first described and used for clinical IVF is also effective in enriching a population of putative fertilizable sperm if reagents for buoyant density centrifugation are unavailable

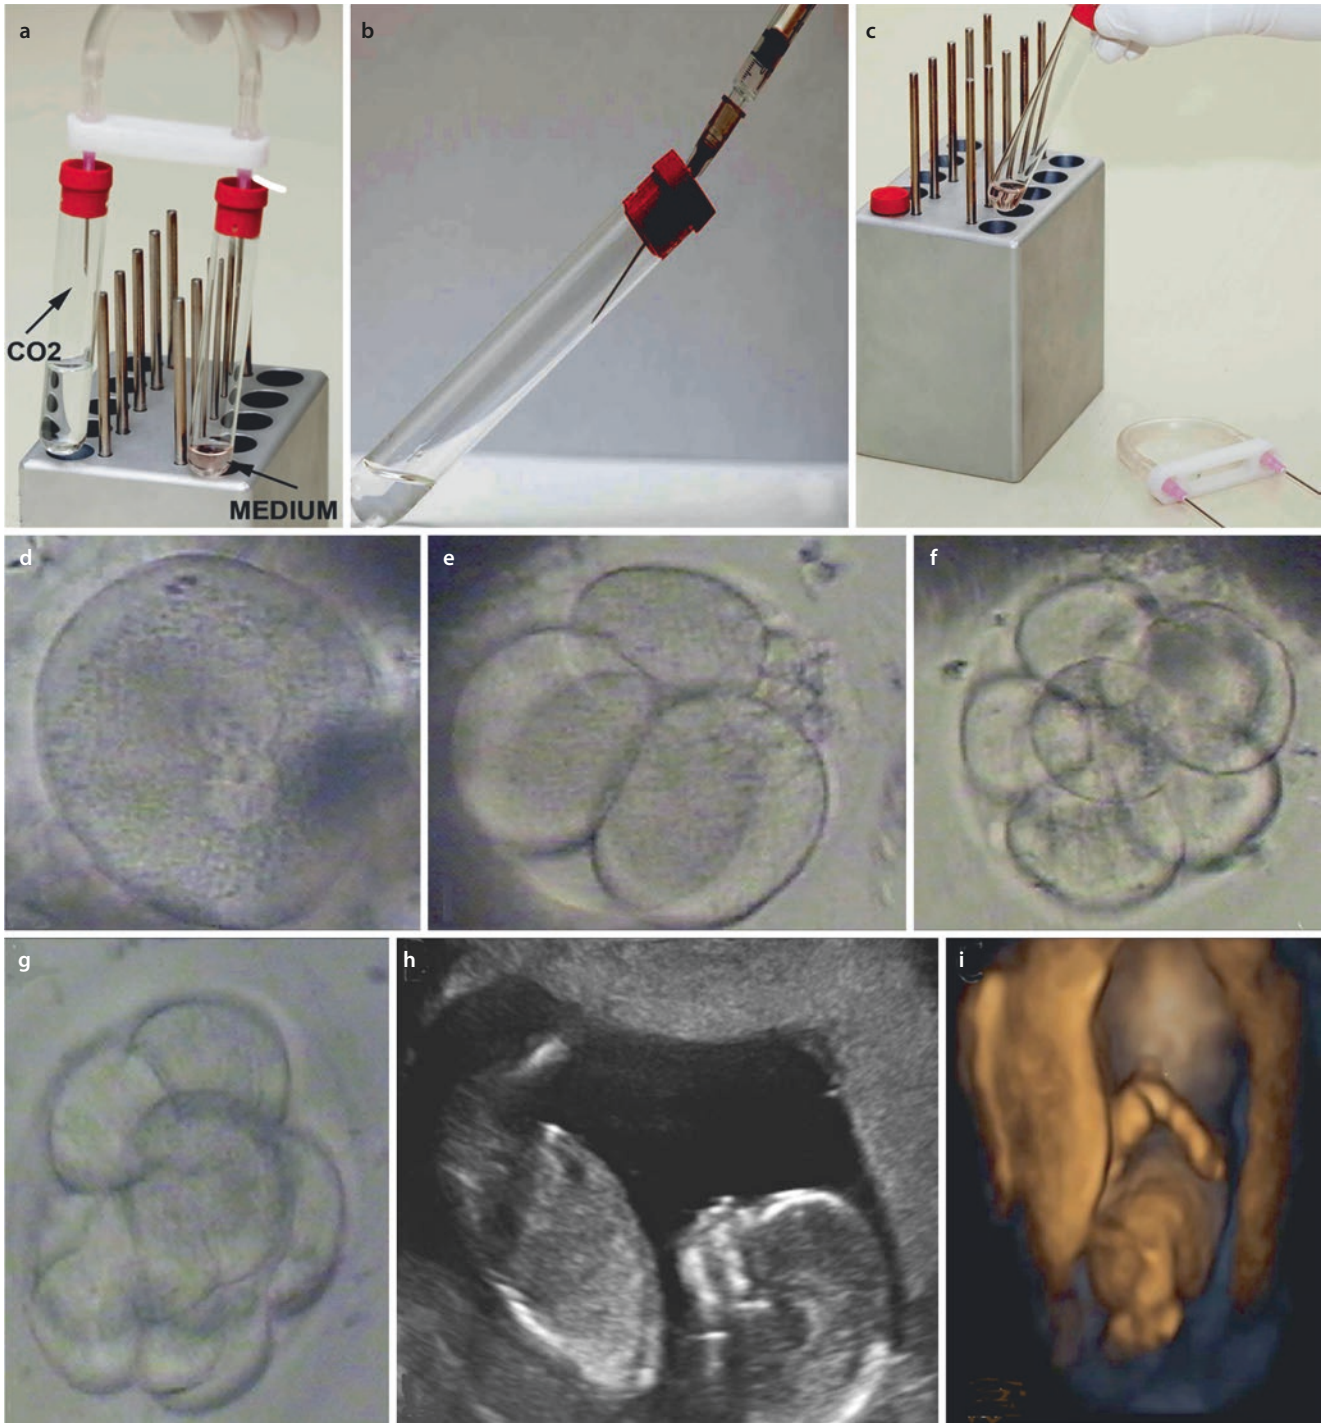

Fig. 18.1 The basis of the simplified culture system is shown in panel **a**: CO2 generated by the reaction between citric acid, sodium bicarbonate, and water passes into a second tube containing culture medium optimized for human IVF and embryo culture through the preimplantation stages. After equilibration, the pH, CO2, and O2 concentrations in the culture tube are consistent with fertilization and normal embryogenesis and remain stable virtually indefinitely as long as the stoppered seal remains intact. The addition of sperm and oocytes for IVF through a needle is shown in panel **b** and returned to an aluminum heating block **c** for culture in a water bath or simple incubator at 37 °C. Alternatively, the culture tube can be incubated in a high-efficiency thermos or in thermal beads at 37 °C. Panels **d**–**i** show the typical developmental performance of embryos conceived using this low-cost system. Panels **d**–**g** were taken in situ, that is, through the glass culture tube at the pronuclear (**d**), four (**e**)-, and eight (**f**)-cell stage. The eight-cell embryo in panel (**g**) resulted in the first birth with this system and as a fetus at 13 weeks of gestation observed by 2D and 3D ultrasound shown in panels H and I, respectively. (From Van Blerkom et al. [10])

and sperm concentrations and motility are appropriate for this technique. Of particular interest in the Van Blerkom et al. [10] report was the achievement of similar normal fertilization rates when the SCS was used for oligozoospermic individuals who would normally be classified as candidates for ICSI. In these instances, the SCS system rather than ICSI was used if a few thousand sperm showing normal motility and forward velocity could be recovered from one or more ejaculates after preparation for IVF. One potential benefit associated with the low sperm concentrations used in the SCS is that triploidy resulting from dispermic fertilization was exceedingly rare. After insemination, culture tubes can be returned to an aluminum heating block as shown in Fig. 18.1c for culture in a small, non-tissue culture incubator, a water bath, or more recently, conventional water bath where water is replaced by thermal beads (► labarmor.com) and the culture tubes completely immersed in the beads; this is a highly effective and reliable means to maintain 37 °C for the entire duration of incubation from fertilization to the hatched blastocyst stage. In either instance, multiple patients can easily be accommodated with temperature changes minimized significantly during inspections for fertilization and developmental progression by the placement of these instruments adjacent to a dissecting microscope. In addition, the placement of a common electric space heater at the air intake, or depending upon design within the interior of a laminar flow hood, can maintain the temperature at near 37 °C on the dissecting microscope surface further minimizing potential reductions in culture medium temperature during inspections (see below).

Because the SCS is a closed system, confirmation of fertilization by the presence of two pronuclei some 12–18 h after insemination can be somewhat different from standard embryology where surrounding cumulus and coronal cells are mechanically removed under direct visualization. Here, gentle vortexing for 10–30 s removes most, if not virtually all of these cells, giving a sufficient view of the cytoplasm for pronuclear detection. Where these cells are resistant to displacement, use of the long stainless steel needle described above can be introduced for mechanical denudation as would be done with conventional IVF, followed by removal in microliter volumes, of abnormally fertilized eggs (e.g., mono- and tripronuclear) and cellular debris. It is worth noting that in the experience of this author and others who have used this method, including embryologists in the Walking Egg Program, most oocytes requiring this type of aggressive denudation are meiotically immature. Other embryologists using the SCS prefer to remove all of the inseminated and cumulus-enclosed oocytes and mechanically denude using standard commercially prepared "stripper" pipets designed for this purpose in an externally heated laminar flow hood. In this instance, all normally fertilized (2 pronuclear) eggs are transferred to a new culture tube containing equilibrated medium (e.g., Fig. 18.1d), since a supply of equilibrated culture tubes is easy to have on hand. If necessary, both methods work equally well, but as noted above, ambient temperature is maintained at or as close as possible to 37 °C. Selection for transfer of preimplantation stage human embryos using the SCS is similar to protocols in standard embryology that include the following criteria: (i) stage-appropriate timing of early cell divisions; (ii) gross morphology and blastomere number and uniformity during the cleavage stages; (iii) absence of extracellular cytoplasmic fragments, and if present, their relative abundance and size, and at the expanded blastocyst stage; and (iv) cell numbers in the trophectoderm estimated empirically and when possible, by nuclear counts, and the relative size and organization of the inner cell mass [12–14].

There are several factors that recommend the SCS for use in clinical IVF for both high- and low-resource settings, where a significant proportion of couples in need of this infertility treatment are unserved because of cost or accessibility to an IVF program. The relative simplicity of design, operation, and execution with appropriately trained personnel is evident by outcome with patient costs significantly minimized with respect to laboratory charges. Where possible, treatment could include ICSI and cryopreservation by vitrification, in which the cost of the latter should also be minimized in comparison to the older-controlled rate freezing method because an expensive instrument required to perform this type of cryopreservation is no longer needed, and operator time is reduced from hours to minutes. For ICSI, use of the SCS is the same as for conventional IVF but as noted above, may be unnecessary in certain cases of oligozoospermia if a few thousand sperm with normal morphology and progressive forward motility are recovered.

18.6 Current Outcome Results with the Simplified IVF Culture System

Figure 18.1d–i shows various stages of development from fertilization (panel D) and cleavage (panels E–G) and, by ultrasonography, fetal images of the first baby conceived using the SCS [10]. It is noteworthy that the images of preimplantation development in this figure were taken in situ, that is, through the glass of the culture tube. Outcome results from the most recent IVF series using the SCS in the Genk Walking Egg Program during 2016 and 2017 are consistent with those first described by Van Blerkom et al. [10]. For example, the most current series is a prospective non-inferiority study comparing ICSI with the SCS on a selected group of patients with a least 6 oocytes recovered at follicular aspiration from women less than 43 years old, and where a total motile cohort of at least 300,000 sperm could be recovered for insemination. Sperm velocity and forward motility alone, rather than morphology, was the primary consideration for insemination in this study. Eligible patients required IVF as assessed by the standard protocol of infertility evaluation. Oocyte cumulus complexes were randomly allocated for ICSI or SCS insemination and when odd numbers, the extra complex was alternately placed in one or the other group. Of 170 cycles initiated, 163 retrievals resulted in the recovery of oocytes. Based on standard stage and morphological criteria

used for developmental competence assessments in clinical IVF [10], embryo transfers were performed on day 3 or 5. For this series, the primary outcome result was a clinical pregnancy confirmed ultrasonographically by the presence of a gestational sac and fetal heartbeat at 8 weeks of gestation. Secondary outcome measures were the fertilization rate and positive hCG prior to week 8.

Out of the 163 oocyte retrieval cycles, no embryo transfer was performed in 18 cases (11%) due to the absence of a good quality embryo (2 cases) or because of an increased risk for OHSS (16 cases), in which case all embryos were cryopreserved. No fertilization occurred in 8 (4.9%) SCS and 2 ICSI patients (1.2%), respectively. Excluding the no fertilization cases for SCS insemination that includes immature and abnormally MII oocytes, which unlike ICSI, could not be detected while cumulus enclosed and therefore eliminated for insemination, the average fertilization rate was approximately 70.8% and virtually the same for ICSI (71.2%) with only normal-appearing MII oocytes. Of the 145 embryo transfers based on "best" embryo selection criteria, 56.5% were from the SCS group and 43.5% from ICSI insemination. A single embryo transfer was performed in 73.2% of the SCS (60/82) and 69.8% of the ICSI (44/63) cycles, respectively. According to the protocol, double embryo transfers were performed for the remaining 41 patients owing to maternal age or previous IVF failure.

hCG-positive outcomes occurred in 46.3% and 39.6% of SCS and ICSI cases, respectively, which resulted in a clinical pregnancy rate of 32.9% (27/82) for SCS patients and 31.7% (20/63) for patients inseminated by ICSI, a difference that is not statistically significant. It is reassuring that the most recent outcome results are consistent with those reported from the first clinical trial [10], and moreover, demonstrate that the SCS, as used in the Walking Egg Program, is at least as effective as conventional IVF methods with respect to fertilization rates and clinical pregnancy outcomes, and in the present trial, as effective as ICSI.

18.7 Perinatal Outcomes Using the Simplified Culture System

With the above study excluded, up to June 30, 2017, 83 births have occurred since the introduction of the simplified IVF system at the ZOL Medical Center in Genk, Belgium, in 2012, which is the clinical testing site for the simplified culture system and the Walking Egg Program. In August 2017, the first baby conceived in Africa using this culture method and the walking Egg IVF model was born in Accra, Ghana: (► http://www.graphic.com.gh/news/general-news/ghana-adopts-walking-egg-technology-to-produce-baby.html). With respect to pregnancy duration, birth weight, admission to the neonatal care unit, congenital malformations, and method of delivery, data from these births were compared with the perinatal outcomes of 3265 ART babies (IVF/ICSI) born in Belgium in 2014 and reported in the Belgian Register of Assisted Procreation (BELRAP), and 3974 babies born after IVF in Flanders and reported in the Study Center for Perinatal Epidemiology of Flanders (SPE). The SCS cohort delivered 5 twin and 73 singleton pregnancies, 55 after fresh embryo transfer, and 18 after cryopreservation and transfer of up to 2 thawed embryos (Ombelet et al. 2014). The mean birth weight of fresh singletons was 3302 ± 468 grams, compared to 3211 ± 588 grams reported in BELRAP and 3328 ± 520 grams reported in the SPE registry. Prematurity (<37 weeks) occurred in 1.4% (1/55) of singletons compared with 14.2% and 9.1% in SPE and BELRAP databases, respectively. Birth weight <2.5kg was observed in 1.4% if singleton SCS babies compared to 11.6% in the SPE group and 10.4% in the BELRAP group. The Caesarean section rate was 17.5%, 23.8%, and 33.7% in the SCS, SPE, and BELRAP groups, respectively. For the 18 babies born after cryopreservation, the mean birth weight of 3827 grams was similar to the BELRAP data as was prematurity and low birth weight, occurring in only 1 of the 18 babies. Twin pregnancies delivered at 33, 34, 37, 38, and 39 weeks, with birth weights between 1250 and 3340 grams. While no congenital malformation could be detected in the SCS births and while perinatal outcomes with this system remain reassuring, according to protocols for the Walking Egg Program, strict follow-up of all babies born using the SCS method is mandatory.

18.8 Suggested Endocrine Protocols for Ovarian Stimulation Best Suited to the Simplified IVF Culture in Low-Resource Settings

A review of the literature shows that protocols using so-called mild ovarian stimulation regimens have been of value in ART settings [15]. The use of clomiphene citrate, a very inexpensive oral drug, has proven in many studies to be an effective means in IVF when a relatively small number of fertilization-competent oocytes are desired, with minimal side effects, a very low complication rate, and acceptable outcome results [15–17]. In a selected group of patients, Ferraretti et al. [18] showed that mild stimulation using a fixed protocol of clomiphene citrate (100 mg/d from cycle days 3–7) in combination with low doses of gonadotropins (150 IU of recombinant FSH) on cycle days 5, 7, and 9), and a GnRH antagonist resulted in a cumulative delivery rate of 70%. This relatively low-cost approach to ovarian stimulation is but one example that might be well-suited in a low-cost IVF setting. In other circumstances where a center can perform cryopreservation by vitrification at low cost, more aggressive ovarian stimulation to produce higher numbers of oocytes may be desirable. In this regard, it is worth emphasizing that the least costly items in the entire SCS model are the glass tubes used to generate CO2 and culture embryos. As noted above, it is a trivial matter to have on hand numerous culture tubes that are pre-equilibrated with respect to atmosphere and pH and which will retain this condition for prolonged periods. Therefore, several premade culture tubes/patient can be available to accommodate a higher number of cumulus-oocyte complexes that typically result from more aggressive (and costly) ovarian stimulation regimens, if that is determined to be best suited to a successful outcome for a

particular patient or more consistent with a program's philosophy of ovarian stimulation for ART/IVF.

In the Walking Egg model, monitoring of follicular development in an IVF cycle and the timing of hCG administration to induce ovulation can be done solely on sonographic criteria, especially with clomiphene citrate stimulation, using comparatively inexpensive, basic ultrasound equipment, thereby likely avoiding the need of expensive and frequent measurements of endocrine function determined by bioassays of hormone levels (e.g., estradiol, progesterone). Nevertheless, although very promising results from use of the SCS and Walking Egg protocols have occurred, there is still the need to perform feasibility studies that examine different ovarian stimulation options to determine which protocol(s) might be the most effective with respect to outcome, based on the patient population and their budget for treatment which, current experience suggests, will likely differ between centers adopting this low-cost IVF model.

18.9 Time-Lapse Microscopic Imaging and Streaming Video of Embryos Using the Simplified Culture System

Time-lapse microscopy is one of the more recent noninvasive methods to assess developmental competence to have entered the IVF laboratory owing to its ability to continuously record temporal, spatial, and morphokinetic characteristics of human embryos from fertilization through blastocyst hatching currently thought to indicate normal embryogenesis. Several commercially available instruments specifically designed for this purpose combine proprietary software-controlled digital image capture and embryo culture in microchambers where they remain fixed in position in a few microliters of medium (e.g., EmbryoScope, VitroLife; GERI, Genea Biomedx; ESCO Miti Time Lapse Incubator, ESCO Global). Typically, these instruments include proprietary algorithms for specific biometrics used to assess competence-related characteristics such as the timing of cleavage divisions, compaction, cavitation, and blastocyst formation as well as the uniformity of early cell divisions. Collectively, these and other characteristics have long been the mainstay of so-called static morphology-based competence assessment for selection in "standard manual embryology" [19], that is, periodic operator-dependent judgments of developmental performance during culture in IVF-appropriate incubators using largely subjective embryo "grade" or "score" assigned on the basis of time- and stage-appropriate morphology.

The extent to which an investment in time-lapse technology may improve outcome over manual embryology with experienced observers such that its use would benefit all IVF patients is currently a contentious issue, especially considering the high cost of these instruments and required culture peripherals for some [19–23]. Selection of the "best" embryo(s) for transfer at the blastocyst stage, which has become more prevalent than during the cleavage stages, is typically based on trophectoderm or inner cell mass characteristics, or both. However, the relative contribution of each to developmental competence is currently unsettled [12–14] as is the value of morphokinetic analysis in detecting aneuploid embryos with high accuracy, which would clearly be a very significant basis for routine use in IVF programs [22, 24–29]. Further confounding the routine use of time-lapse analysis is an apparent plasticity in the timing of competence-associated phenotypes identified during the preimplantation stages that while thought to be relatively fixed with respect to time after insemination/fertilization, appear to be associated with several factors including maternal age, cumulative FSH dose and method of fertilization [30]. Their findings indicate that the "origin of the embryo" can significantly confound the interpretation of morphokinetic analyses and may well need to be taken into the calculus of competence assessment for embryo selection at transfer. Nevertheless, as discussed below, the detection of certain transient, stage-related morphokinetic phenotypes that might be missed in "static" manual inspections can be highly useful in "deselecting" embryos that while seeming to progress normally when examined, have experienced earlier anomalies that reduce significantly the likelihood of a successful outcome [21, 31, 32]. It is worth noting that some of these anomalies may occur at inopportune times when embryologists are not available to perform developmentally relevant inspections.

One drawback to using current time-lapse instruments for IVF assessments is that ICSI may be required, which can add considerable cost if otherwise unnecessary because of the absence of a male factor. Unlike conventional IVF, where the tightly associated somatic cells of the corona radiata and cumulus oophorus are removed mechanically from the zona pellucida some hours after insemination when determinations of fertilization and its normality are made (i.e., for the presence of two pronuclei), imaging with commercially available time-lapse instruments requires their complete removal and ICSI if embryogenesis from the earliest stages is to be recorded. A hybrid approach uses conventional IVF in a culture dish where denudation of cumulus and corona occurs, usually some 16–21 h later, followed by transfer of normally fertilized pronuclear eggs to the micro-incubation system for individual time-lapse imaging. A potential benefit in a low-cost IVF program using the SCS is that after conventional IVF, denudation of cumulus and coronal cells occurs in situ, that is, in the same culture tube, and provides sufficient visualization of the oocyte to detect pronuclei and preimplantation embryogenesis.

18.10 Adding Time-Lapse Microscopy and Streaming Video to the Simplified Culture System Using Conventional Insemination for IVF

The current high cost of commercial instruments that integrate embryo culture with high-resolution time-lapse imaging and biometric analyses is inconsistent with a truly low-cost IVF model for both low-resource countries and for developed countries where IVF is available but, owing to cost, can prelude treatment for a large segment of the infertile population.

For the SCS in particular, integrating time-lapse would seem to be an unlikely prospect because IVF and embryogenesis occur near the curved bottom of a glass culture tube under constant 37 °C in environments where imaging would be problematic, if not impossible. Even if possible, the utility of using time-lapse in the SCS is questionable because unlike commercial instruments where each embryo is imaged separately and sequentially in specially designed microchambers, multiple embryos are usually clustered together at the bottom of a single round bottom culture tube, which could be a significant problem for image clarity and for identifying specific embryos for transfer on days 3, 5, or 6. Perhaps the most challenging issue, however, is how to reliably maintain a constant 37 °C environment during culture that will allow continuous microscopic imaging from the early pronuclear stage. Clearly, other methods used successfully with the SCS, such as water or thermal bead baths, would not allow imaging although depending on patient load, multiple simple incubators (i.e., not for tissue culture) or enclosed chambers that could house one or more microscopes may be cost-effective. While there are time-lapse instruments designed to operate within an incubator and transmit images to a nearby computer, limitations on focal length show they work best with cells/embryos on the surface of standard culture dishes such as those used in conventional IVF, and also, that one device would be needed for each dish/patient. However, our experience with such systems indicates difficulty in obtaining useable embryo resolution through the glass tube, especially at the very bottom of the culture tube where embryos reside. Finally, there is the issue of cost for specialized time-lapse software, video cameras, computers, and whether continuous streaming video to IVF program embryologists, patients, or other authorized individuals can be established; potential regulatory issues discussed below, even if addressed, might add such significant costs as to make the addition of time-lapse prohibitive in a low-cost model. Collectively, these concerns suggested that integrating necessary features for time-lapse into the tube-based simplified culture system would not be a viable option, or able to offer the same image resolution engineered into commercial instruments needed to characterize morphokinetic and morphological features that maybe related to developmental competence as preimplantation embryogenesis progressed from the pronuclear stage.

The following discusses how these issues were addressed and led to several iterations that could be integrated into the low-cost SCS/IVF model to produce time-lapse data highly suitable for competence assessment.

18.11 Temperature Regulation in an Open Incubation System for Time-Lapse Microscopy

The foremost challenge from both a safety and potential regulatory perspective encountered during the development of the SCS was to demonstrate that a constant ambient temperature of 37.0–37.1 C could be accomplished outside an incubator engineered for tissue culture or a simple one that only maintained a specific temperature. The same issue confronted the addition of a low-cost time-lapse capacity as continuous imaging and recording from insemination to the hatched blastocyst stage (i.e., for some 6–6.5 days of culture) through the glass SCS culture tube, which required its placement directly above an objective lens on the stage of an inverted microscope (Fig. 18.2b). Several iterations of external incubation from the least expensive, a simple fan-driven electric space heater for each microscope to a similarly heated Plexiglas enclosure that could accommodate several microscopes, to setting up a dedicated 37 °C mini-warm room in which embryos from multiple patients could be monitored were tested. As described below, the simplest iteration as shown in Fig. 18.2 uses a common electric space heater delivering up to 4000 btu/h with high, medium, and low presets to a single microscope. Although the easiest to setup and maintain, it may, however, be the most contentious design with respect to assuring regulatory agencies of its safety and effectiveness.

When the heater is properly positioned at a predetermined height and distance from an inverted microscope (e.g., Fig. 18.2a, b), a curtain of heated air surrounds the microscope and continuously maintains an ambient temperature of 37 C (± 0.1–0.2 C) at the microscope stage where embryo culture in the SCS tube occurs directly above the objective lens (Fig. 18.2b, asterisk, Fig. 18.2c). A small dark room where the system can remain largely undisturbed during culture should be dedicated for this purpose. A logging thermometer with accompanying software that transmits temperature at predetermined intervals for graphing provides a continuous level of assurance that temperature remains constant during the entire imaging/recording process (e.g., Omega HH802W, Omega Inc., Norwalk, CT). Further assurance of thermal stability can be achieved by the addition of a bench-top temperature controller that immediately shuts the heater off should temperatures between 0.1 and 0.2 °C above a 37 °C set-point occur unexpectedly, and then turns on once the normal temperature is detected (e.g., BriskHeat, SDC120JCA, BriskHeat Inc., Columbus, OH). The thermocouple connected to the temperature controller is placed at the site of embryo imaging or directly on the culture tube as described above. Temperature controllers with similar sensitivities that monitor and regulate multiple zones are readily available to control temperature on multiple microscopes. Indeed, temperature monitoring with a digital thermometer, preferably with logging functions, can be done by positioning the tip of a thermocouple at the site of embryo culture for added assurance of thermal stability (asterisk, Fig. 18.2c) or in a sham culture, where the thermocouple is in the culture medium in a stoppered SCS tube, or both. Our studies have shown that when largely left undisturbed, temperature remained stable within the 37 °C range for at least 14 days. The right-hand arrow in Fig. 18.2b shows the temperature measured with an alcohol thermometer that is slightly below 37 °C, while the digital thermometer in Fig. 18.2b reads 37.2 °C. Experience with this time-lapse configuration has shown that for this purpose, digital measurements are more accurate than those from standard analog thermometers. Indeed, with a long thermocouple whose tip is placed where

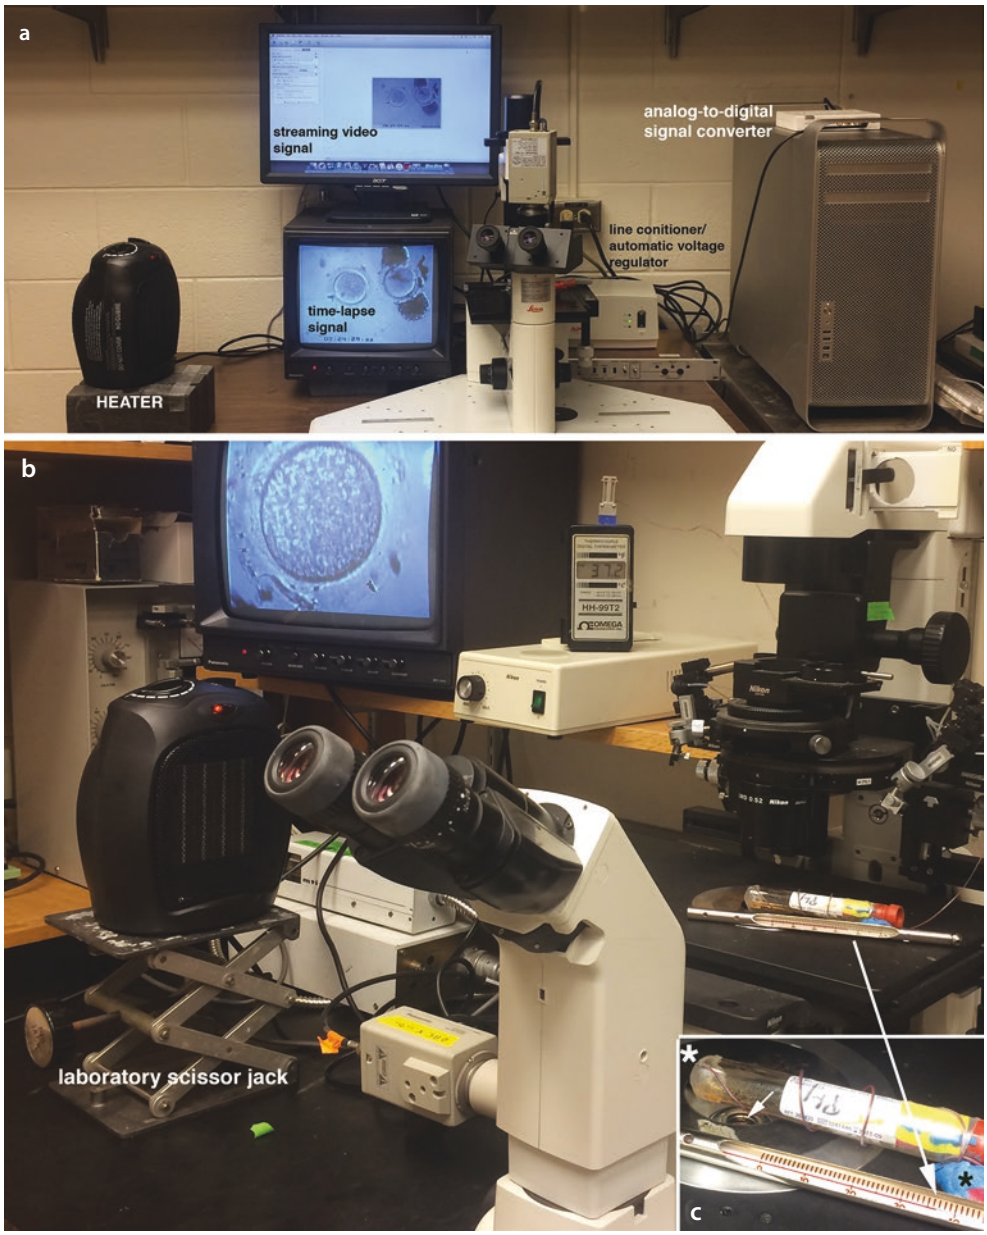

Fig. 18.2 The setup for time-lapse microscopy and streaming video in its simplest iteration for use with the simplified culture system is shown in panel **a**. Each of the components is labeled and a constant 37 °C temperature at the site of culture on the microscope stage (indicated by arrow in insert extending from the microscope stage) is maintained by a curtain of heated air from a common electric space heater placed at a predetermined distance and height from the site of culture above the objective lens. The lower monitor shows two pronuclear eggs in the process of being imaged by time-lapse, while the upper shows the same image being streamed through the internet to remote observers on a secure website. Figure **b** shows how the thermocouple wire from either a temperature controller or digital thermometer (shown in **c**) is wound around the culture tube with the thermal sensing tip located at the site of embryo culture. A standard alcohol-based analogue thermometer is shown at the same location with a temperature measurement of 36.5 °C, compared to the 37.2 °C with the digital thermometer in **c**. These values are within the 37 °C acceptable range for each type. In this instance, both embryos developed to the hatched blastocyst stage after 6 days of culture

embryos are being recorded, the actual thermometer does not have to be in close proximity to the microscope, or for that matter, even in the same room.

Because embryo culture in this iteration of a time-lapse capacity has the culture tube sitting on a microscope stage above the objective lens, it is essential that a backup power source be available to immediately supply electricity as temperature will drop in this type of open incubation and the potential benefits of undisturbed embryo development in the closed SCS would likely be lost if prolonged. Common APC units are sufficient to maintain the peripherals in this system such as computers, video cameras, and microscope light source. However, as with any IVF unit, backup electricity for high-demand instruments such as laminar flow hoods and incubators is a necessity, and the same would be required to keep a constant 37 °C whether using the air curtain described above for a single microscope or a Plexiglas chamber containing several microscopes communicating with a computer and

ambient temperature controlled as described above. Likewise, if voltage fluctuations are a chronic issue, an inexpensive in-line filter that regulates voltage will maintain normal computer, temperature regulation, and video camera functions during time-lapse imaging, as shown for this simplest iteration in Fig. 18.2a.

18.12 Time-Lapse Microscopy Beginning at the Pronuclear Stage After Conventional Insemination or ICSI

Time-lapse imaging for the SCS was designed to record and stream online preimplantation embryogenesis from conventional insemination or ICSI in cumulus and corona cell-free embryos from pronuclear through the hatched blastocyst stage in the same culture tube. As described previously [10], denudation of cumulus and coronal cells by gentle vortexing to check for fertilization is typically effective to visualize pronuclei. In instances where cumulus and coronal cell removal is problematic or incomplete, insertion of the same 23-gauge needle used to deposit gametes (see above) can be used to mechanically denude oocytes by standard "stripping" procedures. This is usually effective for creating a cell free or clear area for time-lapse imaging as cellular remnants can be removed with the same needle, as can abnormally fertilized eggs, such as those containing a single or three or more pronuclei. Despite an extra step in the SCS protocol with conventional IVF, removal of all normal pronuclear eggs in a small volume of medium followed by transfer to a fresh tube of equilibrated medium and repositioning of embryos as described above is the preferred method for prolonged time-lapse recording of multiple embryos. The simultaneous time-lapse recoding signal and streaming video function of this time-lapse system adapted for the SCS is shown in Fig. 18.2a for two pronuclear stage human embryos, one of which has been completely denuded of cumulus and coronal cells and the other with two regions of the intact cells whose presence does not interfere with pronuclear detection. The streaming function for remote viewing in the IVF unit or by another authorized observers online is secured though an encrypted website to which only authorized users would have access.

Typically, as many as 6 pronuclear stage embryos can be effectively imaged by time-lapse at any one time if embryo transfer is planned for day 2 or 3, that is, cleavage stages. After gentle embryo deposition at the bottom of the culture tube as described above, it is kept in a vertical position for 5–10 min at 37 °C followed by a slow tilting to a near horizontal position directly above the objective lens on the stage of an inverted microscope warmed to 37 °C by a curtain of heated air (see Fig. 18.2b). Once embryos are located, the culture tube is secured in place at an angle of ~10° to the horizontal with a small piece of modeling clay placed near the stopper (asterisk, Fig. 18.2c). If necessary, closer embryo clustering can be achieved by moving the stage in a gentle rocking motion using the X- and Y-axis stage adjuster. Alternatively, centrifugation at low speed (≤100 rpm) in a common clinical fixed angle centrifuge for ~20 s usually places embryos in juxtaposition near the bottom of the tube, and they tend to move together to its side when placed nearly horizontal, which promotes imaging with minimal distortion from the glass. After final location for imaging, embryos typically remained fixed in position during recording. When embryo culture is extended to day 5 or 6, a maximum of three embryos/tube is preferable and some repositioning may be required during blastocyst expansion and hatching owing to embryo-generated movement during emergence from the zona pellucida and continued blastocoel expansion when free. Up to day 4, when compaction occurs, individual embryos can usually be identified for selective purposes based on location and embryo-specific morphokinetic and morphological characteristics. During blastocyst formation, this generally becomes more difficult if more than 3 expanding embryos are present owing to their natural morphokinetic activity that generates movements, which can place one or more embryos or the ICM out of the field of view.

Our studies of different optical platforms (brightfield, phase contrast, differential interference contrast) showed that imaging of embryos taken through the glass culture tube was surprisingly clear and largely distortion-free under brightfield illumination with low power 5X and 10X plan-apochromatic objectives with high numerical apertures. Imaging can be performed on basic inverted microscopes (e.g., Leica, Nikon, Olympus, etc.) with only brightfield illumination and appropriate low-cost lenses. Long working distance objective lenses are preferable for pronuclear through hatched blastocyst stage because they provide the depth of field necessary to resolve fine cellular and nuclear details, as discussed below. For use in low-resource settings, used or donated inverted microscopes may be available from a variety of sources, including IVF programs that update or change equipment, especially those that utilize commercial time-lapse instruments.

18.13 Time-Lapse Microscopy and Streaming Video Under Very Low Light Illumination

With respect to cost versus quality of imaging of human embryos in the SCS model with brightfield optics at very levels of low illumination, relatively inexpensive analog or digital monochromatic cameras designed for surveillance purposes are readily available and can provide sufficient high resolution needed to detect morphokinetic activity during from the pronuclear to the hatched blastocyst stage. Because embryos are colorless, we show examples from an analog Panasonic WV-BP110 CCTV monochromatic camera (i.e., black and white; Fig. 18.2a). Transformation of an analog to a digital signal for computer-based video streaming and time-lapse imaging requires an analog-to-digital converter (Fig. 18.2a, e.g., Canopus ACDV110: Grass Valley, Hillsboro, OR.), which is unnecessary with digital cameras but while usually more costly, did not provide enhanced

resolution or greater depth of field in our experience. Placement of a 630 nm long pass filter in the optical path eliminates light in the far blue and ultraviolet range emanating from a halogen light source and as an added benefit, noticeably increases the contrast of the black and white images. Filters of this type are readily available online in diameters and thickness that can be placed in the light path of inverted microscopes. In practice, low light microscopy is achieved by closing the field and condenser diagrams until an embryo image on the video display is just detectable without loss of resolution due to increased graininess; this was found to be sufficient to provide developmentally relevant morphokinetic details of embryo performance from pronuclear to blastocyst stages that are similar to what is obtained from commercial instruments and used for purposes of embryo competence assessment. Under these conditions of illumination, which measured <0.55 lux at the site of embryo culture, red light is barely visible to the naked eye. As discussed below, time and stage of development from pronuclear to fully hatched blastocyst stage in the SCS, with or without time-lapse using sibling embryos, were similar, if not indistinguishable, indicating that while this iteration of the SCS time-lapse platform has logistical limitations, it can be an effective one for embryo competence assessment in a low-resource setting. As noted below, illumination does not have to be continuous but can be programmed to be on or off at predetermined intervals.

18.14 Time-Lapse Microscopy and Video Streaming Software for Use in the Simplified Culture System at Low Cost

As with most time-lapse imaging software available online, including those available at little or no cost, user information and manuals for setting image capture parameters (time, brightness, contrast, etc.) and establishing a unique website to stream images to external observers (e.g., patients, embryologists) are usually sufficiently thorough and well-written for an individual versed in basic information technology to incorporate this capacity into the SCS and set up a secure streaming video website. This is the case for each of the software programs noted below where live images during 6 days of preimplantation embryogenesis were securely streamed to interested observers on several continents in order to demonstrate the expected resolution and clarity of imaging, and the type of morphokinetic information that could be obtained to characterize embryo performance for selection purposes. One very useful feature usually included in the software is the ability to stop recording if no light signal from the microscope is detected and when detected, resume imaging. This allows recordings to be discontinuous and timed to when certain developmentally significant benchmark events during preimplantation human embryogenesis would be expected to occur, such as the first cell division, morula to cavitation, blastocyst formation, and hatching. In this way, light exposure during prolonged and continuous time-lapse recording, as would occur from pronuclear to blastocyst hatching, can be further minimized by having the microscope light source interface with a simple event timer with multiple preset-time points. Alternatively, some software allows preprograming of recording set to times that bracket expected developmentally relevant events currently thought to be predictive of normal blastocyst formation and implantation, such as the initial cleavage divisions [20].

The availability of software from multiple online sources as either freeware or at very low cost was a surprising outcome in our investigation of programs that could be used for time-lapse application in the SCS. While most were found to be designed for video surveillance and consequently had limited functionality in cell biology, including documentation of human embryo morphokinetics, as of this writing, the following were found to be suitable for use with the SCS in the iteration described here: EvoCam5, Security Spy, SwiftCapture, Sky Studio Pro, Chronolapse, VLC, SpyCam, and Gawker. However, with respect time-lapse/streaming capabilities, the EvoCam5.0 (▶ evological.com), and SwiftCapture, SecuritySpy (▶ bensoftware.com) provided the most useful features, functions and high-quality image capture under very low light conditions. Each of these programs can accommodate and simultaneously display inputs from several microscopes, which may benefit IVF programs that want to monitor and record the embryos of several patients simultaneously while retaining a low-cost structure. Other important considerations in the selection of software include support for a wide variety of digital and analog video cameras, such as the basic Panasonic monochromatic video camera noted above (◘ Fig. 18.2a), auto brightness and contrast functions, and the capacity for discontinuous recording. This last feature can be very useful if the software can be programmed to turn on or off recording at predetermined times and intervals. As noted above, this can be done in concert with the microscope's light source controlled by a simple multi-event timer, allowing time-lapse recordings to occur around the time when morphokinetic events considered relevant for competence assessment should occur. These events would normally include pronuclear formation and dissolution, first and second cleavage divisions, morulation, cavitation, delineation of the inner cell mass, and blastocyst expansion and hatching.

Time-lapse data is saved as JPEGs or as Quick-time files, which facilitates image processing, for playback, if necessary. For practical purposes, images are usually captured at 5-min intervals and in our studies during development of this application, for up to 165 h (day 0.5–7). All images from time-lapse sequences discussed and shown below are "raw," that is, as recorded and without any post-capture digital imaging processing.

Video monitoring provides an important clinical dimension to the SCS because it allows embryologists and clinicians within the IVF unit to follow the progression of preimplantation development in real time without disturbing embryo culture until transfer with embryo selection for transfer based on morphokinetic information obtained during culture. The

video streaming function also allows outside observers to securely view the same embryo for the purposes of quality control (see Fig. 18.2a), training or when combined with simultaneous communication (e.g., Facetime, Skype), and to assist technical staff in embryo grading for transfer or cryopreservation. In this way, low-cost programs can provide a robust online platform for low-resource/developing countries that can include remote and secure internet access for others.

It is important to emphasize that unlike the commercial time-lapse instruments currently in use in clinical IVF, this system has a limited capacity with respect to the number of patients and embryos that can be monitored at the same time. This needs to be understood in the context of the regime of ovarian stimulation, that aggressive gonadotropin stimulation protocols designed to produce large numbers of antral follicles and consequently high numbers of embryos is largely inconsistent with both the low-cost SCS model and this time-lapse application.

18.15 How the Application of Time-Lapse Microscopy Contributes to Embryo Selection to Improve Outcome Using the Simplified Culture System Platform

With relatively simple optics and a basic inverted microscope in a well-controlled thermal environment, fine cellular details during undisturbed culture from the pronuclear through hatched blastocyst stage can be resolved to offer morphokinetic and temporal information for embryo selection. Although not shown, common fertilization abnormalities at the earliest stages of human embryogenesis such as triploidy (three pronuclei) or activation without second polar body formation (single polar body and single pronucleus) are as easily detectable as is the case with properly timed static inspections for fertilization by conventional IVF culture. Panels 1–6 in Fig. 18.3a are individual images taken from a time-lapse sequence that began with pronuclear detection 14 h post insemination by conventional IVF and after cumulus and corona cell denudation (PN) and continues through pronuclear membrane dissolution that precedes the first cell division (arrows, panels A5 and 6). These images illustrate the level of resolution attainable in this system with imaging through the glass culture tube that is sufficient to resolve fine cytoplasmic and nuclear details such as the size, location, and number of nucleolar precursor bodies (*n*) within the male and female pronuclei (Fig. 18.3a1–4). Of particular practical interest in this sequence is a somewhat earlier breakdown of the juxtaposed pronuclear membranes in the embryo on the right-hand side in panels 3–5. Asynchrony in pronuclear membrane breakdown, (often termed syngamy), may reflect differences in the time of sperm penetration or intrinsic differences in oocyte activation that may have downstream developmental relevance if the delay is significantly prolonged rather than by just an hour or two. However, nucleolar characteristics (often referred to as nucleolar precursor bodies) have long been suggested to be relevant early biomarkers of developmental competence when observed in static inspections at the first check for pronuclei after IVF [33], but changes in their location and orientation during the pronuclear stage may be of equal relevance and, in practice, detectable only by time-lapse imaging [34, 35]. In the same respect, the orientation of the pre-breakdown pronuclei with respect to the first or second polar bodies, or both, has also long been suggested to be an important biomarker of developmental competence (see Papale et al. [33]) that may be best detectable by time-lapse imaging owing to their own morphodynamic activity in the newly fertilized human embryo.

Abnormalities at the first cleavage division(s) that may indicate developmental abnormality, incompetence, or the likelihood of mitotic aneuploidy that are routinely detectable in commercial IVF time-lapse systems are also observable in this iteration of a low-cost time-lapse application for the SCS and include the following: (i) nonuniform, highly asymmetric, or abnormally delayed early cleavage divisions; (ii) a first cleavage division from one to three cells; (iii) cytokinesis of one or more blastomeres that is significantly premature with respect to the normal human blastomere cell cycle; (iv) multi-nucleation; (v) degree of fragmentation and perhaps the strangest anomaly; and (vi) stage reversion/ reverse cleavages. Panels 1–6 in Fig. 18.3b show apparently normal pronuclear formation and dissolution between 14 and 21 h following conventional IVF (accessory sperm, SP evident in zona pellucida). However, some 100 min later, the first cleavage division clearly produces three blastomeres (panel B7), a phenomenon normally associated with dispermic fertilization (triploidy) and a tripolar spindle. Cleavage divisions during the subsequent 16 h resulted in an apparently normal six-cell embryo with uniform blastomeres and no evidence of fragmentation (panel 8). Static inspections, first to determine pronuclear status and later whether cleavage on day 2 or 3 was normal, might have missed this abnormality in early cytokinesis that would have likely produced a normal-appearing embryo classified as transferable but unknowingly, with a high probability of being aneuploid.

Panels 1–10 in Fig. 18.4a show another advantage of time-lapse analysis during early cleavage detectable with the described application for the SCS. In this instance, an abnormality in cell division timing affecting one blastomere occurs at the two-cell stage, with potential downstream consequences of mitotic chromosomal aneuploidy/mosaicism. This sequence begins at pronuclear membrane dissolution at 19 h 20 min after conventional IVF (arrow, panel A1). The first cleavage division at 22 h seems normal and results in what appears to be a typical two-cell embryo with even blastomeres and no evident extracellular fragments (panel A3). However, about 2 h later, the nascent blastomere indicated by an asterisk in panels A2 and A3 divides again forming three cells, each of which appears mononucleated (*N*, panel A4, arrows panel A5). The first cleavage division for the other blastomere occurs at 36 h (panel A6) and produces a transient five-cell embryo (one cell out of plane of focus in panel A7) and at least three are mononucleated (arrows; panel A7). Although subsequent cell divisions seem to be largely normal

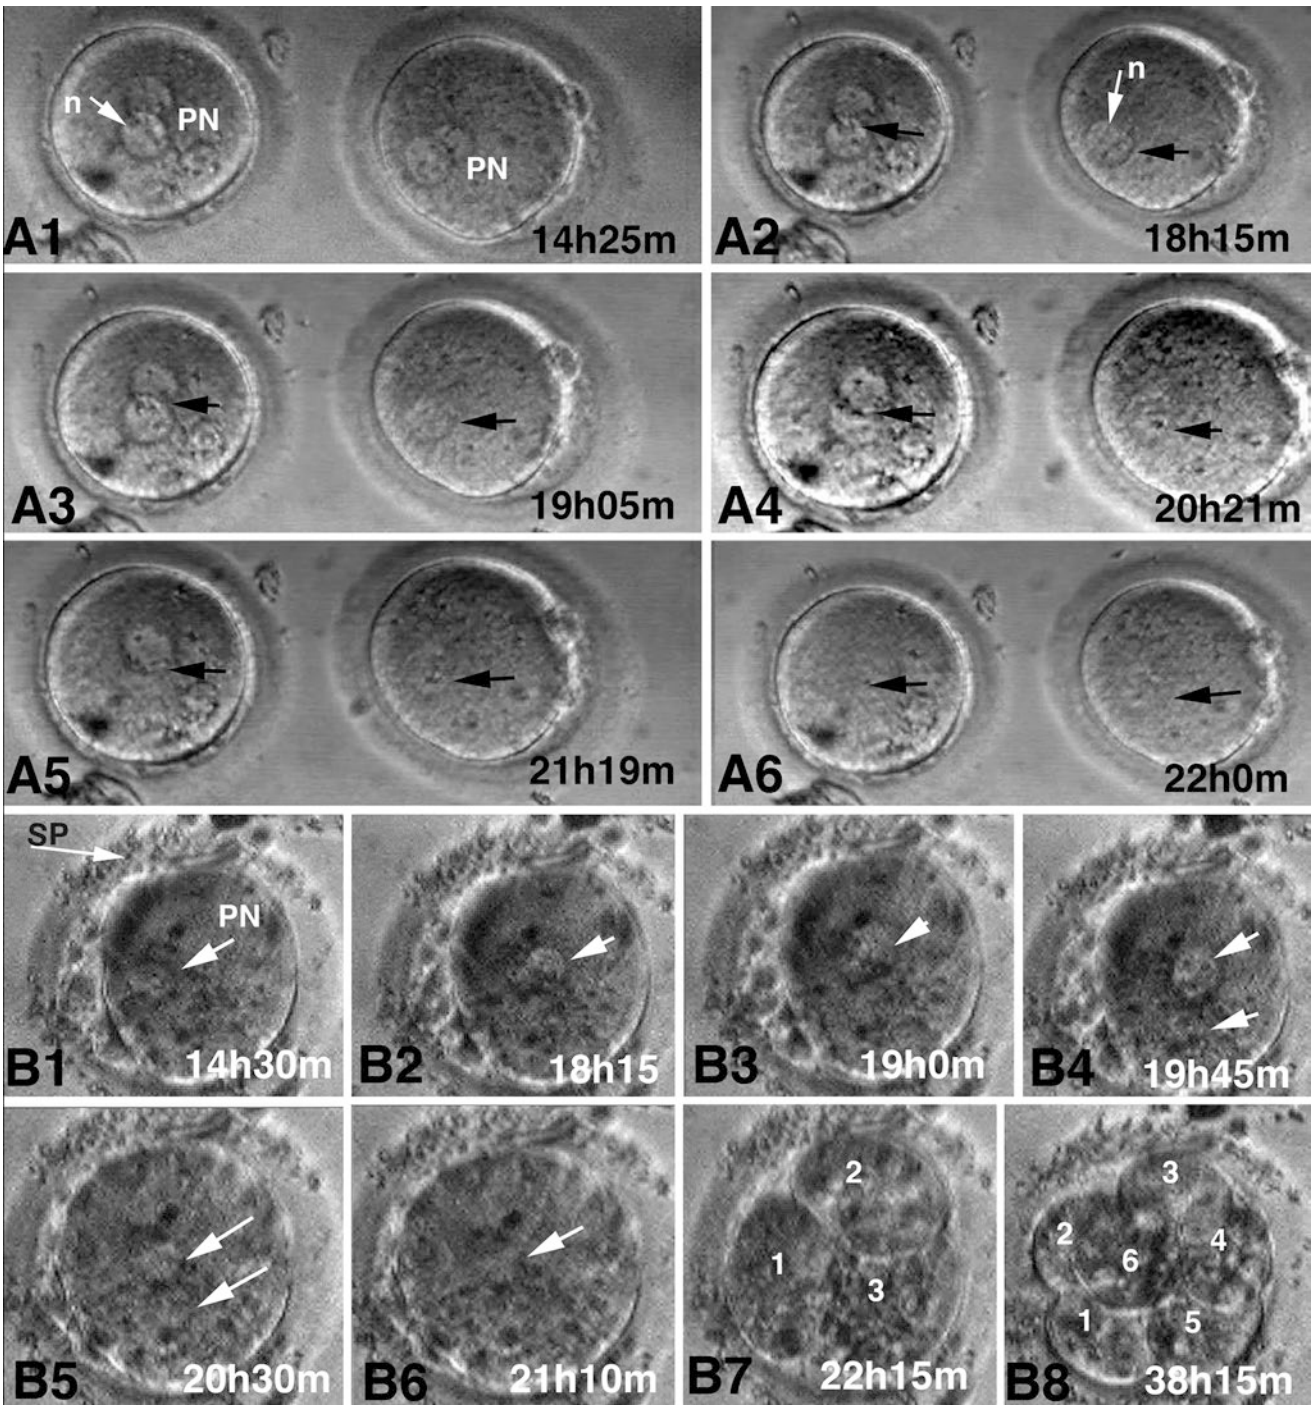

Fig. 18.3 Selected sequence from a time-lapse video showing normal pronuclear juxtaposition (panel **a**1) after conventional insemination in the glass SCS culture tube, followed by pronuclear membrane (PN) dissolution for the embryo on the right (panel **a**2) and somewhat later for its sibling embryo on the left (panel **a**5). These images were recorded near the bottom of the culture tube positioned directly above a 10X objective lens using brightfield optics and filtered 630 nm, low light illumination (0.05lux). The resolution was sufficient to detect individual nucleoli (nucleolar precursor bodies, *n*) in each pronucleus. In Fig. **b**, the oocyte was naturally darker, probably due to high lipid content. Pronuclear evolution (PN, arrows, panels **b**1–4), membrane dissolution (panels **b**5 and 6), and the first (panel **b**7) and second cleavage divisions (panel **b**8) are shown in this sequence. Of particular note is the first division into three cells (panel **b**7) followed in 16 h by a second division that produced a normal-appearing six-cell embryo (panel **b**8). Time from conventional insemination (SP, sperm) is shown at the lower right

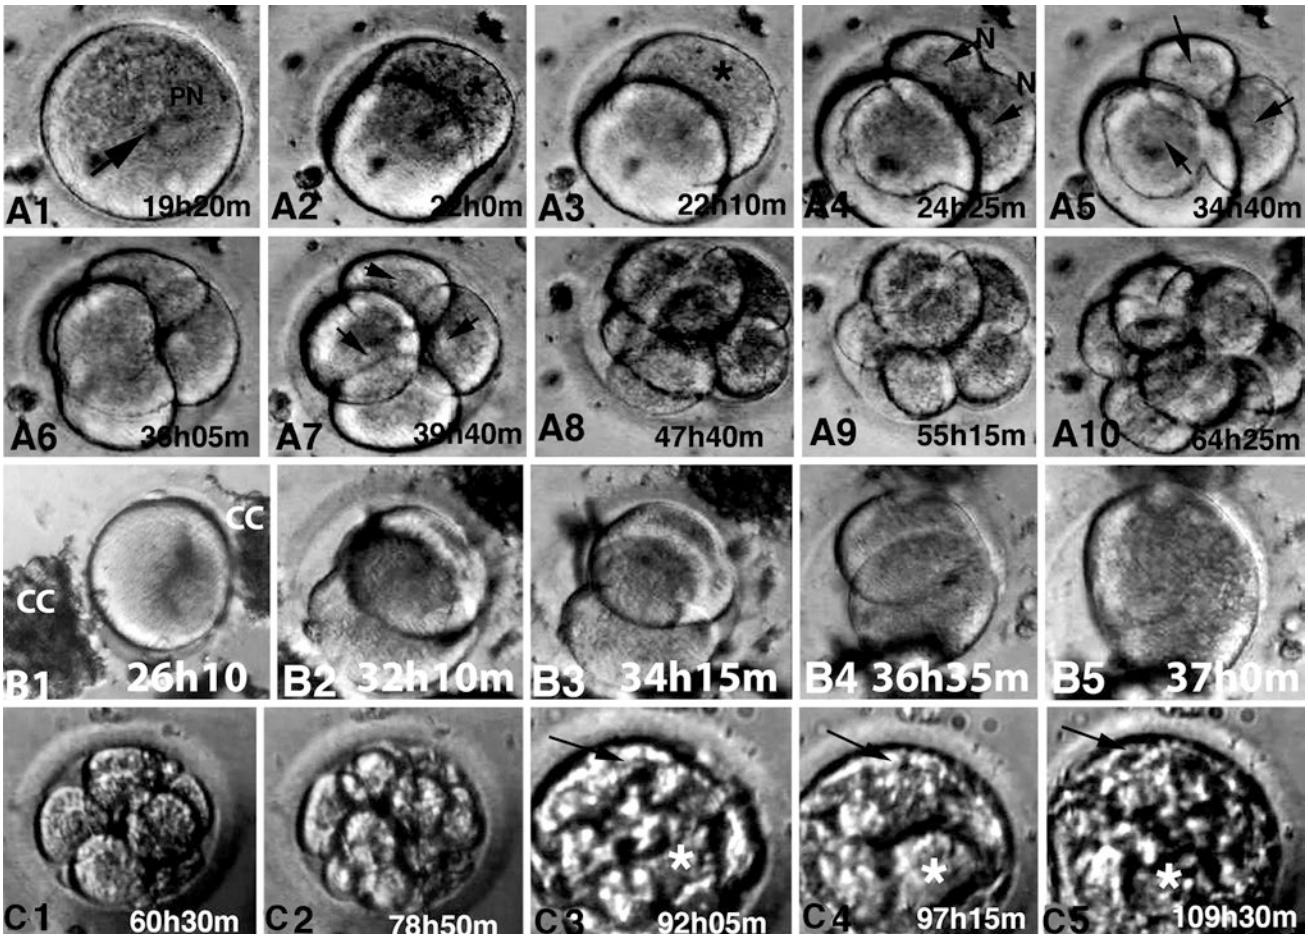

Fig. 18.4 In panels **a**1–10, a time-lapse sequence beginning at 19 h after insemination reveals an abnormal pattern of early cleavage division. Panel **a**1 is a normally fertilized egg near the end of the pronuclear membrane dissolution stage, which is followed by an apparently normal first cleavage division some 3 h later (panels **a**2 and 3). However, what time-lapse revealed was that 2 h later, the nascent blastomere indicated by an asterisk in panel **a**3 divided again into three apparent cells (panel **a**4), each of which was clearly mononucleated (panel **a**5). At 36 h, the second blastomere divided normally producing a five-cell embryo (panel **a**6). The three cells from the prematurely dividing blastomere shown in panel **a**5 were still mononucleated (indicated by arrows in panel **a**7). The fifth cell, the product of an apparently normal cell division of the second blastomere in **a**5 is out of the plane of focus in panels **a**6 and 7. Continued cell divisions produced blastomeres of largely even size (panels **a**8 and 9), but at 64 h, the embryo appears morphologically normal and by static evaluation, would likely have been considered stage appropriate for transfer (panel **a**10). The panels in Fig. **b** show the ability of this time-lapse microscopy system as applied to a simplified culture system to record so-called reverse cleavage. The post-pronuclear dissolution stage embryo in panel **b**1 undergoes an apparently normal first cell division as shown in panels 2–4. However, approximately 1 h after the completion of cytokinesis (panel 5), an abrupt reversion to a single cell is observed representing a phenomenon termed "reverse" cleavage (cc, cumulus cells). The panels in Fig. **c** show normal cleavage divisions (panels 1 and 2), morulation (panel 3), and early cavitation indicated by internal fluid accumulation (asterisks, panels 3–5). The arrows in panels 3–5 indicate a progressive thinning of outer cells that will later become trophectoderm. Times from conventional insemination shown at the lower right

(panels 8 and 9), by day 2.5 (panel A10), the eight-cell embryo appears stage- and time-appropriate and would likely be classified by a static inspection as morphologically normal for a day 3 transfer.

So-called reverse cleavage, the reversion of presumably separated daughter blastomeres to the previous stage. Was clearly detectable with this imaging system, as shown in Fig. 18.4b, panels 1–5. Panel B1 is a post-pronuclear breakdown stage embryo that is divided into an apparently normal-appearing two-cell embryo (panels 2–4). The partial rotation of this particular embryo evident in these selected images was due to two clusters of motile cumulus cells on opposite sides at the one-cell stage (cc, panel 1) that had not been removed completely during the denudation step. However, the two-cell embryo (panel 4) suddenly reverts to a one-cell stage (panel B5) in about 25 min. In some infrequent instances, continued culture in situ showed one or more cell divisions some hours later that resulted in what could be classified as a morphologically normal four-cell embryo. However, preliminary cytogenetic findings from the few embryos examined to date showed all were chromosomally abnormal (mosaic).

Figure 18.4c shows the normal process of compaction (panels 1–3) and cavitation (panels 3–5) at the morula stage where fluid accumulation (region indicated by an asterisk) begins the formation of what will later be an expanded blastocyst cavity or blastocoel. The resolving power of this time-lapse imaging system is clearly illustrated during the process of blastocyst formation and hatching. The panels in Fig. 18.5 A and B are representative images of a time-lapse sequence taken in a fully expanded blastocyst during hatching with both trophectoderm and inner cell mass clearly delineated in figure b. Of particular note with respect to the quality of imaging obtained through a plane glass culture tube is the ability to detect cell division in the trophectoderm, as shown in panels A1 and A2. The dark region indicated by an arrow in panel 1 is a trophectoderm cell nucleus in cytokinesis and in panel 2, the two nascent daughter nuclei after the completion of cell division (arrow).

Panels 5B1–8 are images from a time-lapse sequence of blastocyst hatching on day 5.5 of culture after conventional IVF in the SCS system. In addition to potential morphokinetic information, this sequence demonstrates the clarity of imaging that can be obtained in this simplified time-lapse system without additional image processing or enhancement, as evidenced by the cellular detail observed as the embryo progressively emerges from within the zona pellucida (white arrow). It also demonstrates significant differences in the timing of complete emergence for two sibling embryos that appeared stage- and time-appropriate during earlier preimplantation stages. Although the embryo on the left-hand side is somewhat smaller than its sibling due to a cycle of collapse during emergence, after hatching is complete, continued expansion of the blastocoel results in embryos of a similar diameter and appearance.

The selected images in Fig. 18.5c are from a time-lapse sequence of preimplantation embryogenesis beginning at the eight-cell stage (panel 1) and continuing through subsequent cleavage divisions (panel 2), compaction/morulation (panels 3 and 4), early fluid accumulation during cavitation (panels 4 and 5), blastocoel expansion (panels 6–9), and finally, failed hatching (panels 9–14). Despite evident zona thinning (small asterisk, panels 2, 5–6, and 10) during blastocoel expansion denoted by a large asterisk in panels 5, 6, and 8, with delineation of the ICM, several consecutive cycles of blastocoel collapse and re-expansion occurred with a final collapse at 149 h post insemination (panel 10; day 6.2). Depending upon the position of the embryo at the start of culture in the SCS, slender cellular processes emanating from one or more clusters of trophectodermal cells often penetrate and extend through the zona pellucida (black arrow, panels 7–14). These cellular extensions can be highly motile and are likely the kinetic structures termed "zona breakers" by Sathananthan et al. [36] owing to their suggested function in creating the initial rent in the zona that is permissive for hatching. Despite their presence, hatching in the embryo shown in Fig. 18.5c failed, despite the persistence of kinetic activity for these transzonal structures for up to 24 h.

For purposes of selection for transfer on days 5–6, usually three expanded blastocysts can be observed at one time with a low power objective lens (e.g., 5X long working distance) and can usually be identified individually after removal from the culture tube by virtue of (i) whether they are intact, hatching, or hatched and (ii) appearance and organization of a detectable ICM (e.g., compact, nodular, laminar, or disorganized). Gentle side-to-side movement of the microscope stage is sufficient to bring the ICM of a hatched embryo into focus for morphological assessment. In this context, according to certain ICM grading schemes the embryo on the right-hand side in panel 8 would be classified as high grade and the one on the left, at a lower grade with respect to the selection for single embryo transfer [12–14].

Whether terminally collapsed embryos such as shown in panel C14 could re-expand and emerge from the zona pellucida after laser-assisted hatching either in situ or by removal and placement in conventional culture was examined in preliminary studies. None of the 24 embryos showing the panels C11–14 phenotype (i.e., with several previous cycles of collapse and re-expansion) benefited from this treatment by re-expanding. This finding tentatively suggests that such embryos maybe terminally compromised with respect to development competence and would be unlikely to either implant or progress through gestation after transfer. However, while the validity of this interpretation requires further study, it does support the use of time-lapse with the SCS for multiple patients using a multiple microscope iteration as described above.

18.16 Limitations and Future Prospects

The intended "take-home message" from this chapter is that it is possible to simplify what would normally appear to be complex aspects of IVF into a platform suitable for an IVF setting in most locations in developed and developing countries. While primarily intended for patients that do not unambiguously require ICSI, this culture system, with or without time-lapse/streaming video, can be used to reduce laboratory costs to a significant extent and thereby allow more patients to afford or have access to treatment. The time-lapse system described here and methods for maintaining a constant and normal culture temperature, while unconventional, represent only one possible template for introducing a "high-tech" method in a low-cost setting. As noted above, one possible iteration that may be a reasonable and cost-effective means for its adoption in a low-resource setting that would likely address or comply with potential regulatory concerns is to have several microscopes in a common temperature-controlled enclosure, in essence a mini "warm room," with image transmission for recording and live streaming using available software such as described here.

18.17 Lessons from the Introduction of the SCS Through the Walking Egg Program in Resource-Poor/ Developing Countries

During the past few years, experience from establishing a low-cost IVF program, such as the Walking Egg, using the SCS technology in low-resource settings for which the system was initially intended, has been mixed. On the setup and operational side, the experience has been rewarding because it works as designed, but somewhat disappointing with respect to adoption. A lack of commitment, enthusiasm, or willingness to take advantage of a low-cost IVF option has been surprising given that reluctance often comes from the very same sources that have long championed women's reproductive rights, and as a matter of social justice and equality, decried the lack of an affordable treatment for infertile couples claiming availability only for the very wealthy [1–3, 5, 37, 38]. The current reality has been somewhat different, however, where so-called reproductive rights seem to focus mostly on contraception rather than conception that requires medical intervention to create families using assisted reproductive technologies. While considerable opposition from the few established and well-connected high-cost IVF centers was not unexpected, it has become apparent that despite claims for low-cost ART/IVF services from well-intentioned individuals, medical institutions, certain foundations, and government officials, in actuality, they seem unready or unwilling to consider the adoption of a viable option developed specifically to address their often-stated pleas for such advanced reproductive technologies.

Although more than 98% of the population in developing countries is excluded from IVF because of expense or lack of treatment centers, or both, establishing local low-cost programs seems to be a low priority. As former US Secretary of State Colin Powell once said, "A dream doesn't become reality through magic; it takes sweat, determination and hard work." While the "dream" of the Walking Egg Program to provide truly low-cost IVF in developing countries was realized with the SCS system, one lesson learned was that to achieve implementation, a receptive political, governmental, and clinical community are essential preconditions. Fortunately, these preconditions have been met elsewhere where the value of the SCS/Walking Egg Program has been recognized as a viable means of providing affordable IVF. The irony of this experience is that a technology and model for its delivery designed and clinically tested successfully in a high-resource setting(s) specifically for use in low-resource/ developing countries may witness wider application and adoption in developed countries where advanced infertility treatments such as IVF need to become more accessible and affordable as well for their own population.

A second lesson from the Walking Egg experience in so-called developing countries is that the critical shortage of medical doctors, especially those with some familiarity with reproductive medicine, is a major barrier to providing affordable IVF. It is remarkably easy to educate and train laboratory technicians in the SCS method. In contrast, it was much more difficult to train clinicians to perform a well-structured infertility work-up, make an accurate infertility diagnosis where IVF would not be effective without prior intervention (see below), or how to monitor and interpret findings during an IVF cycle, which are elements of treatment largely assumed to be the case in developed countries. In this respect, the streaming video incorporated into the low-cost time-lapse system described here will likely benefit the ongoing training of laboratory personnel owing to access to experts in similar albeit remote laboratories, but is unlikely to have the same utility for an under-trained clinical staff. A third lesson from the Walking Egg experience is that because reproductive healthcare education is virtually nonexistent in parts of Africa, many infertile couples wait too long to seek treatment, mostly due to financial reasons. By this time, 90% of women over age 35 evaluated for infertility have never gotten the message that increasing age is an important prognostic factor in outcome, and when evaluated, are found to have

Fig. 18.5 Panels 1–8 in Fig. **a** demonstrate the level of resolution and fine morphokinetic details of blastocyst expansion and hatching that can be obtained for static imaging or time-lapse microscopy though the glass culture tube of the SCS. The arrow in panels **a**1 and 2 shows that cytokinesis in the trophectoderm is clearly detectable as the single cell in panel 1 becomes two in panel 2. Panels 1–8 in Fig. **b** are from a longer sequence of embryogenesis that begins for two sibling embryos about 4 h (panel **b**1) after the embryo on the right had completely emerged (hatched) from the zona pellucida. While the earlier hatched embryo continued to expand, its slower sibling on the left completed its emergence some 10 h later (panel 7) but by 16 h (panel 8), had expanded to reach a diameter that was similar to its earlier sibling. Both embryos hatched in a continuous fluid motion with no cycles of collapse or expansion of the blastocyst cavity (blastocoel). Panels **c**1–14 show progressive embryogenesis from cleavage (panels 1 and 2), morula (panel 3), cavitation (large asterisk, panel 4), blastocyst expansion with formation of the blastocoel cavity (large asterisk, panels 5, 6, and 8), delineation of the trophectoderm (TR, panel 7), and inner cell mass (ICM, panel 8). However, although apparently normal with respect to morphokinetic activity and morphology during blastocyst formation, hatching failed despite the elaboration of trophectodermal plasma membrane specializations termed "zona breakers" thought to facilitate hatching (black arrow, panels 8–14). The projection detached from the embryo during collapse yet retained independent motility for some hours thereafter within and on the surface of the zona pellucida (panels 11–14). A progressive thinning of the zona pellucida, which is a normal feature of the expansion phase, is evident by comparing thickness from cleavage to expanded blastocyst stages (small asterisk, panels 2, 4, 5, 6, and 10). Time from the start of culture is shown at the bottom of each panel

large myomata, uterine polyps, or Asherman disease, which greatly reduces the chances of a successful outcome, whether by the SCS method or with a conventional high-resource IVF laboratory.

Our current experience with the SCS platform and Walking Egg model for its delivery under not atypical conditions for low-resource settings has been successful although challenging. Where advanced infertility treatments are essential to create families, IVF using the SCS can indeed be successful, affordable, and made accessible in both developing and developed countries, but appropriate clinical training in reproductive medicine is a necessary prerequisite for success in low-cost settings and for all settings; educational programs on reproductive health that include the causes of and treatments for infertility are an important component. The ability to proactively address anticipated challenges and productively solve those unanticipated has reinforced the notion that concepts such as the SCS, time-lapse recording, and video streaming for training purposes and embryo selection can be combined with infertility treatment paradigms such as the Walking Egg model in general, and for low-resource settings in particular. For the latter, SCS methodology can be further simplified and adapted to become a truly effective means of treating infertility at low cost. However, the real challenges that now lie ahead in both developed and developing countries may not be technical or with appropriate clinical training, but rather competing interests that promote reluctance or opposition to adoption on the part of established programs and their supporting professional societies in reproductive medicine that can have significant influence on regulatory authorities and philanthropic organizations, including those that champion the reproductive rights and equality for women.

Review Questions

1. What are the basic elements of culture needed to support successful human fertilization and preimplantation embryogenesis in vitro?
2. What modifications could be made to address potential concerns from regulatory authorities about thermal stability for time-lapse microscopy using the simplified culture system?
3. Given the limitations of the simplest iteration of a time-lapse system application for the simplified IVF culture system compared to current commercial systems, what patients may benefit the most with respect to outcome from its use?
4. Why might there be resistance to the introduction of a lower-cost IVF model in both developing and developed countries if treatment can be more affordable and accessible?

In Vitro Culture of Oocytes and Embryos with Micro-vibration: "Naturalization" of Routine IVF Procedure

Vladimir Isachenko, Karl Sterzik, Gohar Rahimi, Peter Mallmann, and Evgenia Isachenko

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_19

Learning Objectives

- All fertilization steps in nature take place inside the fallopian tube under micro-vibration.
- By routine procedure, embryos are not subjected to ever-changing dynamic processes.
- Limitations of in vitro development of human oocytes/embryos after fertilization.
- It is important to determine whether there is any difference in the viability of embryos after in vitro culture under static and mechanical micro-vibration conditions.
- Evaluation of developmental and "baby-take-home" rates of embryos.

19.1 Introduction

Infertility is the inability of a person to reproduce by natural means. It is usually not the natural state of a healthy adult organism [1]. In that way infertility is a disease, in essence. A reasonable question to propose is whether cell transplantation may be a viable option for the treatment of this disease. In fact, the most effective method of treatment for sterility is harvesting and transplanting embryonic cells (embryo).

Embryo transplantation refers to a step in the process of assisted reproduction in which embryos are placed into the uterus of a female with the intent of establishing a pregnancy. This technique is often used in connection with in vitro fertilization (IVF). In vitro embryo culture is a stage of IVF in which embryos are allowed to grow in an artificial medium [1].

IVF is a process by which an oocyte is fertilized by sperm in vitro. The process involves monitoring and stimulating a woman's ovulation, removing oocytes from the ovaries and letting sperm fertilize them in vitro. The fertilized oocytes are cultured for 2–6 days in a growth medium and are then transplanted into the uterus with the intention of establishing a successful pregnancy. It is a technique of assisted reproductive technology for treatment of sterility [1].

All fertilization steps in nature (receiving the ovulated oocytes, fertilization of oocytes, and embryonic development with subsequent transport to the uterus) take place inside the fallopian tube. The tubal mucosa is arranged as longitudinal folds and consists of a single layer of cuboidal or columnar epithelium. The major cell types of this epithelium are secretory and ciliated cells [2], whose cilia have a vibration [3] (beat). Some investigations have shown an increase in ciliary beat frequency to 5.8 ± 0.3 Hz in the fimbrial section of the tube during the secretory phase [2] compared with the proliferative phase (4.9 ± 0.2 Hz).

What is known about micro-vibration in general? Vibration is a natural phenomenon that refers to mechanical oscillations about an equilibrium point. Since life began, the Earth has subjected all living things to a natural pulsation frequency. This natural phenomenon was predicted in 1952 [4] and named the global electromagnetic resonance phenomenon or Schumann resonances. Schumann resonances are quasi-standing electromagnetic waves that exist in the Earth's "electromagnetic" cavity (the space between the surface of the Earth and the ionosphere). Schumann resonances are the principal background in the electromagnetic spectrum between 3 and 69 Hz and appear as distinct peaks at extremely low frequencies of around 7.83 (strongest), 14, 21, 27, 39, and 45 (weakest) Hz. In daily life, this vibration could be "desirable" (e.g., musical instruments) but more often is undesirable (wasting energy and creating unwanted sound – noise).

The stimulating effect of vibration on living systems is well known and plays a relevant role in mechanical transduction, which is essential for the survival of both cells and higher organisms.

A retrospective analysis was done using a cohort of patients who received intracellular sperm injections (ICSI) at a German private fertility center about 2 years ago [5]. In vitro culture was performed either in a static environment with single oocyte/embryo culture (n = 291 patients) or under micro-vibration and group culture (n = 244 patients). In the static group, oocytes/embryos were cultured individually, while in the micro-vibration all the oocytes were cultured together and up to four embryos were cultured in the drop with a three-dimensional vibration of 56 Hz for 5 s/60 min. Authors observed a significant increase in the fertilization rate in oocytes cultured in groups and under micro-vibration conditions compared to oocytes cultured individually in a static culture (82% vs. 78%); there was also an increase in the implantation rate under these conditions (42% vs. 35%). At the same time, authors noted that the clinical pregnancy rate showed a tendency to be higher in the micro-vibration group but it did not reach significance (47% vs. 43%) [5].

The aim of our investigations was to determine whether there was any difference in the viability of embryos after in vitro culture under static and mechanical micro-vibration conditions.

19.2 Materials and Methods

The authors confirm that all ongoing and related trials for this drug/intervention are registered. Clinical trial registration: ISRCTN13773904 "In vitro culture and transfer of human embryos."

The current work was performed from January 2011 to December 2015 at a private medical center (Endokrinologikum Ulm, Praxisklinik Frauenstraße, Ulm, Germany). Permission was granted by the Ethical Commissions of Medical Faculties of the University of Ulm, Germany (permission 321/10-UBB/bal. from 12.11.2011), and the University of Cologne, Germany (permission 13–147 from 20.11.2013), for the in vitro culture of embryos under mechanical micro-vibration. In vitro culture of embryos of

each odd couple was performed in accordance with routine methodology in a static system (without micro-vibration). Each even couple was offered the choice of the in vitro culture of oocytes and embryos according to the standard routine or with mechanical agitation (micro-vibration) until transplantation. Written informed consent was obtained from all the participating couples. Eight participants did not agree to the in vitro culture of their embryos with micro-vibration, and their embryos were cultured in a static "traditional" system.

All patients with infertility were stimulated for IVF cycle or intracytoplasmic spermatozoa injection (ICSI) cycle with triptorelin (Decapeptyl®, Ferring, Kiel, Germany) and recombinant follicle-stimulating hormone (FSH; Puregon®, MSD Sharp & Dohme GmbH, Haar, Germany; or Menogon®, Merck Serono GmbH, Darmstadt, Germany; or Gonal-f®, Merck Serono) according to the "short" protocol. Ovulation was induced by the administration of 5000 IU of human chorionic gonadotropin (hCG; Brevactid®, Ferring), and oocytes were retrieved 34–36 h later and inseminated with the partner's sperm through conventional IVF and ICSI techniques.

Patients were alternately assigned to the two embryo culture groups. Only two or three embryos per patient were cultured, as according to German law no more than three pronuclear oocytes/embryos from one patient (usually two) can be cultured in vitro and all cultured oocytes/embryos must be later transferred to the patient independently of the developmental rate of these embryos.

Oocytes for the culture of pronuclear embryos were obtained from 4436 patients who provided informed consent (aged 26–44 years, median age 32.8). Pronuclear embryos (two or three per patient) were cultured in vitro under two different conditions: Group 1 ($n = 4821$), without mechanical agitation of the culture medium (standard routine conditions), and Group 2 ($n = 4803$), with mechanical agitation (44 Hz delivered over 5 s once every hour) and acceleration (660 mV/g at 3.3 V: $X = \pm 1.0$ g, $Y = \pm 0.7$ g, $Z = \pm 0.15$ g).

Mechanical agitation was achieved using the developed device Viboviduct 1500 (SimSoTec GmbH, Cologne, Germany). Before using the device, it was calibrated by measurement of vibration with special device PCE-VT 2700 (PCE Instruments UK Ltd., Southampton, UK). Viboviduct 1500 generates micro-vibrations by use of a special electric motor with low electromagnetic noise. The generated vibrations are forwarded directly to the plate containing affixed Petri dishes with embryos. Harmful high frequencies are dampened and smoothed by the intelligent control software developed on the microprocessor. The control software monitors the motor movements. The device is designed and developed for use in a CO_2 incubator.

Embryo development rates were determined on the day of transfer (Day 2, Day 3, or Day 5). The embryos were cultured in 50 µl of culture medium (Sage, Los Angeles, CA, USA) under mineral oil (Sigma-Aldrich, St. Louis, MO, USA) for their transfer.

The embryos were graded on Day 2 and Day 3, as described by Steer et al. [6], as follows: Grade A, equal sized symmetrical blastomeres; Grade B, uneven blastomeres with <10% fragmentation; Grade C, 10–50% blastomeric fragmentation; and Grade D, > 50% blastomeric fragmentation. Day 5 embryos were graded according to Veeck and Zaninovic [7].

Embryo transfer was performed on Day 2, Day 3, or Day 5 after retrieval of oocytes. Pregnancy was defined as an increase in hCG serum concentration (20 IU/L), which was determined 11 and 13–15 days after embryo transfer. Clinical pregnancy was recorded when the fetal sac was visualized on an ultrasound at gestational weeks seven to eight.

19.3 Statistical Analysis

Quality of embryos, amount of transferred embryos, amount of morphologically ideal developed embryos (Grade A and B), amount of sacs, pregnancy outcome (ongoing pregnancy, abortion, abrasion, biochemical pregnancy), and baby-take-home rate (the number of live births per number of IVF/ICSI treatments (cycles) (expressed as percentages)) were evaluated by analysis of variance (ANOVA). Various characteristics were summarized by mean and standard deviation (SD) within groups. The level of statistical significance was set at $P < 0.05$. Clinical pregnancy rates were analyzed by ANOVA for categorical variables using the CATMOD Procedure of SAS Institute Inc. (Cary, NC, USA). Comparisons between age groups were performed by pairwise contrasts and Bonferroni-Holm adjustment for multiple comparisons using the MULTTEST procedure of SAS.

19.4 Results

The mean numbers of transferred embryos per patient for the static group and the micro-vibration group were 2.17 ± 0.32 and 2.17 ± 0.36, respectively.

For groups ≤29 years, 30–34 years, 35–39 years, and ≥40 years, the following rates of high-quality embryos without fragmentation were observed (2–4 blastomeres on Day 2; 6–8 blastomeres and compacting morula on Day 3; blastocyst, expanded and hatching blastocyst on Day 5) (static vs. vibration, respectively): 65.2% vs. 70.8%, 44.3% vs. 69.3%, 67.% vs. 76.4% (for statistic significant differences between respective rates in these three groups $P < 0.05$), and 67% vs. 66% ($P > 0.1$) (Tables 19.1 and 19.2).

The following baby-take-home rate was detected for groups ≤29 years, 30–34 years, 35–39 years, and ≥40 years, respectively (static vs. vibration): 30% vs. 31% ($P > 0.1$, increasing only on the level of tendency), 28% vs. 37%, 23% vs. 29%, and 9% vs. 15% (differences between respective rates in these three groups with $P < 0.05$) (Table 19.3).

Table 19.1 High-quality embryos in different age groups just before transplantation: in vitro culture in static system

Quality of embryos	Age of patients			
	≤29 years	30–34 years	35–39 years	≥40 years
Day 2				
2A	26%	13%	12%	6%
4A	35%	25%	49%	59%
Total high-quality embryos [*n* (%)]	18 (61%)	23 (38%)	110 (61%)	71 (65%)
Day 3				
6A	17%	5%	13%	15%
8A	46%	29%	48%	48%
8A compacting	9%	6%	9%	9%
Total high-quality embryos [*n* (%)]	55 (64%)	98 (40%)	524 (70%)	393 (72%)
Day 5				
EB	14%	14%	17%	24%
B3	1%	1%	1%	2%
B2	18%	1%	19%	11%
B1	27%	24%	24%	20%
B1h	9%	15%	8%	6%
Total high-quality embryos [*n* (%)]	264 (69%)	633 (55%)	568 (69%)	292 (63%)*

(2A) 2 blastomeres, no fragmentation; (4A) 4 blastomeres, no fragmentation; (6A) 6 blastomeres, no fragmentation; (8A) 8 blastomeres, no fragmentation; (8A compacting) 8 blastomeres, beginning of compacting; (EB) early blastocyst; (B3) blastocyst with small blastocoel; (B2) blastocyst; (B1) expanded blastocyst; (B1h) fully expanded or hatching blastocyst
Only underlined rates (percentages) were compared (Table 19.1 vs. Table 19.2). Only rates (percentages) marked with (*) have no significant difference ($P > 0.1$) (Table 19.1 vs. Table 19.2)
The rest of respective rates (percentages) are significantly different ($P < 0.05$) (Table 19.1 vs. Table 19.2)

19.5 Discussion

There was no significant difference between the quality of embryos from some groups (e.g., in group ≥40 years), but the baby-take-home rate was significantly different. We believe the subjectivity of the process by which embryos are evaluated may affect the results, as interpretations vary depending on the embryologist performing the evaluation. However, the number of babies born is an absolutely objective rate that is free from subjectivity and we have drawn our conclusions based on this parameter.

The conditions of embryonic development in vivo include ciliary beating from the moment ovulation begins, fertilization, and during embryo transport via the oviduct to the uterus [8]. "Ciliary" refers to the cilia, which is Latin for vibrating hairs. Baseline cilia beating frequencies have been reported to vary widely between individuals in the range of 5–20 Hz [9, 10]. Ciliary beat has the following characteristics: (i) its rate is remarkably uniform [1]; and (ii) the beat of a particular cilium and its adjacent cilium appears to be well coordinated and a definite metachronal wave is established [11]. This metachronism is defined as coordinated oscillation including a definite phasing of micro-vibration between the cilia of a single cell and a definite phasing of this vibration between the cilia of adjacent cells. The fluid that surrounds the cilia and forms a blanket above the tips of the cilia is a suspension of mucus [12].

The positive effect of pulsatile mechanical micro-vibration for the cytoplasmic maturation of in vitro mature pig oocytes was described in a previous study [13]. These authors subjected cumulus–oocyte complexes cultured in micro-drops to pulsatile mechanical vibration at a frequency of 20 Hz with acceleration (660 mV/g at 3.3 V: $X = \pm 1.0$ g, $Y = \pm 0.7$ g, $Z = \pm 0.15$ g; instruction of manufacturer). During in vitro maturation, vibration did not affect the proportion of oocytes reaching the metaphase II stage. However, blastocyst formation rates after the activation of oocytes exposed to vibration were significantly higher than those obtained for oocytes matured without mechanical vibration (27% vs. 12% and 26 vs. 15%, respectively, for the 5 s and 10 s pulses).

Table 19.2 High-quality embryos in different age groups just before transplantation: in vitro culture with micro-vibration

Quality of embryos	Age of patient			
	≤29 years	30–34 years	35–39 years	≥40 years
Day 2				
2A	22%	16%	20%	20%
4A	44%	48%	51%	38%

(2A) 2 blastomeres, no fragmentation; (4A) 4 blastomeres, no fragmentation; (6A) 6 blastomeres, no fragmentation; (8A) 8 blastomeres, no fragmentation; (8A compacting) 8 blastomeres, beginning of compacting; (EB) early blastocyst; (B3) blastocyst with small blastocoel; (B2) blastocyst; (B1) expanded blastocyst; (B1h) fully expanded or hatching blastocyst
Only underlined rates (percentages) were compared (Table 19.2 vs. Table 19.1). Only rates (percentages) marked with (*) have no significant difference ($P > 0.1$) (Table 19.2 vs. Table 19.1)
The rest of respective rates (percentages) are significantly different ($P < 0.05$) (Table 19.1 vs. Table 19.1)

In medicine, the embryonic development rates and clinical results were compared between a static culture group (n = 159 cycles) and a micro-vibration culture group (n = 166 cycles) in poor responders. A micro-vibrator was set at a frequency of 42 Hz for 5 s/60 min duration of embryo development [14]. In poor responders, the embryonic development rate was improved to a limited extent under the micro-vibration culture conditions, but the clinical results were significantly improved[15].

It should be noted that the vibration at a frequency of 44 Hz and the acceleration described above are the parameters of movement of the plate on which Petri dishes with culture medium and embryos are located. The study laboratory's observations on bovine oocytes have shown that the amplitude of vibration of embryos as well as acceleration of cells is lower than the rates with which the plate is vibrating (data not shown). This fact is due to the inertness of oocytes suspended in a liquid environment; vibration is drastically suppressed by the culture medium and is dependent on the composition and volume of this medium. Parameters of the "real" vibration of embryos are calculated mathematically and make up 33 Hz. It is necessary to emphasize that the observations in vivo and published rate of vibration of cilia are different because the embryo is "swimming." Therefore, knowing the rate of embryonic development is a criterion for adjusting the frequency of the apparatus vibration.

The acceleration accompanying any movement ($\mathbf{a} = \mathbf{r}\boldsymbol{\omega}^2$ and $\boldsymbol{\omega} = 2\pi\mathbf{f}$, (**a**) acceleration, (**r**) radius of movement, (**f**) frequency) is crucially important for biological objects. The maximal rate of acceleration is achieved at a maximal frequency of 50 Hz. That is why it would not be correct to use the "optimal" rate of vibration frequency established for an apparatus. It is also important to note that apparatus with the same frequency may have a different acceleration rate that should be taken into consideration.

In conclusion, in vitro culture of embryos under micro-vibration (mimicking conditions in nature whereby oviductal fluid is mechanically agitated by the epithelial cilia) significantly increases the baby-take-home rate for patients 30 years of age and older.

Table 19.3 Number of formed sacs and "baby-take-home" rate after transplantation of developed and transferred embryos in different age groups: in vitro culture in static system and with micro-vibration

	In vitro culture in static system				In vitro culture with micro-vibration			
	≤29 years (496 embryos from 250 patients)	30–34 years (1457 embryos from 715 patients)	35–39 years (1751 embryos from 804 patients)	>40 years (1117 embryos from 457 patients)	≤29 years (527 embryos from 277 patients)	30–34 years (1469 embryos from 690 patients)	35–39 years (1911 embryos from 850 patients)	≥40 years (893 embryos from 393 patients)
Number of sacs [*n* (%)]	149 (30%)	525 (36%)	595 (34%)*	68 (16%)	268 (51%)	646 (44%)	671 (35%)*	286 (32%)
Singleton [*n* (%)]	88 (59%)	315 (60%)	327 (55%)	178 (76%)	145 (54%)	323 (50%)	463 (69%)	254 (89%)
Twins [*n* (%)]	61 (41%)	204 (39%)	268 (45%)	43 (24%)	123 (46%)	200 (48%)	201 (30%)	32 (11%)
Triplets [*n* (%)]	0 (0%)*	6 (1%)*	0 (0%)*	0 (0%)*	0 (0%)*	13 (2%)*	7 (1%)*	0 (0%)*
"Baby-take-home" rate [*n* (%)]	149 (30%)*	408 (28%)	403 (23%)	100 (9%)	163 (31%)*	543 (37%)	556 (29%)	134 (15%)

Baby-take-home rate notes the number of life births per number of IVF/ICSI treatments (cycles) in percent
Only respective rates (percentages) marked with (*) have no significant difference ($P > 0.1$)
The rest of respective rates (percentages) are significantly different ($P < 0.05$)

Review Questions

1. Is the routine procedure of in vitro culture of oocytes/embryos mimicking conditions in nature?
2. What are the limitations of in vitro development of oocytes/embryos?
3. What is the source of micro-vibration in the testing equipment?
4. Is using of micro-vibration beneficial by in vitro culture of oocytes and embryos?

Learning Objectives

This chapter aims at informing the reader of the following:

- Potential uses of microfluidics in gamete and embryo isolation, manipulation, and analysis
- State of the art of microfluidics and gamete and embryo culture in numerous species
- Practical reasoning for use of microfluidics for gametes and embryos
- Futuristic view of how and where microfluidics might be used in human ART

20.1 Introduction

20.1.1 Introduction of Human ARTs (Assisted Reproductive Technologies)

Human ARTs refer to all treatments or procedures that include the in vitro handling of human oocytes, sperm, and embryos, for the purpose of establishing a pregnancy. This includes, but is not limited to, in vitro fertilization and embryo transfer, gamete and embryo cryopreservation, oocyte and embryo donation, and gestational surrogacy [1]. Since 1978, the world's first "test-tube" baby—Louise Brown—was born via in vitro fertilization (IVF), and the past three to four decades have seen a rapid evolution in human ARTs. Advances in ARTs, including the use of donor gametes and intracytoplasmic sperm injection (ICSI), have led to increased numbers of infertile couples being treated with ARTs in recent years.

20.1.2 Present Shortcomings of ARTs

The continuous refinement of ARTs in the past decade has mainly been the modification of medium components, concentrations, and the addition of new elements at specific time points. While there have been many advances in in vitro manipulation of embryos in regard to the efficiency and the quality, these embryos are still suboptimal compared to their in vivo counterparts [2]. These differences in the quality of embryos are believed to be partially associated with stresses that are imposed on the oocyte/embryo during the ART procedures. It begins as early as the time of transvaginal oocyte retrieval, as small temperature fluctuations can have significant effects on oocyte quality, which can negatively influence the following IVF procedure [3]. Once the oocyte enters the laboratory, there can be as many as 20 manipulations that potentially impose stress (change in pH, osmolality, temperature, and light) on the oocyte/embryo [4, 5]. Such continued stresses have their adverse effects directly on the gametes/embryos, which can be detrimental to subsequent embryo development potential. Most research, with aims of reducing these types of stresses during ART procedures, have focused on the media modulation rather than finding systems that could reduce the stress introduced by the manipulation. Furthermore, the physical microenvironment and chemical/physical aspects of that microenvironment that support oocyte short-term culture, maturation, fertilization, and embryo culture require enhanced study and refinement.

Despite the wide application of ARTs around the world, two major problems remain; low implantation rates and high multiple gestation rates. As a significant cause of physical, emotional, and financial distress for women undergoing infertility treatments, pregnancy failures happened to approximately two out of three couples during ART cycles [6]. A reasonable explanation for the high rate of failure in ART cycles is the inability to determine the embryos with highest developmental and/or implantation potential. During the past three to four decades, morphology and cleavage rates have been the major methods used for embryo assessment and selection for uterine transfer in clinics. Currently, individual embryo chromosome normalcy is being assessed with the goal of improving implantation rates. Other embryo-specific biomarkers could also assist in selecting embryos with the greatest development and implantation potential. Besides the stresses on the oocyte/embryo from manipulation in vitro, there are also human factors associated with ARTs, which can result in losses of oocytes/embryos at each manipulation step. During the treatment of human infertility, where costs of embryos are high, loss of any oocyte/embryo, at any step, could be potentially detrimental to the success of patients in family building, the infertility clinic success, and good standing.

20.1.3 Practical Logic of Why, and How, Microfluidics May Be Applied to Human ART

One possible solution to reduce these stresses on gametes/embryos may be the application of micro- and nanotechnologies to laboratory ARTs, particularly microfluidic technologies. In relation to cell biology, microfluidic technologies first emerged in the late 1980s and early 1990s with initial reports of individual cell fusion in a silicone fluidic device and transport of animal cells [7, 8].

Microfluidics is a fast growing, highly interdisciplinary subject, covering physics, engineering, chemistry, and biology. From a technology perspective, microfluidics refers to microscale devices that can precisely manipulate fluids. Microfluidic technologies were first developed by the semiconductor industry and later expanded by the microelectromechanical systems (MEMS) field. These devices could be applied to biology studies to facilitate complex assays through (1) minimizing the sample volume needed, (2) reducing the reagent consumption and maximizing information collected from scarce samples, (3) expanding screening scope and capacity of batch sample processing, and (4) providing researchers precise control and expectedness of the spatial-temporal dynamics of the microenvironment.

In order to solve problems in biology and clinical research, biomedical engineers are devoted to developing comprehensive microfluidic technologies. Application of microfluidics

to embryo manipulation in vitro may alleviate some of the drawbacks that traditional microdrop-culture places on embryo culture. Microfluidic technologies are promising in human ART, providing the capability to manipulate gametes and embryos in considerably small volumes of culture medium, in a nano- to microliter range. The physical characteristics of liquids in microenvironments have been well studied; thus, it may be advantageous for biologists and engineers to work together in developing microfluidic devices for manipulating gametes or embryos in microenvironments.

These microfluidic platforms could precisely simulate in vivo microenvironments in relation to fluid volume/cell mass ratios, as well as reduce the cost of reagents. Furthermore, through reducing the sample volume, beneficial paracrine and autocrine factors that promote embryo development may be concentrated around the embryos [9–12]. Microfluidic devices may also improve the fertilization rate in vitro by allowing spermatozoa and oocytes to interact in a more in vivo-like environment, whereby only a few motile spermatozoa flow past the oocyte and participate in the insemination/fertilization process. More important, microfluidic devices can facilitate the study of dynamic processes of embryo development. With the application of microfluidic technologies in ART laboratory platforms, the stress imposed on embryos may be reduced or alleviated, since the embryo would grow in an environment where suitable osmolality, temperature, and pH are maintained. Another advantage of microfluidics is the automated control of media changes and flow rates. Thus, utilizing microfluidic devices would not only eliminate mechanical/biological stress on gametes and embryos, but would also remove potential human error. Finally, microfluidic devices would permit gametes and embryos to grow in dynamic microenvironments that more closely imitate the in vivo development environment, with automatic experimental manipulations. Numerous interdisciplinary groups are actively researching the potential benefits of microfluidic gamete/embryo manipulation and culture.

20.2 State-of-the-Art Research of Microfluidics and ART in Rodents, Domestic Animals, Nonhuman Primates, and Humans

20.2.1 Microfluidics for Male Gametes

20.2.1.1 Microfluidics for Semen Analysis

Despite multiple and evolving approaches to evaluating and diagnosing male factor infertility, routine semen analysis is often the first and most important test performed. Total concentration and motile percentage of spermatozoa are two major factors to be addressed in semen quality assessment. When comparing ejaculates, significant trends are apparent in relation to total sperm concentrations, motile sperm percentages, and morphologies between fertile and infertile males [13]. Throughout the current decade, the microfluidic technologies have been evaluated in the clinical context, including human semen analysis [14–17].

As sperm are motile cells capable of forward movement, microchannel devices may offer a qualitative assessment of sperm motility and ability to separate motile sperm from nonmotile sperm [14], and they also enable quantification of the motile sperm content of human ejaculates. These devices can also couple microfluidic engineering with fluorescence labeling of live sperm and use a microfluorometer to quantify motile sperm [17, 18]. A novel technology was presented, in which the device is lightweight and disposable, making it appropriate for testing human ejaculate outside of the clinical laboratory. The addition of fluorescence labeling of sperm and a microfluorometer to the microfluidic design described has enabled quantification of the motile sperm component of a semen specimen; the signal recorded by the microfluorometer is hypothesized to correlate with the motile concentration of a given semen sample. Other components of the ejaculate, including dead, immotile, or nonsperm cells, or particulate matter, cannot contribute to the signal. Results demonstrated a significant correlation of signal strength with various computer-assisted semen analysis (CASA) parameters, including total and progressive motile sperm concentration, as well as sperm concentration. This microfluidic device was small and fully integrated, and it may find application outside of the traditional laboratory setting, perhaps further opening the door to reliable male subfertility screening at home.

Another configuration of the microfluidic device for assessing the total number of sperm and the percentage of motile sperm is based on the principles of the sperm's random swimming and sedimentation [19]. This platform can also provide information about numbers of motile and immotile sperm, thus assessing both total sperm concentration and motile sperm percentage simultaneously. This microfluidic device is suitable for sperm quality analysis without the aid of expensive microscopes.

Lastly, and very promising, there is a microfluidic device that can discriminate between normal, apoptotic, and necrotic cells without any labeling [20]. This is quite interesting in that apoptosis is directly related to subsequent DNA fragmentation. While not yet reported to have been applied to semen or washed sperm, if feasible, this device has the potential to separate the different sperm population subtypes. Isolating normal from apoptotic spermatozoa has the potential for increasing not only in vivo and in vitro fertilization rates but also ongoing pregnancy rates.

20.2.1.2 Microfluidics for Sperm Functional Tests

Semen analysis is often the first step performed to investigate semen quality. Good semen analysis results do not always imply that the spermatozoa are functioning properly. To further investigate the ability of spermatozoa to fertilize an oocyte, sperm function tests have been established [21–23]. Several sperm function tests exist today, which can be divided into tests that investigate the functioning of the spermatozoa directly by interaction assays and indirectly by biochemical

assays [24, 25]. For example, sperm characteristics such as the acrosome state and DNA integrity have shown significant impact on ART outcome [26, 27].

Advanced sperm selection techniques focus on additional sperm characteristics such as DNA integrity, apoptosis, membrane maturation, and ultramorphology. Ideally, ART procedures are performed using viable, morphologically normal spermatozoa with a high DNA integrity and intact plasma and acrosomal membranes. Especially, ICSI treatments are dependent on accurate selection, since only one spermatozoon is used during each procedure. However, most selection procedures and sperm quality-related studies rely on population-based approaches, which are not applicable (yet) on the single-cell level. The lack of comprehensive single-cell information could explain why sperm selection based on functional characteristics, which showed correlation with fertilization potential in population-based studies, fails to achieve clinical relevance in ART procedures. Wagenaar and his colleagues report the design of a simple polydimethylsiloxane (PDMS) microfluidic platform in which sperm cells were entrapped noninvasively by hydrodynamics [28]. Sperm characteristics such as the cell viability, the acrosome state, and chromosomal content were studied on individual entrapped sperm cells. This platform allows (noninvasive) analysis on the single-cell level and has the potential to be a versatile tool for selection applications or fundamental studies on spermatozoa. However, the current analysis techniques depend on the use of fluorescent labels, which limits the use of entrapped sperm cells after analysis. Therefore, future single-cell analysis must be performed label-free and noninvasively to retain good sperm quality for ART applications after analysis.

20.2.1.3 Microfluidics for Sperm Sorting

One in six couples of reproductive age worldwide is affected by some form of infertility, and male factor plays a role in approximately 50% of the cases of subfertile couples [29, 30]. Various disorders caused by spermatogenesis abnormalities, hormonal disturbances, and physical and psychological problems can cause male factor infertility. However, in the clinical context, it is often difficult to determine the etiology for each individual, although infertile male patients can have low sperm production and poor sperm quality. Assisted reproductive technologies provide a set of powerful techniques to assist couples facing infertility issues. Intracytoplasmic sperm injection (ICSI) is a method, which currently serves as the standard for managing male-factor infertility, that can increase fertilization rates compared to other technologies [31, 32]. Intracytoplasmic sperm injection enables fertilization of an egg with one sperm selected from ejaculated/surgically retrieved spermatozoa. Therefore, sperm quality parameters, including motility, morphology, viability, DNA integrity, apoptosis, and maturity, are important determinants of successful ICSI and ART outcomes [33–35].

The ICSI procedure starts with adding a fraction of the sperm suspension to a mineral oil-covered microdroplet [36], then the sperm to be injected is selected within a microinjection pipette. Sperm selection during the ICSI procedure can be a laborious and time-consuming process. Selection of sperm with good quality is crucial to successful ICSI because fertilization of the oocyte, and ultimately a viable birth, depends largely on sperm viability [37]. Thus, technologies to facilitate identification and selection of healthy sperm can greatly improve the success rate of ICSI, IVF, and other ARTs.

Selection of appropriate sperm for IVF and ICSI is generally based on sperm motility, because motile sperm are viable sperm. The swim-up and density gradient-based centrifugation methods are major traditional sperm-selection techniques [38, 39]. The swim-up method enables separation of motile sperm from nonmotile sperm and semen; however, the technique can be problematic in regard to low yield of motile sperm. The density gradient-based centrifugation can select sperm based on their density; however, density gradient centrifugation has also been shown to potentially have negative effects on sperm viability and give rise to sperm DNA fragmentation [40]. Moreover, these traditional methodologies are less useful for samples with low sperm counts and/or reduced sperm motility [41, 42]. Thus, the limits of traditional methodologies present an opportunity for developing new methods of sperm selection.

The advent of novel micro- and nanodevices presents promising solutions to a wide range of clinical problems. Recently, studies have employed microfluidics to sperm sorting, representing significant progress for improving ART [14]. One of the advantages of utilizing microfluidic devices in ARTs is one-step sorting without the need for centrifugation. Eliminating the centrifugation step minimizes the exposure of sperm to reactive oxygen species (ROS) and further DNA fragmentation [43]. Inspired by in vivo natural sperm sorting mechanisms where vaginal mucus becomes less viscous to form microchannels to guide sperm toward the egg, a microfluidic device was presented that efficiently sorts healthy, motile, and morphologically normal sperm without centrifugation [44]. The design consists of a single channel and a retrieval chamber with a polycarbonate membrane filter (Fig. 20.1). This method resulted in a higher percentage of sorted sperm with retained DNA integrity and fewer reactive oxygen species compared to samples sorted using the conventional swim-up method. Lately, a clinically applicable microfluidic device was described that isolates sperm based on the progressive motility in 500 parallel microchannels and represents a one-step procedure for sperm selection with high motility and high DNA integrity sperm [45]. This device could process up to 1 ml of semen. These types of device improvements and multiscaling are positive steps forward and will yield microfluidic devices that are more likely to find acceptance in clinical laboratories of the future.

20.2.2 Microfluidics for Female Gametes

20.2.2.1 Oocyte In Vitro Maturation (IVM)

Among the various steps of gamete manipulation in ARTs, selecting the best oocyte is considered to depend on subjective criteria. It is generally the result of visual estimations of morphological properties of the oocyte itself and surrounding cumulus cells. Application of the microfluidic system in reproductive biology opens new possibilities for the development of

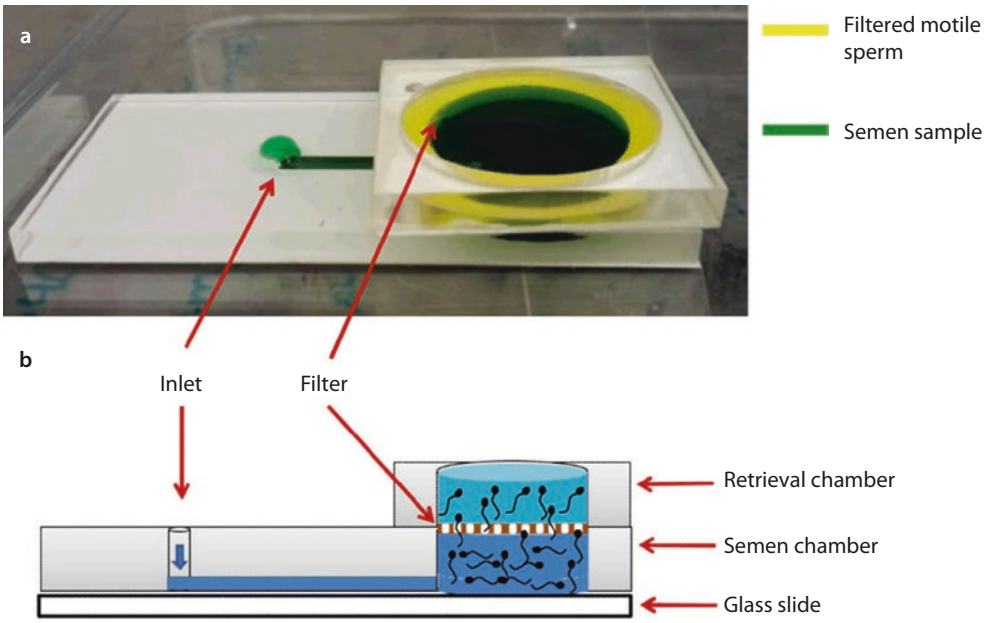

Fig. 20.1 Schematic of macro-microfluidic sperm sorter (MSS) for selection of functional human sperm with higher DNA integrity and fewer reactive oxygen species [44]. **a** The photo of the MSS showing inlet, filter, and two polymethylmethacrylate (PMMA) chambers. techniques available for the assessment of developmental competency manifested by mammalian oocytes and embryos.

While most human ART procedures currently use in vivo matured oocytes, the potential benefits of human oocyte in vitro maturation (IVM) have been appreciated for decades [46–49]. Human oocyte IVM is a technique in human ARTs that has drawn much attention due to its extremely low cost and reduction of ART-associated disorders such as ovarian hyperstimulation syndrome (OHSS) [50]. Oocyte maturation is a complex coordination of cytoplasmic maturation and nuclear maturation that occur in a synchronized manner to embrace successful fertilization. In vivo, mammalian oocytes acquire cytoplasmic maturity and the competence to resume meiosis during follicle and oocyte growth. Thus, proper maturation of the oocyte to metaphase II is a prerequisite for fertilization and preimplantation development. It has been hypothesized that the microfluidic environment may more closely resemble oocyte maturation and/or embryo development conditions in vivo compared to the static microenvironment in a microdrop [51]. Therefore, in the last few decades, much effort has been devoted to improve oocyte maturation. Walters and colleagues demonstrated that porcine oocytes matured in microchannels could achieve the same nuclear maturation as those matured in microdrop. The microchannel has also been used to culture porcine embryos, which resulted in the birth of normal piglets [52]. Hester and coworkers subsequently found that the blastocyst development rate was better when oocyte IVM was performed in microchannels compared to standard static procedures [53]. In 2011, Yuan and colleagues compared two different types of microchannel; each one of these had a subgroup: static or rocking. This study demonstrated the microfluidic well system can successfully mature oocytes individually without compromising oocyte quality or subsequent blastocyst formation after IVF [54]. In 2015, Siavash and colleagues reported a microfluidic device that integrated oocyte trapping and maturation. The device was constructed using standard soft lithography techniques in a way that oocytes were individually monitored and tracked in the devices during their maturation [55]. These studies showed that microfluidic devices have the potential for efficient and healthy culturing and maturation of oocytes.

20.2.2.2 Oocyte Cumulus Cell Removal

Researchers have attempted to develop microfluidic technology for other important procedures during oocyte manipulation, such as cumulus cell removal and/or zona pellucida removal. Cumulus removal is a routinely necessary operation before human oocyte ICSI [56]. There are two conventional methods used to remove the cumulus cells: mechanically by vortexing (in domestic animal IVP) [57] or pipetting with hyaluronidase exposure (human ART) [58]. Microfluidic devices have been adapted to perform cumulus removal. Zeringue and colleagues began studies of microfluidics for cumulus cell removal by identifying optimal device designs and materials for cumulus removal in 2000 [59]. Utilizing fluid flow driven manually via attached syringes, exposing oocytes to chemical and physical manipulation, cumulus cells were removed from bovine oocytes after IVF. Following these pioneering experiments, Zeringue and coworkers further explored the impact of two cumulus cell removal techniques on embryo production: traditional (vortexing or chemically) versus a microchannel device [60]. Results suggested that microfluidics could effectively alleviate the pressure imposed on oocytes during the cumulus removal procedure.

20.2.3 Microfluidics for In Vitro Insemination

20.2.3.1 Microfluidics for Conventional In Vitro Insemination

Following successful isolation of gametes, the next procedure is in vitro insemination. The process of in vitro insemination involves coincubation of oocytes with an appropriate number of

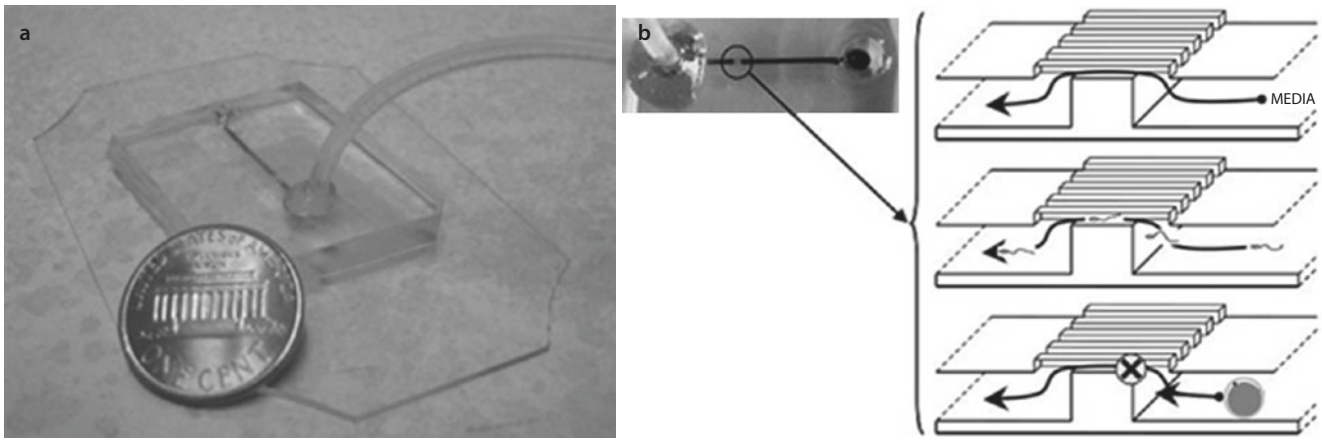

Fig. 20.2 A modified microfluidic platform used to perform fertilization of mouse oocytes [61]. **a** Actual device size in comparison to a US penny. Microchannel was filled with blue dye. **b** Schematic angle view. The three-dimensional construct of the channel prevents movement of the oocyte beyond the grate, but allows for flow of medium and sperm through the channel

motile sperm in an easily controllable and physiologically suitable environment. Present IVF techniques basically utilize culture dishes, culture tubes, or microdrops covered by mineral oil to provide a proper sperm concentration for in vitro insemination; the total number of sperm needed for fertilization is dependent on system volume. Media volumes may range from 20 μl to 1 ml [61]. Such techniques sometimes are inadequate for conventional insemination in an IVF cycle. Alternatively, ICSI is a complementary treatment of male factor infertility [62, 63].

Microfluidics may be particularly suitable to conventional insemination in IVF cycles, for a number of reasons. Firstly, the microenvironment of a microchannel more closely mimics in vivo fertilization microenvironment than a culture dish or microdrop. Secondly, the application of microfluidic channels allows for nonturbulent bathing of gametes with fresh media throughout insemination and coincubation. Sperm-oocyte interactions occur in such an active environment, rather than the static conditions present in a culture dish or droplet. In addition, via laminar flow, microfluidics may enable a more predictable delivery of sperm to oocytes during IVF comparing with the random interaction between sperm and oocyte in a culture dish. Lastly, conventional in vitro insemination requires a high number of sperm, which then deplete metabolic substrates and produce potentially harmful waste products in the IVF media; microchannel environments utilize extremely small volumes of media, theoretically achieving insemination concentrations with fewer sperm compared to standard IVF with larger concentrations and volumes. Several microfluidic systems have been developed for in vitro insemination [64, 65]. Suh and colleagues demonstrated successful in vitro fertilization of mouse oocytes with a polydimethylsiloxane (PDMS) microfluidic device which consisted of a series of open slots within a microchannel [61] (Fig. 20.2). Han and colleagues reported a novel microwell-structured microfluidic device that integrates single oocyte trapping, in vitro fertilization, and subsequent embryo culture [61]. This device achieved similar fertilization rates to standard oil-covered drops in Petri dishes while simplifying oocyte handling and manipulation.

20.2.3.2 Microfluidics for Intracytoplasmic Sperm Injection Insemination (ICSI)

Recently, a paper evaluated using microfluidics for ICSI [66]. Matsuura and colleagues demonstrated microfluidics could be used for the porcine ICSI process, which reduced time for manipulation procedures. These proof-of-concept studies in animal models are the beginning. Wagenaar and his colleagues designed a simple PDMS microfluidic platform in which sperm cells were entrapped noninvasively by hydrodynamics [28]. Sperm characteristics such as the cell viability, the acrosome state, and chromosomal content were studied on individual entrapped sperm cells. This platform allows noninvasive analysis at the single-cell level and has the potential to be a versatile tool for selection applications or fundamental studies on spermatozoa. With single sperm trapped and analyzed, it shows promise for single sperm manipulation in ICSI. While human ICSI is widely used, and highly successful, the multiple highly technical steps are labor-intensive and time-consuming, which can lead to human error and individual technician variability. If integration of microfluidics to insemination in conventional IVF and/or ICSI can reduce laboratory human error or variability, and/or reduce the cost while maintaining similar or improved results, microfluidics may have practical utility in future ICSI protocols.

20.2.4 Microfluidics for Embryo Culture

Culture of preimplantation embryos is widely employed every day in IVF centers and consists of one of the key steps in ART protocols. Although it has been used in clinics since the 1970s, protocols for the culture of human preimplantation embryos are neither standardized nor optimized. Current human fertilization in vitro circumvents the female oviduct and manually inseminates, fertilizes, and cultivates embryos in a static fluid environment containing appropriate compounds.

The in vitro environment is important when considering that embryos are held in media for up to 7 days. Standard in vitro protocols use one or two media during embryo culture [67]. This is in contrast to the in vivo situation in which embryos grow in fluid (medium) with a constantly changing environment as they move through the oviduct to the uterus. Some metabolites necessary during one phase of development may not be needed during other stages [67, 68]. One of the first dynamic embryo culture systems was the formulation of sequential media, where each phase of embryo development had specific substrate concentrations [69]. The disadvantages of these systems are the number of times that the operator has to handle embryos, the volume of media, and the potential reduction of positive effects of embryo trophic factors [70]. In such a scenario, microfluidic embryo culture devices may be a better method to deliver sequential media in a dynamic situation. A microfluidic/microchannel system for embryo culture may provide an improved in vivo-mimicking environment to enhance the in vitro development of embryos in the laboratory.

Compared with static fluid environments, microfluidics has the following potential advantages: (1) dynamic culture microenvironment, (2) reduced culture volume, (3) precise control over culture environment, and (4) decreased embryo manipulation, alleviating the stress imposed on embryos.

Thus far, there have been encouraging outcomes with microfluidic embryo culture technology. Several articles have discussed the potential applications and advantages of dynamic environments for embryo culture obtained with microfluidics. The first embryo culture microfluidic device laid the foundation for application with the demonstration of improved blastocyst development, higher survival rates, and fewer degenerated embryos compared to control microdrop culture [71]. This study employed static microchannel culture, allowing for a direct comparison with static microdrop systems. The improved developmental outcome was presumably due to the lower volume and the embryo's enhanced ability to regulate its microenvironment with paracrine and/or autocrine factors. Although the addition of flow conditions is more similar to in vivo environments of embryo culture, it was discovered that simple continuous media perfusion within a microchannel during embryo development was detrimental to embryo development across a range of flow rates accessed [69]. Multiple reasons may relate to these poor outcomes, but principal reasons may be a loss of paracrine and autocrine factors and the inability of embryo self-regulation of its microenvironment due to poor fluid movement control in the microfluidic device.

Subsequently, Dr. Takayama and colleagues reported on a computer-controlled microfluidic platform using vertically moving Braille pins to facilitate integrated pumping of channel-contained fluids through localized deformation of channels made of elastic compounds [72]. This provided a way to precisely regulate fluid flow in microchannels with computer programming, which could be applied to embryo culture platforms. Microfluidic devices allow nano- to microliter volumes of fluids to realize precise and dynamic control of the cell culturing environment. However, evaporation can be especially detrimental to cell/embryo culture in microfluidic chips, where even the slightest amount of evaporation from the small liquid volumes present in microfluidic systems would result in a significant increase in osmolality [73]. Heo and colleagues came up with a solution of evaporation-mediated osmolality shifts with application of a PDMS-parylene-PDMS hybrid membrane. This PDMS-parylene-PDMS hybrid membrane not only greatly suppressed evaporation and osmolality shifts but also possessed the thinness and flexibility necessary to interface with deformation-based microfluidic actuation systems [73]. In addition, it maintained the clarity for optical microscopy and enabled the successful development of single-cell mouse embryos into blastocysts under static conditions, as well as the culture of human endothelial cells under dynamic recirculation of submicroliter volumes of media. These findings shed light on how to overcome evaporation-associated effects in microfluidic cell/embryo cultures.

Afterward, Heo and colleagues developed a dynamic microfunnel embryo culture system that cultured mouse embryos with media refresh in a physiologically pulsatile manner. Compared with embryos cultured in static microdrops and microfunnels, the mouse embryos subjected to microfunnel pulsatile culture had significantly higher number of blastomeres per blastocyst. More importantly, dynamic microfunnel culture significantly improved embryo implantation rates and ongoing pregnancy rates over static culture to levels approaching that of in utero-derived preimplantation embryos [51].

In 2010, Han and colleagues reported an integrated microfluidic device that performed single oocyte trapping, fertilization, and embryo culture of the IVF process [65]. In 2015, Huang and colleagues demonstrated a novel digitalized microfluidic device powered with electrowetting on a dielectric (EWOD). This device cultured an embryo, in a single droplet, in a microfluidic environment to mimic the in vivo environment of embryo development. Embryos developed well and resulted in live births [74]. These results show that the dynamic culture powered with EWOD can manipulate a single droplet containing one mouse embryo and can support culture to the blastocyst stage. Esteves and colleagues also reported that mouse preimplantation embryos could be cultured in microfluidics and studied the impact of fluid flow, embryo density, and media volume [75]. Kieslinger and colleagues have demonstrated that human embryos can be grown in microfluidic devices [76]. These encouraging studies validate the potential for microfluidics being a powerful tool for science research and potentially having clinical applications in the future.

20.2.5 Microfluidics for Embryo Selection

20.2.5.1 Metabolomics

With the application of microfluidics, the ability to culture embryos in very small volumes provides opportunities for research on critical molecular mechanisms of gametogenesis and early embryo development. The ability to automatically

sample and potentially even test small volumes of medium from multiple locations in the device would be critical to permit analyses of embryo metabolism, protein production, viability markers, and other cellular processes during real-time culture of a live oocyte or embryo.

Over time, significant data have accumulated to demonstrate the metabolism of oocytes and preimplantation embryos (mainly) to be a critical functional parameter measured [77–80]. Metabolic biomarkers, including specific pathway substrates (carbohydrates or amino acids, oxygen) and products (ammonium, carbon dioxide, lactate), may provide insight into oocyte/embryo developmental potential. In relation to energy metabolism, it has been demonstrated that noninvasive means of measuring glucose consumption from culture media and lactate production and release into media, as an estimate of embryo glycolytic activity, can be useful in the selection of qualified human embryos [80, 81]. Yet these measurements can be very laborious and not conducive to application in the clinical laboratory workflow.

Concepts of indirect analysis of single embryo health, based on media nutrient level changes, have significant potential as functional assays. To date, there have been at least three reports using microfluidics to perform noninvasive measures of embryo metabolomics. In 2006, O'Donovan and coworkers developed a respirometric microfluidic cartridge to monitor oxygen consumption of two-cell and blastocyst stage mouse embryos [77]. In 2008, Urbanski and colleagues performed proof-of-concept experiments to demonstrate the use of microfluidics to measure embryo metabolism [82]. They designed and tested a microfluidic chip that performed automated metabolic assays to measure glucose, pyruvate, and lactate from submicroliter volumes. In 2012, an automated computer-controlled microfluidic platform for both embryo culture and metabolic analysis on a single integrated device was reported; this system was able to measure time-dependent nutrient consumption by single or multiple (10) live mouse blastocyst-stage embryos, at 20-minute intervals, in real time, with high sensitivity [83].

20.2.5.2 Proteomics/Secretome

The proteome is estimated to consist of over a million proteins, and being derived from the transcriptome, is responsible for cell identity and cell function [84]. Proteomics may be a useful metric on which to base decisions regarding which embryo has the highest developmental potential. Whereas the analysis of the proteome requires cellular extraction and precipitation steps, followed by fractionation (e.g., electrophoretic, chromatographic) and detection (spectroscopic, fluorometric), it is feasible to noninvasively analyze a large number of proteins and peptides secreted by an individual human embryo, the secretome, by sampling the surrounding culture medium [85]. Analysis of the secretome bypasses these earlier preparatory steps, but remains an indirect biomarker of oocyte or embryo physiology. Katz-Jaffe and coworkers identified an 8.5-kDa protein whose abundance increased only in the secretome of developing blastocysts, indicating a potential relationship between this protein and developmental potential [86]. Such analyses can be done without microfluidics, yet integration of microfluidic platforms may be advantageous.

Microfluidic devices are ideally suited to profiling single blastocyst secretomes in culture media, and could easily accommodate cell lysates as well (if desired). Proof-of-concept microfluidic devices have been employed for on-chip cell lysis and protein digestion, ELISA, and protein mass spectroscopy [87, 88]. These microfluidic devices could efficiently analyze proteomics at very high sensitivity [89]. However, at present there are no commercially available microfluidic devices demonstrated for detecting oocyte or embryo biomarkers based on secretome differences. There is also still a lag in clinical translation of assays of specific protein candidates that have reported correlation to embryo implantation potential. Therefore, a combination of proteomic with genomic assays in a microfluidic device may lead to the next "proteogenomic" revolution for embryo diagnostics.

20.2.5.3 Transcriptomics

Complementary to proteomics analysis, single-cell transcriptome sequencing is a high-throughput tool for quantifying gene expression heterogeneity in populations of cells [90]. Since the first single-cell transcriptome sequencing (RNA-seq) was presented by Tang, many techniques have developed to perform RNA-seq on individual cells. For convenience, the molecular approaches applied in genomics, methylomics, and transcriptomics described can be summarized into four main steps: (1) cell lysis or fractionation, (2) DNA and/or RNA purification, (3) amplification, and (4) sequencing. Recently, Aaron and colleagues adapted a previously developed strategy for single-cell RNA-seq that has shown promise for superior sensitivity and implemented the chemistry in a microfluidic platform for single-cell whole-transcriptome analysis [91]. In this approach, single cells are captured and lysed within the closed microfluidic device, where mRNAs with poly(A) tails are reverse-transcribed into cDNA. Subsequently, double-stranded cDNA is collected without potential contamination. Microfluidics provides a more precise and sensitive method compared to conventional tube-based protocols. With 0.2 M reads per cell, it's capable of reconstructing a majority of the bulk transcriptome with 10 single cells; this feature makes large-scale single-cell gene expression profiling possible. Whether this technology could find application in human ART or testing of oocyte and/or embryo developmental competencies remains to be demonstrated.

20.2.5.4 Genomics

Whole-genome amplification (WGA) for next-generation sequencing has seen wide applications in biology and medicine when characterization of the genome of a single cell or few cells is required [92]. Single-cell sequencing characterizes the genome of individual cells, which is suitable for embryology to deduce information from an embryo. Microfluidics-based systems can be used to detect copy number variations (CNVs) in DNA samples derived from embryos or other cell types.

The WGA uniformity is critical for CNV detection, whereas the WGA accuracy is essential for avoiding SNV (single-nucleotide variation) detection errors, either false positives or false negatives [93]. Fu and colleagues reported a new method, emulsion whole-genome amplification (eWGA), to use the small volume of aqueous droplets in oil to improve the WGA chemistry for uniform amplification of a single cell's genome [94]. By distributing single-cell genomic DNA fragments into a large number of droplets, a few DNA fragments in each droplet are allowed to reach saturation of DNA amplification. They compared normal diploid human cells with a monoclonal human cancer cell line having inherited CNVs. The results validated that eWGA not only offered higher coverage, but also enabled simultaneous detection of SNVs and CNVs with higher accuracy. The application and integration of a microfluidic platform for gamete/embryo culture and genomic analysis has the potential to reduce molecular and operator error, but is yet to be realized. Demonstration of proof-of-concept utility of microfluidic genomic analysis in clinical ART is wanting.

20.2.5.5 Methylomics

DNA methylation is an epigenetic modification essential for normal development and maintenance of biological functions, such as gene repression, parental imprinting, X-chromosome inactivation, and suppression of repetitive genomic elements. Chemical base modification in DNA by DNA methyltransferase, specifically methylation, has been well studied as an important mechanism of epigenetics. DNA methylation is a crucial element in the epigenetic regulation of mammalian embryonic development [95]. Therefore, the determination of DNA methylation of, for example, 5′-methylcytosine in the CpG sequence in mammals has attracted attention [96, 97]. Furthermore, microfluidic technology can be applied to DNA methylation analysis because the microfluidic platform offers the advantage of making it possible to perform thousands of DNA methylation reactions in small reaction volumes, resulting in a high-throughput analysis with high sensitivity. Recently, Ronen and colleagues reported on a universal, high-throughput, microfluidic-based fluorometric assay for studying DNA methylation in vitro, utilizing methylation-sensitive endonuclease digestion of DNA substrate probes [98]. Coupling this assay with a high-throughput microfluidic platform may open new horizons for epigenetic research and even lead to novel therapies to reverse aberrant methylation patterns responsible for aberrant development and/or diseases. The microfluidic approach can provide an advantageous approach to determining DNA methylation, and epigenomic information, because of its rapid and efficient processes.

20.2.6 Microfluidics for Cryopreservation

20.2.6.1 Slow-Rate Freezing/Thawing and Vitrification/Warming

Since the first live birth from human embryo cryopreservation three decades ago [99], cryopreservation has become an important component of ARTs. Cryopreservation techniques have evolved, leading to higher success rates and the introduction of oocyte, sperm, zygotes, and embryo cryopreservation into IVF clinics worldwide. Cryopreservation of oocytes, zygotes, and embryos has significantly expanded the scope of infertility treatment. There are two basic techniques applied to the cryopreservation of human oocytes: slow-rate freezing and ultra-rapid cooling by vitrification. These techniques have been compared and discussed extensively as indicated in the following reviews [99–101].

Independent of the technique used for cryopreservation, minimizing cell damage throughout the cryopreservation process is critical to enhancing the overall outcome. Osmotic shock sustained during the loading and unloading of cryoprotectant agents (CPAs) is a major source of cell damage during the cryopreservation process. A microfluidic approach may allow greater precision in CPA exposure and reduced osmotic shock to cells during cryopreservation. Cryoprotectant agents are necessary to eliminate formation of damaging intracellular ice crystals, yet CPA exchange procedures exert osmotic stress. Osmotic stress refers to the stress experienced by cells due to changes in osmotic pressure within and outside the cell. While lethal osmotic stress during vitrification and warming has largely been overcome (high cryosurvival rates), sublethal effects remain and affect oocyte function, embryo development, and treatment outcomes. Osmotic stress is especially a challenge for oocyte and zygote cryopreservation because their fluid volumes, which need to be exchanged with CPAs, are several orders of magnitude larger than other mammalian cells. In addition, the high concentration of CPAs used in vitrification can also be problematic in relation to sublethal osmotic stress [101]. Initial work using microfluidics and cryopreservation was focused on freezing of HepG2 cells and demonstrated benefit in cell survival [102]. Song and his colleagues developed a microfluidic approach to control the loading and unloading of CPAs using diffusion and laminar flow. This microfluidic approach minimized the osmotic shock during the CPA loading phase before freezing and the CPA unloading phase after thawing. The device possesses a long microfluidic channel with three inputs and one outlet, which offers a long distance to develop a complete diffusion along the channel (Fig. 20.3). By changing injection flow rates at the inlets, the diffusion pattern along the microfluidic channels could be controlled. This microfluidic approach, using diffusion phenomena, yields concave and convex CPA concentration profiles along the channel during loading and unloading steps, respectively. The novel microfluidic-based approach improved post-thaw cell survivability by up to 25% on average over conventional cryopreservation protocols. The method developed in this study provided a platform to cryopreserve cells with higher viability and functionality and minimal intertechnician variability.

Recent studies on mature human oocyte cryopreservation demonstrated that vitrification has enhanced outcomes in terms of higher survival rates, cleavage, and pregnancy rates compared to its slow-rate freezing alternative [103]. The osmotic fluid control provided by microfluidics gives an

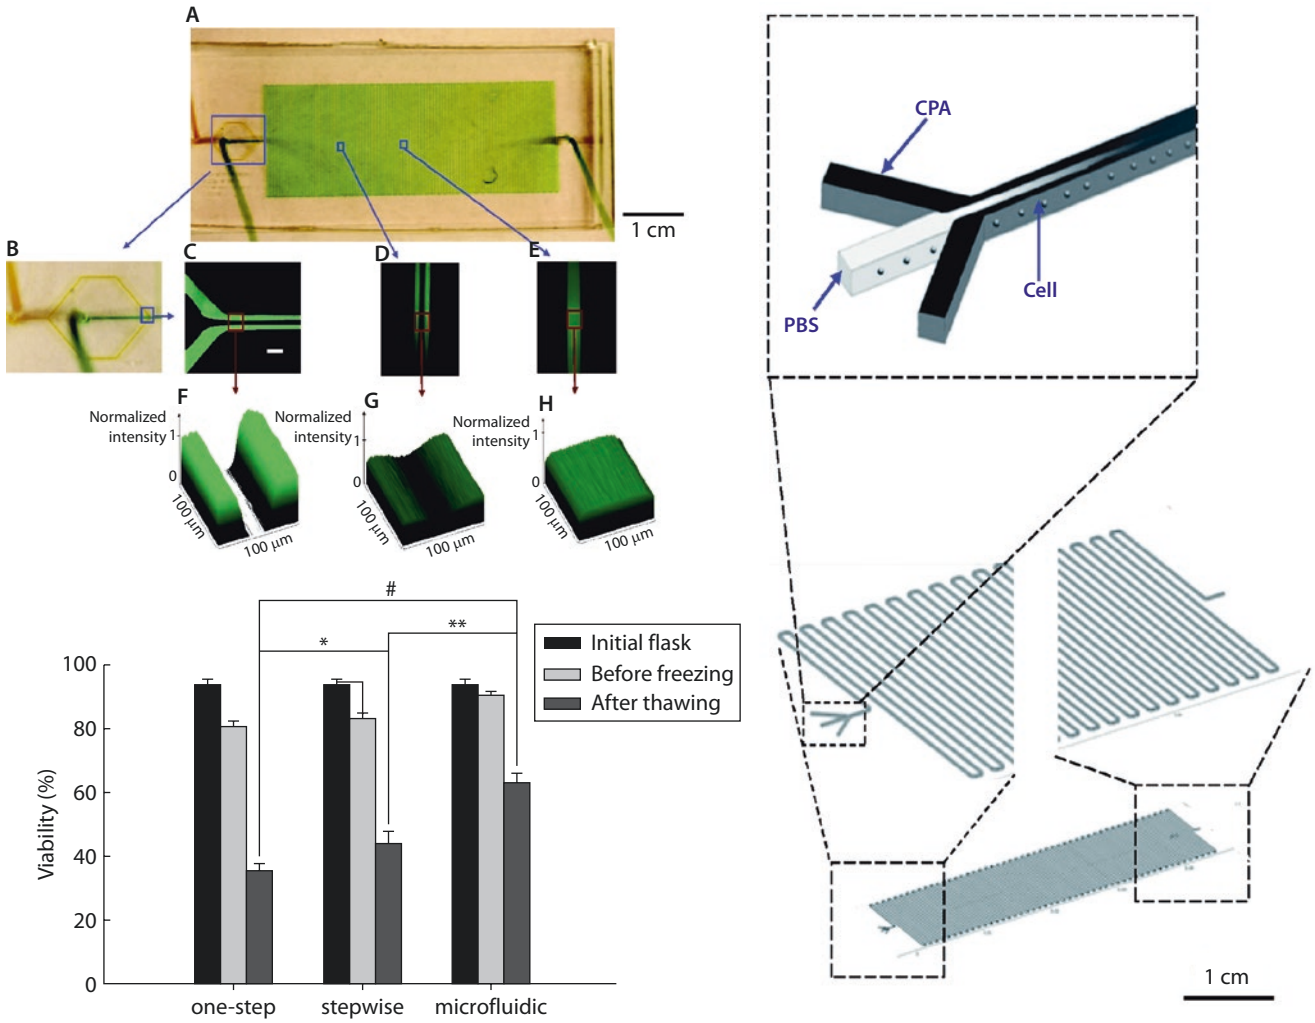

Fig. 20.3 Device structure and increased viability achieved by osmotic shock reducing during cryopreservation process [102]. Increased viability is achieved by reducing osmotic shock during cryopreservation process through gradual exposure of CPA concentration to the cells

unprecedented level of precision and osmolality control not available with manual pipetting. This is particularly important in vitrification, where higher concentrations of cryoprotectant agents (CPAs) are used. In an effort to lower the osmotic stress the cells experience, a protocol for fluid exchange was developed that moves solution over cells at increasing concentrations of CPAs to lessen the osmotic change. A minimum osmotic stress cryo-exchange profile made possible by microfluidics demonstrated that minimizing osmotic stress improved embryo development in comparison to manual pipetting vitrification protocols. Microfluidics provided the capability of continuous perfusion, essentially an infinite amount of steps, and is capable of providing real-time and continuous optical microscopy and lab-on-a-chip automation for reproducibility by eliminating operator variability. Osmotic stress was accurately predicted using computer modeling by Kedem-Katchalsky equations and known permeability parameters [104]. Recently, another microfluidic device using both permeable and impermeable solutes was designed to further confirm the remarkable accuracy of the Kedem-Katchalsky equations to model osmotic stress of oocytes and zygotes for vitrification. By using a combination of both permeable and impermeable solutes, the device was capable of controlling the shrinkage rate of the cell independent of its minimum cell volume. The study demonstrated the importance of the shrinkage rate and its effect on sublethal damages [105]. The minimization of the shrinkage rate had no effect on the cryosurvival of murine zygotes, as both manual and microfluidic CPA exposure had 100% cryosurvival. The shrinkage rate, however, did have an effect on sublethal damages. The lowering of the shrinkage rate, and therefore sublethal damage, significantly increased the developmental competence of cryopreserved murine zygotes. This study is the first to experimentally and mathematically separate the effects of the shrinkage rate from minimum shrinkage volume and the first to demonstrate reduced sublethal cell damage to zygotes with microfluidic-exchanged CPA, which resulted in improved subsequent embryo development. Studies evaluating microfluidics for thawing or warming gametes, zygotes, or embryos are still necessary to evaluate the final practical utility of microfluidics in cryopreservation.

20.2.7 Future Investigative Needs and Integration and Automation of Microfluidics

Assisted reproductive technologies have been evolving for the last several decades as a combination of assisted reproduction, cellular/molecular biology, and genomic techniques. To date, most research using microfluidics in ART has only focused on a single component of the entire IVF system, for example, sperm selection, oocyte maturation, embryo culture, fertilization, or cumulus removal. There is considerable enthusiasm about the potential applications of the microfluidic platform for assisted reproduction, as many of the important functions necessary for IVF have already been demonstrated. Indeed, only a few examples have integrated more than one step in the IVF process [65]. These results provided evidence that all phases of the IVF process could be integrated on a single microfluidic platform. A goal of microfluidic integration of all phases of IVF, in a stepwise fashion, into a singular self-contained device should be achievable. To be successful, integration must accommodate multiple concerns, such as the size difference of an expanded cumulus-oocyte complex versus a denuded zygote, the removal of cumulus cells, movement of spermatozoa in specific channel designs to optimize fertilization during coincubation with the oocyte, blastocyst expansion, and even hatching. In addition, microfluidic devices should provide medium at the optimal time, place, and flow rate to minimize gamete/embryo handling and improve outcomes. The act of microfluidic automation, in and of itself, may prove beneficial in removing potential human error and subjectivity, while at the same time providing a more biomimetic environment for improving human embryo development, pregnancy outcomes, and offspring health.

20.3 Conclusion

Application of microfluidic devices in ARTs has been shown to improve manipulation processes and developmental efficiencies. Such improvements will lead to lower costs, increased access, and decreased physical stress on gametes and embryos. Microfluidics allows oocytes and embryos to be handled in a more precise and gentler manner than traditional pipetting techniques. Instead of moving embryos from one microdrop to another, the embryo can be moved into a specified location and "parked." Then different media (maturation, fertilization, and/or embryo culture) can be moved to the embryo in either a static or dynamic flow paradigm. These media changes can be achieved gradually, reducing environmental stress on the gamete and/or embryo. Furthermore, microfluidic devices can contain much smaller volumes of media than traditional microdrop culture systems allowing the addition of expensive growth factors (if desired and warranted) at a fraction of the cost of microdrop systems. In addition to providing a more in vivo-like culture environment, microfluidic technology is ideally suited for complex embryo manipulations, such as removal of the cumulus cells, ICSI, embryo biopsy, and integration with bioassays that may evaluate genomic, transcriptomic, proteomic, and methylomic normalcy.

Although the full potential of microfluidic technology has yet to be realized for assisted reproduction, there have been many exciting developments and demonstrations of different aspects of IVF and embryo/oocyte manipulation using microfluidic principles and devices. Microfluidic techniques provide numerous advantages for biological and biomedical research, including ease of modularity, small sample requirement, potential of automation, and high throughput. One could expect that these novel single-cell techniques on microfluidic devices will be important in numerous biomedical areas. Furthermore, it allows for development of new methods for IVF and other assisted reproductive technologies. The microfluidic platform may open many potential new avenues of investigation to improve our knowledge of basic gamete and embryo physiology. Lastly, new technologies such as 3-D printing may vastly improve our ability to develop physical systems that closely mimic the in vivo environment and enable noninvasive oocyte/embryo analysis [106]. Such breakthroughs will lead to new avenues of investigation to improve our knowledge of basic embryo physiology and translate into laboratory improvement and patient care.

Review Questions

1. What are two potential benefits of using microfluidics for embryo culture?
2. Why might one use microfluidics for sperm isolation? Specifically address a functional sperm benefit.
3. What are the benefits and limitations of using microfluidics for embryo bioanalysis?
4. Can microfluidic-controlled delivery of cryoprotectants reduce osmotic stress? If so, explain the reported advantages in cryopreservation of gametes/zygotes/embryos.

Time-Lapse Microscopy for Embryo Culture and Selection

Andrey V. Dolinko and Catherine Racowsky

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_21

Learning Objectives

- To provide an overview of time-lapse microscopy (TLM) technology
- To introduce embryo morphology and morphokinetics that can be identified with the use of TLM
- To review the literature on the use of TLM to predict blastocyst formation, implantation, and live-birth potential
- To discuss the effects of embryo, laboratory, and maternal factors on morphokinetic parameters as observed by TLM

21.1 Introduction

The first live human birth following in vitro fertilization (IVF) was achieved with insemination of a single oocyte almost 40 years ago [1]. However, in the early years of IVF, reported pregnancy rates even among good prognosis patients were as low as 6% per retrieval [2]. In an attempt to increase pregnancy rates, controlled ovarian stimulation regimens were developed, resulting in more oocytes retrieved and embryos obtained. The trickledown effect was that multiple embryos were transferred and success rates increased, with resulting pregnancy rates being as high as 30%. However, this brought high rates of multiple-gestation pregnancies, which are associated with significant risks to fetal and maternal health. Maternal complications, including preeclampsia, gestational diabetes mellitus, and preterm labor, occur two to ten times more frequently in pregnancies with multiple fetuses than singletons. In turn, perinatal morbidity is significantly increased in multiple-gestation pregnancies, resulting in low (<2500 g) and very low (<1500 g) birth weight, and preterm birth. These result in dangerous consequences, such as cerebral palsy, retinopathy, bronchopulmonary dysplasia, polycythemia, hypoglycemia, necrotizing enterocolitis, and death [3].

To avoid these complications, elective single-embryo transfer (eSET) has emerged as the most effective method for reducing assisted-reproductive technology (ART)-associated multiple births [4]. A variety of approaches have been taken to identify the most viable embryo(s) to be transferred in eSET cycles. Two of these approaches, the evaluation of embryo morphology and embryo morphokinetics, rely on the fact that the human embryo typically develops along a predictable timeline during preimplantation development. A recent entrant into the field of ART that allows for continuous evaluation of both embryo morphology and morphokinetics is time-lapse microscopy (TLM).

21.2 TLM Technology

The basic concept of TLM is the use of a digital camera to capture images of embryos at set and frequent time intervals; these images can then be played back as a time-lapse sequence to observe embryo development and to evaluate embryo morphology and the timing of various events throughout that development. The major tenant of TLM is, therefore, that a more complete picture of embryo development can be acquired compared with conventional morphology (Fig. 21.1).

A number of TLM systems have been created, including the EmbryoScope® (Vitrolife), the Primo Vision™ system (Vitrolife), Early Embryo Viability Assessment (Eeva™, Auxogyn, Inc.), the Geri™ (Genea Biomedx), and Miri TL™ (Esco). These systems differ in important ways (Table 21.1). While the EmbryoScope, Geri, and Miri TL are stand-alone combined TLM-incubator systems, both the Primo Vision and Eeva™ are TLM systems that are installed into existing incubators. Furthermore, the systems use two different lighting techniques to photograph the embryos, bright field versus dark field.

Dark-field technology creates contrast by taking advantage of light scattering and can thus only detect cytokinesis. In contrast, bright-field technology takes advantage of the embryo absorbing light to create contrast and can therefore capture both cytokinesis and the presence of nuclei and other morphological subtleties [5]. A major advantage of this is that it allows for distinguishing large fragments and blastomeres within the developing embryo (see ▶ Sect. 21.3.2.2), as well as clearly identifying other abnormalities such as the presence of multinucleation (see ▶ Sect. 21.3.2.1).

Notably, both technologies expose embryos to less light than conventional IVF techniques and most systems eliminate short wavelengths of light below 550 nm that are known to be damaging to embryo development [6, 7]. Specifically, Eeva uses a dark-field microscope with a light-emitting diode (LED) at a wavelength of 625 nm. Eeva captures images at a single focal plane every 5 min, exposing embryos to 0.032 s of light per image for a total of 114–363 mJ/cm^2 over 3 days; this is equivalent to 15–48 s on a conventional IVF micro-

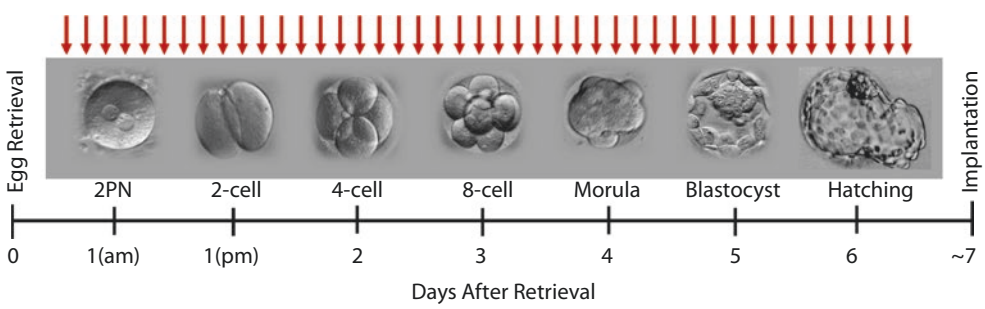

Fig. 21.1 Progression of human embryos through preimplantation development. Compared with static observations (shown by the photographic images), time-lapse microscopy allows images to be acquired at preset time intervals (red arrows; every 2–60 min), with integration into time-lapse videos and subsequent analysis

Table 21.1 Characteristics of commercially available time-lapse microscopy (TLM) systems

TLM system	Incubator type	Light source	Focal planes	Image frequency	Dish	Embryos per dish	Dishes per system	Culture type	Software
EmbryoScope®	Standalone	Bright field 635 nm	1–9	2–10 min	EmbryoSlide	12	6	Single	EmbryoViewer ± KIDScore
EmbryoScope +®	Standalone	Bright field 635 nm	11	10 min	EmbryoSlide+	16	15	Group	EmbryoViewer ± KIDScore
Eeva™	Modular	Dark field 625 nm	1	5 min	Eeva Dish	12	1	Group	Eeva Test
Geri	Standalone	Bright field long λ	1–11	5 min	Geri Culture Dish			Group	
Miri TL™	Standalone	Bright field 635 nm	3–7	5 min	Individual or Communal Reservoir CultureCoin	14 14	6 6	Single Group	Miri TL Software + Assist
Primo Vision EVO	Modular	Bright field 550 nm	3–11	5–60 min	Primo Vision Microwell Group Culture Dishes	9–16	1	Group	Primo Vision Software
Primo Vision EVO+	Modular	Bright field 590 nm	3–11	10–60 min	Primo Vision Microwell Group Culture Dishes	9–16	1	Group	Primo Vision Software

scope [8]. In contrast, the EmbryoScope uses a bright-field system with a single LED at 635 nm. This system is also more customizable, allowing embryologists to capture images from 1 to 9 focal planes with the recommended default set at acquisition of images in 7 focal planes every 10 min. At this setting, an EmbryoScope exposes embryos to 53–99 J/m^2 of light over 5-day culture, as compared to 394–776 J/m^2 in a conventional IVF microscope. The Miri TL, in turn, captures images over 0.064 s per image in 3–7 focal planes every 5 min at a wavelength of 635 nm. Finally, the Primo Vision EVO uses a green LED at 550 nm to capture images of all embryos at 3–11 focal planes every 5–60 min, while the Primo Vision EVO+ uses an amber LED at 590 nm to capture images of individual embryos at 3–11 focal planes every 10–60 min.

The systems also use different culture dishes. The EmbryoScope uses a proprietary culture dish, the EmbryoSlide. One of these dishes contains 12 individual microwells under a confluent oil cover. The EmbryoSlide+, for use with the EmbryoScope+, in turn can hold up to 16 embryos under a confluent oil cover in 2 culture compartments of 8 individual microwells under a common media droplet. The Eeva uses the Eeva Dish, which is a standard-sized petri dish with individual microwells in the center of the dish, but also sharing common medium. The Primo Vision Microwell Group Culture Dishes contains 9–16 microwells under a single drop of culture medium. Finally, the Miri TL requires either the Individual CultureCoin, which can hold up to 14 embryos in individual microwells for isolated culture, or the Communal Reservoir CultureCoin, which can hold 14 embryos in individual microwells with a culture medium and oil overlay that is shared by all embryos for group culture.

Other differences between the various TLM systems include their temperature regulation, management of oxygen and carbon dioxide tensions, and filtration systems. Each system also comes equipped with its own proprietary software for image analysis and annotation.

Regardless of the system, all can be used to evaluate embryo morphology and morphokinetics throughout the early stages of embryo development.

21.3 Embryo Morphology

To date, morphologic assessment of embryos has been the standard of care for the evaluation of embryonic developmental potential. Conventional morphologic analysis encompasses evaluation at static time points, as first described by Edwards and colleagues [9]. This allowed for the determination of developmental rate (i.e., assessing if

certain milestones are reached within a particular time frame) and morphological characteristics at particular times after insemination. Various scoring systems have been proposed for evaluating zygotes at the pronuclear stage, cleavage stage, and blastocyst stage [10]. Within these approaches, evaluation can be done either at a single time point or at several stages during development. While existing studies suggest that one or more morphological parameters can independently predict viable embryo selection, implantation rates of embryos selected and transferred on day 3 are typically no higher than about 40% [11]. This suggests that embryo morphology identified at a single or even at multiple time points is not always reflective of embryo viability [11].

In addition to evaluating embryos at the conventional time points, TLM allows for the identification of developmental milestones normally missed by traditional approaches without disturbing the system. However, a limitation of TLM systems is that they do not allow for rotation of the embryos, limiting potential morphological evaluation at any individual time point, in particular when blastomeres overlap or a high degree of fragmentation is present [12].

21.3.1 Pronuclear Stage Embryo

The first morphologic event assessed approximately 16–18 h after insemination is the presence of two pronuclei (PNs) at the fertilization check. The use of a single static time point can miss the appearance and disassembly of one or both PNs. With continuous recording, TLM can help identify the transient PNs and avoid discarding diploid zygotes that have undergone early PN disappearance or fusion of the 2PNs to form only 1PN [13]. TLM also allows monitoring of PN position within the cytoplasm. In normal development, the PNs migrate into apposition in the center of the cytoplasm, and failure to do so is associated with lower blastocyst development potential [14].

21.3.2 Cleavage Stage Embryo

Normally developing embryos undergo the first cleavage division late on day 1 and have reached the four-cell and eight-cell stages, respectively, on days 2 and 3 after insemination. Morphological assessment of cleavage stage embryos includes evaluating the number of blastomeres, the extent of fragmentation, blastomeric symmetry, multinucleation, and the presence of compaction [10]. However, these factors are fluid and can change rapidly during dynamic embryonic development, meaning the presence or absence of certain parameters is highly dependent on the timing of assessment. This opens up the possibility for using TLM to observe and track the appearance and disappearance of fragments and multiple nuclei [13].

21.3.2.1 Multinucleation

Blastomere multinucleation has been suggested as a possible marker of aneuploidy and implantation potential. Because this event is a transient occurrence, TLM can identify it with greater sensitivity than single time-point assessment. As previously mentioned, though, only bright-field TLM has the ability to visualize nuclei, while dark-field TLM is limited in this regard.

In one study, of embryos found to have multinucleation using TLM, only 27.6% (44 of 159 embryos) could be detected within the timeframes proposed by ESHRE/ALPHA consensus (22–24 h, 25–27 h, or 44–45 h postintracytoplasmic sperm injection [ICSI]) [15, 16]. Two other studies further demonstrated that multinucleation is a transient occurrence. In one study, while 43.2% of embryos demonstrated multinucleation at the two-cell stage, only 15.0% were found to be multinucleated at the four-cell stage. Of particular interest, 52% of multinucleated two-cell embryos cleaved into entirely mononucleated four-cell embryos [17]. In the other study, 42.53% of embryos were multinucleated at the two-cell stage, and only 14.47% demonstrated multinucleation at the four-cell stage, with 73.4% of the former cleaving into mononucleated four-cell embryos [18]. Of note, not all embryos that demonstrated multinucleation at the four-cell stage were multinucleated at the two-cell stage.

Multinucleation is reflective of the timing of morphokinetic parameters of developing embryos. In the studies mentioned above, embryos with multinucleation at the two-cell stage had significantly longer times from insemination to two- through five-cell stages than embryos that did not demonstrate multinucleation throughout early development ($p \leq 0.001$ in both studies).

The association between aneuploidy and multinucleation is less clear. Balakier et al. [17] found no significant difference in multinucleation between euploid and aneuploid embryos. Furthermore, nuclear correction (i.e., embryos demonstrated multinucleation at the two-cell stage and not at the four-cell stage) was seen in both euploid (78%) and aneuploid (57%) embryos, suggesting that this phenomenon is not an indicator of ploidy status [17].

The association between multinucleation and embryo viability also remains to be clarified. While Ergin and colleagues found that embryos with evidence of multinucleation at the two-cell stage had significantly lower implantation rates than nonmultinucleated embryos (23.3% vs. 43.6%, respectively, $p < 0.001$) [15], Aguilar and colleagues found no difference in implantation rate for embryos multinucleated at the two-cell stage ($p = 0.07$). However, the latter group did find a significantly lower implantation rate in embryos with multinucleation at the four-cell stage ($p = 0.001$) [18].

21.3.2.2 Fragmentation

Known causes of fragmentation include abnormal pH, temperature, and oxygen tension. With conventional assessment, as fragmentation increases, the incidence of blastocyst formation decreases. This is thought to be due to loss of

cytoplasm and associated mitochondria and cytoplasmic proteins [19]. Large fragments can be distinguished from blastomeres only by the absence of the nucleus. Unfortunately, single time point assessment can miss the presence of the nucleus, which is disassembled during the mitotic phase, thus erroneously categorizing blastomeres as large fragments. This, in turn, significantly affects the accuracy of embryo scoring [20].

While fragmentation is thought to be a marker of poor developmental potential, a recent TLM study demonstrated no difference in blastocyst or good quality blastocyst formation rates between embryos exhibiting <10% or 10–50% fragmentation when either at the two-cell or four-cell stages. This suggested that the occurrence of fragmentation during cell division is not a useful index of high developmental ability [19].

In contrast, another study investigated whether the presence of large fragments (>45 μm without a nucleus) and abnormal cell divisions (production of more or less than two blastomeres per cell division) influenced correlation between live-birth rate and number of blastomeres detected on day 2 by conventional scoring. By conventional scoring, embryos with four cells on day 2 had higher live-birth rates than embryos with less than or greater than four cells. Via time-lapse-assisted reassessment, abnormal cell divisions and/or a recalculated fragmentation of >25% was recognized in 18.3% of transferred embryos. None of these embryos resulted in live birth. Once they were excluded from the analysis, the number of blastomeres on day 2 had no impact on live-birth rate [20]. This suggests that fragmentation and abnormal cell division are crucially important to developmental potential.

21.3.2.3 Irregular Cleavage

Several abnormal cleavage behaviors have been described in the literature, including direct cleavage (<5 h from two to three cells), abnormal cleavage (origination of more than two cells from a single cell division event), chaotic cleavage (disordered cleavage behavior up to the four-cell stage), reverse cleavage (fusion of two daughter blastomeres after complete separation or failed cytokinesis after karyokinesis), disordered division (division of one blastomere in previous cleavage was delayed after the other blastomere had undergone the next cleavage), and failure to achieve six intercellular contact points (ICCPs) at the eight-cell stage. One study that evaluated irregular cleavage patterns found that 15.6% of embryos demonstrated abnormal cleavage at either the first cleavage (from one to more than two daughter cells) and/or the second cleavage (from two to five or more blastomeres, instead of four) [21]. In another study, 337 (97.7%) of 345 embryos derived from immature oocytes that underwent in vitro maturation (IVM) demonstrated abnormal cleavage patterns, including one or more of the following: direct cleavage, uneven blastomeres, fragmentation, big fragments, distorted cytoplasmic events, developmental arrest, or disordered division [22]. Importantly, a third study subsequently found low rates of good quality blastocysts (as defined by Gardner criteria) among embryos with severe abnormal cleavage patterns, including large fragmentation, developmental arrest, direct cleavage, fragmented blastomeres, asymmetric cleavage, cell-cell fusion (i.e., reverse cleavage), and mixed patterns of irregular cleavage [23].

The question arises as to whether these irregular cleavage patterns influence blastocyst formation and transfer outcomes. The first study addressing this question was performed by Athayde Wirka and colleagues, albeit with small numbers of embryos. In that study, implantation rates were lower for all abnormal phenotypes assessed (Fig. 21.2) [24]. In a subsequent study with larger numbers, Yang and colleagues found that embryos that demonstrated severely abnormal cleavage patterns, including developmental arrest, direct cleavage, disordered division, and fragmentation, had very low rates of blastocyst formation. Embryos with less severe cleavage abnormalities—such as distorted cytoplasmic movement, uneven blastomere formation, and big fragmentation formation—also demonstrated lower blastocyst-formation rates, although not as profound. A hierarchical model from A to F, depending on the timing of

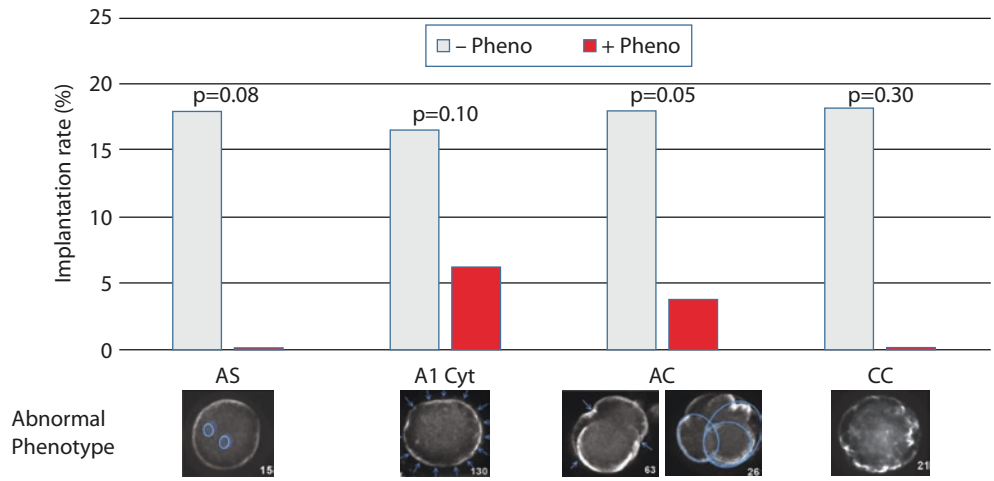

Fig. 21.2 Relationship between implantation rate and abnormal phenotypes in cultured human embryos: AS abnormal syngamy, A1Cyt abnormal first cytokinesis, AC abnormal cleavage, CC chaotic cleavage. (Adapted with permission; from Athayde Wirka et al., *Fertil Steril* 101(6):1637–1648; 2014)

an abnormal cleavage pattern (at first, second, or third divisions), was shown to have good predictive value for overall blastocyst formation (from 94.8% to 21.2%, $p < 0.001$) and good quality blastocyst formation (70.8% to 3.8%, $p < 0.001$). In a prospective observational study to validate this model, the authors demonstrated an implantation rate ranging from 67.0% down to 0.0% from Grades A to D ($p < 0.001$) [22].

In another study, Liu and colleagues found that embryos failing to achieve six ICCPs at the eight-cell stage resulted in a significantly lower proportion of eight-cell embryos at 68 h postinsemination, worse morphology scores, and reduced implantation rates [25].

Despite the above observations, a significant caveat is that the presence of irregular cleavage patterns does not preclude successful outcomes. In one study, embryos with irregular cleavage patterns were transferred in 16 women who did not have embryos with regular cleavage patterns available. These resulted in three live births [21].

21.4 Embryo Morphokinetics

TLM and continuous monitoring of embryos allow for identification of the precise timing of various milestones in embryonic development. Reported milestones include second polar body extrusion; the appearance of the 2PN and the subsequent fading of the 2PN/syngamy; cleavage to two, three, four, five, six, seven, eight, and nine cells; morula formation; start and completion of compaction; start of blastocyst cavitation/blastulation/blastocoele formation; full blastocyst formation; expanded blastocyst formation; and blastocoel cavity contractions.

Using these time points, researchers have defined a variety of calculated parameters that describe how long an embryo spends in any particular phase of development and how long it takes an embryo to go from one phase to another. Unfortunately, the nomenclature used by various authors to define these parameters is not consistent, nor are the reference time points the same from which they base their timing calculations. These inconsistencies make it difficult to compare studies, draw sound conclusions, and validate described models in new settings. To reign in these variations, two groups have proposed uniform, but distinct, sets of nomenclatures for currently identified TLM markers and potential future markers.

Notably, both nomenclatures depend on three general principles. First, they each define a standard referent for all cycles. Kaser and Racowsky [26] suggest setting the referent time point at the moment of appearance of the first cytokinesis furrow. This event is clearly identifiable regardless of whether bright-field or dark-field microscopy is used, and it is independent of the method of insemination (IVF or ICSI, see *Insemination Technique*). Ciray et al. [27], on the other hand, suggest that the referent time point should be set at the time of insemination. The disadvantage of the latter is that the mean time of injection of oocytes is typically used, which introduces inaccuracy particularly when a large number of oocytes are injected.

Second, they provide guidelines for defining all the other stages. While Kaser and Racowsky suggest that stages be defined as the "time of first definitive identification of an event," Ciray and colleagues set the time record for all events as the first or last TLM-generated frame/image at which an event is identified.

Finally, both groups suggest annotations for the derivation of time intervals and the duration of any specific stage of embryo development. Using different nomenclature, both groups suggest a general formula in which the duration of an event or phase is equal to the timing of a later developmental event minus the timing of an earlier developmental stage.

Although a few years have passed since both nomenclatures were proposed, neither has been universally adopted. Without this standardization, it has become progressively more difficult to compare studies.

21.4.1 Blastocyst Development

While blastocyst-stage fresh transfers may have higher pregnancy and live-birth rates than cleavage-stage fresh transfers [28], the cumulative live-birth rates may not be different [29, 30]. Moreover, extended in vitro embryo culture does not come without risks. In humans, ART has been associated with genome-wide disturbances of methylation reprogramming and parent-specific imprinting, including higher rates of Beckwith-Wiedemann and Angelman syndromes [31]. Extended culture and blastocyst transfers have also been shown to be associated with higher rates of monozygotic [32, 33] and monochorionic twinning [34], as well as a higher risk of congenital malformations and preterm birth among singletons [35, 36]. Thus, having the ability to predict which embryos will successfully develop into blastocysts and thus have a higher chance of implanting and leading to a live birth without exposing said embryos to extended culture is an attractive option.

The first study to suggest that TLM-monitored morphokinetic parameters can accurately predict successful blastocyst formation was published in 2010. In this study, 100 supernumerary thawed embryos were cultured in a TLM system; 33–53% developed into blastocysts over four experiments. The authors then identified that by setting certain time limits on the duration of three morphokinetic parameters—the duration of first cytokinesis, the duration of the two-cell stage, and the time interval between the appearance of cleavage furrows of the second and third mitoses (yielding a four-cell embryo)—they could accurately predict which embryos went on to reach the blastocyst stage with 94% sensitivity and 93% specificity. Unfortunately, none of these embryos were subsequently transferred for implantation. Thus, this first study did not allow any conclusions to be drawn regarding the potential for live birth of those embryos meeting these criteria compared with those whose morphokinetics fell outside these ranges [37].

Since 2010, multiple other groups have published studies that support the possibility of predicting blastocyst develop-

ment using morphokinetic parameters through the cleavage stage. Most of the early studies investigating these parameters simply evaluated the differences in timing between embryos that developed into blastocysts and those that did not. Some of those studies also evaluated the difference in timing of embryos forming high- versus low-quality blastocysts as defined by morphologic criteria.

Hashimoto and colleagues found that embryos developing into high-quality blastocysts took significantly less time to develop from the two-cell stage to the seven-cell and eight-cell stages, and accordingly spent significantly less time in the second cleavage (three- to four-cell) and third cleavage (five- to eight-cell) stages than poor-quality embryos [38]. Similarly, Dal Canto and colleagues found that embryos that successfully developed into blastocysts took significantly less time to reach seven or eight cells and spent less time in the interval between four and eight cells and in the third cleavage stage. Furthermore, of the embryos that reached the blastocyst stage, those that went on to become expanded reached the eight-cell stage significantly faster than blastocysts that did not expand [39]. Desai and colleagues also noted in a sample of 648 embryos, that those forming high-quality blastocysts reached the 8- and 9+ cell stages significantly faster than embryos that formed poor-quality blastocysts or embryos that arrested prior to blastulation [40].

Whether a difference exists regarding blastocyst formation for timing of the earlier cell divisions is more controversial. Two of the studies listed above found no significant differences in the timing of progression to the two-, three-, four-, five-, or six-cell stages for those embryos that were arrested after the eight-cell stage versus those that successfully developed into blastocysts [39] or for those that became high-scoring versus those that were low-scoring blastocysts [38]. In contrast, Cruz and colleagues showed that good-morphology blastocysts progressed through the early cleavage cycles faster than poor-morphology blastocysts, reaching the four- and five-cell stages faster. This study also demonstrated that embryos forming blastocysts progressed through these early cleavage cycles faster than embryos that arrest early, taking significantly less time to reach the two-cell, three-cell, and four-cell stages [41]. Similarly, the embryos that formed high-quality embryos in Desai and colleague's study took significantly less time to reach the two- and four-cell stages than embryos that formed low-quality embryos [40]. Accordingly, the times spent at the two- and three-cell stages were also significantly shorter in both studies.

One relatively consistent finding is that embryos with high developmental potential seem to develop faster than embryos with poor outcomes. Furthermore, faster development to the blastocyst stage appears to be on a continuum, with high-quality blastocysts developing faster than low-quality blastocysts, which in turn develop faster than embryos that arrest prior to blastulation.

Subsequent studies took the next step to determine if morphokinetic parameters can be used to predict blastocyst formation. Kirkegaard and colleagues used previously identified parameters to create models to describe embryonic potential to develop into high-quality blastocysts versus low-quality blastocysts/arrested development. Based on 571 2PNs in their cohort, the authors found that the duration of first cytokinesis, duration of the three-cell stage, and the absence of direct cleavage can predict development of high-quality blastocysts (area under the curve (AUC) of 0.63, 0.63, and 0.58, respectively). The combination of all three variables modestly improved on that prediction to an AUC of 0.69 [42]. Another study analyzed 17 morphokinetic parameters in a cohort of 3354 embryos. They found that 16 of the 17 parameters were significantly different between embryos of top and good quality versus embryos of bad quality (as defined by Gardner's classification) and arrested embryos. The authors subsequently built receiver operating curves (ROC) for each of those variables, noting that the three highest AUCs were from derived time variables, specifically the duration of time from five to eight cells, the cleavage synchronicity from four to eight cells, and the cleavage synchronicity from two to eight cells (AUC 0.778, 0.776, and 0.786, respectively) [43].

One of the seminal studies in the field of time-lapse imaging was published by Conaghan and colleagues in 2013. This study developed what is now known as the *Eeva Test*. First, in the development phase, the authors recorded embryos using the Eeva microscope and identified the timing of the first cytokinesis (P1) and the durations that the embryos are in the two-cell stage (*P*2; *t*3–*t*2, where *t* = time) and the three-cell stage (*P*3; *t*4–*t*3). They then built a classification tree model to determine optimal timing windows for embryo development to predict blastocyst formation, from which was created an automated image software that allowed the Eeva system to automatically track the embryos and provide a score based on the classification tree. This *Eeva Test* originally categorized embryos into two groups—Eeva High and Eeva Low, depending on the probability of blastocyst formation—based on two of the three parameters: P2 and P3. More recently, the test was expanded to define Eeva Medium embryos [Fig. 21.3; [44]].

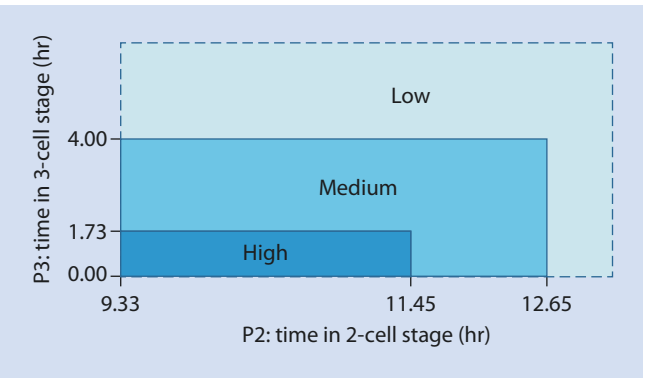

Fig. 21.3 Diagram depicting the modified *Eeva™ Test* which utilizes time in the two-cell stage (P2) and time in the three-cell stage (P3) for classification of embryos as having high, medium, or low potential to form a blastocyst. This test was designed to be used in conjunction with conventional morphological evaluation. (Drawn from data in VerMileya et al., *Reprod Biomed Online* 29(6):729–736; 2014)

Subsequently, embryologists at five different fertility centers performed further investigations of the *Eeva Test* for prediction of blastocyst formation on day 3, using either conventional morphologic assessment alone or the combination of morphology and *Eeva Test* results. In this test phase, the authors found that the adjunct information from the *Eeva Test* significantly increased both the specificity (84.7% vs. 52.1%, $p < 0.0001$) and the positive predictive value (54.7% vs. 34.5%, $p < 0.0001$) of predicting usable blastocysts over morphologic evaluation alone [8].

Since that time, multiple studies have attempted to validate these results. In the first of these validation studies, five embryologists independently predicted blastocyst formation in two cohorts of embryos using day 3 morphology alone or using day 3 morphology in combination with *Eeva Test* results. In this population, blastocyst formation rates were significantly higher in the Eeva High group than in the Eeva Low group. Having the adjunct information from the *Eeva Test* increased the odds ratio of correctly predicting blastocyst formation from 1.68 to 2.57 among embryos graded as good or fair based on day 3 morphology alone [45]. Taken together, these data support the utility of the *Eeva Test* as an adjunct to day 3 morphology in choosing embryos able to form blastocysts.

Subsequently, Aparicio-Ruiz et al. [46] retrospectively analyzed a cohort of 3002 embryos derived from oocyte donation cycles. In this study, the authors evaluated blastocyst formation based on morphology up to day 3 as defined by the ASEBIR (asociación para el Estudio de la Biología de la Reproducción) criteria and/or a modified *Eeva Test* classification. The Eeva classification in this study stratifies embryos into three groups as suggested by VerMilyea and colleagues [44]. Using Eeva classification alone, the AUC to evaluate blastocyst prediction was 0.717. In turn, logistic regression of blastocyst potential based on the ASEBIR morphology categories alone yielded an AUC of 0.728, and using the Eeva classification as an adjunct to ASEBIR only modestly increased the AUC to 0.788 [46]. Thus, available data indicate that the *Eeva Test* only modestly improves prediction of an embryo to blastulate, although it may serve as an adjunctive tool.

While the *Eeva Test* was the first to be created and marketed as an adjunctive blastocyst prediction tool, other groups have also attempted to develop their own blastocyst predicting models. Milewski and colleagues observed 432 embryos from 77 patients as they developed in an EmbryoScope and noted the timing of the following parameters: the time to two through five blastomeres and the timing intervals from two to three blastomeres and three to four blastomeres. The values for each of those six parameters were divided into quartiles and assigned a score from 0 to 2. In this cohort, univariate logistic regression demonstrated that all of the parameters are significantly associated with blastocyst development. Using the most significant values, the authors carried out a multivariate analysis to create a score based on time to two and five blastomeres and the time an embryo spends in the two-cell stage. This combined score was then divided into quartiles, and significant differences were observed among quartiles in the percentage of embryos that developed to the blastocyst stage, with values ranging from 18% to 90% ($p < 0.001$). Of note, the combined score was significantly higher for embryos that developed to the blastocyst stage than those that did not. An ROC based on this combined score yielded an AUC of 0.806. The authors then validated this model on an independent set of 271 embryos, 116 of which formed blastocysts. The results of the ROC analysis were similar with an AUC of 0.813, and the combined score values for embryos that developed to blastocyst were significantly higher than for arrested embryos [47].

Motato and colleagues [48] in turn performed an observational retrospective study of 7483 zygotes that developed into 3215 blastocysts from 990 first treatment ICSI cycles. The authors classified the embryos according to two binary timing variables: time to morula formation (81.28–96.00 h) and t8–t5 (≤8.78 h). A hierarchical regression model based on these two variables yielded an AUC of 0.849, with the rate of blastocyst formation decreasing from 84.4% in the embryos where both times fell within the defined parameters to 13.8% in the embryos where their timing of development fell outside those ranges.

Another group also used a big-data approach to develop a blastocyst prediction algorithm. Using data collected from 24 clinics on 3275 embryos transferred on day 3, the authors created an algorithm (KIDScore) using the following parameters: the number of pronuclei equals 2 at the one-cell stage, time from insemination to pronuclei fading at the one-cell stage, and time from insemination to the two-, three-, five-, and eight-cell stages. The embryos were then ranked into five groups based on the derived algorithm to yield an AUC of 0.650, with a sevenfold difference in implantation rate between KIDScore 1 (5.18% implanted) and KIDScore 5 (36.17% implanted). The authors then validated the study on data from 11,218 embryos cultured to day 5 in 31 clinics and noted that the KIDScore algorithm could predict blastocyst formation with an AUC of 0.745 and blastocyst quality with an AUC of 0.679 [49].

In turn, Storr and colleagues created an algorithm in their own embryo population to predict the quality of blastocysts based on Gardner criteria. They found that the timing of their synchrony stage (i.e., time to eight blastomeres minus time to five blastomeres) was the single best individual predictor prior to embryo compaction of a top-quality blastocyst (i.e., inner cell mass and trophectoderm grades AA or BA), with an AUC of 0.585. As they measured timing parameters all the way through the blastocyst stage, the time to expanded blastocyst was the best predictor of top-quality blastocysts regardless of embryo stage (AUC 0.727). Accordingly, a model based on the third synchrony stage (time between division to five cells and subsequent division to eight cells), the time to eight cells, and time to expanded blastocyst could predict the formation of a top-quality blastocyst with an AUC of 0.748 [50]. This model, though, is of limited clinical utility as it is dependent on the embryos developing to the blastocyst stage in vitro.

Notably, Storr and colleagues also attempted to validate the model developed by Cruz and colleagues in 2012 (see above). Unfortunately, none of those parameters had any statistically significant predictive ability in the new embryo population. Only the duration of the second cell cycle could predict top or good quality blastocysts with an odds ratio of 1.88 (95% CI 1.11–3.19) [50].

Wang and colleagues, who found low rates of good quality embryos among those with severe abnormal cleavage patterns (see ▶ Sect. 21.3.2.3), also developed a hierarchical embryo selection model based on the development of 1728 embryos. In univariate logistic regression models, they found that the time to pronuclei disappearance, two, three, four, and five blastomeres, and the lengths of the second cell cycle (time to transition from two-cell to three-cell embryo) and third cell cycle (time to transition from three-cell to four-cell embryo) were all significantly associated with good quality blastocyst formation. Subsequently, in a multivariate logistic regression model, the time to five blastomeres (≤49.07 h) and the length of the third cell cycle (≤0.50 h) were the most predictive values. A hierarchical embryo selection model that began with excluding embryos with severe abnormal cleavage patterns and then selected embryos based on the length of the third cell cycle and the time to five cells found that embryos that were within the timing ranges were likely to develop into good quality blastocysts 68.8% of the time, as compared to only 35.71% of the time for embryos that were out of range [23].

21.4.2 Implantation Potential

While it is useful to predict blastocyst potential or blastocyst quality early in embryo culture, showing that TLM can help predict implantation would be much more indicative of the technology's potential. A limitation of the conclusions discussed below is that implantation rate is defined differently in various studies, with some studies simply defining it as simply a rise in serum beta across two consecutive blood tests or a positive urine hCG 14 days after single embryo transfer [23], while others evaluated patients for the presence of a gestational sac with or without a fetal heartbeat at various stages of gestation.

The first study to show that early embryo morphokinetics may differ between embryos that went on to implant and those that did not showed that embryos that implanted trended toward a faster appearance of the nucleus in the first blastomere after cleavage. These embryos also had a significantly faster time to synchrony (time from nuclear appearance in first blastomere to nuclear appearance in second blastomere) [51].

21.4.2.1 Meseguer's Hierarchical Model

In 2011, Meseguer and colleagues published a seminal paper evaluating the timing parameters of 247 embryos with known implantation data. The authors found significant differences in the timing of the early cleavage stages; embryos that implanted reached the two- through five-cell stages faster than embryos that did not implant, and they spent less time as two-cell and three-cell embryos. The authors then divided the exact timing of those early cleavage cycles by quartiles and established optimal ranges reflecting the highest probability of implantation (which were not necessarily found in the fastest-dividing embryos). Using these quartiles, the authors created a hierarchical model of embryo grading based on morphokinetic parameters (time to five-cell stage, duration of the two-cell stage, and duration of the three-cell stage) and morphologic exclusion criteria. The embryo categories ranged from A through E, with implantation potentials decreasing from 52% down to 8% across the categories [52].

The same group subsequently performed first a retrospective study and then a randomized controlled study (RCT) to evaluate the hierarchical model that they developed. In both studies, the group compared implantation rates of embryos cultured in an EmbryoScope and then selected for transfer using the hierarchical embryo grading system to embryos cultured in a standard incubator and selected using conventional morphologic grading. In the retrospective study, the authors noted that embryos cultured in and selected using the TLM system had significantly higher implantation rates than embryos from the conventional incubator group (adjusted odds ratio 1.201, 95% CI 1.059–1.363, $p = 0.0043$) [53]. In the RCT, the authors reached similar conclusions, with the implantation rate of transferred embryos greater in the TLM group than the conventional morphology group (RR 1.43, 95% CI 1.05–1.39, $p = 0.02$) [54].

Using the data from the RCT, the authors also prospectively validated their hierarchical embryo grading system. They showed that implantation rates had a direct relationship with the morphokinetic category, decreasing from 52.9% in Category A to 13.7% in Category E embryos [55] and have since further refined it (◘ Fig. 21.4; [56]).

Unfortunately, other groups have not been successful in reproducing the results of Meseguer's group in their own populations. Yalcinkaya and colleagues performed a retrospective analysis using Meseguer's hierarchical model on 910 transferred embryos with known implantation data cultured in an EmbryoScope. They found that the highest pregnancy rates were in groups C+ and A- (48.2%) and the lowest rate in group E (19.7%). Of note, the laboratory techniques used in this study differed from those used by Meseguer's group, including different media (single step versus sequential culture) and oxygen concentrations (~20% vs. 7.0%) [57].

Similarly, Freour and colleagues attempted external validation of Meseguer's hierarchical model in an unselected population with various transfer days (days 2, 3, 4, 5, or 6). The first noteworthy difference was that the overall implantation rate in this study was lower than in Meseguer's study (22% vs. 38%, respectively), given the fact that the latter included patients with better prognoses. Evaluating the model itself, the authors found that the correlation coefficients were significantly lower in this study than those in

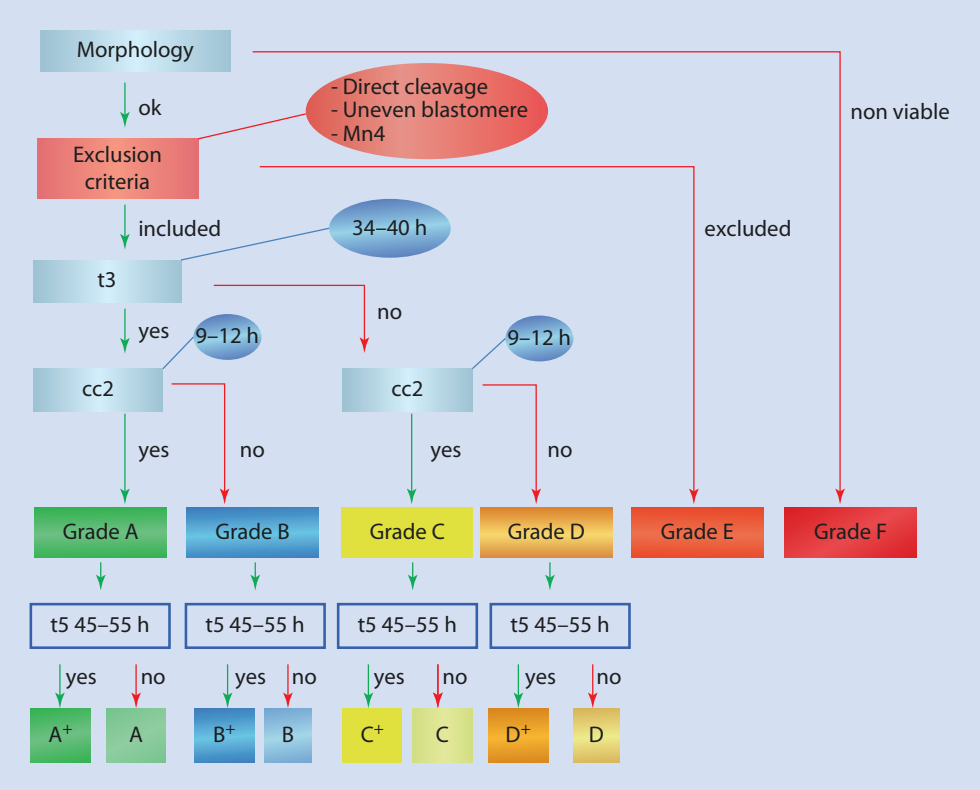

Fig. 21.4 Hierarchical classification of embryos based on conventional morphological screening, time-lapse observed morphologic criteria, and three morphokinetic parameters. Expected implantation potential increases based on classification of an embryo from right to left. (Published with permission; from Basile et al., *Hum Reprod* 30(2):276–283; 2015)

the original publication ($r = -0.66$ overall, -0.52 blastocyst stage transfer, and -0.54 cleavage stage transfer vs. -0.92; $p < 0.001$) [58].

In a small RCT of 64 patients, Kahraman and colleagues randomized good prognosis patients to an EmbryoScope group (embryos cultured in an EmbryoScope and selected for transfer based on morphology and morphokinetics using Meseguer's model) or a conventional incubator (with selection based on day 5 morphology alone). The authors found no difference in blastocyst development rate, the rate of good and top quality blastocysts, or ongoing pregnancy or miscarriage rates between the two groups. Furthermore, there was no difference in the morphokinetic parameters between implanted and nonimplanted embryos [59].

Collectively, the above results suggest that each lab may need to create its own TLM algorithm based on its own techniques and patient population.

21.4.2.2 Eeva Test Extension/Validation

Several studies have attempted to use the *Eeva Test*, originally developed for the prediction of blastocyst development (see ► Sect. 21.4.1), to predict implantation potential. One group performed a retrospective analysis of the *Eeva Test* at three different clinics with various lab parameters (i.e., the Eeva scores were blinded and not considered during embryo selection). While the implantation rates were different at each clinic, collectively, Eeva High and Eeva Medium embryos had significantly higher implantation rates than Eeva Low embryos (37% and 35% vs. 15%; $p < 0.0001$ and $p = 0.0004$, respectively) [44].

In contrast, another group did not find such positive results with the *Eeva Test*. Using an EmbryoScope, rather than the Eeva microscope, Kirkegaard and colleagues analyzed data from 1518 transferred embryos with known implantation outcomes at seven clinics from three countries. They retrospectively grouped embryos into usable and nonusable based on the timing parameters for Eeva High and Eeva Low embryos, respectively. The odds ratio for implantation between usable and nonusable was 1.60, with an AUC of 0.57 for prediction of implantation. Notably, 50.6% of embryos that implanted would have been categorized as nonusable by the model. As the authors write, "this hypothetical experiment illustrates the risks of defining too narrow time intervals for optimal division in order to achieve a high specificity at the expense of a low sensitivity" [60].

More recently, Adamson and colleagues reported the results of a nonrandomized prospective concurrent-controlled pilot study in which they compared the combination of automated TLM assessment using the *Eeva Test* and day 3 morphology (TLM was also used to exclude abnormal cleavage behaviors) to day 3 morphology alone. In this study, the test group had a significantly higher implantation rate than the control group (30.2% vs. 19.0%, $p = 0.003$). Patients in the test group who had at least one Eeva High embryo had significantly higher implantation rates than patients with only Eeva Low embryos (36.8% vs. 20.6%, $p = 0.03$). Furthermore, among morphologically good embryos, Eeva High embryos were significantly more likely to implant than Eeva Low embryos (44.1% vs. 20.6%) [61]. A notable limitation of this study is that different culture dishes were used in the two groups.

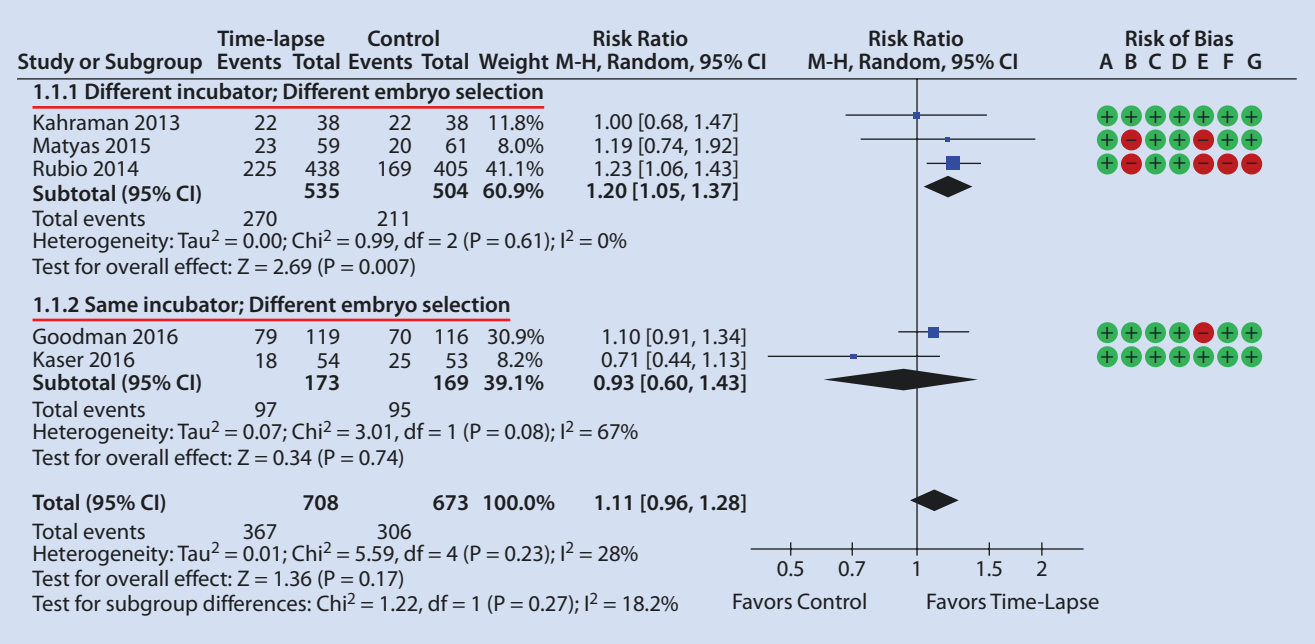

Fig. 21.5 Forest plot of ongoing pregnancy per woman randomized in randomized controlled trials to date. Risk of bias legend: (*A*) selection bias, (*B*) performance bias, (*C*) detection bias, (*D*) attrition bias, (*E*) reporting bias, (*F*) other bias. (Updated from Racowsky et al., *J Assist Reprod Genet* 32(7):1025–1030;2015)

Aparicio-Ruiz and colleagues, who performed a successful validation of the *Eeva Test* for blastocyst formation (see ▶ Sect. 21.4.1), subsequently transferred embryos based on the *Eeva Test* and standard morphology evaluation. The study found increasing implantation rates across Eeva categories after both day 3 (Low 26.1%, Medium 31.7%, and High 38.2%) and day 5 transfer (Low 31%, Medium 50%, and High 66.7%). Using the combination of *Eeva Test* and day 3 morphology allowed the authors to predict implantation with an AUC of 0.650 [46].

In a large prospective, observational, two-center pilot study with a propensity matched control group, Kieslinger and colleagues also evaluated the *Eeva Test*. In the test group, embryos underwent continuous culture with selection based on *Eeva Test* and morphology. In the control group, embryos were exposed to interrupted culture with selection based on morphology alone. The authors found no difference in implantation rate, clinical pregnancy rate, ongoing pregnancy rate, or live-birth rate between the groups. However, they did note that for patients who received suboptimal quality embryos (≠8 cells or ≥ 25% fragmentation), Eeva testing led to higher implantation, clinical pregnancy, and ongoing pregnancy rates. Furthermore, the ongoing pregnancy rate was significantly higher in the Eeva High (35.3%) and Eeva Medium (41.8%) embryos than in Eeva Low (18.4%) [62]. These results suggest that although Eeva testing may not be universally applicable, it may play a role in embryo selection for transfer in patients who have no optimal embryos.

Of note, all the above studies were either retrospective or prospective and observational. To date and to our knowledge, only one RCT has been performed to evaluate the *Eeva Test*. The results of this recent pilot RCT do not support the utility of this test as an adjunct in embryo selection [63]. In this trial, adjunctive use of the *Eeva Test* with conventional morphology on day 3 failed to result in clinical outcomes equivalent to day 5 selection with conventional morphology alone. When applied on day 5, the *Eeva Test* yielded lower pregnancy rates than selection with conventional morphology alone on day 5. Moreover, a systematic review and meta-analysis of published TLM studies failed to show an improvement in implantation rate when TLM is incorporated into an embryo selection algorithm (relative risk (RR) and 95% confidence intervals (CI): RR 1.20; 95% CI 1.05–1.37 [64]; and such clinical equipoise remains after updating this meta-analysis with the recent, yet-to-be-published Eeva RCT (RR, 1.11; 95% CI = 0.96, 1.28; Fig. 21.5).

Based on the above discussion, we conclude that further well-designed RCTs are required to determine the value of incorporating TLM with conventional morphology for embryo selection.

21.4.2.3 Other Implantation Potential Studies

Other groups have also explored the potential application of TLM for prediction of implantation potential. In a retrospective analysis of 270 embryos with known implantation after day 3 transfer, one group proposed a hierarchical deselection model based on poor conventional morphology, abnormal cleavage patterns as identified by TLM (direct cleavage, reverse cleavage, or <6 intercellular contact points at end of four-cell stage), <8 cell at 68 h postinsemination, duration of the three-cell stage, and time to five cells. The proposed model had an AUC of 0.762 for embryos graded A+ to F, with no significant difference between IVF and ICSI embryos. The

authors then prospectively validated the model on 66 embryos with known implantation data using two different culture media, yielding AUCs of 0.750 and 0.820 for each media and an overall AUC of 0.783 ($p < 0.001$) [65].

Milewski and colleagues, building on their prior algorithm (see ► Sect. 21.4.1), created a predictive equation using time to two and five blastomeres and the length of the second cell cycle to yield a combined score. Stratifying the combined score into quartiles, the authors found significant differences in pregnancy rates, ranging from 16.9% to 36.0% ($p = 0.009$). The combined score values were significantly different between embryos that implanted and those that did not, although the AUC of 0.61 was not as high as the AUC of 0.806 for blastocyst prediction. Furthermore, the differences in distribution of morphokinetic parameters between embryos that implanted and those that did not were not clearly apparent [66].

Recently, Goodman and colleagues published one of the few existing RCTs in this field. The authors randomized embryos to either conventional once-daily morphology embryo evaluation or additional TLM evaluation for selection. All embryos were cultured in an EmbryoScope. For the control group, embryologists had the ability to scroll through the seven focal planes at 42, 66, 90, 114, and 148 h postinsemination, but they were restricted from viewing time-lapse footage. In the TLM group, embryos that had suitable morphology were also graded based on morphokinetic parameters, with negative points assigned for a second cell cycle shorter than 5 hrs, multinucleation, and irregular division and positive points for falling within prespecified time limits to reach the five-cell stage and the start of blastulation, the time spent as a three-cell embryo and a five- to eight-cell embryo within certain time limits. The study noted a tendency toward increased clinical pregnancy and implantation rates in the experimental group, although the differences were not significant [67].

21.4.3 Live-Birth Potential

The ultimate goal of IVF, though, is for patients to take home a healthy live-born infant. Unfortunately, few of the TLM studies published to date have explored this outcome.

In one retrospective analysis of patients allocated to embryo culture in an EmbryoScope as part of an RCT, Ahlstrom and colleagues assessed conventional morphology using EmbryoScope images and retrospectively annotated morphokinetic parameters [68]. In univariate analysis of morphology, each additional four-cell embryo available and presence of early cleavage both significantly increased odds of a live birth. Conversely, increases in grade of fragmentation at 43–45 h postinsemination significantly decreased the odds of a live birth. Univariate analysis of morphokinetics found that multiple parameters were significant predictors of live birth with shorter times in all, although these yielded poor AUC values.

In a linear regression model, the authors found an AUC for live-birth prediction of 0.73 based on early cleavage and fragmentation grade (i.e., morphological annotations). The AUC based on time to two blastomeres alone was 0.67. Combining all three yielded an AUC of 0.73, which was no different from morphological evaluation alone.

In a classification tree model using the time spent as a one-cell embryo, the time to pronuclear fading, and the time spent with a pronucleus, the authors increased the AUC to 0.83. However, on validation, the AUC dropped to 0.61. Taken together, these data suggest that morphokinetic evaluation does not outperform morphological evaluation, and may actually do worse.

Notably, these authors also attempted to apply the *Eeva Test* to live-birth prediction. They found no significant differences between groups, and in fact showed a tendency to a lower live-birth potential in the Eeva High group (17.2%) than in the Eeva Low (23%) or Eeva Medium groups (24.1%) [68].

In turn, Siristatidis and colleagues performed a prospective cohort study of TLM monitoring in PrimoVision versus conventional monitoring. In the study group, embryos were selected only by TLM monitoring rather than in combination with morphological evaluation. The authors found significantly higher clinical pregnancy (65.7% vs. 39%), ongoing pregnancy (55.7% vs. 31.3%), and live-birth rate (45.7% vs. 28.4%) in the TLM monitoring group than in the conventional morphology group. However, live birth in this study was defined as a viable pregnancy at 20+ weeks gestation, rather than as a live-born infant, thereby limiting its interpretation [69].

21.5 Embryo Factors

21.5.1 Aneuploidy

Aneuploidy is a common occurrence in human embryos, with estimates ranging from 20% to 90% depending on the woman's age [70]. The only currently existing method to identify aneuploid embryos prior to transfer involves invasive embryo biopsy with genetic screening. Any possibility of identifying these embryos using a noninvasive technology such as TLM and subsequently excluding them from transfer would be most beneficial. Unfortunately, existing data regarding the ability of TLM and morphokinetic analysis to discriminate between euploid and aneuploid embryos are conflicting.

Some studies show no significant differences in morphokinetic parameters between euploid and aneuploid embryos. One early study showed no difference in time to syngamy, duration of first cytokinesis, first cleavage, duration of two-cell stage, timing of eight-cell stage, or the start of cavitation between five euploid and four aneuploid embryos [71]. Several large studies—each evaluating between 152 and 454 embryos—similarly found no significant differences in multiple morphokinetic parameters [72–75].

However, some published studies do support the utility of morphokinetic analysis for aneuploidy screening. In 2012, Friedman and colleagues first reported that embryos with abnormal morphokinetic parameters are more likely to be aneuploid [76]. In a follow-up publication, the same group analyzed the ploidy status of each blastomere at the four-cell stage among 53 embryos after tracking three morphokinetic parameters—duration of the first cytokinesis, time from two to three blastomeres, and time from three to four blastomeres. The authors noted that aneuploid embryos with meiotic errors exhibited a greater spread of times in all three morphokinetic parameters and that aneuploid embryos with mitotic errors had greater variation in timing of two of the three parameters than euploid embryos [77].

Several other studies also found significant differences in the timing of division of euploid and aneuploid embryos. Unfortunately, these studies do not agree on whether euploid embryos divide faster or slower than aneuploid embryos. Two groups found that multiple morphokinetic parameters are significantly shorter in euploid embryos [78, 79]. Another group found the exact opposite, with aneuploid embryos dividing faster than euploid embryos [80]. To add to this mix, a fourth study found that some timing parameters were shorter in euploid embryos while others were longer [81].

Despite these uncertainties, two groups have attempted to create models based on morphokinetics to predict embryo ploidy status. Noting significant differences in the time to start of blastulation and formation of full blastocyst, Campbell and colleagues proposed a classification model for unscreened embryos, with the risk of aneuploidy increasing from low (probability 0.37) to medium (probability 0.69) to high (probability 0.97) [78]. In a follow-up study, the same group retrospectively applied this model to embryos from 69 infertile couples. Embryos in the low-risk group had significantly higher rates of implantation (72.7% vs. 25.5%, $p < 0.0001$) and live birth (61.1% vs. 19.2%, $p = 0.01$) than embryos in the medium-risk group. None of the embryos that were retrospectively classified as high-risk implanted [82]. This was the first study to show that TLM-derived morphokinetics could potentially be used to risk-stratify embryos for aneuploidy and correlate this information with a clinically significant outcome. However, a separate group of researchers was not able to successfully validate Campbell's algorithm. In a retrospective analysis of a cohort of 106 blastocysts with known ploidy status, Kramer and colleagues found that observed aneuploid frequencies were significantly different from those predicted by the model for all three risk categories ($p < 0.02$), and they were not significantly different from uniform expectation in each group. Furthermore, this group noted that interpatient variability in the timing of most morphokinetic markers was greater than intrapatient (interembryo) variability [83].

Another group also attempted to devise a euploid-embryo predicting algorithm. Evaluating the morphokinetics of 504 embryos (71.7% aneuploid rate) from 125 patients undergoing preimplantation genetic testing for aneuploidy (PGT-A), Basile and colleagues found significant differences in the time it took euploid and aneuploid embryos to reach the five-cell stage, the amount of time embryos spent in the two-cell and three-cell stages, and the time to go from the two- to the five-cell stage. After defining optimal ranges for these three-derived parameters, the authors created a hierarchical model which subdivided embryos into four categories (A–D). In this model, the likelihood of normal chromosomal content decreased serially from 35.90% (Category A) to 9.80% (Category D) [80]. Given that only 1/3 of embryos demonstrating the three optimal morphokinetic milestones were euploid, this specific model is unlikely to supplant PGT-A. Furthermore, two other research groups failed to find significant differences between the four categories defined by this model after attempting to perform retrospective validation in their own clinics [73, 74].

21.5.2 Embryo Gender

The ability to noninvasively identify embryo gender could be beneficial to selecting appropriate embryos for transfer in situations involving sex-linked disorders. Published literature, however, has not supported this possibility. Two studies have found no significant differences in the morphokinetics of male and female embryos [84, 85]. Nevertheless, one of the studies attempted to use logistic regression to identify embryos more likely to be female. Based on the time it takes an embryo to go from three cells to four cells and the time to morula formation, Bronet and colleagues proposed four categories, ranging from 71% to 42% in the likelihood of an embryo being female. Unfortunately, the two middle categories (B and C) both resulted in 50% chance of female gender, suggesting that the model cannot differentiate between genders [84]. No other studies have yet attempted to validate this particular model.

More encouragingly, Bodri and colleagues found that female gender was associated with late cleavage (time to eight cells), time to morula, and time to several blastocyst stage variables. After defining optimal timing parameters for the latter, the authors could predict 74–78% of female embryos [86]. Although encouraging, these results remain to be validated.

21.6 Laboratory Factors

As is well known, developing embryos are particularly sensitive to environmental factors. Laboratory techniques are thus designed to maintain maximum stability of optimum in vitro conditions. The effect of various techniques on embryo development is thus important to study, not only to define their effect on the ultimate outcome of embryo development (i.e., blastocyst formation, implantation, live birth, and long-term health) but also on how embryos develop under particular conditions.

21.6.1 Culture Media

Several studies have explored the effect of culture media on embryo morphokinetics. As TLM allows for undisturbed embryo culture, three studies have explored the effect of single-step vs. sequential media. One of these studies with randomization of sibling embryos to single versus sequential media showed significantly faster progression to time of pronuclear fading and time to the two- through five-cell stages in single media [27]. Another study found conflicting results, with embryos grown in a single-step medium taking longer to develop to seven and eight cells and from three to four and five to seven cells. Furthermore, another group reported no difference in most of the measured morphokinetic parameters [87]. In support of these results, a third group found no difference in any measured morphokinetic parameters for embryos grown in a single medium with or without renewal on day 3 [88].

Furthermore, none of the three studies found significant differences in blastocyst formation rate, in the proportion of good quality blastocysts, or in implantation, pregnancy, or live-birth rates between single step and sequential media [27, 87, 88].

Based on these data, the morphokinetics of early embryo development does not appear to be significantly impacted either by use of single versus sequential media or by whether single medium is renewed or not.

21.6.2 Insemination Technique

Early studies suggested that ICSI-derived embryos progress through the early stages of development faster than IVF-fertilized oocytes. However, it was not until the advent of continuous TLM monitoring that this could be studied in depth.

As with other studies on morphokinetics, the results of existing studies are conflicting. Early on, Hashimoto and colleagues showed no difference in the time required for second cleavage (three to four cells) and third cleavage (five to eight cells) between conventional IVF insemination and ICSI [38]. Another group showed that although embryos generated by IVF took longer to reach the two- and three-cell stages than ICSI-derived embryos, the former spent less time as two-cell embryos; thus, cleavage kinetics were realigned from the four-cell stage up to the eight-cell stage [39].

In a larger study, Cruz and colleagues cultured oocytes inseminated by IVF (n = 622) or ICSI (n = 581) in a TLM system, either immediately after insemination (ICSI) or starting on day 1 after confirmation of fertilization (IVF). When the time of reference was set at the time of insemination, ICSI-derived embryos appeared to reach pronuclear fading and the two-, five-, seven-, and nine-cell stages significantly faster than IVF-derived embryos. However, when the reference time was reset to a clearly identifiable standard, i.e., time of pronuclear fading, all differences in embryo kinetics between groups disappeared [89].

These results are in concordance with the findings of Bodri and colleagues. Before setting a clearly defined reference time, the authors found that ICSI-derived embryos develop faster during the early cleavage stages (up to four cells). However, when the reference time was once again set to time of pronuclear fading, differences in cleavage-stage parameters disappeared. However, this was not so for progression to the blastocyst stage; even after standardization, the timing of each blastocyst-stage parameter was significantly shorter among IVF-fertilized embryos than after ICSI [90].

Thus, more research is still required to determine whether different optimal timing parameters need refinement based on method of fertilization. However, these studies do reinforce the fact that the nomenclature used for TLM studies needs to set a clearly identifiable stage in development as the referent time for all morphokinetic parameters (reviewed by [26]).

21.6.3 Blastomere Biopsy

Blastomere biopsy is an invasive method used to isolate embryonic genetic material for analysis of aneuploidy and specific genetic disorders. It has been shown that removing two cells versus one cell from cleavage-stage embryos results in a lower blastocyst formation rate, suggesting that blastomere biopsy is detrimental to embryo development [91, 92]. Several morphokinetic studies have reinforced these results.

In the first study, embryos spent significantly more time in the stage at which they were biopsied than did the unbiopsied control embryos. Subsequently, biopsied embryos took significantly longer to reach later stages in development, including compaction, morula formation, early blastocyst formation, and full blastocyst formation [93]. A second study confirmed these results, finding that blastomere biopsy significantly delayed the timing to the first cleavage after biopsy, as well as the time to compaction and the start of blastulation. This study also noted that blastomere biopsy also affected postembryo transfer development, with embryos that did not implant demonstrating a significant delay in both the time of morula formation and the start of blastulation as compared to embryos that implanted successfully [94].

21.6.4 Cryopreserved Oocytes

As elective fertility preservation has emerged as a viable option for many women, an increasing number of embryos in the coming years will be derived from thawed cryopreserved oocytes. One study noted that embryos derived from fresh oocytes reached the two- to four-cell stages faster than embryos derived from thawed vitrified oocytes, although no differences were observed in the time to five cells or in the duration of the two- and three-cell stages [95]. In another study, embryos derived from thawed versus fresh oocytes showed no significant difference in the timing of nine developmental events or five measured time intervals up to the five-cell stage [96].

21.6.5 Stimulation Cycle Medications and Hormones

The maternal hormonal milieu may also significantly affect oocyte quality and embryo development. Several studies have explored this issue by concentrating on embryo morphokinetics.

The first study noted no difference in any morphokinetic parameters between embryos obtained from stimulation cycles using follicle stimulating hormone (FSH), human menopausal gonadotropin (HMG), or both. However, as the dose of recombinant FSH (rFSH) increased, the longer it took for embryos to reach the two-cell, the 6 through 9+ cell stages, to begin blastulation, and to complete maximal blastocyst expansion. Furthermore, differences in serum estradiol concentration were significantly associated with the timing of most developmental milestones through the time of blastulation. Serum progesterone levels, in contrast, were associated only with differences through the first four cell division cycles [97].

The same group subsequently explored whether the medications used for controlled ovarian stimulation and ovulation trigger affected early embryonic developmental kinetics. While embryos derived from GnRH agonist with hCG trigger cycles took longer to reach the two- through five-cell stages compared to embryos derived from a GnRH antagonist with GnRH agonist trigger cycle, differences in timing did not persist further [98].

In a follow-up to this study, a separate group specifically explored whether the ovulation trigger used affects embryo kinetics. The authors found that embryos reached several developmental milestones significantly faster after a GnRH agonist trigger versus an hCG trigger, while other milestones and developmental phases were not affected [99].

Based on these studies, we can conclude that the clinical manipulation of maternal hormones is associated with embryo kinetics. However, more studies are needed to tease out these affects and their impact on efficacy of TLM algorithms for embryo selection and clinical outcomes.

21.7 Maternal Factors

21.7.1 Age

Increasing maternal age is generally associated with decreasing oocyte quality, increased risk of aneuploidy, and resultant decreasing embryo quality. Based on limited data, though, maternal age does not seem to have an effect on embryo developmental kinetics. One study showed no significant differences based on donor age for times required for embryos to go from three to four cells and from five to eight cells [38]. A separate study found no difference in any morphokinetic parameters between embryos that successfully implanted from women <35, 35–37, or ≥ 38 years old [100].

21.7.2 Body Mass Index (BMI)

Obesity has been shown to be correlated with lower implantation and pregnancy rates following ART [101, 102]. The effect of obesity on embryo kinetics is currently inconclusive.

Specifically, Bellver and colleagues found no significant kinetic differences between embryos derived from obese (BMI ≥ 30 kg/m^2) versus normal weight (BMI = 20–24.9 kg/m^2) women with infertility. After subsequently categorizing the embryos in each group based on Meseguer's hierarchical model (see ► Sect. 21.4.1), they also found no significant differences between groups in the proportion of embryos in each category (A–E) [101].

In contrast, Leary and colleagues noted that while embryos from overweight women (BMI ≥ 25 kg/m^2) are less likely to complete development postfertilization than embryos from normal weight women (BMI < 25 kg/m^2), those that do develop tend to reach the morula stage significantly faster. Interestingly, those embryos developed into significantly smaller blastocysts with fewer cells in the trophectoderm and displayed an altered metabolic pattern [103].

21.7.3 Polycystic Ovary Syndrome (PCOS)

Similarly to obesity, PCOS has significant effects on gene expression and defects in oocyte maturation [104]. The effect of these changes on embryo kinetics has been explored in a couple of studies to date.

Wissing and colleagues used TLM to evaluate embryo morphokinetics among three groups of women: 20 normo-ovulatory controls, 25 women with hyperandrogenic PCOS, and 26 women with normoandrogenic PCOS. The authors noted that embryos from hyperandrogenic PCOS seemed to develop slower through the early cleavage stages, although no differences were found between groups by the morula stage of development [104].

On the other hand, Sundvall and colleagues found that embryos from women with PCOS took significantly less time to initiate compaction and reach the morula stage than embryos from normo-ovulatory women. They noted no significant differences in the other timing parameters after adjusting for age, BMI, fertilization method, and male infertility. Interestingly, though, the proportion of multinucleated cells at the two-cell stage was significantly higher among PCOS embryos than non-PCOS embryos [105].

Given the conflicting findings of these two studies, further research is essential to discern if PCOS has detrimental effects on embryo kinetics.

21.8 Conclusions

Time-lapse imaging of embryos offers the opportunity to evaluate embryo morphology and kinetics with a noninvasive method in an undisturbed culture environment. Much insight

into early developmental characteristics has been revealed with this technology. Indeed, over 20 unique morphokinetic variables for normal embryo development have been described to date, and TLM has helped identify numerous abnormal morphological events that may otherwise be missed by static morphologic evaluation. Some of these markers have been found to be predictive of blastocyst development or implantation, while others have been identified as atypical markers of embryos with lower developmental potential. Nevertheless, despite the development of several TLM algorithms designed to predict implantation potential, unfortunately, few of the incorporated parameters have been successfully validated in multiple studies and none of the algorithms have been found to be consistently predictive of live birth, the ultimate goal of ART.

Based on existing studies, it is unlikely that TLM will supplant the existing standards of care of conventional morphologic evaluation with or without PGT-A. However, TLM may eventually evolve as an effective adjunct laboratory technique to enhance the deselection of otherwise morphologically normal-appearing embryos and the selection of the most developmentally competent embryo that is most likely to result in pregnancy and birth. Prior to that occurring, though, existing models need to be validated further, and additional well-designed prospective and randomized controlled trials need to be performed to determine whether or not use of TLM results in improved implantation and live-birth rates. Without such validation, we take the position that TLM should continue to be considered experimental and that patients should not be charged to have their embryos time-lapse imaged.

Review Questions

1. What are the different types of time-lapse microscopy (TLM) systems and what are the advantages and disadvantages of each?
2. What morphological characteristics have been described and/or better defined with the help of TLM?
3. What are the characteristics of an effective nomenclature system for TLM?
4. What parameters have been found to be predictive of blastocyst development? What parameters make up the *Eeva Test* and how has the *Eeva Test* been validated?
5. What types of models have been described for prediction of implantation potential? Please describe hierarchical selection models.
6. What are the conclusions of studies that have evaluated the use of TLM to predict live birth?
7. Can TLM be used to predict aneuploidy? How about gender?
8. Does insemination technique affect morphokinetic parameters? How about blastomere biopsy?
9. Do any maternal factors affect embryonic morphokinetic parameters?

Sperm Assessment: Traditional Approaches and Their Indicative Value

Tania R. Dias, Chak-Lam Cho, and Ashok Agarwal

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_22

Learning Objectives

- Traditional approaches of semen assessment represent the cornerstone in the initial evaluation of male fertility potential.
- Macroscopic evaluation of semen includes assessment of liquefaction, age, appearance, color, viscosity, volume, and pH.
- Microscopic evaluation includes sperm agglutination, motility, concentration, morphology, and presence of non-sperm cells.
- Adjunct tests including assessment of vitality, presence of white blood cells by peroxidase staining (also called Endtz test), and fructose tests may provide additional information in specific clinical scenarios.
- Current status of computer-assisted sperm analysis (CASA).
- Overview of recently developed home testing and smartphone-based kits for semen analysis.

22.1 Introduction

Male subfertility and infertility affect many couples during their reproductive age. The prevalence of these conditions has been increasing over the years [1], representing a major burden for health care systems [2]. This has been related to intentional delayed child-bearing by couples, particularly in developed countries, as well as environmental and lifestyle factors [3]. When a couple seeks medical counselling and assistance to achieve conception, workup of female factors usually comes first since it is commonly perceived that female factors are more significant in predicting the choice and success of assisted reproductive technology (ART) [4]. However, the recognition of male factors has been increasing and they contribute either directly or indirectly to 20–70% of infertile couples [4].

Semen analysis is the key investigation of infertile men because it reflects the overall functionality of sperm production by the testes, the patency of the genital tract, as well as the secretory activity of all accessory glands [5]. This information contributes to the effective establishment of individual diagnoses [6] and serves as the essential basic investigation of male factors in an infertile couple [7].

Standardization of semen analysis constitutes an important aspect of the investigation, not only to obtain valid and useful information but also to minimize intra- and inter-laboratory variations. The World Health Organization (WHO) defined reference values for several characteristics of human semen that are widely followed since the publication of the first manual in 1980. These reference values have been revised over the years, with the most recent and fifth update being issued in 2010 [8]. The latest WHO recommendations are based on semen parameters from approximately 2000 fertile men, from eight countries and three continents, whose partners had achieved pregnancy within 12 months of unprotected sexual intercourse [9]. This represents the first attempt to set reference values in an evidence-based approach. However, the one-sided criteria used to define normality in this edition, as shown in Table 22.1, led to criticism and controversy among clinicians and researchers, due to the huge switch in the definition of the lower cut-off limits for normality relative to previous editions [10, 11]. The inclusion of only semen analysis results from fertile patients in formulating the reference values is another pitfall. The WHO criteria should not be regarded as standard but rather a recommended reference for interpretation of human semen analysis results. It is likely that the reference values need to be revised regularly based on more recent data in addition to technical advances in semen analysis. Therefore, the reference limits for semen analysis should not be over-interpreted to distinguish fertile men from infertile men [12]. A specific diagnosis should be analyzed within the context of a patient's clinical history and physical examination.

Attempts have been made to improve "manual" semen assessment by laboratory technicians by incorporating more complex and innovative technological equipment and software to reduce individual subjectivity. However, despite all the advances, computer-assisted sperm analysis (CASA) techniques are still not widely used due to lack of accuracy and efficiency [13]. In this chapter, the conventional techniques used in routine semen analysis at Andrology laboratories, taking into account the reference values defined by

Table 22.1 Reference values for human semen assessment according to the WHO fifth edition criteria[a]

Parameter	Reference value
Liquefaction	15–30 min
Semen age	0–60 min
Color/appearance	White-gray/opaque
Viscosity	Disperse drops (thread <2 cm long)
Volume	≥1.5 mL
pH	≥7.2
Total motility (progressive + non-progressive)	≥40%
Progressive motility	≥32%
Sperm concentration	$\geq 15 \times 10^6$/mL
Total sperm count	$\geq 39 \times 10^6$/ejaculate
Undifferentiated round cells	$< 1 \times 10^6$/mL
Morphology (normal forms)	≥4%
Vitality	≥58%
Peroxidase-positive leukocytes	$< 1 \times 10^6$/mL
Seminal fructose	≥13 µmol/ejaculate

[a]World Health Organization (WHO) guidelines for human semen analysis (low reference values, fifth centile, 95% confidence intervals) [8]

WHO 5th edition criteria, are presented. Semen analysis adjunct tests, as well as the recent advances in CASA and its clinical role, are also discussed.

22.2 Conventional Semen Analysis

Semen analysis comprises a series of steps in the following sequence: collection, macroscopic evaluation, and microscopic evaluation (Fig. 22.1) [14]. A proper collection of the specimen and subsequent liquefaction are crucial steps for semen assessment as this procedure attempts to mimic the natural deposit of semen in the female reproductive tract as much as possible. If liquefaction does not occur properly, the physical and chemical properties of the specimen may be compromised [15]. Following liquefaction, simple characteristics such as semen age, appearance, viscosity, volume, and pH constitute the macroscopic analysis. Finally, microscopic evaluation consists of assessment of agglutination, presence of undifferentiated round cells, motility, concentration, and morphology [9, 16]. Adjunct tests including evaluation of vitality, presence of leukocytes, and concentration of seminal fructose may be helpful for specific patients depending on the clinical feature [17]. Although the coexistence of multiple altered seminal parameters increases the risk for infertility *per se*, it is important to understand that semen characteristics should be interpreted in the context of the patient's clinical history [7].

22.2.1 Specimen Collection for Diagnostic Purposes

The collection of the specimen influences the quality of the ejaculate and is dependent on the method used. Collection of semen should ideally mimic the in vivo situation. In practice, the collection of fresh ejaculate into a non-toxic sterile plastic container by masturbation represents a non-physiological situation and is a compromise for convenience. Under natural conditions, the male partner delivers the ejaculate in a sequential manner into the female reproductive tract [18]. The first fraction is from the bulbourethral glands that function as a lubricant to the urethra. This is followed by the emission of spermatozoa from the epididymis and prostate secretions that are expelled through the urethra in several boluses [19]. The initial spurts represent the richest sperm fraction of the ejaculate. In the following spurts, there is a gradual dominance of fluid from the seminal vesicles, as well as a gradual decrease in the amount of spermatozoa [20]. In contrast, for diagnostic purposes, the sample is collected at the clinical laboratory or at home and all the semen secretions are mixed at a single time into a specific container [14]. Ideally, the specimen collection should be made in a diagnostic laboratory under rigorous quality control standards. However, for the patient's convenience, there are also commercially available kits for sample home collection. There is evidence supporting the production of a better quality ejaculate when it is collected at home [21].

The most important issue of sample collection is the abstinence time, i.e., the number of days without ejaculation. Before sample collection, spermatozoa are stored in the epididymis until ejaculation. However, the epididymal storage is not completely emptied in a single ejaculation and the remaining spermatozoa stay until the next ejaculation [9]. On the other hand, there is an accumulation of spermatozoa in the absence of ejaculation, which will ultimately be reabsorbed. Ideally, the duration of sexual abstinence before the collection should be 2–3 days [8]. There is evidence supporting the use of shorter abstinence periods for certain ART procedures, which could be particularly important for oligozoospermic men [22].

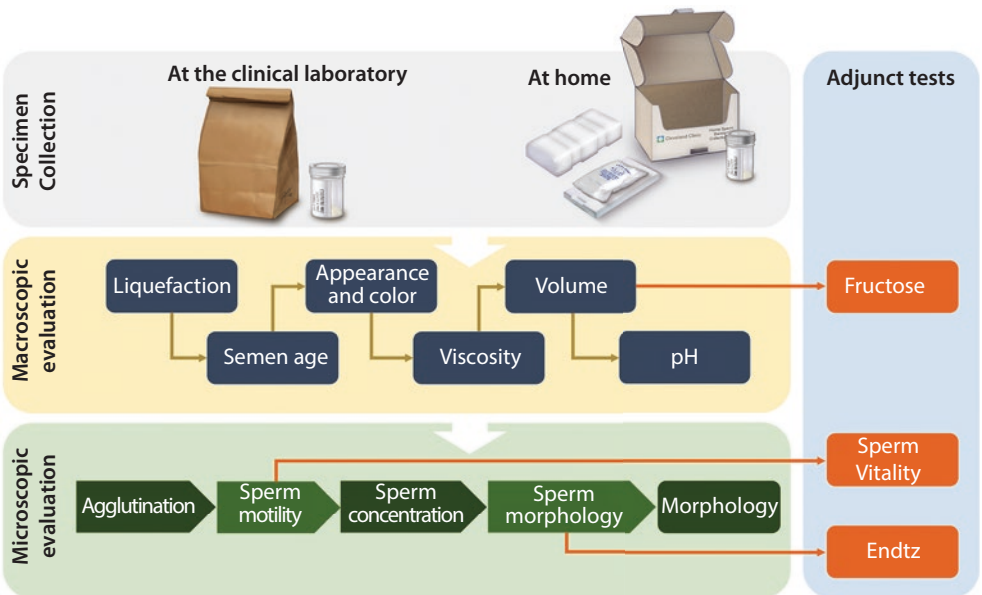

Fig. 22.1 Schematic representation of the semen analysis sequence, collection, macroscopic evaluation, and microscopic evaluation, as well as common adjunct tests performed when some parameters of semen analysis are abnormal

Due to the biological variability between samples from an individual, at least two separate seminal analysis are analyzed to achieve a definitive and accurate diagnosis [7]. The interval between separate semen analyses is arbitrary and is generally recommended to be of 2–4 weeks. Moreover, the same abstinence period is advised for repeated sample collections to facilitate comparison between results [23].

22.2.1.1 Collection at the Clinical Laboratory

Instructions for sample collection should be given to patients in advance. The specimen should be collected by masturbation into a wide-mouthed container and without using any lubricants or condoms with spermicidal agents [8]. Complete specimen collection is important since an incomplete collection may lead to misinterpretation of the results (e.g., hypospermia) [24]. Furthermore, the sample should be collected in a private room near the laboratory to minimize the transportation time to the laboratory. Time of collection should be noted by patient or laboratory staff.

22.2.1.2 Home Collection

For home collection, the same recommendations should be followed. Patients should be advised to record the time of collection and the specimen should be brought to the laboratory within 1 h [14]. Extra care should be taken during the transport of the sample by keeping it close to the body to maintain physiological temperature. The use of any condoms should be avoided. However, in the case of inability to produce a sample by masturbation and to avoid losing the first portion of the ejaculate by means of *coitus interruptus*, non-spermicidal condoms or silastic (silicone and elastic) sheaths may be used [25]. These condoms are specifically developed for specimen collection, although their toxicity to spermatozoa still needs to be scientifically tested.

22.2.1.3 Sample Handling at the Laboratory

The technician should record all the details of semen collection, including the patient's name; time of collection; time received; date, place, and method of collection; abstinence length; and completeness of collection. The clear and accurate recording of the information will avoid misinterpretations. During semen analysis, the technician should practice universal precautions to avoid contamination. The analysis should be completed within 60 min in a stepwise consecutive manner to avoid the possible deterioration of semen parameters.

22.2.2 Macroscopic Evaluation

Macroscopic semen analysis should begin with the examination of liquefaction, preferably within 30 min to 1 h after collection. Delay in processing may lead to dehydration or alterations in semen quality due to temperature and environmental changes since the specimen is being deposited in a non-natural environment. Routine macroscopic evaluation includes a quick examination of liquefaction, semen age, appearance, color, viscosity, volume, and pH.

22.2.2.1 Liquefaction

After ejaculation, human semen forms a loose gel-like coagulum in a few seconds [15] by the crosslinking of seminal vesicle proteins, semenogelins (I and II), and fibronectin [26]. The formation of this coagulum entraps spermatozoa to minimize the back-flow after deposit into the vagina and protects them from the acidic vaginal environment and immune attack. Subsequently, prostate-specific antigen (PSA) cleaves this clot to release the spermatozoa [27]. The ability of this enzyme to gradually digest the coagulum dictates the liquefaction time, which varies between a few minutes in vivo to 15–30 min in vitro [8].

Liquefaction can occur at room temperature, though it is recommended to maintain the specimen at 37 °C. Continuous gentle mixing or rotation of the sample container may facilitate the liquefaction process.

How Can It Be Evaluated?

Immediately after collection, the appearance of ejaculate is typically a gelatinous mass. During liquefaction, different components can be distinguished and the sample is described as a suspension of small gelatin-like drops in a fluid [28]. The sample is allowed to liquefy at room temperature or in the incubator at 37 °C for 15–20 min. The specimen is considered completely liquefied when homogenous and presenting a watery consistency [9].

What If Liquefaction Does Not Occur?

When liquefaction does not occur within 30 min, the sample should be incubated for an additional 30 min either at room temperature or in a 37 °C incubator [8]. An incompletely liquefied sample is suboptimal for semen analysis [17]. If a semen sample fails to liquefy within 60 min, this is defined as delayed liquefaction [9] and additional mechanical or enzymatic actions are needed to break down the coagulum and increase fluidity (see ▶ Sect. 22.2.2.4).

Clinical Interpretation of Delayed Liquefaction

Delayed liquefaction may indicate an incomplete collection of the ejaculate. Losing the last portion of the ejaculate may be a possibility. If the collection of the specimen was complete and it fails to liquefy, it may indicate impairment of the secretory activity of male accessory glands, in particular the prostate [29]. An abnormal liquefaction may also signify ejaculatory duct obstruction (EDO), congenital absence of the seminal vesicles (CASV), or genital tract infection [29, 30].

22.2.2.2 Semen Age

Semen age is given by the time interval between the collection and the start of the semen analysis after liquefaction. Semen age should not exceed 60 min to avoid deterioration of sperm quality due to environmental factors [8].

22.2.2.3 Semen Appearance and Color

A normal liquefied semen sample has a homogeneous appearance and a white-gray opaque color [8]. When it appears more transparent than usual it may indicate a low sperm concentra-

tion. Sometimes the semen sample may appear reddish-brown due to the presence of red blood cells (hematospermia) [29]. A yellowish color may occur in man with jaundice or after the ingestion of certain foods, vitamins, or drugs [9].

22.2.2.4 Viscosity

After liquefaction, the viscosity of the sample should be tested. Liquefaction and viscosity constitute distinct semen parameters with different clinical interpretations. While physical property of semen changes over time from a semi-solid to a liquid state during liquefaction, viscosity refers to the elastic properties of the sample after liquefaction.

How Can It Be Evaluated?

Viscosity of the semen can be evaluated by using a disposable plastic pipette of approximately 1.5 mm diameter. After aspirating a portion of the semen sample, it should be allowed to drop with gravity by pressing slowly. When small disperse drops are observed without the formation of any semen threads, the viscosity is considered as normal [8]. Conversely, the formation of a semen thread with more than 2 cm in length indicates hyperviscosity [15]. Hyperviscosity can be graded as slight, moderate, or high according to the length of the thread formed. Semen samples with a thread length of 2–4 cm are considered slightly hyperviscous; samples with a thread length of 4–6 cm are categorized as moderately hyperviscous; and those with a thread length greater than 6 cm are labelled as highly hyperviscous [15].

How to Proceed in Case of Hyperviscosity?

Hyperviscous semen specimens generally show elastic and sticky properties, reflected by the strong adhesion to the pipette tip while trying to aspirate, and its consistency will not change with time. This condition should be treated before further analysis as it may compromise sperm handling and quality during the assessment of sperm motility and concentration. To reduce viscosity, semen can be mechanically or enzymatically processed. Mechanical approach involves dilution of the sample with an equal volume of physiological medium followed by repeated pipetting [15]. These techniques are more effective in samples with slight and moderate hyperviscosity since vigorous and repetitive pipetting may seriously damage spermatozoa. For highly hyperviscous samples, reduction of viscosity can be achieved by the addition of proteolytic enzymes such α-chymotrypsin [31]. The enzyme α-chymotrypsin (5 mg) can be added to a hyperviscous semen sample (requirement of 0.5–5 mL in volume), which should then be incubated for an extra 10 min at 37 °C [32].

Clinical Interpretation of Abnormal Viscosity

Semen hyperviscosity is estimated to occur in 12–29% of the patients [15] and may reflect accessory glands dysfunction. Abnormal viscosity has been correlated with hypofunction of the prostate or seminal vesicles as their secretions are most abundant in seminal plasma. On the other hand, infections and inflammation of accessory glands or other male fertility-related diseases may also lead to semen hyperviscosity in men with functionally normal accessory glands [31].

Hyperviscosity impedes normal sperm motility and the tension of the trapping effect may interfere with the amount of energy needed to achieve a certain velocity, thus compromising sperm quality [15]. Although the underlying mechanisms by which hyperviscosity affects male fertility still need clarification, it has been associated with lower fertilization rates during ART, disrupted embryo development, and pregnancy failure [33].

22.2.2.5 Volume

Semen volume gives an indication of the overall functioning of the accessory sex glands [17]. Interestingly, the secretions from seminal vesicles are expected to decrease with age, thus having a major contribution to the decrease in the ejaculated volume over time [34]. According to the WHO manual, a sample is considered normal when the volume is at least 1.5 mL [8]. Calculation of total number of spermatozoa and undifferentiated round cells in an ejaculate requires an accurate measurement of semen volume. The ejaculated volume also varies with the abstinence length. The WHO recommends an abstinence period of 2–3 days prior to semen analysis [8].

How Can It Be Measured?

The volume can be measured using a graduated disposable serological pipette or by aspirating the entire specimen into a graduated tube.

Clinical Interpretation of Abnormal Volume

The semen volume is considered abnormal when it is less than 1.5 mL. A falsely low semen volume may be the result of incomplete collection and short period of abstinence. Ejaculatory duct obstruction and congenital bilateral absence of the vas deferens (CBAVD) are important differential diagnoses resulting in less fluid secretion [29]. Transrectal ultrasonography (TRUS) allows the evaluation of seminal vesicles and ejaculatory ducts and may be helpful in diagnosis [23]. Partial retrograde ejaculation represents another possibility of low semen volume. The complete lack of ejaculate is defined as aspermia [35].

22.2.2.6 pH

The measurement of pH constitutes an important part in semen analysis. While secretions from seminal vesicles are basic in nature, prostatic secretions are acidic. The predominant volume of secretion from seminal vesicles dictates the overall alkaline pH of semen under normal circumstances [17]. Although the reference value established by the WHO for semen pH is a one-sided value of ≥7.2, the pH should not be higher than 8 [8].

How Can It Be Measured?

For pH measurement, a drop of 3 μL of semen should be spread onto the pH paper (pH range 6.0–8.0), and the resultant color should be compared with the calibration strip [14].

Clinical Interpretation of Abnormal pH

Abnormal pH may indicate dysfunction of the accessory glands or incomplete collection of the ejaculate or an infection if pH exceeds 7.8 [8]. Conversely, for semen samples with pH <7.0, low volume, and low sperm numbers, ejaculatory duct obstruction and CBAVD are the differential diagnoses [36].

22.2.3 Microscopic Evaluation

The microscopic assessment gives information regarding the quality of sperm as well as the presence of non-sperm cells, including epithelial cells, immature germ cells, leukocytes, and debris. Microscopic evaluation of semen includes assessment of sperm agglutination, motility, concentration, morphology, and the presence of mucus strands and round cells (immature germ cells and leukocytes). The liquefied sample is thoroughly mixed in the original container, and only a small representative portion of the sample (about 50 μL) will be used for microscopic evaluation [37].

22.2.3.1 Agglutination

Agglutination means the attachment of motile spermatozoa to each other forming clumps. Different sites of attachment can be observed: head-to-head, head-to-tail, tail-to-tail, or mixed [8].

How Can It Be Evaluated?

A wet preparation is prepared by adding 10 μL of semen onto a clean slide and covering it with a coverslip. The dimension of the coverslip should be standardized according to the amount of sample used to create an approximate depth of 20 μm, which is ideal for sperm to move freely. The preparation should be left untouched for a few seconds, so the sample can stop drifting. Examination of the slide should be made under phase-contrast microscope at ×100 magnification [8].

Clinical Interpretation

In normal samples, no agglutination is present. The presence of any agglutination should be reported as it may interfere with the assessment of semen parameters and may indicate an immunological infertility [8]. Additional evaluation of anti-sperm antibodies is recommended in the presence of large and gross sperm clumps (see ▶ Chap. 23).

22.2.3.2 Sperm Motility

Sperm motility is one of the most important parameters when assessing sperm quality as it is an indicator of spermatozoa fertilizing competence [38]. Different types of sperm movement can be distinguished in a semen sample: progressive motility, non-progressive motility, or no motility [9]. While progressive motility describes a very active "space-gaining motion" in which spermatozoa can move linearly or in a large circle, non-progressive motility consists of all other patterns of motility [8]. These two categories of movement do not consider the speed of the spermatozoa to avoid individual bias and are mostly analyzed together as a measure of total motility.

How Can It Be Evaluated?

Sperm motility should be assessed as soon as possible after liquefaction, preferably within 30 min after ejaculation. Longer periods up to 1 h are acceptable but should be avoided to limit the bias from dehydration or changes in pH and temperature. At a clinical setting, disposable sperm counting chambers (Fig. 22.2a) are the most popular because they allow a one-step analysis for both sperm motility and concentration [14]. A drop of 5 μL of liquefied semen sample is loaded onto a counting chamber and examined under phase-contrast microscope with an eyepiece grid (Fig. 22.2b), at a magnification of ×200 in a minimum of five different fields [14]. The total number of progressive motile sperm should be counted first, followed by the total number of non-progressive motile sperm, and finally the total number of immotile sperm [8]. A laboratory counter is recommended for scoring and only intact spermatozoa should be considered. A minimum of 100 intact cells should be counted in the total of the 5 fields regardless of the category. The percentage of total motility is obtained by dividing the number of total motile cells (progressive + non-progressive) by the total number of cells counted (motile + immotile), multiplied by 100 [8].

Clinical Interpretation of Abnormal Motility

Men with low total sperm motility (<40%) and/or sperm progressive motility less than 32% are classified as asthenozoospermic. A falsely low motility may occur in a non-liquefied or hyperviscous sample. Low total or progressive motility can also be due to a delayed analysis [8].

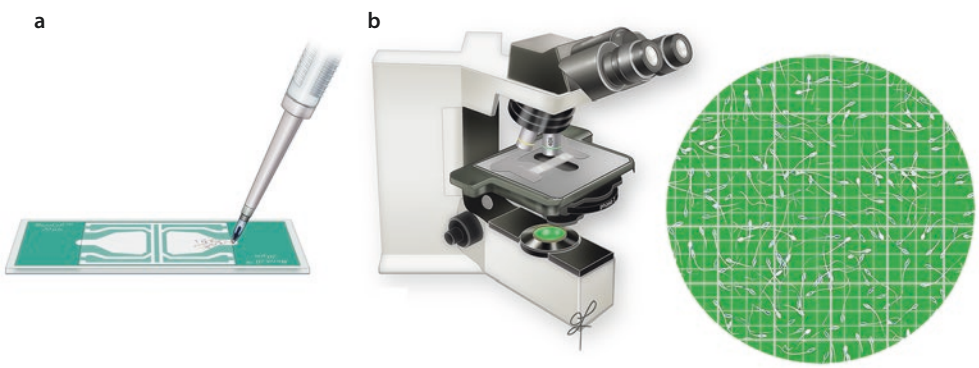

Fig. 22.2 Example of a disposable sperm counting chamber **a** and its analysis under a phase-contrast microscope with an eyepiece grid **b**

Abnormal motility may indicate ultrastructural sperm defects, including morphological deficiencies, or necrozoospermia [7]. These abnormalities can be induced by oxidative stress, which damages the sperm cell membrane and axonemal structure of sperm flagellum [39]. The presence of antisperm antibodies has also been associated with poor motility, mostly due to sperm clumping by agglutination [40, 41]. Primary ciliary dyskinesia is a less common cause of asthenozoospermia [7].

22.2.3.3 Sperm Concentration

Sperm concentration is defined by the number of spermatozoa per mL of ejaculate [8]. Sperm concentration should not be confused with total sperm count, which is defined by the total number of spermatozoa per ejaculate (sperm concentration multiplied by semen volume). In contrast to sperm concentration that is influenced by the functioning of other reproductive organs, total number of sperm per ejaculate is a direct measure of testicular sperm output. In addition, total number of progressively motile spermatozoa can be calculated by multiplying the total number of spermatozoa in the ejaculate by the percentage of progressively motile cells. The parameters of total number of sperm and progressively motile sperm in an ejaculate are widely adopted in the selection of ART treatment [42].

How Can It Be Evaluated?

Sperm concentration can be assessed using a hemocytometer (100 µm deep) [8]. However, it is quite laborious and time consuming. A large variation in proficiency testing also hinders its clinical use [43]. The one-step approach with disposable counting chambers is a reliable option that is adopted by many diagnostic laboratories. Several parameters have to be considered when using disposable counting chambers: (i) the number of fields counted, (ii) the magnification factor of the microscope, (iii) the number of rows counted (row factor), and (iv) the dilution factor. The microscope factor should be calculated individually for each microscope [14]. The first one or two rows of the grid should be counted for samples with high sperm concentration, while the whole grid should be examined for samples with low concentration. Proper dilutions with phosphate buffered saline (PBS) solution should be made to facilitate the counting. Thus, sperm concentration is calculated according to the following formula:

$$\frac{\text{Total number of sperm counted}}{\text{Total number of fields counted}} \times \frac{\text{Microscope factor}}{\text{Total number of squares in the grid}} \times \frac{\text{Total number of rows in the grid}}{\text{Number of rows counted}} \times \text{Dilution factor}$$

Clinical Interpretation of Abnormal Concentration

For sperm concentration below 15×10^6/mL, the patient is classified as oligozoospermic [8]. Patients with suspected azoospermia should provide at least two samples on different days. The samples should be centrifuged to allow the deposition of any spermatozoa [17]. Azoospermia is usually classified as obstructive or non-obstructive with an extensive list of differential diagnoses including hypogonadism, testicular failure, CBAVD, and ejaculatory duct obstruction (EDO) [29]. Additional findings of low semen volume, low pH, and lack of fructose on semen analysis are suggestive of obstructive etiologies. Endocrine evaluation, including the assessment of serum follicle-stimulating hormone (FSH) and testosterone levels, which reflect germ cell epithelium and Leydig cell status respectively, may be useful in cases of oligozoospermia and non-obstructive azoospermia [23].

22.2.3.4 Undifferentiated Round Cells

Round cells include immature germ cells and leukocytes. Using the same preparation as for the assessment of sperm motility and concentration, the number of round cells can also be estimated under phase-contrast at a magnification of ×200. The number of round cells should be counted in the whole grid (100 squares) by applying the same rule of counting the cells that touch the upper and left edges and in five random fields [14]. Consequently, the total concentration of undifferentiated round cells is given by the following formula:

$$\frac{\text{Total number of round cells counted}}{\text{Total number of fields counted}} \times \frac{\text{Microscope factor}}{\text{Total number of squares in the grid}}$$

Concentrations of more than 1×10^6/mL round cells in semen are considered abnormal. An abnormally high number of immature germ cells may indicate testicular damage, while leukocytospermia is suggestive of inflammation. The characterization of leukocytes can be further confirmed by assessing the peroxidase activity with the Endtz test [14]. Moreover, an increased number of epithelial cells and the presence of large amounts of debris should be documented. Although the findings are regarded as abnormal, they are non-specific in diagnosis [8].

22.2.3.5 Morphology

The assessment of sperm morphology is crucial for the evaluation of sperm quality. This is particularly important for ART treatment because morphologically normal cells are selected and associated with a better reproductive outcome [44]. Morphology is the most complex and difficult sperm parameter to analyze and interpret as the shape of spermatozoa varies within an ejaculate of one individual, as well as between different samples from the same individual [45].

How Can It Be Evaluated?

Although the normal morphological features of human spermatozoa have been described, microscopic assessment of sperm morphology remains challenging. According to the WHO guidelines, the reference value for normal sperm morphology by the strict criteria is 4% [8]. A smear is prepared by placing a drop (5–15 µL) of the well-mixed sperm suspension onto a slide. After air-drying, slides should be

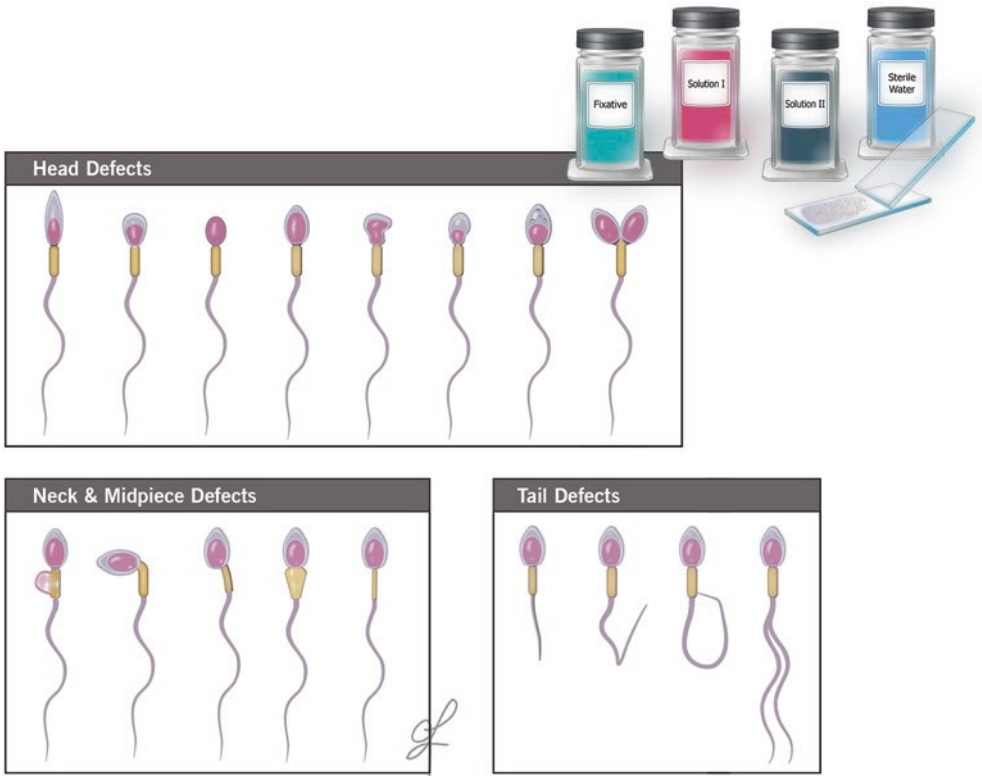

Fig. 22.3 Diff-Quik staining kit and common morphological defects of sperm head, neck and midpiece, and tail

fixed and stained by recommended staining methods: Papanicolaou, Shorr, or Diff-Quik. Diff-Quik (Fig. 22.3) is the most commonly used staining method at a clinical setting [8]. Although the slides can be directly examined under a microscope, the use of coverslip is recommended when long-term storage of the slides is required. Two hundred spermatozoa should be counted in each replicate (or twice in the same slide) in random fields using a bright field at ×1000 magnification with oil immersion to calculate the percentage of normality [8].

Clinical Interpretation of Abnormal Morphology

Abnormal sperm morphology (<4%) is classified as teratozoospermia. The origin and impact of some morphological abnormalities are still poorly understood. However, certain adverse sperm morphologies are attributed to abnormal spermatogenesis or sperm maturation, and suggestive of certain pathologies. Abnormal morphology may have an impact on chromatin condensation, acrosome reaction, sperm motility, and apoptosis/necrosis. Specific morphological defects, such as globozoospermia, sperm macrocephaly syndrome, multiple tail abnormalities, or headless spermatozoa, may be associated with genetic abnormalities [46].

22.3 Adjunct Tests for Semen Analysis

22.3.1 Vitality

The evaluation of sperm vitality (or viability) differentiates live or dead immotile spermatozoa. Assessment of sperm vitality is considered an adjunct test because it is recommended for samples with low sperm motility [8]. Analysis of sperm vitality is based on the integrity of sperm cell membrane. The most common methods include eosin-nigrosin staining technique and the hypo-osmotic swelling test. The reference value for normal vitality is ≥58% for both testing methods [8]. The presence of a large proportion of vital but immotile cells may be indicative of structural defects in the flagellum [47], whereas a high percentage of non-viable cells (necrozoospermia) may suggest epididymal pathology [48].

22.3.1.1 Eosin-Nigrosin Staining

Eosin-nigrosin staining is one of the most common methods to assess vitality. A drop of sperm suspension is mixed with two drops of eosin and nigrosin solutions (Fig. 22.4a) and a smear is prepared onto a slide and covered with a coverslip [49]. Eosin will penetrate the nucleus of membrane-damaged spermatozoa by staining non-viable sperm light-to-dark pink, while intact living cells will have the ability to exclude the dye and appear white (Fig. 22.4a). The background purple color of nigrosin facilitates the analysis. The examination of the slides under the microscope should be made using a bright field at ×1000 magnification with oil immersion. A total of 200 cells should be counted in different random fields and in replicate slides, and the percentage of viable cells can be calculated [50].

22.3.1.2 Hypo-osmotic Swelling Test

The hypo-osmotic swelling test is based on the principle that only living cells with intact membranes will swell under hypo-osmotic conditions (150 mOsmol/L). The influx of fluid into viable cells is reflected by the curling of sperm tails

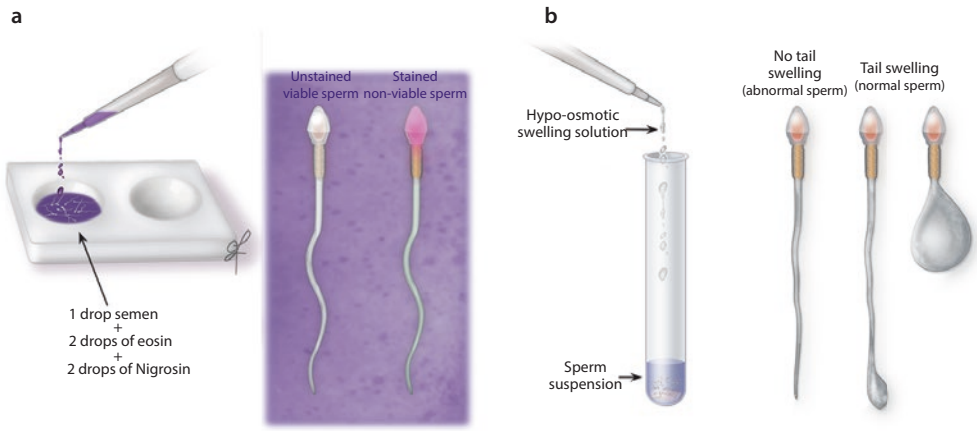

Fig. 22.4 Sperm vitality tests. Eosin-nigrosin staining **a** and hypo-osmotic swelling **b**

(Fig. 22.4b) [51]. One of the advantages of this test is that it does not kill the spermatozoa which allows the utilization of those spermatozoa for ART [52]. In this method, the sperm sample should be mixed with the hypo-osmotic solution and incubated at 37 °C for 30 min (5 min if the sample is going to be used for ART). After incubation, a wet preparation should be made to assess the sample under a phase-contrast microscope (×200 or ×400 magnification). A total of 200 spermatozoa should be counted and classified as dead or alive [8].

22.3.2 Endtz Test

Granulocytes (polymorphonuclear leukocytes) are the most abundant type of leukocytes in human ejaculates and neutrophils are the most common subtype. A simple histochemical test, also referred to as Endtz test, is used to detect peroxidase within neutrophils, thus allowing the screening of granulocytes in the semen. This test relies on the ortho-toluidine staining of peroxidase-positive cells and should be performed when an abnormal concentration of round cells is detected ($>1 \times 10^6$/mL) [53]. However, Endtz test detects neither peroxidase-free leukocytes (e.g., lymphocytes, macrophages, or monocytes) nor those granulocytes that have already released their granules [8].

A 20 µL drop of semen is mixed with the same volume of PBS and the double volume of freshly prepared working Endtz solution. The mixture is incubated for 5 min at room temperature and protected from light. After incubation, 5 µL of the mixture is placed into a Makler chamber and analyzed under a bright field optic (×200 magnification). The whole grid (100 squares) of the counting chamber should be analyzed by counting all the dark brown-stained peroxidase-positive cells [54].

A concentration of leukocytes $\geq 0.2 \times 10^6$/mL in a semen sample is generally considered Endtz positive [54]. However, a higher reference value is usually acceptable for routine semen analysis, and an Endtz positive sample is defined with a concentration of leukocytes $\geq 1 \times 10^6$/mL [8]. Abnormal leukocyte count is a common finding in subfertile men and may reflect an underlying inflammatory/infective ethology [55]. The incidence of leukocytospermia in infertile men varies between 3% and 23% and has been correlated with clinical and subclinical genital infections, elevated anti-sperm antibody levels, and high levels of reactive oxygen species (ROS) [56, 57].

22.3.3 Fructose Test

Fructose in semen is a marker for seminal vesicles function and is usually performed to localize the level of obstructive azoospermia in men with low ejaculate volume. The concentration of fructose can be evaluated by a biochemical assay, which is based on the ability of fructose to form a colored complex with the indole [58]. This method should be performed after concluding the routine semen analysis since it requires the centrifugation (1000 × g for 10 min) of the semen to separate seminal plasma from spermatozoa. A 5 µL drop of seminal plasma should be diluted in 50 µL of distilled water and then mixed with $ZnSO_4$ (63 µmol/L) and NaOH (0.1 mol/L) to allow deproteinization. After incubation of the mixture for 15 min at room temperature, the sample should be centrifuged at 8000 × g for 5 min. Then, 50 µL of the supernatant is mixed with the same volume of indole reagent and 5 mL of hydrochloric acid (HCl 32% v/v) and incubated at 50 °C for 20 min, followed by 15 min of cooling on ice. The absorbance of the formed complex is measured with a spectrophotometer at 470 nm and the concentration of fructose in the sample is calculated according to a standard curve. The lower reference limit for fructose defined by the WHO is 13 µmol per ejaculate [8]. A low content of fructose in seminal plasma together with a low semen volume and low pH supports the diagnosis of obstructive azoospermia [59]. Low fructose is also characteristic of CBAVD or in men with partial retrograde ejaculation [60, 61].

22.4 Computer-Assisted Sperm Analysis (CASA)

Computer-Assisted Sperm Analysis (CASA) systems have been developed in the last three decades with the main objective of reducing the subjectivity of the current semen assessment technique and possibly decreasing intra- and

inter-observer variability [62]. These systems also aim to reduce the labor-intensive and time-consuming nature of the standard techniques. However, the complexity of semen analysis which includes multiple parameters and a wide spectrum of microscopic skills poses difficulties in the development of automated computer systems. Currently, many CASA manufacturers are using different software and principles. Most of these systems establish a centroid for each spermatozoon and evaluate cell motion based on centroid trajectory, while others focus on bulk movement of the sperm population. Another type of system uses continuous images to correlate properties of each pixel in one image with temporal fluctuations of the signal from the same pixel to the subsequent image [62]. This variety of algorithms together with the increasing sophistication of hardware complicates the comparison of results between different CASA systems. Nevertheless, many laboratories have included CASA in the routine assessment of sperm parameters mainly as a control for the comparison to standard technical analysis, rather than as a stand-alone replacement technique [63]. There is still a lack of consensus regarding the clinical application of this technology, especially due to the low number of studies supporting its accuracy and correlation with reproductive outcomes.

22.4.1 Which Semen Parameters Can Be Evaluated by CASA?

The majority of currently marketed CASA systems allow the analysis of sperm concentration, vitality, and motility, while only a handful of systems available in the market have incorporated the computer-aided sperm morphometric assessment (CASMA) tool [63]. Sperm concentration is an objective parameter of semen analysis. The principle of evaluating sperm concentration is the same between manual and computer counting thus resulting in comparable sperm counts [64]. However, the computed-assisted method is faster and allows the analysis of more samples in a shorter time. The accuracy of sperm concentration analysis by CASA is highly dependent on the sperm counting chamber that is specifically affiliated to it [65]. Recent CASA systems have improved the accuracy of sperm concentration analysis by the incorporation of DNA fluorescent-staining. This allows a better distinction of spermatozoa from non-sperm particles by using a fluorescent microscope [66]. Moreover, a few systems incorporated mathematical algorithms specific for tail-detection to avoid overestimation of sperm concentration by counting non-intact spermatozoa or debris. However, the precision of the measurement by CASA decreases outside an optimal range of sperm concentration between 2 and 50×10^6/mL [67]. The same fluorescent principle is used by some CASA instruments for the determination of sperm vitality. Recently, some CASA manufacturers are trying to implement the assessment of eosin-nigrosin staining automatically in order to reduce the costs associated with fluorescence microscopy [68].

Sperm motility and morphology involve a subjective assessment by the technician during standard semen analysis, and one way to overcome this issue is by defining objective criteria for assessment of sperm motility and morphology. The assessment of sperm motility with CASA is based on system-specific algorithms to measure the sperm kinematics, i.e., the characteristics that describe sperm movement, as opposed to the proportion of motile cells. Sperm kinematics is reflected by three parameters: sperm motion velocity, velocity ratios, and wobble (Table 22.2) [63]. Therefore, the assessment of multiple objective criteria by CASA systems may be particularly helpful when assessing sperm progressive motility. The information allows more detailed categorization of sperm motility into four grades: (i) Grade 4, rapidly progressive cells; (ii) Grade 3, slowly progressive cells; (iii) Grade 2, weakly twitching cells (non-progressive); and (iv) Grade 1, immotile cells, compared to the three-grade system recommended by the WHO guidelines for manual assessment. At least 100 spermatozoa should be counted in a total of 5 random fields [14]. After calculating the percentage for each category, the predominant grade should be reported. Subclassifications of progressive motility into rapid and slow subgroups by CASA would not be feasible with manual assessment without significant bias [69].

The use of CASMA tool for sperm morphology allows the classification of a spermatozoon as normal or abnormal according to the dimensions of the head and midpiece, head ellipticity, and regularity, and they can identify the acrosome area by a staining method [8]. The multitude of unpredictable shapes and defects that spermatozoa may present in the sample, as well as its similarity with other non-sperm cells represents the major obstacle in efficient assessment of sperm morphology by automated systems.

22.4.2 Advantages and Disadvantages of CASA

CASA systems have the potential to revolutionize semen analysis. The technique decreases subjectivity during standard manual semen analysis. The system also allows more rapid analysis of a larger sample which will reduce sampling error. More importantly, introduction of novel concepts in assessment of motility by kinematics may better reveal the overall quality of sperm. CASA also provides advanced image tools that allow the recording of pictures and videos throughout the analysis (Fig. 22.5), which may be helpful for standardization and quality assurance. This would also give the possibility of data re-analysis whenever needed by a clinician while establishing a diagnosis or selecting an ART treatment.

The limited number of parameters that can be measured by CASA compared to standard procedures represents a major pitfall of the system. The cost-effectiveness of using the CASA system in Andrology laboratories is doubtful when a significant portion of macroscopic and microscopic evaluation of semen samples has to be done manually. In addition, the equipment requires constant supervision and calibration,

Table 22.2 Characteristics of sperm kinematics evaluated by the CASA instruments [63]

Characteristics	Parameters	Abbrev	Meaning	Details
Sperm motion velocity	Curvilinear velocity	VCL (μm/s)	Time-averaged velocity of a sperm head along its actual curvilinear path	Highest value among sperm motion velocity parameters
	Straight-line velocity	VSL (μm/s)	Time-averaged velocity of a sperm head along the straight line between its first detected position and its last, reflecting the net space of a sperm's forward motility during the observation period	Lowest value among sperm motion velocity parameters
	Average path velocity	VAP (μm/s)	Time-averaged velocity of a sperm head along its average path, which is determined by smoothing the curvilinear trajectory according to specific algorithms	VAP is almost identical to VSL when the sperm motion trajectory is very regular and linear, and it is much higher than VSL when the sperm motion path is irregular
Sperm velocity ratio	Linearity	LN	VSL/VCL ratio	Linearity of a curvilinear path
	Straightness	STR	VSL/VAP ratio	Linearity of the average path
	Wobble	WOB	VAP/VCL ratio	Oscillation of the actual path in comparison with the average path
Sperm wobble	Amplitude of lateral head displacement	ALH (μm)	Magnitude of lateral displacement of a sperm head about its average path	Can be expressed as a maximum or an average of such displacements
	Beat-cross frequency	BCF (Hz)	Average rate at which the curvilinear path crosses the average path	Useful parameter assessing the changes in wobble way of a sperm flagellum
	Mean angular displacement	MAD (degrees)	Time-averaged absolute values of the instantaneous turning angle of the sperm head along its curvilinear trajectory	Very sensitive to the sampling rate

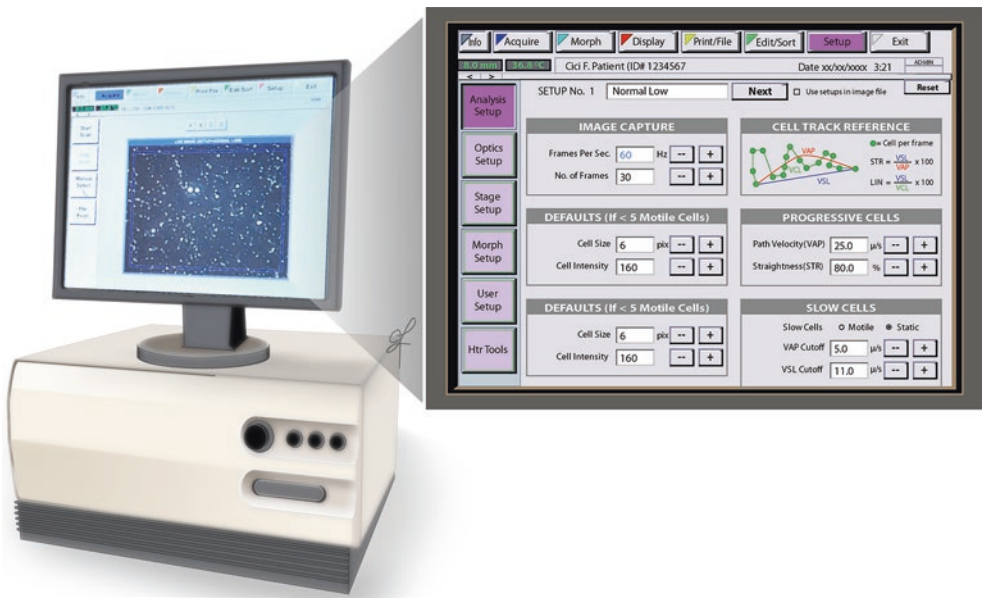

Fig. 22.5 Representative image of a computer-assisted semen analysis (CASA) system and display of the obtained results

as well as specific supplies such as counting chambers and well-trained personnel. There is currently a huge variety of hardware and software available in the market. The lack of standardization of CASA systems makes the comparison of results among different CASA instruments impossible. Another drawback is the insufficient robustness of CASA as a stand-alone technique, which is mostly due to concomitant biological factors and technical errors. Biological factors

including semen hyperviscosity, presence of other cell types, the highly pleomorphic nature of sperm, and sperm agglutination may significantly hinder CASA interpretation without prior specimen preparation. Technical errors due to improper sample preparation and loading into the chamber, excessive time taken from sample preparation to analysis, and lack of internal quality control and training may represent another source of error during CASA semen analysis [68]. There is also a lack of accuracy in CASA semen analysis due to the limited capability of the available software to distinguish spermatozoa from other objects of similar size such as round cells, cytoplasmic droplets, and debris, as well as difficulties inherent to sperm clumping.

Furthermore, only a small number of studies provide evidence for the significance of sperm analysis through CASA in the prediction of reproductive outcomes. A significant association has been observed between the CASA analysis of sperm concentration and progressive motility with the fertilization rates and time to conception [70, 71]. Moreover, CASMA tools were also reported as significant predictors of in vitro fertilization rates [72] and natural pregnancy in subfertile couples [67]. More studies are needed to clarify the significance of CASMA automated tools using larger samples. Currently, there is no consensus on the clinical utility of CASA systems for diagnostic purposes. Further studies on standardization of reference values and proper training of technicians are essential for better credibility and acceptance of CASA semen analysis in clinical practice.

22.5 Recent Advances in Semen Analysis

Recent technological advances led to the development of some new approaches of semen analysis, particularly the home testing methods, in an attempt to increase compliance rates and privacy [73]. The technology possibly reduced the reluctance of patients to seek medical fertility advice and minimize embarrassment in collecting a semen sample at a clinical laboratory. Moreover, it also allows immediate testing upon sample collection, thereby reducing potential errors due to transportation and handling. One of the products which are commercially available with promising accuracy is the SpermCheck Fertility Test. This test is based on a color change antibody reaction that allows a quick estimation of sperm concentration in the ejaculate. It is an easy-to-use stepwise method that gives a positive result when sperm concentration is at least 20×10^6/mL and negative result below that limit [74]. Similar tests with the same principle are available, such as Fertell and SwimCount devices, to estimate total motile count and a paper-based test that estimates concentration, motility, and viability [73]. Interestingly, several smartphone-based approaches have been proposed such as the Trak device or the YO Sperm Test. Trak is provided as a package including a centrifugation device and disposable microfluidic chambers which is sufficient to perform four tests. This device allows the classification of sperm concentration as low ($<15 \times 10^6$/mL), moderate (15×10^6/mL), or optimal (55×10^6/mL) for conception, and the provided smartphone app allows users to enter data and track their sperm count. The YO sperm test includes a device that can be directly connected to a smartphone to see the results within the app itself. It allows the estimation of the concentration of motile sperm by using the phone's camera and flash to record a video of the sperm in the sample [73]. Smartphones are a worthy testing platform since they are commonly used; have computing power, internet access, and high-resolution cameras; and allow data storage [75]. Their use may serve as a screening tool for patients before seeking medical assistance for further confirmatory testing and it may increase the awareness for a possible fertility problem. In contrast to traditional laboratory tests, the easy repeatability of the tests at a low cost allow the recording of changes in sperm parameters over time and may serve as a convenient means to monitor treatment response. Although these promising tests have shown high percentage of accuracy in pilot studies, they are also associated with some drawbacks inherent to their novelty. One of the main issues is that most of these home testing devices can only provide information on a single or a few sperm parameters at a time.

22.6 Conclusion

The correct interpretation of semen analysis results is based on a combination of multiple sperm parameters together with clinical information. Coexistence of multiple altered seminal parameters signifies the probability of sperm dysfunction and is associated with male infertility. Therefore, proper handling of sample and standardization of semen analysis is of utmost importance for diagnosis and evaluation of infertile men. The development of automated systems such as CASA aims to overcome at least some of the current limitations of semen analysis by providing objectivity, precision, and reproducibility compared to standard manual analysis. However, questionable efficiency, lack of standardized guidelines, inconsistency between different equipment, and high costs of CASA systems limit its current clinical application. Finally, home testing approaches have shown promising accuracy and may be adopted as a valuable tool. The technology may be a cost-effective self-screening test before seeking medical assistance.

Review Questions (MCQ Format)

1. Which of the following statements concerning semen analysis is incorrect?
   (a) Semen analysis is the most widely used laboratory test in male fertility assessment.
   (b) The World Health Organization manual provides reference values for semen analysis.
   (c) 7–10 days of abstinence is suggested before semen sample collection.
   (d) Evaluation of specimen should start after liquefaction.

2. What is the type of information provided by traditional semen analysis?
   (a) Information regarding the patient's semen quality
   (b) Information about the patient's fertilizing potential
   (c) Information about the function of the accessory glands
   (d) All of the above

3. Which of the following parameters is not part of routine microscopic evaluation of a semen sample?
   (a) Sperm concentration
   (b) Sperm motility
   (c) Sperm morphology
   (d) Sperm vitality

4. Which of the following sentences is correct about routine semen analysis?
   (a) A single parameter can discriminate between infertile and fertile men
   (b) Three altered parameters indicate a diagnosis of infertility
   (c) Routine semen analysis by itself is not sufficient to establish fertility status
   (d) All the sentences are incorrect

5. Which of the following statements concerning computer-assisted sperm analysis (CASA) systems is correct?
   (a) Standard manual semen analysis will gradually be replaced by CASA.
   (b) Sperm kinematics is a novel concept in assessment of sperm motility by CASA.
   (c) CASA systems report semen parameters in the same way as standard semen analysis.
   (d) Sperm morphometric assessment provides accurate results.

6. What are the factors hindering the clinical implementation of computer-assisted sperm analysis (CASA) systems?
   (a) Lack of standardization and inability of comparison between systems
   (b) Ability to record pictures and videos during the analysis
   (c) Increased objectivity relative to standard procedures
   (d) Analysis of many samples in a short time

7. What are the advantages of smartphone-based approaches in the assessment of infertile men?
   (a) First screening before seeking medical advice
   (b) Easiness to perform the test and quickness of the results
   (c) Low-cost and high correlation with laboratory results
   (d) All of the above

8. Which of the following statements concerning home testing approaches in semen analysis is correct?
   (a) Home testing kits are not commercially available currently.
   (b) The approach allows convenient sample collection and immediate analysis at home.
   (c) Home testing devices provide assessment of multiple semen parameters.
   (d) The use of home testing kits requires special training.

Answers

1. (c)
2. (d)
3. (d)
4. (c)
5. (b)
6. (a)
7. (d)
8. (b)

Sperm Assessment: Novel Approaches and Their Indicative Value

Tania R. Dias, Chak-Lam Cho, and Ashok Agarwal

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_23

Learning Objectives

- Limitations of conventional semen analysis
- Laboratory semen assessment beyond routine procedures
- Assessment of prooxidant-antioxidant semen profile: reactive oxygen species (ROS) levels, total antioxidant capacity (TAC), and oxidation-reduction potential (ORP)
- Methods to evaluate sperm DNA fragmentation
- Assessment of sperm fertilization capacity: acrosome reaction and sperm mitochondrial function
- Tests for antisperm antibodies
- Clinical value of advanced semen and sperm assessment

23.1 Introduction

Conventional semen analysis is the essential basic investigation for male fertility assessment during the evaluation of an infertile couple [1]. However, the enthusiasm in male factor infertility has diminished since the introduction of intracytoplasmatic sperm injection (ICSI) in 1992. Sperm without the ability to penetrate the ovum could be directly injected into the oocyte cytoplasm to achieve fertilization by ICSI. This revolutionized the approach of reproductive medicine toward assisted reproductive technology (ART) and shifted the emphasis away from evaluation of infertile men, as the most severe form of male infertility could be possibly bypassed by ICSI [2]. However, the possible threat to the offspring's health remains a concern, since defective sperm may fertilize an ovum by ICSI [3]. The identification and correction of male factors is essential to improve the reproductive outcomes of infertile couples.

Standard semen analysis has its own drawbacks in establishing the fertility status of a man and is prone to errors. Although the equipment and techniques have changed over time, the basic principles of semen analysis remained the same over the years [4]. Multiple altered semen parameters are found in infertile men, but the findings are usually nonspecific for diagnostic purposes [5]. Abnormal semen parameters cannot accurately predict infertility. On the other hand, a significant proportion of infertile men have apparently normal semen parameters and are classified as idiopathic male infertility [6]. The imprecision of standard semen analysis to predict the reproductive outcome is essentially due to the inherent biological variability between ejaculates [7] and subjectivity of human manual analysis [8]. Despite all the efforts of World Health Organization (WHO) to standardize semen analysis procedures and define reference values, different laboratories continue to use different techniques and guidelines [9]. The pitfalls of conventional semen analysis led to the exploration of novel approaches. Evaluation of sperm function represents one of the most important research targets. Normal sperm function involves multiple interrelated factors that are essential to achieve fertilization, pregnancy, and embryonic development. The attempt to detect abnormal sperm function has prevailed for decades without success and constitutes one of the major challenges to fertility specialists. Some sperm function tests have long been developed to assess sperm-oocyte penetration, capacitation, acrosome reaction, and antisperm antibodies with the aim to overcome the limitations of conventional semen analysis. However, none of the tests has been widely implemented in clinical practice and only a few remained after the emergence of ICSI. Currently, acrosome reaction testing, sperm mitochondrial activity assay, and antisperm antibody tests are utilized by some of the andrology laboratories.

The novel concept of OS has been identified as a major cause for male infertility. The clinical significance of laboratory tests to evaluate OS by measuring reactive oxygen species (ROS), total antioxidant capacity (TAC), and oxidation-reduction potential has been investigated. Sperm DNA fragmentation represents one of the consequences of OS and a target for laboratory assays. The negative implication of high sperm DNA fragmentation to reproductive outcomes has been demonstrated by various studies. However, emerging evidence supports the ability of these tests to provide additional information and better discriminate between infertile and fertile men. The wide clinical application of the tests is still predestined to further research. This chapter will cover the principles and clinical value of currently available laboratory tests beyond routine semen analysis, as well as future directions for the development of new approaches.

23.2 Assessment of Prooxidant-Antioxidant Semen Profile

23.2.1 Reactive Oxygen Species

23.2.1.1 What Are Reactive Oxygen Species?

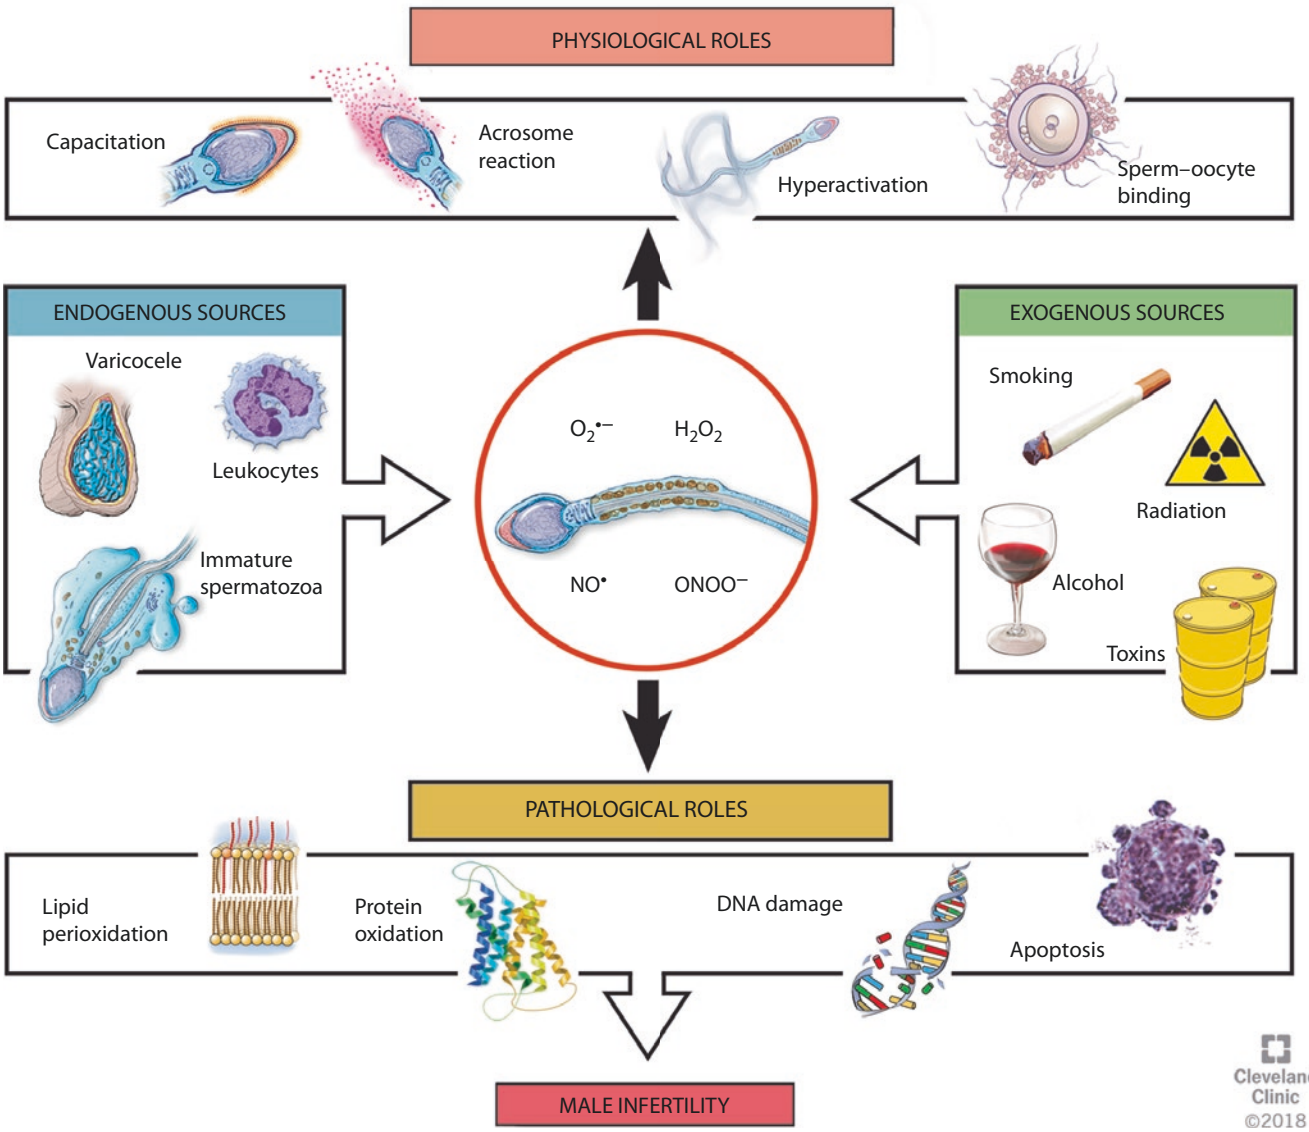
The term ROS refers to by-products of the normal metabolism of oxygen [10]. They can be free radicals, which are unstable and highly reactive compounds due to the presence of at least one unpaired electron in an outer orbital. Examples of free radicals in biological systems include superoxide anion ($O_2^{\bullet-}$) and hydroxyl radical ($^{\bullet}OH$). However, some non-radical oxygen derivatives are also included in the ROS category such as singlet oxygen ($^1O_2$), hydrogen peroxide (H_2O_2), peroxynitrite ($ONOO^-$), and hydrogen hypochlorite ($HOCL^-$). These non-radical compounds do not contain unpaired electrons, but they are still potentially reactive and can be converted to radical ROS [11]. Another important type of ROS prooxidant includes those containing nitrogen in their constitution, sometimes called as reactive nitrogen species (RNS). Nitric oxide ($NO^{\bullet}$) and nitrous acid (HNO_2) are examples of radical RNS, while nitrogen dioxide (NO_2) and dinitrogen tetraoxide (N_2O_4) are non-radical RNS [12]. Throughout this chapter, the abbreviation ROS will include all the aforementioned types.

The main sources of ROS in semen are immature or abnormal spermatozoa and leukocytes. ROS are physiologically generated by mitochondria during energy production [13]. Although

most of the oxygen consumed by the mitochondrial electron transport chain is reduced to water, a small proportion is converted to ROS. Nicotinamide adenine dinucleotide phosphate (NADPH) oxidase on the plasma membrane is also another source of cellular ROS [14]. Pathological conditions such as varicocele or other exogenous factors including cigarette, radiation, or drugs are major stimuli for ROS overproduction.

23.2.1.2 How Do Reactive Oxygen Species Affect Sperm Quality?

ROS have a physiological role and are essential for the regulation of cell signaling pathways, enzymatic activities, and immune defenses [15]. In addition, ROS play an important role in sperm fertilization, as they are one of the triggers for hyperactivation, capacitation, acrosome reaction, and sperm-egg fusion (◘ Fig. 23.1) [16]. Excessive ROS that are not used for biological processes are stabilized or eliminated by antioxidant defenses, so that the prooxidant-antioxidant homeostasis can be maintained. However, OS is established when excessive ROS production overwhelms the capacity of cellular antioxidant system, or when antioxidant reserves are abnormally low. OS can compromise sperm quality via impaired spermatogenesis, defective sperm function, or even apoptosis [17]. Among the most common ROS produced in sperm are superoxide anion, hydrogen peroxide, nitric oxide, and peroxynitrite. ROS can "steal" an electron from a target molecule to attain stability. The molecule that loses the electron becomes a free radical itself, which will also take an electron from a nearby molecule. This will trigger a cascade of reactions that, if uncontrolled, will result in severe cellular damages and even cell death. Proteins, lipids, and DNA are the core targets of ROS, resulting in protein oxidation, lipid peroxidation, and/or oxidation of DNA bases, respectively [11]. Spermatozoa are particularly susceptible to oxidative



◘ **Fig. 23.1** Physiological versus pathological roles of reactive oxygen species (ROS) in spermatozoa and the main endogenous and exogenous ROS sources

damages due to their limited intracellular defense system. During spermiation, most of the sperm cytoplasm is removed, thus removing most of the antioxidant defenses as they are mostly present in the cytoplasm. Besides, the sperm plasma membrane is rich in polyunsaturated fatty acids (PUFAs), which are prone to oxidation in the presence of ROS, generating lipid peroxyl radicals. Those radicals contribute to the formation of hazardous adducts, such as the 4-hydroxynonenal (4-HNE) and thiobarbituric acid reactive species (TBARS), which initiate a chain reaction of free radical generation described as lipid peroxidation. Consequently, there is a loss of fluidity in spermatozoa membrane that results in impaired sperm motility and fertilization failure [18]. Sperm proteins constitute another target of ROS attack. Oxidation of proteins by ROS leads to the addition of carbonyl groups to their side chain. This alteration in the structural conformation of proteins can result in the inactivation of key enzymes involved in sperm function. The effects on sperm DNA will be discussed later in this chapter.

23.2.1.3 Methods to Measure Reactive Oxygen Species

Several methods can be used to evaluate ROS generation in semen or specifically in spermatozoa. The short half-lives of ROS constitute the major obstacle in the direct measurement of ROS. Alternatively, ROS can be measured indirectly by the assessment of end-products generated after ROS attack to semen/sperm biomolecules. Fresh samples are preferred for ROS measurement because sample storage (at −80 °C or cryopreservation) has been associated with a higher production of ROS [19, 20].

Chemiluminescence

One of the most common techniques to measure ROS levels in semen is by chemiluminescence [21]. This method is based on the production of light through the reaction between a probe and ROS. The emitted light is converted to an electrical signal (photon) by a luminometer and the ROS levels in the sample are calculated as relative light units (RLU) per second (Fig. 23.2) [22]. This method allows a real-time monitoring by a computer system. Two main types of probes can be used: luminol for both intracellular and extracellular ROS and lucigenin for extracellular ROS. Luminol is an uncharged membrane permeable molecule that can react with a variety of ROS, including $O_2^{\bullet-}$, H_2O_2, OH, and peroxynitrite. Lucigenin carries a positive ionic charge, which makes it membrane-impermeable and it reacts mainly with $O_2^{\bullet-}$ [23]. The resulting value is then normalized to the sperm concentration in the semen to estimate ROS generated by spermatozoa. Recently, a reference value of <102 RLU/s/million sperm was proposed as normal for ROS levels in whole ejaculates [24]. There are multiple confounding factors which may affect the result of chemiluminescence assays, including sample volume, time of analysis, viscosity of the sample, concentration of reactants, reagent injection, temperature, and background luminescence [24]. Advantages and disadvantages of the test are presented in Table 23.1.

Fluorescence: Flow Cytometry

The intracellular levels of ROS can be measured by flow cytometry using non-fluorescent probes. 2,7-Dichlorofluorescein diacetate (H_2DCFDA) is a stable cell-permeable probe that de-esterifies in the presence of H_2O_2 to form a fluorescent 2,7-dichlorofluorescein (DCF) product. Other ROS such as peroxynitrite, hypochlorous acid, and OH• can also oxidize this probe and may significantly contribute to the positive signals observed in defective spermatozoa [25]. Another probe, dihydroethidium (DHE), can be oxidized mainly by superoxide ions and to a much lesser extent by other ROS [26], resulting in the hydroxylation at the 2-position forming 2-hydroxyethidium with red florescence emission at 488 nm, which will stain the mitochondrial and nuclear DNA [25]. The oxidation of these dyes results in fluorescent derivatives that can be detected by the flow cytometer. These probes can be used along with vitality (SYTOX green) or apoptotic (propidium iodide)

Fig. 23.2 Luminometer and real-time monitoring of reactive oxygen species (ROS) levels through a connected computer

Table 23.1 Advantages/disadvantages of the available methods to measure reactive oxygen species (ROS)

Method	Type of sample	Principle	Advantages	Disadvantages
Chemiluminescence	Whole ejaculate	Measures ROS production in real time using specific probes: luminol/lucigenin	Robust High sensitivity High specificity Measure intracellular and extracellular ROS Reproducible	Expensive Time-consuming Limited half-lives of the probes and ROS Requires large sample volume
Fluorescence	Whole ejaculate	Measures the fluorescent signal emitted by the oxidation of non-fluorescent probes by ROS	A large number of cells can be analyzed High specificity for intracellular ROS Accurate Allow discrimination between different cell types Allow analysis of ROS-generating live cells	Requires sophisticated and expensive hardware The results do not quantify the target ROS
TBARS	Whole ejaculate Seminal plasma	Measures lipid peroxidation by detecting MDA-TBA complex formation	Simple Rapid Inexpensive	Nonspecific for any ROS type Indirect method Requires rigorous standards
NBT	Whole ejaculate Leukocytes Spermatozoa	Estimates ROS production by NBT reduction to formazan	Simple Low cost Readily available Allow cellular-specific estimation	Lack of specificity due to cross-reactivity with oxidoreductases

ROS reactive oxygen species, *TBARS* thiobarbituric acid reactive substances, *MDA* malondialdehyde, *TBA* thiobarbituric acid, *NBT* nitroblue tetrazolium

markers to identify the percentage of live cells generating ROS. The results of ROS levels are interpreted as percentage of fluorescent spermatozoa. Fluorescent techniques have a higher specificity, accuracy, sensitivity, and reproducibility for intracellular ROS detection, compared to chemiluminescence (Table 23.1). Samples tested negative by chemiluminescence may have high intracellular H_2O_2 generation that can be detected by flow cytometry [27]. Global ROS measurement by chemiluminescence was positively correlated with the estimates of overall intracellular levels of H_2O_2 and of peroxynitrite assessed by flow cytometry [25]. Flow cytometry allows the discrimination of the contribution of each cell type to the ROS levels, which may be of great value at a clinical setting [25, 27].

Thiobarbituric Acid Reactive Substances (TBARS)

Thiobarbituric acid reactive species (TBARS) are formed as a by-product of lipid peroxidation and can be detected by a reaction with thiobarbituric acid (TBA). One of those TBARS products is malondialdehyde (MDA), which forms a pink complex when reacting with TBA at high temperature (90–100 °C) and low pH [28]. MDA-TBA complex can be colorimetrically measured at 530–540 nm or fluorometrically at an excitation/emission wavelength of 530/550 nm. Results are expressed as nmol MDA 10^{-7} sperm [29]. MDA is just one of the products generated by lipid peroxidation and it is not exclusively generated through this process. Some authors have established the normal limit value of TBARS method for sperm (0.0287 ± 0.0162 nmol/10^8 sperm) and seminal plasma (0.65 ± 0.17 nmol/mL) [30].

Nitroblue Tetrazolium (NBT)

Nitroblue tetrazolium (NBT) is a yellow water-soluble nitro-substituted aromatic tetrazolium compound that forms an insoluble purple-black product called formazan when it is reduced. When isolated cells such as spermatozoa or leukocytes are incubated with NBT solution, they take up the tetrazolium salt into their cytoplasm and convert it to water-insoluble purple-black formazan crystals by the activity of superoxide anions [23]. Those intracellular formazan crystals can be visualized under an optical microscope. The cells stained with NBT are NBT-positive cells, and there is a relation between the NBT-positive cells and the levels of ROS in the same suspension [31]. Alternatively, a cell suspension (whole ejaculate) can be combined with NBT solution, and the formed formazan crystals can be released using a solubilization reagent and quantified spectrophotometrically [32]. However, the specificity of this test has been questioned (Table 23.1), hindering its clinical use. In theory, not only superoxide anion but any enzyme capable of reducing NBT will result in the formation of formazan. The same response can be generated by a number of oxidoreductases present in seminal plasma using alternative electron donors [33].

23.2.2 Antioxidant Capacity

23.2.2.1 Which Are the Antioxidant Defenses in Semen?

Antioxidants are compounds with the ability to scavenge ROS or act as cofactors for the cellular enzymatic antioxidant defenses, thus preventing OS-induced damages [34]. Most of the sperm cytoplasm and organelles are removed during spermiation; thus, the sperm endogenous defense system becomes limited. Sometimes the cytoplasm removal is not complete, and spermatozoa retain a residual cytoplasmic droplet, which contains ROS-promoting enzymes [35]. Spermatozoa are then dependent on the protection provided by epididymal fluid and seminal plasma during their maturation processes. These fluids are endowed with enzymatic antioxidants, such as superoxide dismutase, catalase, glutathione peroxidase, glutathione transferases, peroxiredoxins, and thioredoxins, and non-enzymatic antioxidants, including vitamin C (ascorbic acid), vitamin E (tocopherol), and zinc [36, 37]. The non-enzymatic antioxidants constitute the main defense system to scavenge excessive ROS as they account for approximately 65% of the total antioxidant capacity (TAC) of the seminal plasma [38].

23.2.2.2 Methods to Measure Total Antioxidant Capacity

Measuring TAC in semen can give important information regarding the seminal environment and sperm protection. Many studies showed that decreased antioxidant capacity is associated with impaired sperm function [39, 40]. TAC can be measured by evaluating the reducing ability of various seminal antioxidants against an oxidative reagent such as hydrogen peroxide and measuring the effect on the substrate. This will serve as an OS measurement from another facet in addition to ROS production. Reduced TAC will increase the susceptibility to ROS-induced damages and may contribute to OS. Measuring the TAC may provide more relevant biological information compared to that obtained by the measurement of individual components, as it considers the sum of endogenous and food-derived antioxidants present in plasma or body fluids. Different modes of action of antioxidants led to the development of hydrogen atom transfer (HAT) and single electron transfer (SET) assays. HAT-based assays measure the capability of an antioxidant to quench free radicals (generally, peroxyl radicals) by H-atom donation. SET-based assays simulate the antioxidant action by a redox potential probe. The capacity of an antioxidant to reduce the oxidant result in a color change that can be spectrophotometrically quantified [41]. If possible, fresh samples should be used since antioxidants are prone to oxidation during sample storage.

Ferric Reducing Antioxidant Power (FRAP)

Ferric reducing antioxidant power (FRAP) is based on the ability of antioxidants to reduce ferric to ferrous ions (Table 23.2). Antioxidants present in the seminal plasma can reduce ferric-tripyridyltriazine (Fe^{3+}-TPTZ) complex to Fe^{2+}-TPTZ generating a blue-colored complex. Absorbance at 593 nm is measured over time. The comparison between the changes in absorbance from the beginning to the end of the test gives an estimate of the amount of iron reduced and can be correlated with the antioxidant capacity of the sample [42]. Trolox or ascorbic acid can be used as reference. A statistically significant positive correlation was observed between the TAC measured by FRAP and sperm parameters such as concentration, motility, and morphology ($p < 0.05$) [43].

2,2-Diphenyl-1-Picrylhydrazyl (DPPH)

This assay is based on the ability of antioxidants to reduce the stable organic nitrogen radical 2,2-diphenyl-1-picrylhydrazyl (DPPH•) to DPPH. Formation of DPPH upon absorption of hydrogen atom from an antioxidant results in the decrease of UV absorption at 515 nm that can be spectrophotometrically measured. This reaction is accompanied by a change in color from the initial deep purple color of DPPH• to a colorless product. Trolox is used as standard antioxidant [44].

Trolox Equivalent Antioxidant Capacity (TEAC)

This antioxidant assay is based on the principle that both aqueous and lipid antioxidants in the seminal plasma can reduce the stable radical 2,2′-azino-bis (3-ethylbenzthiazoline-6-sulfonic acid) ($ABTS^{\bullet+}$) to ABTS. ABTS is prone to oxidation by peroxyl radicals or other oxidants present in the seminal plasma, forming a blue-green colored $ABTS^{\bullet+}$. The ability of antioxidants to reduce it causes a suppression of the absorbance at 750 nm and a simultaneous loss in color. The signal measured by spectrophotometry is proportional to the antioxidants' concentration. The capacity of seminal antioxidants to prevent ABTS oxidation is compared to that of standard trolox. Results are reported as micromoles of trolox equivalent [41].

Oxygen Radical Absorbance Capacity (ORAC)

This method measures the antioxidant scavenging activity against the peroxyl radical, induced by 2,2′-azobis-(2-amidino-propane) dihydrochloride (AAPH), at 37 °C. The peroxyl radical reacts with a fluorescent probe to form a non-fluorescent product which can be quantitated by a fluorometer. Antioxidant capacity is determined by a decreased rate and amount of product formed over time. Commonly used probes include fluorescein and H_2DCFDA, which are more stable and less reactive than the previously used B-phycoerythrin probe [44].

Enhanced Chemiluminescence

The enhanced chemiluminescence assay is the most commonly used method to measure the TAC in the seminal fluid (Table 23.2). This test was adapted from the total radical-trapping antioxidant parameter (TRAP) assay [44]. It allows the quantification of the ability of seminal antioxidants to block oxidation of specific reagents. A signal reagent (luminol plus p-iodophenol) is mixed with an oxidant source of peroxyl radicals (horseradish peroxidase (HRP)-linked immunoglobulin) to produce ROS, which in turn is mixed with a substrate, hydrogen peroxide (H_2O_2). The system

Table 23.2 Methods for the assessment of total antioxidant capacity (TAC)

Method	Type of sample	Principle	End-product determination	Advantages	Disadvantages
FRAP	Whole ejaculate Seminal plasma Spermatozoa	Measures the antioxidant potential through the reduction of ferric iron (Fe^{3+}) to ferrous iron (Fe^{2+})	Spectrophotometry	Measure the antioxidant capacity of all the antioxidants in a sample Simple Inexpensive Reproducible	Does not measure thiol antioxidants Low precision Time-dependent
DPPH	Seminal plasma	Measures the ability of antioxidants to reduce radical $DPPH^{\cdot}$ to DPPH	Spectrophotometry	Simple Rapid	Small linear reaction range Not a competitive reaction because DPPH is both radical probe and oxidant
TEAC	Seminal plasma	Measures the ability of antioxidants to reduce radical $ABTS^{\cdot+}$ to ABTS	Spectrophotometry	Simple Rapid Work in a wide pH range Determine both hydrophilic and lipophilic antioxidant capacities	Interference with peroxidases Do not differentiate water-soluble from lipid-soluble antioxidants
ORAC	Seminal plasma	Antioxidant reaction with peroxyl adicals, induced by AAPH	Fluorometry	High specificity Responds to several antioxidants Differentiates water- and lipid-soluble compounds Reliable	Time-consuming Temperature sensitive Requires specific equipment
Enhanced chemiluminescence	Whole ejaculate Seminal plasma	Antioxidant capacity to inhibit light production by luminol-derived radicals	Luminometry	Accurate High sensitivity High specificity Reproducible	Expensive equipment Time-consuming Limited half-lives of the probes Requires high sample volume

FRAP ferric reducing antioxidant power, *DPPH* 2,2-diphenyl-1-picrylhydrazyl, *TEAC* trolox equivalent antioxidant capacity, *ORAC* oxygen radical absorbance capacity, *AAPH* 2,2′-azobis-(2-amidino-propane) dihydrochloride

generates ROS at a known and steady rate, where the luminescence intensity remains almost constant for several minutes. This steady light emission is temporarily interrupted when an antioxidant is added to the system. The emission is subsequently restored once the ROS scavenging ability is depleted. The power of the seminal antioxidants to reduce the chemiluminescence of the signal reagent is compared with a standard. That standard is generally trolox, a water-soluble tocopherol analogue, and the results are reported as molar trolox equivalents [45]. In seminal plasma, the normal limit was established as TAC >2000 μmol of trolox [46].

23.2.3 ROS-TAC Score

Taking into account both sperm ROS levels and seminal TAC measurements by chemiluminescence, the parameter ROS-TAC score was suggested. This score reflects the overall level of oxidative stress (OS) by the balance between prooxidants and antioxidants in a sample. Based on ROS and TAC values from healthy donors, a series of equations to calculate the ROS-TAC of seminal sample have been proposed [47]. The ROS-TAC score showed a higher predictive value than ROS and TAC alone when it is used in discriminating fertile from infertile men. Infertile men have low ROS-TAC scores, and it was estimated that infertile men with higher ROS-TAC scores were more prone to initiate pregnancies than those who had low scores [47].

23.2.4 Oxidation-Reduction Potential (ORP)

23.2.4.1 What Is the Principle of ORP?

Oxidation-reduction potential (ORP) measures the redox potential of a semen sample or seminal plasma [48]. Redox reactions involve the transfer of electrons between two

Fig. 23.3 Representative image of a MiOXSYS system and sample loading into the disposable sensor trip

chemicals. The chemical that loses electrons is oxidized, while the one that accepts electrons is reduced. ORP provides an estimate of the proportion of oxidants and antioxidants present in the sample. This test can be performed by using the MiOXSYS system (Fig. 23.3). The sample is loaded through a disposable sensor strip, and the results are obtained in a few minutes. ORP measurement is based on Nernst equation E (ORP) = E_0 – RT/nF ln([Red]/[Ox]), where E_0 is the standard reduction potential relative to hydrogen electron, R universal gas constant, T absolute temperature in degrees Kelvin, n number of moles of exchanged electrons, F Faraday's constant, [Red] concentration of reduced species, and [Ox] concentration of oxidized species [49]. The results are given by the "static ORP" parameter (mV), which is a snapshot of the current OS in the sample. This value should be normalized to the sperm concentration in the semen sample (corrected ORP). This parameter gives an estimate of the antioxidant reserves expressed as mV/million sperm/mL [50].

23.2.4.2 What Is the Reference Value?

ORP values higher than the established reference values are indicative of OS. ORP values between 1.36 and1.42 mV/million sperm/mL showed the ability to distinguish fertile from infertile men [51–53]. ORP value of 2.59 mV/million sperm/mL is a good predictor of oligozoospermia [54]. It can be used for both fresh and frozen samples.

23.2.5 Clinical Value of ROS/TAC/ORP Measurement

Elevated ROS levels were detected in the semen of 25–40% of infertile men [47]. The implications of ROS on reproductive outcomes were further supported by the negative associations between increased ROS levels and traditional semen quality parameters [55, 56]. ROS assays may be complementary to conventional semen analysis in better assessing male fertility. This has a particular importance for patients with unexplained male infertility as a significant proportion of infertile men have normal semen parameters and are still infertile [57]. The possible value of measuring ROS may be related to the positive correlations found between high ROS levels and specific markers of male reproductive dysfunction, such as DNA fragmentation, leukocyte concentration, and the incidence of apoptotic or necrotic spermatozoa, which may not be detected by conventional semen analysis [57–59]. Elevated ROS were also associated with increased time to natural conception, impaired IVF pregnancy rates, and recurrent miscarriage [60, 61]. Measuring ROS levels in semen could help identify patients who may benefit from treatment that can potentially decrease OS such as oral antioxidant therapy, varicocelectomy, and lifestyle modifications. The response to the treatment can also be monitored by the ROS measurement. ROS may also play a role for ART. Elevated ROS levels in samples with poor quality may be exacerbated by manipulation and prolonged incubation during the procedures, which further impairs sperm function. Modifications of the media such as the application of antioxidants to minimize oxidative-induced sperm damage may provide its value in protecting sperm from ROS damage during ART.

Besides the increased ROS levels, some infertile men also demonstrate a 30–43% decrease in TAC relative to fertile controls and regardless of semen parameters [43, 62, 63]. In fact, decreased TAC was associated with impaired sperm function [40]. Accordingly, infertile men also have significantly lower ROS-TAC scores [47]. Many studies reported a positive correlation between standard sperm parameters such as concentration, motility and morphology, and TAC levels ($P < 0.05$) [43, 64]. Assessment of TAC in infertile men will provide a more complete picture in the assessment of OS as an etiology of male infertility. Analyzing both ROS and TAC in a semen sample can be an important complement to the conventional semen analysis. The findings from OS testing may alert the clinician to implement means to lower OS in addition to ART and other intervention. In fact, data from several studies indicate that men taking oral antioxidants have a four fold increase in pregnancy rates and an almost five fold increase in live birth rate when undergoing ART [65].

ORP has emerged as a simple test to evaluate OS, which could be easily performed in an office-based setting. The equipment is handy, the test uses very low amount of liquefied sample, the result is available in 2 min after loading the sample, and the measurements are stable up to 120 min [66]. It is also associated with a low intra- and interobserver variability [51]. Preliminary data show high sensitivity, specificity, and accuracy of ORP, which reflects its potential clinical application [48]. ORP levels were negatively correlated with sperm parameters [54]. It has the potential in distinguishing infertile from fertile men [51]. However, additional research is needed to gather solid scientific proofs for the implementation of OS assays in a clinical setting.

23.3 Evaluation of Sperm DNA Damage

23.3.1 What Is DNA Damage?

The maintenance of sperm DNA integrity is vital for fertilization and to transmit the genetic material to the offspring. Sperm chromatin undergoes extensive remodeling during spermatogenesis to protect sperm DNA. In this process, most of sperm DNA histones are replaced by protamines to attain a higher compaction. If these events do not occur properly and spermatozoa retain more histones than they should, sperm DNA becomes more susceptible to damage [67]. However, DNA damage can occur not only during spermatogenesis but also during epididymal transit or even when spermatozoa are collected for ART purposes [68].

DNA damage refers to defects in DNA structure, which include single or double DNA strand breaks, deletion or modification of DNA bases, interstrand or intrastrand DNA cross-linkage, and protamine mispackaging. Single- (ss) or double-stranded breaks (ds) are commonly termed DNA fragmentation. OS is one of the major extrinsic factors leading to sperm DNA damage, but it may also result from pathologies of the male reproductive system [69]. Every 25% increase in seminal ROS levels is associated with a 10% increase in sperm DNA fragmentation rate [62]. Additionally, abortive apoptosis, unresolved strand breaks during spermiogenesis, and defective maturation have also been implicated as potential intrinsic sources of DNA damage [69, 70].

23.3.2 How Can Sperm DNA Fragmentation Affect Sperm Quality?

DNA damage can affect both nuclear and mitochondrial DNA. OS-induced damage to nuclear DNA may accelerate germ cell apoptosis, leading to a decline in sperm production and consequently decreased sperm count in the ejaculate [16]. A positive correlation has been shown between sperm DNA fragmentation and abnormal morphology, which was associated with defects of the sperm tail [71]. Another study showed a higher incidence of aneuploidy in men with high sperm DNA fragmentation [72]. Alterations in mitochondrial sperm DNA may lead to impaired mitochondrial functionality, thus resulting in compromised motility, hyperactivation, and inability to fertilize. The ability of sperm DNA to repair damages is very limited, thus any alteration in DNA structure can lead to the dysfunction of sperm proteins. Although spermatozoa possess the base excision repair (BER) enzyme, they lack oxoguanine glycosylase (OGG1) that is essential for the repair process. This makes spermatozoa susceptible to DNA damages and dependent on the ability of the oocyte to repair any existent damage after fertilization [73]. However, when the DNA damage is extensive, the oocyte's repair capacity is not sufficient, and fragmentation can result in low rate of embryonic development and miscarriage.

23.3.3 Methods to Measure Sperm DNA Damage

Although the clinical utility of sperm DNA fragmentation has not been well-established, it has potential to become an important test for evaluation of male infertility. The available methods can be divided into assays that (i) measure DNA damage by incorporating DNA probes or modified nucleotides at the site of damage, (ii) measure the susceptibility of DNA to denaturation, and (iii) indirectly measure the level of chromatin compaction.

23.3.3.1 Terminal Deoxynucleotidyl Transferase-Mediated dUTP Nick-End Labeling (TUNEL)

This assay is based on the deoxynucleotide (dUTP) binding to the 3'-OH break-ends of single- and double-stranded DNA breaks. A template-independent DNA polymerase called terminal deoxynucleotidyl transferase (TdT) catalyzes the attachment of the dUTP [74]. Moreover, the dUTP are labeled with a fluorescent probe (e.g., fluorescein isothiocyanate), to allow the detection by fluorescent microscopy or flow cytometry. The fluorescent signal will be directly proportional to the number of strand breaks and will be reflected as a percentage of sperm DNA fragmentation. Recent advances in this area allowed an increase in the sensitivity of the test by improving the interaction of TdT with DNA strand breaks [75]. The cutoff values of sperm DNA fragmentation for TUNEL have not been clearly established [76]. A cutoff value of 17% was proposed to discriminate between infertile and fertile men with a high specificity (92%) and high predictive value (91%) [74]. TUNEL availability as a commercial kit is one of the advantages for the clinical implementation of this test (◘ Table 23.3). TUNEL will be described in more detail in ▶ Chap. 24.

23.3.3.2 Comet Assay

The Comet assay is a single-cell gel electrophoretic assay that quantifies broken strands of DNA in individual spermatozoon. First, sperm membranes are lysed and the DNA decondensed in a salt solution. This assay can only measure double-stranded DNA breaks in a neutral buffer, while in an alkaline environment, DNA is denatured so that both single- and double-stranded DNA breaks can be measured [77]. DNA breaks have different mobility when placed in an electrophoretic field depending on the relative size of the fragment. When the electric field is applied, all the broken strands of DNA (negative charge) will migrate toward the positively charged anode, forming a comet tail. Spermatozoa with more DNA breaks will show the most intense and largest comet tail [78]. DNA damage will be assessed using a fluorescence microscope or cytometer. The length of the comet tail and fluorescent intensity will be directly proportional to the degree of DNA fragmentation [79], and the result is presented as a percentage of DNA damage per spermatozoon. It was estimated that results from Comet assay are able to predict the fertilization rates with a 93.3% specificity.

Table 23.3 Methods for sperm DNA damage evaluation

Method	Principle	Advantages	Disadvantages
TUNEL	Directly measures single- and double-stranded DNA fragmentation	High sensitivity and specificity Available as commercial kits Measures a definite endpoint	Labor intensive Requires specific material and expensive equipment Not specific to oxidative damage Thresholds not standardized Results affected by preparation, fixation, and permeabilization
Comet	Quantifies the shape of the single cell nuclei after gel electrophoresis	Requires small number of spermatozoa (5000) High sensitivity Wide pH range Detects single- and double-stranded breaks, as well as altered bases	Labor intensive Requires expensive software High variability of protocols Intra- and interobserver variability Not specific for oxidative damage DNA damage can be overestimated
SCD	Indirect estimation of DNA fragmentation by quantification of the amount of nuclear dispersion (halo)	Differentiates sperm with fragmented and non-fragmented DNA Can use bright field or fluorescence microscopy	Interobserver subjectivity when categorizing the halos DNA damage can be overestimated
AO TB CMA3	Uses cytochemical dyes combined with bright field or fluorescent microscopy to assess sperm chromatin integrity	Simple Fast Inexpensive	Do not measure DNA fragmentation Intra- and interobserver variability Reference values not standardized Rapid fading of fluorescence
SCSA	Indirect analysis of sperm DNA damage by measuring the susceptibility to denaturation	Established clinical thresholds, robust, high sensitivity, requires few cells (10,000)	Involves complex calculations Do not give information about the amount of DNA damage in a single sperm

TUNEL terminal deoxynucleotidyl transferase-mediated dUTP nick-end labeling, *SCD* sperm chromatin dispersion, *AO* acridine orange, *TB* toluidine blue, *CMA3* chromomycin A3, *SCSA* sperm chromatin structure assay

A percentage of DNA fragmentation higher than 40% reflected a 9.5 times higher risk of poor fertilization [80].

23.3.3.3 Sperm Chromatin Dispersion (SCD)

Sperm chromatin dispersion (SCD) test is also known as the halo test due to its availability as a kit – Halosperm® kit [81]. This is a simple assay to estimate the amount of spermatozoa with DNA fragmentation. SCD allows the differentiation between spermatozoa with fragmented or non-fragmented DNA. Similar to comet assay, this test involves a single-cell agarose gel electrophoresis followed by denaturation with an acid or alkaline solution to remove nuclear proteins [82]. Slides can be visualized using bright field or fluorescence microscopy. Sperm showing halos of dispersed chromatin around a dense core are considered normal, while those with a small halo or no halo contain a fragmented DNA because the DNA loops do not diffuse [77].

23.3.3.4 Cytochemical Tests

Simple cytochemical tests can be used to assess sperm DNA integrity, including acridine orange (AO), toluidine blue (TB), and chromomycin A3 (CMA3) (Table 23.3).

AO is a membrane-permeable fluorescent dye that allows the assessment of sperm chromatin integrity. DNA is firstly exposed to an acid environment, which dissociates thiols from DNA thus increasing DNA susceptibility to denaturation. Consequently, AO competes for anionic binding sites by avoiding nonspecific aggregation. AO molecules bind to single-stranded DNA as an aggregate and are intercalated with normal double-stranded DNA. After preparing the slides, determination of DNA integrity is made under a fluorescence microscope. When exposed to wavelengths of 450–490 nm, sperm with normal DNA integrity will emit green fluorescence, while those with abnormal denatured/single-stranded DNA will emit red fluorescence. This allows the calculation of the percentage of spermatozoa with denatured DNA [83].

TB is a cationic dye that binds to negatively charged phosphate residues. It can be used for the identification of sperm chromatin abnormalities. When spermatozoa are stained with TB, those with a tightly bound DNA will have few TB binding sites and will be slightly stained. Spermatozoa with poor DNA integrity will expose phosphate residues, and they will stain dark (purple). Cells are analyzed under a bright light microscope, and the percentage of sperm with abnormal chromatin structure is calculated. A significant correlation was found between AO and TB tests ($R = 0.431$, $p < 0.001$) [84].

CMA3 is a specific GC-rich sequence dye that allows the indirect measurement of the amount of protamines in the

sperm nucleus. CMA3 interacts with DNA at the protamine binding sites. The intensity of CMA3 staining can be visualized under a fluorescent microscope and higher intensities indicate protamine deficiency or aberrant chromatin packing [85].

23.3.3.5 Sperm Chromatin Structure Assay (SCSA)

Sperm chromatin structure assay (SCSA) was developed based on the principle of the acridine orange test; however, it uses flow cytometry to analyze a large number of sperm. This assay estimates the percentage of sperm with higher susceptibility to DNA breaks rather than the amount of DNA damage in a single sperm. Staining by acridine orange is highly precise, reproducible, and comparable between fresh and frozen samples. SCSA allows the calculation of the DNA fragmentation index (DFI), which is the ratio between the percentage of spermatozoa showing red fluorescence (denaturated DNA) and the total fluorescence (red + green) [86]. High levels of DNA fragmentation (≥30% DFI) were associated with a higher risk for low blastocyst rates and failure to initiate an ongoing pregnancy [87]. Besides, it measures the percentage of sperm DNA stainability (% HDS) that is related to the nuclear histones retained in immature sperm. This test may provide important information for the physician before counseling couples to undergo IVF or ICSI. Men with HDS ≥15% demonstrated lower fertilization rates, indicating that ICSI may be recommended in those cases. Besides, men with DFI ≥30% were associated with a higher risk for pregnancy failure [87].

23.3.4 Clinical Value of Sperm DNA Damage Evaluation

Spermatozoa with a higher DNA integrity have a better chance to achieve fertilization and a successful pregnancy. Sperm DNA damage is often found in men with advanced paternal age, unhealthy diet, drug abuse, environmental pesticide exposure, tobacco use, varicocele, medical diseases, hyperthermia, air pollution, genital inflammation, and infectious diseases. Furthermore, sperm DNA damage is significantly increased in men with idiopathic and male factor infertility, which may be related to high levels of seminal OS [83]. However, men with apparently normal sperm parameters (e.g., motility and morphology) can also have high DNA fragmentation. In fact, DNA fragmentation has been pointed as one of the factors behind the commonly classified idiopathic infertility.

High rates of sperm DNA fragmentation were correlated with decreased semen quality [88]. Men with varicocele also present higher levels of sperm DNA fragmentation [89, 90], which may account for their reduced reproductive potential [91]. Sperm DNA fragmentation was also associated with longer time for natural conception, idiopathic infertility, recurrent intrauterine insemination (IUI) and in vitro fertilization (IVF) failure [92], and spontaneous miscarriage [93–95]. ROS-induced damages to mitochondrial and nuclear sperm DNA may also end up in increased birth defects and high offspring morbidity [96]. Currently, routine implementation of sperm DNA damage tests is not supported by guidelines. However, emerging clinical evidence indicates sperm DNA fragmentation as a useful biomarker for male infertility diagnosis and prediction of both natural and assisted reproduction outcomes. The clinical utility of sperm DNA fragmentation assays has been recently proposed in the following situations: (a) infertile men with a normal semen analysis as determined by conventional methods, (b) recurrent spontaneous abortion, and (c) to determine the most suitable ART [97].

23.4 Assessment of Sperm Fertilization Capacity

23.4.1 How Can We Measure the Sperm Fertilization Capacity?

For the spermatozoon to be able to fertilize, it needs to acquire fertilization potential during maturation through the epididymis. However, the ability to fertilize is only activated physiologically when in contact with the female gamete, or it can be induced in vitro using proper media. Sperm function testing also includes the evaluation of sperm mitochondrial function and fertilization events such as hyperactivation, capacitation, and acrosome reaction. Even an apparently normal spermatozoon with normal motility and morphology can be dysfunctional and not be able to fertilize. So, these tests may serve as a valuable tool to infer about the fertilizing potential of an individual before ART.

23.4.2 Methods to Assess Sperm Fertilizing Potential

Several methods have been used over the last decades to evaluate sperm interaction with the oocyte and binding to the zona pellucida. However, most of these tests are not commonly used currently due to the limited availability of human oocytes to conduct the experiments and also to the emergence of ICSI, which bypass the sperm-oocyte interaction. The binding of spermatozoa to the zona pellucida triggers the acrosome reaction of sperm and induces the release of acrosomal components (e.g., acrosin and hyaluronidase). So, the evaluation of acrosome reaction can have greater value to indicate if these mechanisms are occurring properly.

A proper mitochondrial function is vital for sperm function. Mitochondria are the power organelles of cells, essential to produce energy for sperm metabolism, membrane function, and motility. Loss of mitochondrial membrane potential is one of the triggers for cellular apoptosis [98]. Some of the tests used for acrosome reaction testing and evaluation of sperm mitochondrial function will be discussed. These types of tests may be useful when significant head morphological

abnormalities are found during routine semen analysis or in cases of idiopathic infertility, especially with repeated pregnancy failure with ART.

23.4.2.1 Acrosome Reaction Testing

Acrosomal integrity can be assessed by microscopy or flow cytometry using fluorescent lectins that selectively bind to either the outer membrane or acrosomal contents (Fig. 23.4) [99]. After inducing the acrosome reaction with the calcium ionophore A23187, spermatozoa are stained with a fluorescent probe. The fluorescein isothiocyanate-conjugated peanut agglutinin (FITC-PNA) and fluorescein isothiocyanate-conjugated *Pisum sativum* (FITC-PSA) are the most commonly used probes [100]. As acrosomal loss can result from spontaneous acrosome reaction (<5%) or normal sperm death, this test is often used in conjunction with a test of cell viability, which can be done using the Hoechst staining. This test will give the percentage of acrosome-reacted viable spermatozoa [101]. Semen samples with 5–30% of reacted spermatozoa have a higher fertility potential [102].

Another test is based on the ability of spermatozoa to bind to hyaluronic acid. Only spermatozoa that are mature, viable, and with intact acrosomes will bind to hyaluronic acid through specific receptors [103]. This hyaluronic binding assay (HBA) has been used as a sperm selection technique for ICSI. The use of this procedure has been correlated with the selection of spermatozoa with high DNA integrity and low frequency of chromosomal aneuploidies [104].

23.4.2.2 Sperm Mitochondrial Activity

The fluorescent probe JC-1 can be used to distinguish between spermatozoa with poorly and highly functional mitochondria using flow cytometry. The accumulation of the JC-1 dye in sperm mitochondria depends on mitochondrial membrane potential [105]. JC-1 accumulates in the cytosol of healthy sperm as a monomer, whereas in the presence of high mitochondrial membrane potential, it accumulates as aggregates inside the mitochondria. Monomers will emit green fluorescence, while aggregates will emit red fluorescence. The JC-1 ratio aggregates/monomers give an estimation of mitochondrial functionality. When spermatozoa are dying, only JC-1 monomers (green fluorescence) will be present. This technique is simple and is the only method available for the evaluation of sperm mitochondrial function [106]. A recent study proposed that the evaluation of mitochondrial membrane potential in combination with sperm DNA fragmentation testing could be stronger predictors of natural conception relative to standard semen analysis [107].

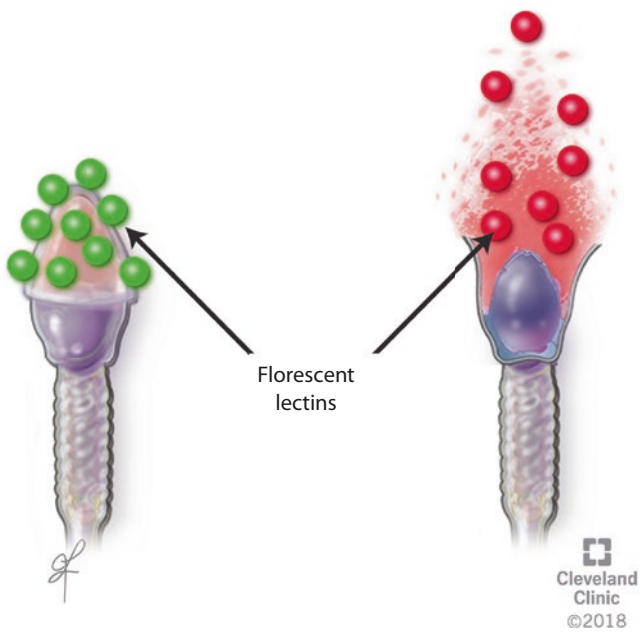


Fig. 23.4 Acrosome reaction testing by fluorescent lectins **a** or acrosomal enzymatic release **b**

23.5 Antisperm Antibodies

Among all the male infertility cases, about 10% are associated with the presence of antisperm antibodies (ASA) [108]. Observation of sperm agglutination during a routine semen analysis is usually an indication for ASA. The presence of ASA can affect sperm function by hindering sperm migration through the female reproductive tract and reducing the number of sperm at the fertilization site. Furthermore, ASA have been associated with the secretion of cytokines which impair sperm function and can eventually lead to cell death [109]. Only antibodies that bind to sperm membrane antigens or are found free in the seminal plasma are of functional significance. IgA and IgG classes are the most abundant, contrastingly to IgM [110]. Many tests have been developed for ASA diagnosis, but only the mixed antiglobulin reaction (MAR) test [111] or immunobead test (IBT) [112] is recommended by the WHO [113]. The MAR test is performed on a fresh semen sample. In this test, spermatozoa are mixed with latex particles which are coated with antibodies (anti-IgA or IgG). A monospecific anti-human-IgG or anti-human-IgA is added to the semen sample. The beads will bind to spermatozoa containing the respective antibodies on their surface. The antibody binding location (sperm head, mid-piece, tail, tail tip, or total sperm involvement) is determined. Agglutination can be seen under a light microscope (phase contrast) as mixed clumps of spermatozoa (Fig. 23.5a) [114].

In IBT, the seminal plasma is removed by centrifugation to isolate spermatozoa. Spermatozoa are mixed with beads that have been coated with IgG (or IgA) class-specific secondary antibodies. The sperm suspension is then observed microscopically for agglutination. The beads will bind to both motile and immotile spermatozoa with surface-bound antibodies (Fig. 23.5b), but only motile sperm should be recorded [115]. Antibodies are considered clinically significant when more than 50% of spermatozoa are coated, when spermatozoa are unable to penetrate the preovulatory human cervical mucus, or when spermatozoa demonstrate impaired fertilizing capacity [113]. Nevertheless, there is a controversy about the correlation of these tests with the reproductive outcome by ART [110].

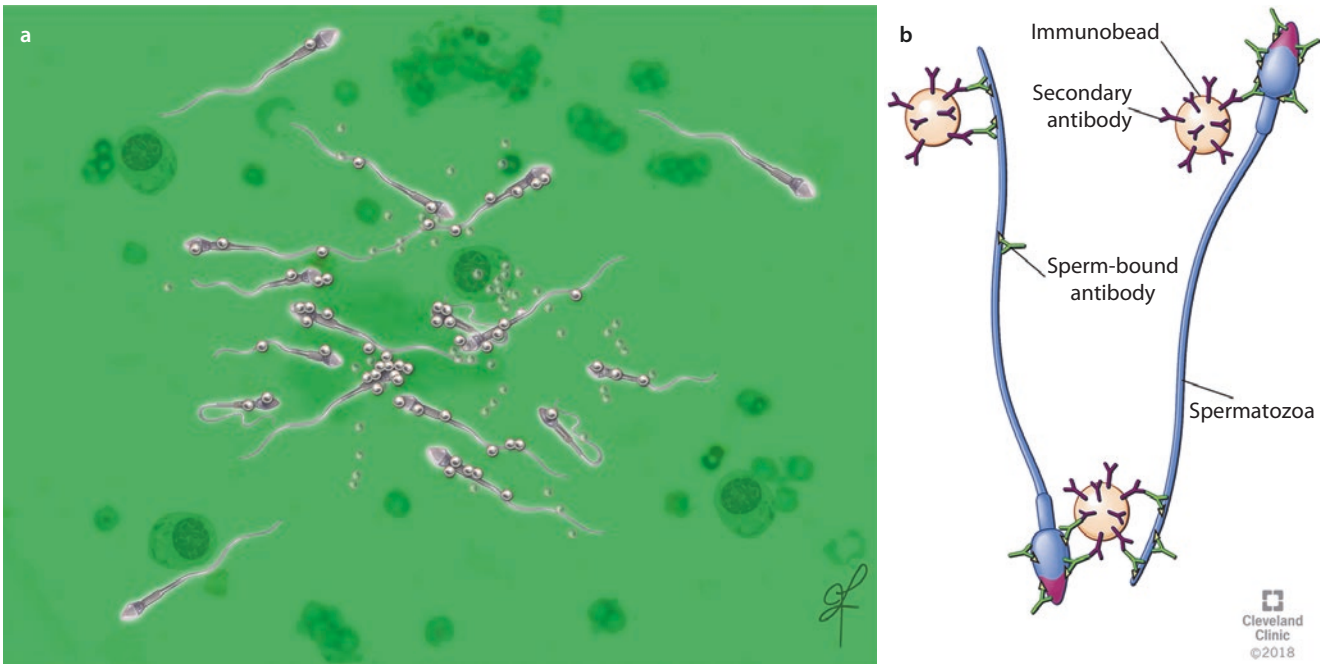

Fig. 23.5 Antisperm antibody testing: microscopic illustration of sperm and bead aggregates by mixed agglutination reaction (MAR) test **a** and immunobead binding test (IBT) principle **b**

Existing data do not support the widespread use of immune testing in clinical practice. Further research is required to determine the stimuli for ASA production and their class-specific effects on individual sperm proteins, which may lead to the development of new tests or therapies [116].

23.6 Future Perspectives

The continuous search for a method to accurately assess fertility potential stimulated the in-depth investigation of the quality and function of the gametes. New approaches are constantly under appraisal. Digital holography microscopy applied to both morphological and motility characterizations of sperm cells has been proposed. The idea is to use quantitative three-dimensional information (e.g., volume, profiles along particular directions) to better underline the differences between normal and abnormal sperm morphology [117]. Besides, advances in biomolecular techniques pointed out promising targets for the development of novel laboratory tests. In particular, the study of semen genomics, transcriptomics, proteomics, and metabolomics is providing new insights into the biochemical basis of defective semen quality. This information can be used to enhance the understanding of the causes of male infertility and in the development of new tools for diagnostic and therapeutic purposes.

23.7 Concluding Remarks

Over the last decades, the necessity for sperm functional testing to overcome the limitations of routine semen analysis has become clear. Although the current available tests can provide important information in counseling and management of infertile couples, the lack of standardization and refinement of the assays represents the major obstacle to wide clinical implementation. Sperm function tests can be a valuable complement to conventional semen analysis for the evaluation of fertility status and to predict the reproductive outcomes either by natural conception or ART. They may also contribute to the identification of causes for idiopathic and unexplained infertility.

Review Questions (MCQ Format)

1. What are the limitations of conventional semen analysis?
   (a) Poor correlation with reproductive outcomes
   (b) Lack of standardization between laboratories
   (c) Inherent subjectivity that lead to intra- and interobserver variability
   (d) All of the above

2. Which of the following parameters are evaluated by sperm function tests?
   (a) Production of reactive oxygen species (ROS)
   (b) Sperm total antioxidant capacity (TAC)
   (c) Sperm DNA integrity
   (d) All of the above

3. Which of the following points support the clinical use of sperm functional laboratory tests?
   (a) They are less subjective than routine semen analysis

(b) They may contribute to identify causes for idiopathic infertility
(c) A single parameter of sperm function analysis can determine a subject's fertility status
(d) All of the above

4. Which of the following sperm function tests have defined reference values by the WHO 5th edition?
(a) Antisperm antibodies by MAR or IBT tests
(b) Sperm DNA damage by TUNEL
(c) ROS levels by chemiluminescence
(d) All of the above

5. Which of the following statements about the current status of sperm functional testing are correct?
(a) Sperm function tests will replace conventional semen analysis
(b) There is sufficient evidence to support the routine clinical implementation of sperm function tests
(c) More studies are needed to establish reference values for sperm function tests before its clinical use
(d) None of the above

Answers

1. (d)
2. (d)
3. (b)
4. (a)

Assessment of Sperm Chromatin Damage by TUNEL Method Using Benchtop Flow Cytometer

Ana D. Martins, Rakesh Sharma, and Ashok Agarwal

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_24

Learning Objectives

- Sperm DNA chromatin packaging of the nucleus occurs during spermiogenesis. The chromatin becomes highly condensed and protamines replace most of the histones. With this high rate of compaction, the DNA is more stable, compact, and resistant to damage. Deficiency of protamines in sperm is related with high risk of DNA damage.
- The major causes of abnormalities in spermatozoa are errors in meiotic recombination, abortive apoptosis, or excess of oxidative stress resulting from exposure to toxic agents or an infection.
- The techniques to evaluate sperm DNA fragmentation are TUNEL assay, comet assay, sperm chromatin dispersion (SCD) test, and sperm chromatin structure assay (SCSA).
- Terminal deoxynucleotidyl transferase dUTP nick end labeling (TUNEL) assay cutoff of 17% with 92% specificity can differentiate infertile men with DNA damage from healthy men.
- The clinical value of including sperm DNA fragmentation is still under discussion; however, in recent years a negative relation between sperm DNA fragmentation and pregnancy rates has been reported.

24.1 Introduction

Spermatozoa are unique cells that are designed to transfer the intact haploid genome to the oocyte. Once spermatogenesis is completed, spermatozoa are on its journey with the final goal of fertilizing the oocyte. To survive this journey and accomplish this goal, spermatozoa experience many significant adaptations in cell organization and function that are different from the somatic cells. In somatic cells, epigenetic modulations and modifications in histone tails control the chromatin structure and transcription of DNA. Spermatozoa are transcriptionally inert and DNA histones are replaced by protamines [1, 2]. Extrinsic factors such as storage temperatures, handling conditions, infections, and post-testicular oxidative stress or gonadotoxic effects of a treatment can cause injuries to spermatozoa DNA. However, sperm DNA is more susceptible if chromatin packing is incomplete during spermiogenesis at the time of protamine replacement. Intrinsic sources of sperm DNA damage include abortive apoptosis, errors in recombination, or oxidative stress.

Assisted-reproductive techniques (ART) have made successful pregnancies possible even when semen parameters are below the reference values established by WHO guidelines [3]. Basic semen analysis remains the first option for assessment of male fertility [4]; however, this analysis fails to predict the fecundity [4]. Consequently, men with normal semen parameters can still be infertile and are considered to present with unexplained or idiopathic fertility [5–8]. Many studies report an association between the increase in DNA fragmentation and the prevalence of infertility [9–12]. Increase in DNA fragmentation is related with an increase in the time to achieve pregnancy [9], the miscarriage rate [13–15], and decrease in the success rate of in vivo fertilization [11, 16]. After fertilization, the oocyte and the embryo have a limited capacity to repair sperm DNA damage [17, 18]. All together, these studies highlight the importance of the evaluation of DNA fragmentation in the treatment of male infertility. The assessment of DNA damage dates back to 1970, when Ringertz and collaborators showed DNA denaturation with acridine orange by microfluorimetry [19]. Later on in 1980, with the progress of advanced molecular technologies and with the discovery of flow cytometry, the sperm chromatin structure assay (SCSA) was developed [20]. In the next decade, the progress of the single cell electrophoresis allowed the development of the comet assay [21]. Also, during these years, the terminal deoxynucleotidyl transferase dUTP nick end labeling (TUNEL) assay was developed to detect DNA fragmentation in human spermatozoa [22]. This technique will be the focus of this chapter. Recently the sperm chromatin dispersion (SCD) technique was developed for measuring DNA damage [23].

24.2 Sperm Chromatin Damage

24.2.1 Sperm Chromatin

In the somatic cell, chromatin is condensed and packed with histones [24]. Through post-translational modifications, histones are responsible for regulating DNA compaction [25] and modulating gene expression by controlling the access of transcription factors to the DNA [25]. The DNA from somatic cells can be packaged in two types: (1) in a nucleosome, a protein formed by an octamer of histones wraps DNA twice, and (2) nucleosomes packaged in solenoids [26–28]. In sperm DNA, the packaging of chromatin is different [26]; throughout spermiogenesis, in order for the sperm nucleus to become highly compacted, majority of the histones are replaced by protamines [29]. Compared to histones, protamines are simpler and smaller [2]. They also have arginine that allows a stronger binding to the DNA. In the final step of sperm epididymal maturation, the protamines undergo cross-linking by disulfide bond formation in the presence of cysteine residues [27]. During the transit through the epididymis, the chromatin volume is compacted six fold [1]. This compaction allows the DNA to be highly stable and resistant to damage. Sperm DNA with protamine deficiency in infertile men is associated with high risk of DNA damage [30–32].

24.2.2 Types of Damage to Spermatozoa

The origin of the human sperm chromatin damage is multifactorial [33]. Many factors are responsible for the disturbances in the highly sensitive biochemical events occurring during spermatogenesis, such as environmental stress [34] and chromosomal abnormalities [35].

24.2.2.1 DNA Fragmentation

DNA fragmentation can be attributed to many factors [36]. These factors can be intrinsic, such as apoptosis and oxidative stress [8, 37], defects in protamination [38], inefficient chromatin remodeling, and impairment of spermatogenesis [39, 40]. On the other hand, external factors such as lifestyle (diet, drug consumption, tobacco) [41–44], advancing age [45–47], environmental exposure (pesticides and air pollution) [48, 49], and medical history (cancer, varicocele, inflammation) [50–52], among others, can also result in sperm DNA fragmentation. Post-testicular damage is one of the most common causes of DNA fragmentation. The damage can occur after spermiation, during transit of the spermatozoa from the seminiferous tubules to the epididymis [53]. Studies show a higher DNA fragmentation in epididymal and ejaculated spermatozoa compared with testicular spermatozoa [53, 54].

24.2.2.2 Abnormal Chromatin Compaction

One of the most important steps in chromatin remodeling during spermiogenesis is the replacement of histones by protamines. This remodeling is assisted by hyperacetylation of the histones and by DNA topoisomerase II which is responsible for the formation of temporary nicks to release the tension that results from supercoiling [55, 56]. Topoisomerase II also repairs the temporary nicks after spermiogenesis and ejaculation. When this process fails, spermatozoa with DNA fragmentation are seen in the ejaculate [57].

24.2.2.3 Chromosomal Aberrations

Chromosomal aberrations affect 2–14% of the infertile men. Both numerical and structural aberrations can result in pregnancy loss, perinatal death, and congenital malformations [58]. Aneuploidies of X or Y chromosome, trisomy of chromosomes 13, 18, and 21, are the most common [59]. Normally, sex chromosome aneuploidies have paternal origin and are attributed to errors during spermatogenesis [60]. The homologous chromosomes are separated during the first and second meiotic division; if an error occurs at this time, this may lead to aneuploid gametes affecting autosomes or sex chromosomes. In the male, aneuploidies are hypothesized to occur by the following mechanisms: (1) during anaphase, chromosomes lag near the equator resulting in the posterior loss of the chromosome, (2) lack of separation of the chromatid pairs during mitosis or meiosis II, and (3) nonseparation of homologous chromosomes during meiosis I [59, 61].

24.2.3 Causes of Sperm Chromatin Damage

Over the years, the number of studies comparing DNA fragmentation with male fertility has increased. A high percentage of sperm DNA fragmentation is seen in men with idiopathic infertility. This may be a result of an increase in the availability of sperm DNA fragmentation assays and its relationship with fertility status. DNA is more vulnerable to oxidative stress and damage associated with the production of reactive oxygen species (ROS) in the absence of repair mechanisms and the transcriptional and translational inactivity in spermatozoa [51, 62, 63]. Abnormalities in spermatozoa can be due to errors in meiotic recombination, abortive apoptosis resulting from exposure to toxic agents, or excess of oxidative stress.

24.2.3.1 Meiotic Recombination

During pachytene stage, meiotic recombination is a crucial event for integrity of the genome and fertility. The number and the localization of this event is highly controlled; however, errors can occur resulting in aneuploid spermatozoa [64]. Compared with fertile men, nonobstructive azoospermic men present either without any meiotic cells or a reduced population of these cells caused by a complete or partial block at the zygotene stage [65]. The absence or reduction in meiotic recombination can result in sperm aneuploidy and spermatogenic arrest, resulting in a reduction of total sperm count and consequently infertility [65, 66].

24.2.3.2 Abortive Apoptosis

With the process of spermatogenesis, germ cells lose their apoptotic capacity, as they are transcriptionally and translationally silent. Sertoli cells are responsible for screening of the germ cells and initiating apoptosis, where up to 60% of all germ cell in meiosis I marked with the *Fas* type marker [67] are phagocytized and removed by the Sertoli cells [62, 68]. Infertile men present a higher incidence of *Fas* positivity [69]. Burrello and colleagues suggested that during spermiogenesis, a dissociation between sperm remodeling and genomic quality occurs, and this can be the reason why morphologically normal cells have aneuploidies or damaged nucleus [70]. When this process fails, some spermatocytes escape elimination and result in release of spermatozoa with increased DNA damage [63], and some of these spermatozoa are able to complete fertilization, although the probability of a live birth is very low [71].

24.2.3.3 Infections

Epididymis and secondary sexual glands are responsible for the presence of leukocytes in the ejaculate. These leukocytes play an important role in removal of abnormal spermatozoa [72] and immune surveillance [73, 74]. Leukocytospermia is indicative of infection and/or inflammation of the male accessory sex glands. Leukocytes are known high ROS producers and consequently result in DNA fragmentation and modifications in DNA bases. However, the effects of leukocytes are not only dependent on the number but also on the activation state [75, 76]. In a physiological state, ROS produced by leukocytes are scavenged by the antioxidants present in the seminal plasma. However, when this balance between ROS production and its effective removal by antioxidants is disturbed, it will result in oxidative stress and sperm DNA damage.

24.2.3.4 Exposure to Toxic Substances

Exposure to toxic substances is particularly harmful to male germ cells, resulting in DNA damage. Many studies report increased DNA fragmentation in men exposed to toxic substances as a result of their occupation, such as coke oven, waste incineration, and factory workers exposed to chemicals [77–79]. Cancer therapies have demonstrated adverse effects on sperm DNA integrity [80, 81]. Radiotherapy has been associated with higher DNA fragmentation after the treatment [82]. Similarly, the lifestyle factors such as men who smoke have higher DNA damage when compared with nonsmokers [83]. Consumption of alcohol and the use of illicit drugs were reported to increase sperm DNA damage [83].

24.2.3.5 Oxidative Stress

Oxidative stress is a subject of discussion in different fields, and male fertility is not an exception. Unlike the other cells, mature spermatozoa lack major DNA repair machinery. Spermatozoa from the testis seem to have low DNA fragmentation when compared to ejaculated spermatozoa [84]. Compared to fertile men, higher levels of oxidative stress are seen in infertile men [85]. Studies show an increase in DNA fragmentation and damage when sperm were exposed to hydrogen peroxide [86]. Sperm DNA fragmentation induced by ROS results in strand breaks, base modification, as well as gene mutations such as polymorphism [87].

24.2.4 Evaluation of Sperm Chromatin Damage

Sperm DNA fragmentation can be measured by a variety of assays that include the direct assays such as TUNEL, comet, and in situ nick translation test. These assays measure the amount of DNA fragmentation using probes and dyes. Indirect assays such as SCSA measure the susceptibility of DNA denaturation to acid denaturation, and SCD test measures the extent of halos formed based on the DNA integrity. The TUNEL assay, the SCSA, and SCD assay are the more common tests utilized for measuring DNA damage.

24.2.4.1 Sperm Chromatin Structure Assay

SCSA was developed during the 1980s. It is one of the most utilized assays to characterize male infertility with sperm DNA damage and chromatin abnormalities. The principle of the SCSA is based on the detection of DNA fragmentation using a flow cytometer, and large numbers of cells can be evaluated [88]. In this assay, following acid denaturation, sperm are stained with acridine orange—a fluorescent cationic dye [89]. The extent of acridine orange staining is determined by measuring the shift in metachromatic staining from green fluorescence to red fluorescence [84]. DNA fragmentation index (DFI) is the most important parameter. DFI is described as a percentage ratio of red fluorescent to green + red fluorescent, and it represents the population of cells with detectable denatured single-stranded DNA. One of the advantages of this assay is it is fast and robust, with a standardized protocol and small interlaboratory variation [88]. However, the need for a flow cytometer is a disadvantage to andrology labs due to the equipment cost. Values of DFI of 20–25% are related with infertility problems [11, 90]. When the DFI > 26% the fertilization can occur, however, most of the times this results in repeat pregnancy loss [91, 92]. In natural conception and intrauterine insemination (IUI), a DFI > 30% was associated with a negative pregnancy outcome [93, 94]. The cutoff values predicting ART outcomes are inversely proportional to DFI; when the DFI increases, the success of ART decreases [11, 90, 93, 94].

24.2.4.2 Terminal Deoxynucleotidyl Transferase-Mediated dUTP Nick End Labeling Assay

The TUNEL assay principle is based on the addition of deoxyribonucleotides to 3′hydroxyl (OH)—single- and double-stranded DNA by a template-independent DNA polymerase called terminal deoxynucleotidyl transferase (TdT; ◘ Fig. 24.1). The terminal deoxynucleotidyl transferase deoxyuridine triphosphate (dUTP) is the substrate added by the TdT enzyme to the free 3′-OH breaks-end of DNA. This assay uses fluorescent nucleotides in the detection of "nicks" or 3′OH free ends of DNA. The samples can be evaluated by flow cytometry (◘ Fig. 24.1) or by fluorescence microscopy. However, the standardization between laboratories is still lacking, which makes the comparison and establishing a uniform threshold challenging [95]. A modified TUNEL protocol using a benchtop flow cytometer can accurately measure a large number of samples [96]. This assay is rapidly gaining popularity among other tests of DNA fragmentation. The assay has high sensitivity and specificity [97]. A cutoff of 17% with >95% specificity can distinguish infertile men with DNA damage from healthy men [96].

In Situ Nick Translation

In this assay the incorporation of biotinylated dUTP on single-stranded DNA breaks by the template-dependent enzyme DNA polymerase I [98] is measured. The test allows the identification of sperm that contain low but varying levels of endogenous DNA damage. It is less sensitive than other tests of DNA fragmentation. There is a lack of correlation of this test with fertilization rates during in vivo studies, limiting the clinical value of the assay [99].

24.2.4.3 Comet Assay

The comet assay measures the amount of DNA damage per spermatozoon using the single cell gel electrophoresis assay [100]. It is a simple and affordable assay to measure sperm DNA damage. The comet assay not only detects single- and double-strand breaks but can also identify altered DNA bases. The DNA fragments coming out of the sperm head resemble a "comet" tail and hence the name of the assay.

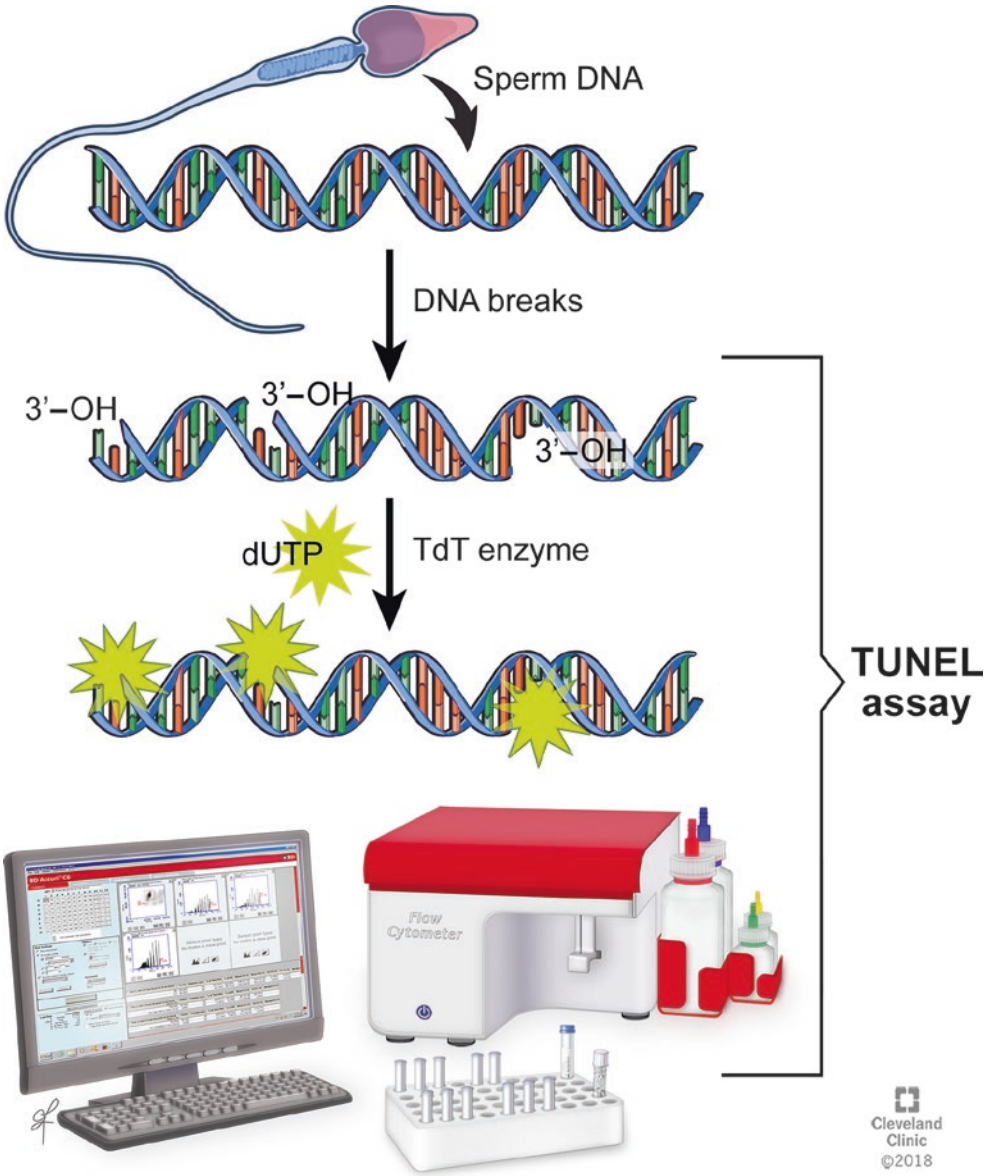

Fig. 24.1 Schematic of the DNA staining by the TUNEL assay

The assay principle is sperm nuclear DNA in an electric field can be separated based on the charge and fragment size that can be stained with a fluorescent dye. The results are qualitative and can be analyzed and graded using a fluorescence microscope, or quantitative and analyzed using an analysis software package [71]. Different types of DNA damage can be analyzed in a single cell and it requires highly specialized personnel and is time consuming [88]. The comet assay can be used to test samples from men with low sperm count. Results of the comet assay correlate with the results from the TUNEL assay [21].

24.2.4.4 Sperm Chromatin Dispersion Test

The SCD test is used to detect DNA fragmentation in spermatozoa using a kit called Halosperm® [101]. The principle of this assay is based on the fact that spermatozoa with fragmented DNA do not present the characteristic halo that is observed in spermatozoa with non-fragmented DNA following acid denaturation and removal of nuclear proteins [88]. In this assay, spermatozoa are immersed in an agarose matrix slide, and the nuclear proteins are removed by the denaturing solution exposing the damaged DNA. After lysis, spermatozoa show the characteristic loops around the sperm nucleus that correspond to spermatozoa with intact DNA; spermatozoa with damaged DNA do not exhibit any loop [88]. This assay can be done using bright-field microscopy with eosin and azure B staining or by fluorescence microscopy using DNA fluorescent probes [88]. It is simple, inexpensive, fast, and highly reproducible and does not require any complex instrumentation. However, this technique has some disadvantages, such as the interobserver variation. The halo boundary cannot be accurately differentiated from the background, the halos are not in the same plane, and some of them can be misread by an analysis software; sometimes the tails are not preserved and the contamination by other cells can be a challenge [87].

24.2.5 Effects of Sperm Chromatin Damage on Pregnancy Outcomes

24.2.5.1 Spontaneous Pregnancy

Many studies have reported that sperm from men with infertility may contain numerical or structural chromosomal defects, and karyotyping is the standard test to evaluate the chromosomal content [102]. Measuring sperm DNA fragmentation is important in the prognosis of achieving a natural pregnancy in couples. TUNEL and SCSA are used for testing the DNA fragmentation in infertile couples that present with recurrent pregnancy loss [8, 9]. A study showed low DNA damage levels, assessed by TUNEL in proven fertile men (11.9 ± 6.8%) when compared with men of unproven fertility (29.5 ± 18.7%) [103]. Another study comparing the sperm DNA fragmentation, assessed by TUNEL, of proven fertile men vs. patients where the partner had recurrent pregnancy loss showed significantly higher DNA damage in patients when compared to proven fertile men [104]. In fact, a higher probability of a successful pregnancy is reported, when men present with a low sperm DNA fragmentation [105]. Zidi-Jrah and colleagues reported a higher percentage of TUNEL-positive (cutoff >20%) sperm in a group with repeated pregnancy loss when compared to proven fertile men [106].

24.2.5.2 Assisted Reproductive Techniques

The effect of sperm DNA fragmentation in the success of pregnancy is dependent on the ART used. In case of in vitro fertilization (IVF), Henkel and colleagues showed a significant correlation between the low pregnancy rates and percentage of TUNEL-positive sperm. The pregnancy rate was 18.7% for TUNEL-positive spermatozoa, while in TUNEL-negative spermatozoa the pregnancy rate was 34.7% [107]. Another study reported a high percentage of DNA damage assessed by TUNEL and lower pregnancy rates in men undergoing IVF [108]. In case of IUI, no pregnancies were reported when the sperm had >12% of DNA fragmentation assessed by TUNEL [109]. Also in IUI cycles, Bungum and colleagues reported significantly lower rates of biochemical pregnancy, clinical pregnancy, and delivery rates in women inseminated with sperm with DFI higher than 30% [110]. Concerning the ART success rates when sperm DNA fragmentation was evaluated, studies demonstrate lower pregnancy rates when the sperm DNA fragmentation is high, but this is not true for intracytoplasmic sperm injection (ICSI) [111]. However, several studies demonstrate an association between the sperm DNA fragmentation and the success rate of ICSI. Host and colleagues reported a negative correlation between DNA fragmentation and fertilization rates where spermatozoa were used for IVF, but not for ICSI [112]. Henkel and colleagues did not find any correlation between TUNEL-positive spermatozoa (>36.5% DNA fragmentation) and fertilization rate using ICSI [107]. Huang and colleagues reported a negative correlation between sperm DNA fragmentation assessed by TUNEL assay and fertilization rates in cases of IVF and ICSI; however, the ICSI group seemed to be less affected [113]. In case of ICSI, Boroni and colleagues demonstrated an increase in pregnancy loss when sperm DNA fragmentation was high [114].

24.3 TUNEL Assay

24.3.1 Principles of TUNEL Assay

Sperm DNA fragmentation (SDF) is a result of activation of the endonucleases which break high-order sperm chromatin into smaller DNA fragments of ~50 kb [57]. DNA strand breaks are labeled by the fluorescein isothiocynate deoxyuridine triphosphate (FITC-dUTP) stain in the presence of TdT. TdT helps transfer the deoxynucleotides to the 3-hydroxyl (3-OH) end of the single- and double-strand breaks (Fig. 24.1). The intensity of labeling is proportional to the number of DNA strand break sites. SDF can be assessed with the benchtop BD Accuri C6 flow cytometer using the APO-Direct kit (BD Pharmingen, Cat. No. 556381) [115]. The kit consists of wash buffer, rinse buffer, reaction buffer, FITC-dUTP, TdT enzyme, and propidium iodide (PI)/RNase staining buffer. In addition, the kit also contains the "Negative control" and the "Positive control" (Fig. 24.2).

24.3.2 Why Should TUNEL Assay Be Used?

The basic semen analysis is the initial approach in the diagnosis of male reproductive status [3, 4]; nevertheless, sometimes this approach fails in the complete understanding of fertility potential in men seeking treatment [4, 116]. Over the years, the attention shifted to molecular structure of spermatozoa [28, 88]. The sperm DNA integrity is related with fertilization and consequent embryo development [28, 88, 117]. Although testing of sperm DNA damage is not recommended routinely for clinical use by the American Society of Reproductive Medicine [118], the importance of testing sperm chromatin fragmentation is recognized and approved by the American Urological Association and European Association of Urology guidelines on male infertility [88]. Based on the increased availability of this test, there is an increase in the number of studies reporting the correlation between sperm DNA fragmentation and successful pregnancies [12, 35, 84, 106, 119–121]. Although TUNEL is considered the gold standard for the evaluation of sperm DNA fragmentation [8], it lacks standardization, and the correlation with clinical outcome is still not clear [88, 94].

24.3.3 Advantages/Disadvantages of TUNEL Assay

TUNEL assay has the pros and cons for its use. One of the advantages of this assay using the flow cytometer is that it

Fig. 24.2 Components of the staining reagents: reaction buffer, TdT enzyme, and FITC vials

can be performed in a sample with low concentration of spermatozoa; it is rapid, robust, and highly sensitive; it is an indicator of apoptosis and can be correlated with semen parameter and consequently fertility; it has minimal interobserver variability; and there are commercial kits available to perform the analysis [28, 103, 122, 123]. On the other hand, the disadvantages of this assay are: it requires a flow cytometer and the threshold is not standardized between labs.

24.3.4 Methodology

24.3.4.1 Sample Preparation for TUNEL Assay

After complete liquefaction, aliquots containing 2.5 × 10^6/mL of sperm are prepared in duplicate, and tubes are labeled as "Test sample," "Negative control," and "Positive control." The "Test sample" and the "Negative control" tubes are centrifuged at 300 × *g* for 7 min; the supernatant is removed and replaced with 1 mL of phosphate-buffered saline (PBS).

Preparation of the Internal "Positive Control" Sample

In the tubes labeled as sperm "Positive control," a working hydrogen peroxide solution is prepared from stock hydrogen peroxide (37%) with PBS (1:15 dilution). One milliliter of the working solution is added to the sperm cells and the tubes are incubated at 50 °C for 60 min. After incubation, the tubes are centrifuged for 7 min at 300 × *g*; the supernatant is aspirated with a transfer pipette and resuspended in 1 mL of PBS 1×. After centrifugation at 300 × *g* for 7 min, the supernatant is removed and replaced with 1 mL of PBS.

The "Test sample," "Negative control," and "Positive control" tubes are centrifuged for 7 min at 300 × *g*. The supernatant is removed and replaced with 1 mL of 3.7% paraformaldehyde for "Fixation." After incubating the samples at room temperature for 15 min and centrifuging at 300 × *g* for 4 min, the paraformaldehyde is carefully aspirated and replaced with 1 mL of ice-cold ethanol (70%).

24.3.4.2 TUNEL Staining Protocol with the APO-Direct Kit

Staining Protocol

The "Negative controls" and "Positive controls" are provided as part of kit components (Fig. 24.2). These are cell lines and not sperm cells. The "Negative controls" and "Positive controls" are vortexed, and 2 mL suspensions of the well-mixed samples are aliquoted into the tubes. "Internal controls"—both positive and negative (two of each)—are also included with each run. The internal "Positive samples" are spermatozoa samples with known DNA fragmentation. The "kit control" samples, "Test samples," and the internal "Positive control" and "Negative control" samples are centrifuged for 7 min at 300 × *g*. After removing the 70% ethanol,

1 mL of the "wash buffer" is added, and the tubes are quickly vortexed and centrifuged at 300 × *g* for 7 min. The supernatant is removed, and this step is repeated. The tubes are numbered consecutively beginning with the kit "Negative control," "Positive control," "Test samples," and "Internal 'Negative' and 'Positive controls.'"

Staining for TUNEL Assay

To prepare the stain for TUNEL assay, the "reaction buffer" vial stored at 4 °C, the "TdT" vial, and "FITC-dUTP" vials stored at −20°C are placed at room temperature for 20 min. The staining solution is prepared by adding the reagents in the sequence shown in ◘ Table 24.1.

All the steps for preparation of the stain must be carried out in the dark. Negative internal controls are prepared by omitting "TdT" from the stain. After adding 50 µL of the "Staining solution" to each tube, the tubes are vortexed and incubated for 60 min at 37 °C. After incubation, 1 mL of "rinse buffer" (red cap) is added to each tube, and the tubes are centrifuged for 7 min at 300 × *g*. The supernatant is carefully removed, and the same step is repeated. Following centrifugation for 7 min at 300 × *g*, the supernatant is aspirated and discarded. The pellet is resuspended in 0.5 mL of PI/RNase buffer, and the tubes are incubated for 30 min at room temperature before running the samples on the flow cytometer.

24.3.4.3 General Setup of the Benchtop Cytometer

After double-clicking the "BD Accuri C6 software" icon on desktop, the software is opened; the reagent bottles are examined to ensure that the fluid levels are fine. The "waste" bottle should be empty, and the "sheath," "cleaner," and "decontamination" bottles must be full. The flow cytometer is turned on by firmly pressing on the power button. The "Traffic light" will turn yellow indicating that the peristaltic pump is working. Allow 5 min for the fluidic line to get flushed with the sheath fluid. Once the cytometer software light turns green, it indicates that the C6 Accuri is connected and ready. The tubing is flushed to remove any bubbles from the cytometer system. A 0.22 µm deionized (DI) water tube is placed on the sheath injection port (SIP) holder. The selection criteria for running the sample are "Run with limits" and "Fluidics" speed as "Fast." Once this is selected, click the "Run" button. At the end of the "flush cycle," the SIP tube is left on the SIP holder.

◘ Table 24.1 Preparation of stain for a single or multiple assay

Staining solution	1 Assay (µL)	6 Assays (µL)	12 Assays (µL)
Reaction buffer	10.00	60.00	120.00
TdT enzyme	0.75	4.50	9.00

24.3.4.4 Instrument Quality Control

The quality control for FL1, FL2, and FL3 channels is performed and validated with 8-peak beads. The 8-peak beads are 3.2 µm particles excited by the blue laser. The beads emit light at eight different wavelengths. The validation of the benchtop flow cytometer is done by running the 8-peak beads and determining the coefficient of variation (CV) and mean fluorescence intensity (MFI) each time the instrument is used. These can also be plotted as CV and MFI in the Levy Jennings chart. The details of the quality control were described in our earlier publication [124, 125] and are also described in the manufacture's manual.

24.3.4.5 Running Kit Controls and Acquisition of Data for Kit Controls

The kit controls are run using the "Kit Control template" (◘ Figs. 24.3 and 24.4). The settings include "Run with limits" for a total of 10,000 events with fluidic speed set as "slow" and threshold set at 80,000 on FSC-H. Data is recorded on four plots: FSC-A/SSC-A, FSC-A/FL2-A, FL2-A/FL2-H, and FL1A/FL2-A. The FITC-positive values are recorded from the upper right quadrant as percent positive value for the negative and positive kit controls.

24.3.4.6 Running Patient Samples

Patient samples are run under the "Collect" tab using the standardized data acquisition template (◘ Fig. 24.5). The complete acquisition data should be saved in a designated folder for patient results. The steps involved in (1) running the sample and (2) data analysis which includes the "Analysis strategy in the collect tab" and "Data analysis in the analysis tab" are described below:

Running the Samples

1. Double-click on the folder for patient results "TUNEL patient template." Select well "F1" and import the standard sample file (.fcs) (◘ Fig. 24.5). This is the file for the "Standard sample" that is tested negative for SDF. The "Standard sample" is used as the internal reference to compare all samples being tested.
2. Select the first well "A1." In the space provided above the well, insert the file name as "TUNEL patient result, tech initials, date and well number." Click save button.
3. Begin with the first sample labeled as tube #1. Remove DI water tube from the SIP holder, vortex the sample, and place on the SIP holder.
4. Set the run parameters by selecting the following:
   1. "Run with limits": check "10,000 events"; "Fluidics" speed: select "Slow."

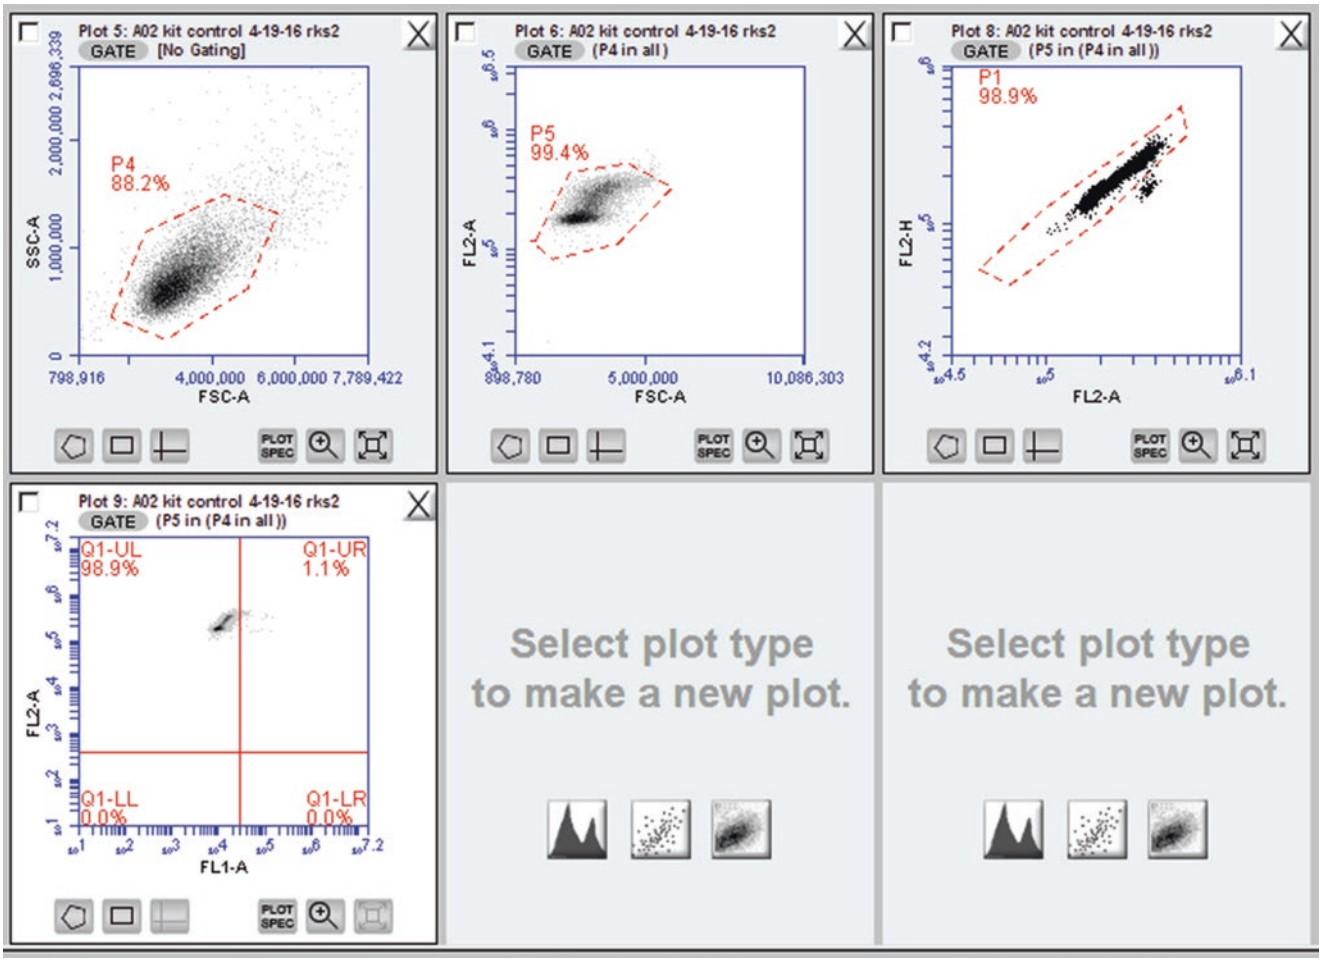

Fig. 24.3 Representative plot of "Negative kit control"

2. Select gate "P3 in P1" and set the threshold at 80,000 on "FSC-H."

5. Begin the acquisition of data by clicking on the "Run" button. The run is completed after 10,000 events.
6. Remove the tube from the SIP and clean the SIP using a lint free wipe. Vortex and place the second sample on the SIP.
7. Select the next well (A2, etc.) for the next samples. The above steps are repeated for each sample to allow processing of all samples.
8. Save the data acquisition workspace under a subfolder, e.g., "TUNEL Patient Results," "date," and "tech initials" C6. Save the workspace and close the file.
9. After all the samples are run, remove the tube from the SIP holder and replace with "bleach tube." Run the "Bleach cycle." A "Bleach cycle" is run to decontaminate the SIP holder and the fluidics using the following parameters:
   1. "Run with limits": 2 min.
   2. "Fluidics" speed: fast.
   3. Threshold: 80,000 on FSC-H.
10. After wiping the SIP at the end of the run, remove the tube and replace it with deionized water tube. Repeat (1–2) in step "D" above with deionized water, and shut down the instrument at the end of the run.

Data Analysis

Alignment strategy is performed under the "Collect tab." For this, the "Standard sample" file is used for alignment of all the samples. Data analysis is performed under the "Analyze tab," and each sample is aligned to "Standard sample" under the "Analyze tab."

Alignment Strategy and Data Analysis in the Collect Tab

The steps involved are described below:

1. Go to file, open workspace or template. Select the acquisition data saved in the TUNEL template (TUNEL patient template). Select an empty well where the standard sample data acquisition file has to be imported. Standard sample is a sample which has a known percentage of DNA fragmentation. Go to the "Standard template" and select it.
2. Click on "File import" and open the workspace.
3. Save the workspace as "TUNEL patient acquisition data analyzed, tech initials and date."
4. Select a single sample as "Standard sample."

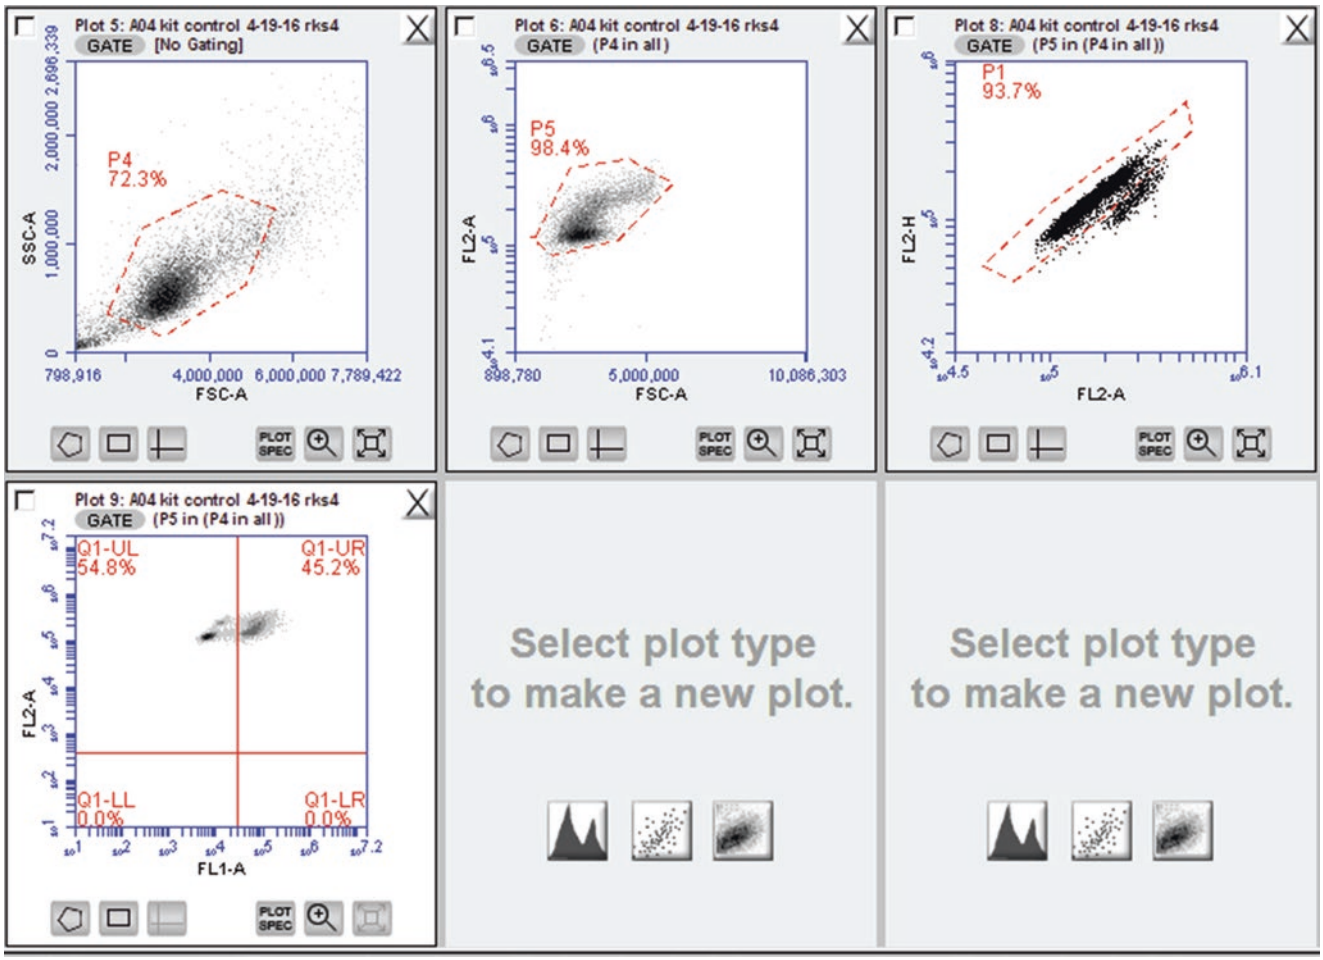

Fig. 24.4 Representative plot of "Positive kit control"

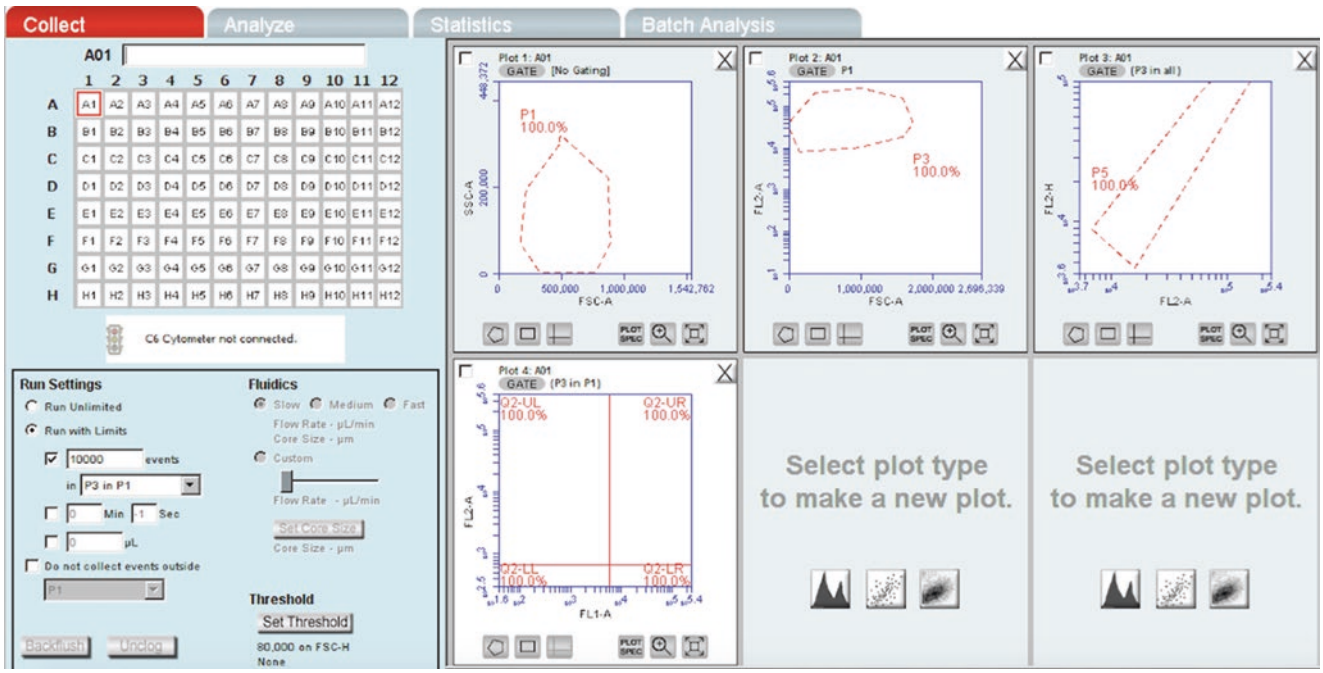

Fig. 24.5 Example of template setup for the analysis of the patient sample

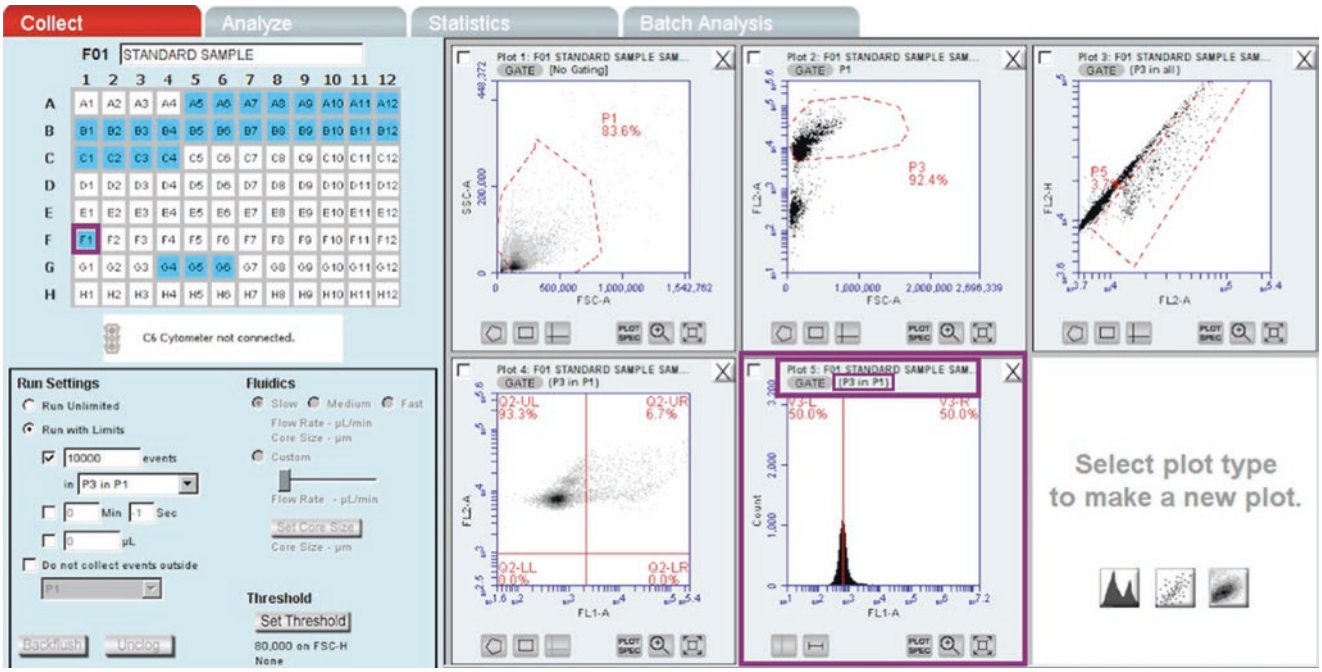

Fig. 24.6 Representation of a "Standard sample alignment"

5. Select the negative peak of the "Standard sample." This is used as a reference to be applied to all samples for alignment (Fig. 24.6).
6. Click on the histogram for the "Standard sample" and change the X-axis parameter from FSC-A to FL1-A.
7. Right-click below the X-axis (FL1-A) and select the "Virtual gain" module for alignment.
8. Change the gate to "P3 in P1" for plot 5. This gate is the same as plot 4, which is a quadrant gate.
9. Select the vertical line icon at the bottom left of the histogram plot, and align the selected blue line to the center of the histogram to obtain 50% cell population on either side (Fig. 24.7).
10. Select the sample to be aligned from the grid of wells.
11. Next align the blue line to the center of the peak of the selected sample. Click the tabs of "Preview" and "Apply."
12. An "Asterisk" will appear below the histogram. This confirms the alignment of the sample (Figs. 24.8 and 24.9).
13. Next hit close button. Go to file and hit "Save" after each sample is aligned.

Data Analysis in "Analyze" Tab

The data acquired in the "Collect" tab is utilized for analysis under the "Analyze" tab within the Accuri C6 software. After opening the "Analyze" tab, a set of three plots are created for each sample: FSC-A/SSC-A, FSC-A/FL2-A, and FL1-A/FL2-A. The same gating strategy that was used in the "Collect" tab is used here as follows:

1. The first plot "FSC-A/SSC-A" has no gating. The cell population is PX.
2. The second plot "FSC-A/FL2-A" will have the gate PX in all events. The cell population is PY.

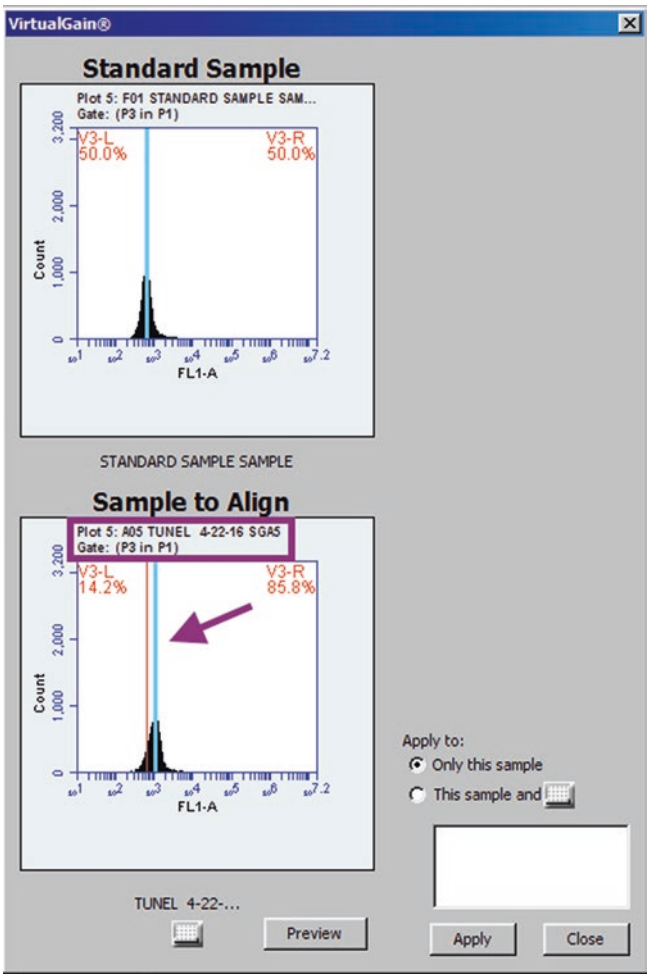

Fig. 24.7 Aligning a test sample to the standard sample

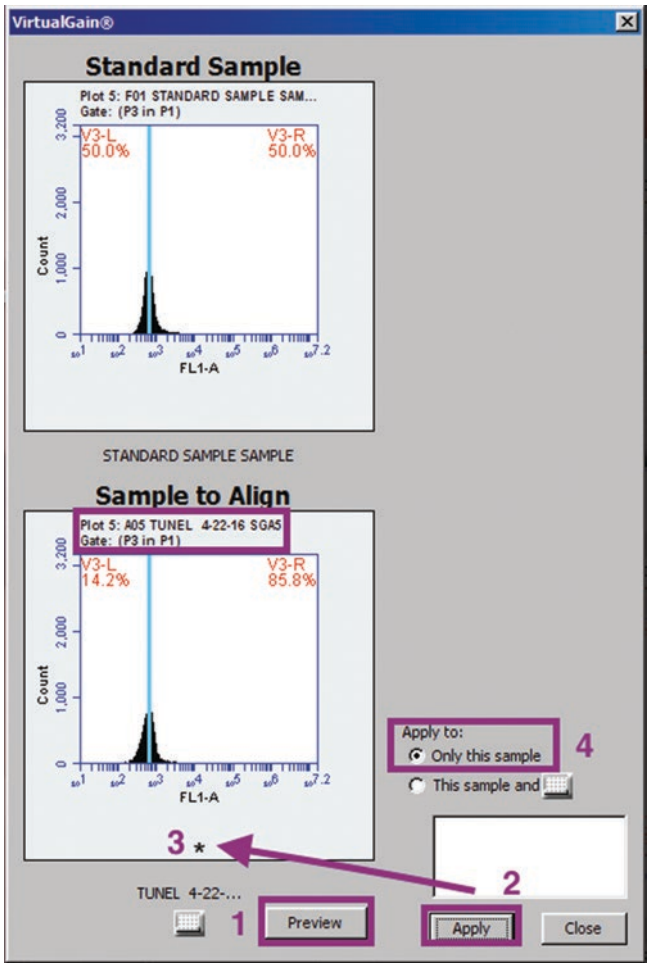

Fig. 24.8 Applying the alignment to the test sample. This is indicated by an asterisk at the bottom of the histogram confirming the alignment of the sample to the standard file

3. The third plot "FL1-A/FL2-A" will have gate of PY in PX in all events.
4. Record the percent damage reflected in the upper right quadrant from the "FL1-A/FL2-A" plot (Fig. 24.10).
5. Record the preliminary results in the "TUNEL Laboratory record form."

Calculation of Sperm DNA Fragmentation Result and Validation of the TUNEL Assay

After subtracting the average value of the "Negative samples" from the percent damage for each sample (Fig. 24.10), the assay is validated if the (1) "Positive control" spermatozoa samples have higher percentage of sperm that are positive for TUNEL assay than percentage of positive spermatozoa in the actual spermatozoa samples and (2) the "Positive kit control" has greater than 30% of spermatozoa positive for TUNEL assay. Currently, the reference value established in our center for SDF is 17%. Samples with SDF <17% are considered as "Normal," and those with >17% SDF are considered as "Abnormal." It is important that each laboratory establishes their own reference values and adopts strict quality control standards. The instrument quality control must be performed regularly using the 8-peak beads provided by the manufacturer. The "Positive" and Negative" controls provided in the kit and appropriate internal spermatozoa "Negative and Positive controls" must be included with each run. The details of the quality control steps are described in our recent publications [124, 125]. Adopting these strategies will help establish the reference values from different labs and increase the confidence of the results obtained. This will help in the clinical management of the patients.

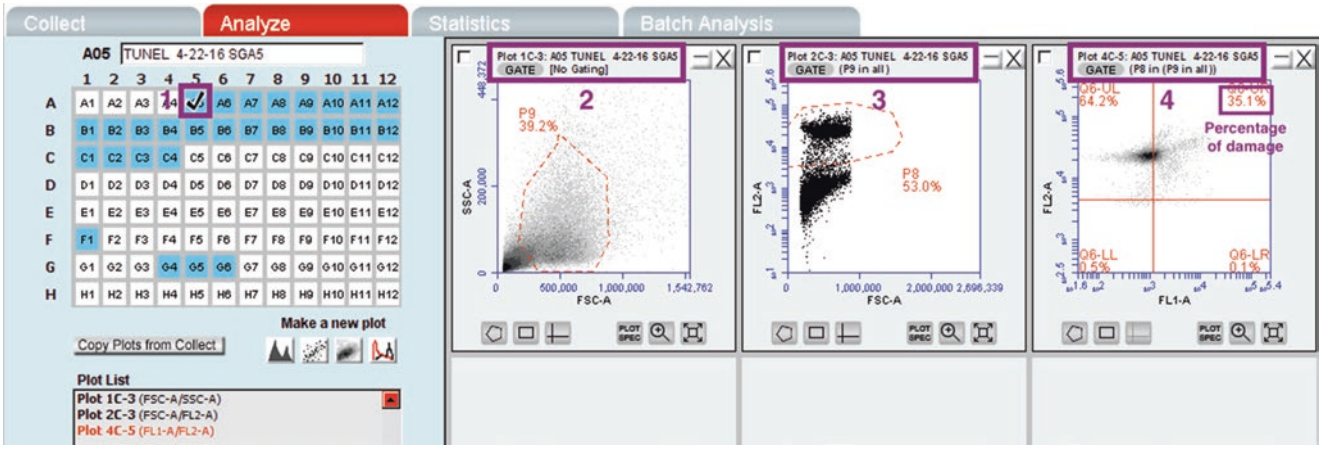

Fig. 24.10 Plot in the analyzed mode showing percentage of DNA damage

24.4 Conclusion

It is important that chromatin from the spermatozoa is correctly packaged and delivered safely to the oocyte. Studies have reported the association between the sperm DNA fragmentation and success rates of ART such as fertilization and pregnancy outcomes. Based on the extent of DNA fragmentation, the appropriate selection of ART is important to make it efficient and cost-effective. The assessment of DNA fragmentation can be performed using different techniques, still the clinical relevance of many tests remains unclear. Nevertheless, TUNEL assay is gaining popularity, and it is important that more laboratories standardize this test and establish the reference values. This is important to establish the guidelines for use of this test to be considered as a "gold standard" in a clinical setting.

Review Questions

1. In sperm DNA, during chromatin packaging the majority of the histones are replaced with:
   (a) Protamines
   (b) DNA topoisomerases
   (c) Disulfide bonds
   (d) None of the above

2. Which of these causes can be responsible for DNA fragmentation:
   (a) Aging
   (b) Lifestyle
   (c) Medical history
   (d) All of the above

3. In the TUNEL assay the samples can be evaluated by:
   (a) Flow cytometry
   (b) Standard fluorescence microscope
   (c) Polymerase chain reaction
   (d) (a) and (b)

4. In the TUNEL assay:
   (a) The intensity of labeling is not proportional to the number of DNA strand break sites.
   (b) The intensity of labeling is proportional to the number of DNA strand break sites.
   (c) There is no relationship between the intensity labeling and the number of DNA strand break sites.
   (d) None of the above.

5. What is the most important parameter in the sperm chromatin structure assay:
   (a) DNA fragmentation index
   (b) Number of DNA strand breaks
   (c) Sperm chromatin packing index
   (d) Protamine concentration

Learning Objectives

- To provide a brief overview of the principles, purposes, and goals of processing of semen samples
- To discuss sperm-processing techniques and provide a step-by-step protocol, with troubleshooting notes
- To provide a literature review on the various sperm-processing and selection techniques that are best suited to different types of samples

25.1 Introduction

The use of sperm preparation techniques as a part of assisted reproduction procedures, including intrauterine insemination (IUI), was initially established to select motile and morphologically normal spermatozoa that are ready to be used in the clinical process and separate them from the debris of the ejaculate and from other cell types present in the ejaculate, such as leukocytes, bacteria, and dead spermatozoa, which produce reactive oxygen species (ROS) that may negatively influence fertilization, embryo development, and implantation [1–3].

Additionally—and mainly when the intended use of the ejaculate is IUI—seminal plasma (the fluid resulting from reproductive tract gland secretions) is removed during the procedure to avoid the unnecessary and harmful presence of (among other things) prostaglandins, which may cause involuntary uterine contractions or spasms. Unprepared semen has been demonstrated to induce pelvic inflammatory disease, infections such as endometritis, cervicitis, or vaginitis, and has been related to increased miscarriage, probably together with increased risks of premature delivery or fetal malformation [4, 5].

Historically the beneficial effect of preparing sperm in assisted reproductive technology (ART) has been well established, and significantly increases the probability of conception after IUI in couples with male subfertility [6], when sufficient spermatozoa are retrieved after the process of sperm selection.

The number of motile and normal spermatozoa after preparation will determine the treatments to be applied and the outcomes. There is a close relationship between the probability of conception after IUI and the absolute number of motile sperm inseminated, until a threshold is reached, beyond which pregnancy rates form a plateau [7–9]. These minimal numbers to maximize results may vary from one million to several million motile sperm. A high yield can lead to a preference for IUI or in vitro fertilization (IVF), whereas a lower yield may lead to a preference for intracytoplasmic sperm injection (ICSI).

These are the reasons why sperm preparation can also be considered, in a way, a diagnostic tool to assist practitioners and patients to select the most convenient ART, depending on the balance between the female factor findings in the initial work-up and the sperm quality (both before and after sperm preparation), mimicking the situation when the sample will be prepared for therapeutic purposes.

On the basis of our criteria (Fig. 25.1), which are based on our own experience and clinical results, we provide our patients with such recommendations to better decide the most convenient approach for them. Different sperm preparation methods are available; the following are the most popular and widely used ones:

1. In the "swim-up" (SU) method, spermatozoa are self-selected on the basis of their ability to swim. This technique involves first mixing culture medium with the liquefied semen, then removing the supernatant after centrifugation, and, finally, smoothly layering the culture medium over the cell pellet, which motile spermatozoa swim up into. After an incubation of 30–45 min, the upper part of the layered medium is then carefully separated for further use.
2. The second most popular method for selecting spermatozoa uses density gradients. In this case, the semen sample is pipetted on top of a column composed of a substance of known density, greater than that of the ejaculate, thus keeping it physically separate, and it is

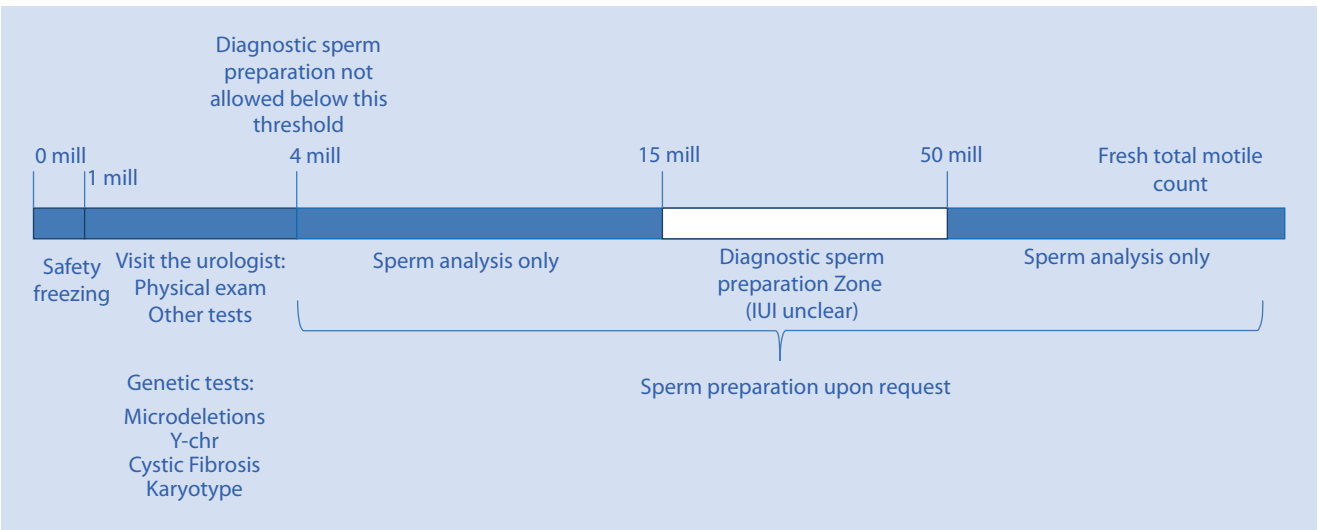

Fig. 25.1 Clinical recommendations and action patterns, depending on the spermiogram results. *Y-chr* Y-chromosome

then centrifuged. The centrifugal forces make motile sperm—and only motile sperm—cross through the density gradient, while keeping the remaining part of the ejaculate in the upper layers. Then, by just removing the upper layers or going through them with, for instance, the help of a Pasteur pipette, one can remove the motile sperm fraction to be washed from the gradients and finally resuspended in fresh culture medium [10].

Probably, these procedures are common to all ART units worldwide and are part of the essential procedures in each laboratory.

In natural conception, we understand very little about the characteristics of sperm populations that lead to reproductive success and what makes them do so. Despite decades of research, we still lack knowledge about the molecular features of optimal sperm and, logically, if we were able to identify or use these cells in ART, the success rate (the sperm to fertilized egg ratio) would be significantly increased.

To this end, instead of the self-selection methods described above, there are several direct selection methods being developed to retrieve sperm, with specific molecular features linked to optimal reproductive results. Unfortunately, many of these advanced sperm selection methods are still under investigation, while others are applicable only to a specific subset of patients. Thus, until further developments are available, there is a need to use classical sperm selection methods in the proper manner to optimize results.

The aim of this chapter is to describe the rationale, the procedures, and the most relevant aspects of routine sperm selection methods used in ART.

25.2 Overview and Essentials in a Sperm-Processing Unit

The minimal technical laboratory requirements and devices needed to run a sperm-processing unit—apart from a suitable building where the laboratory is located, with all of the architectural requirements depending on local regulations—include all of the resources that enable the possibility of obtaining sperm samples so they can be delivered safely to the laboratory, and also include places to conduct personal interviews, filing, semen analyses, and preparation.

Also, there is a need for equipment to perform blood, urine, and semen tests to confirm the absence of infectious conditions (as is often a prerequisite for any sperm preparation), although all of these aspects may be referred to external laboratories.

In this sense, the minimal list of requirements includes:

1. Laminar flow hoods to maintain and handle sperm samples under the most sterile conditions available and incubators with a continuous CO_2 supply to receive and keep the samples until liquefaction is completed properly, permitting (in some cases) sperm cell activity related to sperm preparation (as in the swim-up method). If media with HEPES (2-[4-(2-hydroxyethyl)piperazin-1-yl] ethanesulfonic acid) or MOPS (3-Morpholinopropane-1-sulfonic acid) buffers are used, a warming incubator is required.
2. Bright-field microscopes to analyze the samples and centrifuges to concentrate sperm cells from raw ejaculate, which are needed in some sperm preparation procedures described later in this chapter.
3. Ideally, an electronic filing system, or at least a paper-based filing system, to keep all donor records available.
4. Reference laboratories to perform screening tests for both infectious and genetic disorders, if these tests are not run at the sperm preparation facility.
5. Generation and maintenance of standard operational procedures (SOPs) for each procedure and records of regular maintenance and preparation of all equipment.

Moreover, qualified personnel trained in assisted reproduction laboratory tests—including sperm preparation, quality assessment, and serological tests—are required, together with laboratory directors and technical and administrative personnel.

25.3 Sperm-Processing Media

Many publications have compared different sperm-processing techniques, as outlined below, and some publications have compared the various culture media used in each technique [11–20].

Ficoll® was initially used as a density gradient centrifugation (DGC) medium for preparing spermatozoa, but then Percoll® replaced it. During the 1990s, several different types of media were developed to replace Percoll®—given its risk of contamination with endotoxins, membrane alterations, and inflammatory responses—including IxaPrep® (MediCult, Copenhagen, Denmark), SilSelect® (FertiPro, Beernem, Belgium), PureSperm® (NidaCon Laboratories, Gothenburg, Sweden), and ISolate® (Irvine Scientific, Santa Ana, CA, USA). Nycodenz® medium (Nyegaard & Co., Oslo, Norway), used in DGC, was assessed and found to recover highly motile spermatozoa with a better yield and better survival than other media used for oligozoospermic and asthenozoospermic samples. The remaining media had very low toxicity, but the results of sperm processing using these media varied between laboratories. This fact can be attributed to different conditions of the methodology, making these data impossible to compare. However, the new products were suitable alternatives to Percoll®.

Allamaneni et al. [11] compared the efficacy of two of these available density gradient media—PureSperm® and ISolate®—in different densities of layers: 40–80% in the first instance and 50–90% in the second instance. They compared sperm characteristics and ROS levels after processing the sample with these two gradient media and demonstrated that sperm fractions prepared using PureSperm® had significantly higher total sperm counts and higher recovery rates than those prepared using ISolate®. Therefore, they concluded

25

that higher rates of mature sperm recovery were obtained using density gradients—and, specifically, PureSperm®—which could be advantageous for ART success.

Nine years later, Malvezzi et al. [14] performed a controlled trial to study sperm quality after DGC with three commercial media: PureCeption® (Cooper Surgical, Trumbull, CT, USA), with 40% and 80% gradients; ISolate®, with 50% and 90% gradients; and SpermGrad-125® (Vitrolife, San Diego, CA, USA), with 45% and 90% gradients. For this purpose, they analyzed the percentages of sperm motility, total motile sperm, recovery, and deoxyribonucleic acid (DNA) damage, reproducing the same conditions. They found that although all three sperm-processing media produced good-quality samples, the ISolate® and SpermGrad-125® sperm fractions had higher percentages of sperm motility and total motile sperm than PureCeption®, with the percentage of DNA damage being comparable among the three media.

Similarly, several researcher groups assessed the efficacy of media—in this case, using sperm washing or the swim-up technique. In 1987, Vijayakumar et al. [20] assessed diverse wash culture media to maximize motile sperm recovery after the swim-up technique. They studied WT-6®, Ham's F-10®, and BWW®, and demonstrated that although the largest numbers of motile sperm were recovered with the first two media, the first one produced a higher yield.

Kim et al. [12] also compared the effects of different media but related them to clinical outcomes using the DGC/swim-up method or the swim-up method alone. In this case, they used Ham's F-10® medium or sperm wash medium. They concluded that using either culture medium, the results were comparable, including fertilization and pregnancy rates.

Later, several attempts to improve recovery of the largest number of motile sperm were made by several groups. The likelihood of achieving pregnancy was greater if the number of motile sperm was greater, leading Carlsson et al. [18] to include prostasomes in the swim-up medium when the semen was cryopreserved. They reported that prostasomes might be of benefit in improving outcomes in ART.

Likewise, aiming to avoid contamination in sperm processing for ART, another group [19] supplemented swim-up culture media with antibiotics (penicillin and streptomycin). They concluded that the combination of these antibiotics could remove nonspecific bacteria from semen samples without affecting sperm quality. A similar study was carried out 17 years earlier [15], and the researchers concluded that performing washing and swim-up preparation using culture medium rich in penicillin and streptomycin eliminated microorganisms with a 95% success rate.

Other studies have focused on searching nonanimal alternatives to avoid adding animal substances to culture media [21]. In one study, five different nonanimal macromolecules (Select Phytone™ UF, wheat peptone, dextran, hydroxyethyl starch, and methyl cellulose) were investigated for use as a supplement in culture medium for human sperm cells and compared with bovine serum albumin. However, it was concluded that although there were nonanimal macromolecules available for supplementing sperm culture media, some of them may be unsuitable for ART because of their physical properties.

The ideal option could be to supplement the sperm-processing medium with donor follicular fluid—a biological fluid rich in nutrients, growth factors, and hormones that might improve sperm quality. Following this theory, Bahmanpour [16] supplemented Ham's F-10® sperm medium with 10% follicular fluid, obtaining improvements in sperm quality in terms of survival and maintenance of chromatin integrity when the swim-up technique was used.

25.4 Human Semen Ejaculate

The words "semen" and "sperm" come from Latin (*semen* and *sperma*; the latter means "seed"). Sperm and semen constitute the set of spermatozoa and fluid substances that are produced in the male reproductive tract of all animals, including the human species. Semen is a viscous, slightly yellowish or whitish fluid, which is expelled through the urethra during ejaculation, usually accompanied by orgasm. Ejaculation is composed of two different actions: emission or deposition of seminal fluid from different glands into the posterior urethra, and ejaculation or propulsion of this fluid trough the urethra and out of the penis [22]. This fluid is composed of spermatozoa and seminal plasma. These two components of semen differ in their composition, function, and origin [23].

Seminal plasma is formed by the contributions of the testes, epididymis, seminal vesicles, prostate gland, bulbourethral glands (Cowper's glands), periurethral gland (Littré's gland), and vas deferens [24]. The function of this seminal plasma is to act as a nutrient medium, with suitable osmolality and volume to drive the spermatozoa to the cervical mucus for fertilization and to activate the spermatozoa to improve their motility.

The spermatozoa are formed by the testis from spermatogenetic cells of the seminiferous epithelium during spermatogenesis and are maturated in the epididymis. Their function is to reach the oocyte and fertilize it.

25.4.1 Semen Composition

During ejaculation, the sperm pass through the testes, epididymis, and ejaculatory ducts (vas deferens), and mix with components from the seminal vesicles, prostate gland, bulbourethral glands, and periurethral gland to form the semen. Generally, normal ejaculate has a volume of 1.5–5 mL and an alkaline pH of 7.0–8.5. Its composition depends on the proportions of sperm and plasma, and the size, storage capacity, and secretory output of several organs in the male reproductive tract [22, 23, 25].

25.4.1.1 Seminal Plasma

Seminal plasma is an extracellular fluid able to carry and feed spermatozoa. It represents 90% of the composition of semen. As mentioned earlier, its composition depends on the

secretion of different exocrine glands, each one contributing a different proportion and different components.

The prostate is positioned under the urinary bladder. It produces an opaque and whitish secretion that represents about 20% of the total volume of semen. Its pH is slightly acidic (6.2–6.8) [26] because its main components are citric acid, acid phosphatase, and for its reducing content in sugar. The prostate also secretes proteolytic enzymes, spermine, albumin, zinc, calcium, sodium, potassium, and lipids. The high content of zinc is important because it stabilizes chromatin in the sperm cells, and a deficiency of it can adversely affect spermatogenesis [27]; therefore, zinc plays an important role in reproduction. The main function of the prostatic secretion is liquefication of the sample by means of fibrinolysin, improving sperm motility and neutralizing the acidity of the other seminal fluids during ejaculation [27].

The seminal vesicles, located behind the prostate, secrete an opalescent, viscous, yellowish fluid, which contributes about 70% of the ejaculate fluid. Its pH is alkaline. It is composed mainly of fructose, prostaglandins, fibrinogen, lactoferrin, flavins, proteins, potassium, and bicarbonate, and it has a high content of reducing substances [28]. Its main functions are producing adenosine triphosphate (ATP), because fructose is the main energy source of sperm cells [29], and improving sperm motility and viability. Also, the prostaglandins may assist in fertilization, making cervical mucus more receptive to sperm and moving the ejaculate toward the ovaries.

The bulbourethral glands, or Cowper's glands, are located under the prostate. They secrete alkaline mucus composed of galactose and sialic acid, with a clear secretion into the lumen of the urethra to wash and lubricate it, facilitating the motility of the spermatozoa through the vagina and cervix to the ovaries [28]. These glands contribute about 10% of the ejaculate fluid. The periurethral gland (Littré's gland), located posterior to the urethral mucosa, also produces mucous fluid.

Therefore, human seminal plasma contains a complex range of organic and inorganic constituents, providing a nutritive and protective medium for the spermatozoa during their passage through the female reproductive tract toward the oocyte. Moreover, as mentioned earlier, the alkaline components of the semen compensate for the aggressive environment of the vagina toward the spermatozoa, given that this acidic environment could damage sperm DNA and cause sperm denaturation.

25.4.1.2 Spermatozoa

Less than 10% of the total volume of the ejaculate consists of spermatozoa—from 1% to 5%. The number of spermatozoa can generally vary from 50 million to 150 million per milliliter [30, 31]. The spermatozoa originate in seminiferous tubules inside the testes, then they are maturated in the epididymis to be conducted by the vas deferens through the seminal vesicles and the urethra to the penile meatus [22].

Spermatogenesis, or the sperm cell differentiation process, starts with spermatogonia and finishes with mature spermatozoa [28].

In the first step, spermatogonia migrate among Sertoli cells. These cells secrete a fluid into seminiferous tubes with substances necessary for their nutrition and development. Among these substances are transport proteins such as sex hormone–binding globulin (SHBG) and others, proteases and antiproteases, growth factors, other proteins such as inhibin and clusterin [32, 33], and another type of cells—Leydig cells—which produce testosterone, an essential hormone for sperm generation. During their course through the Sertoli cells, spermatogonia are progressively modified into spermatocytes, which undergo meiosis into secondary spermatocytes, then they are differentiated into haploid spermatids to become spermatozoa.

After spermatozoa are formed, they need to mature to develop the capability for motility and fertilization. For this purpose, they pass through the epididymis in their course from the testis to the vas deferens, where they mature. The epididymis secretes carnitine and alpha-glucosidase for sperm maturation, and motile inhibitory proteins to avoid premature capacitation until after ejaculation [22, 28]. Finally, they remain stored in the epididymis and vas deferens until ejaculation. After ejaculation the sperm acquire mobility and the capacity for fertilization.

25.5 Patient Communication and Preparation

Regarding communication with patients, there are two relevant situations during sperm preparation. The first one concerns the instructions to obtain and deliver the sample to the laboratory. These are the same as the actions requested for providing samples for basic semen analysis, and they can be found in the World Health Organization manual for semen analysis [34].

Another level of communication with patients concerns reproductive counseling after sperm analysis and preparation have been conducted. There is little or no published information about how to deal with the results of the prepared sperm analysis, regarding the sperm count and morphology. That is why, on the basis of our own experience, we have developed our own decision-making chart.

Briefly speaking, when preparing sperm from a diagnostic perspective, it is necessary to determine how the sample will perform functionally on the day when it will be needed for an ART procedure.

Several questions may be raised in this regard. First, in the event that the sample is aimed at IUI, the question is whether there are sufficient spermatozoa with optimal motility to maximize the chances of reproductive success. According to our own data, performing IUI with at least five million total motile cells after preparation will maximize the chance of pregnancy per insemination.

Anything less will, to some extent, hinder that possibility, and this situation should be discussed with patients, to take an agreed decision on the suitability of going ahead with this process. Our own experience and others' show that the

fewer motile sperm cells available, the lower the chance of pregnancy.

The second question that may be raised regarding the decision between classical IVF or ICSI depends on the total motile count available after sperm preparation.

Although the criteria may differ between laboratories, ejaculates in which the recovery rates are below 3–4 million are typically directed to ICSI. Patient also need to be counseled for prior cryo-storage of 1–2 ejaculated in case the husband couldn't collect the sample on the day of egg recovery. Second, patient also need to be informed of the benefit of frequent ejaculations prior to the day of IVF or repeat sample on the day of procedure. Such samples have shown to have improved DNA integrity in cases of high Sperm DFI.

25.6 Laboratory Documentation

Laboratory documentation includes SOPs and consents.

25.6.1 Standard Operating Procedures

Uniformity in all procedures that are carried out in a laboratory is an essential aspect for maintenance of a good level of execution of different methods in clinic embryology. Such uniformity allows us to confirm that all personnel perform techniques in a specific and coherent way, and it facilitates the identification of possible mistakes.

For this reason, the elaboration of SOPs is essential. They are detailed written instructions designed to achieve uniformity in the performance of specific functions. They are a set of step-by-step instructions compiled by an organization to help workers carry out routine operations to achieve efficiency, quality, and uniformity of performance, reducing miscommunication and failure to perform techniques. Moreover, SOPs facilitate the training of new workers and help personnel to remember procedures that are performed infrequently.

These SOPs should be passed on without modification, and if a modification is needed, it should be assessed and approved by the director of the laboratory, generating a new version of the SOP.

This documentation should be kept in the laboratory, and in a place accessible to all workers. The text should be reviewed by the director of the laboratory to change or update aspects, bearing in mind that the existence of these documents is referred to in good laboratory practice and in the International Organization for Standardization (ISO) standard ISO 15189:2003 [35–37].

Given that the elaboration of SOPs is very laborious, there exist different guidelines for how to write this type of documentation [38]. These are certain points that these documents must cover:

- The reason why the procedure is performed
- The principle on which the procedure is based
- If applicable, any specifications about precision, accuracy, etc.
- The type of sample used in the procedure
- Type of candidate suitable for the procedure
- The types of devices needed
- The type of calibration needed
- A description of procedural steps
- Quality controls
- Warnings about possible disturbances
- Expected results
- Information regarding interpretation of results
- Biosecurity warnings
- Any sources of variability

Besides a description of laboratory procedures, the SOP should have indicators that enable us to know if procedures have been performed correctly or not. Therefore, the SOP should contain solutions for each possible accident or mistake. Also, the SOP should be as detailed as possible, so that it would enable a worker from elsewhere to perform the technique without problems or doubts.

25.6.2 Reproductive Health Care Consent

Health care providers must obtain prior consent to treat patients [39], to ensure protection for both the patients and the providers. For this purpose, and to avoid problems, patients need to understand the informed consent that is required. If a patient cannot understand the consent, a legally recognized substitute or judge can provide it, considering that negligence could arise if the consent is not adequately informed. There may be legal limits to the reproductive procedures to which patients may consent, under laws that can be respectfully tested but must be obeyed.

Reproductive medicine professionals explain and confirm correct fulfillment and understanding of all relevant procedural consent requirements. Consents exist for all such treatments—from simple sperm-freezing preservation to the oocyte donation cycle or any analysis.

25.7 Decision Making Prior to IVF/ICSI: What Procedure to Use for Individual Samples

In the majority of patients undergoing IVF/ICSI, the spermatozoa are isolated from fresh ejaculate provided on the day of egg retrieval. For a sample to qualify for conventional insemination, it should yield a good number of sperm with excellent, lasting, and progressive motility postprocessing. As per the classical textbooks, typically 50,000 to 100,000 normal motile spermatozoa per milliliter are used for insemination. There can be variation in the insemination concentration depending on the culture volume (droplets or 4-well dishes/center well), sperm quality (especially in cases of teratozoospermia), etc. Occasionally, higher insemination volumes may be required with short-incubation IVF. Contrary to this, if the insemination is being done using ICSI, the final yield might contain more debris and not be as good and as neat as a conventional insemination case. In ICSI insemination, embryologists prefer

Table 25.1 Recommended sperm-processing/selection methods, depending on the type of sample or case

Type of sample/case	Recommended method
Normozoospermia	DGC/MFSS
Teratozoospermia	DGC/MACS
Asthenozoospermia	DGC/MACS
Oligoasthenoteratozoospermia	Wash and swim-up/DGC
Leukocytospermia	DGC/MACS
Hyperviscosity	Pellet swim-up
Hypospermia	Wash and pellet
Heavy debris	DGC
Retrograde ejaculate	Wash and pellet
PESA sample	DGC/wash
TESE sample	Wash and pellet/DGC
M TESE sample	Wash and pellet/DGC
Frozen–thawed surgical sample	Wash and pellet
Frozen–thawed ejaculate	DGC
Sperm with a high DFI	DGC/MACS
Previous ICSI failure	IMSI/MACS/PICSI
Unexplained infertility	MACS/IMSI/PICSI
Previous RIF	MACS/PICSI
Previous failure of conventional insemination	DGC/MACS
Patient preference	As per discussion/ counseling

DFI DNA fragmentation index, *DGC* density gradient centrifugation, *DNA* deoxyribonucleic acid, *ICSI* intracytoplasmic sperm injection, *IMSI* intracytoplasmic morphologically selected sperm injection, *MACS* magnetic activated cell sorting, *MFSS* microfluidic sperm sorting, *M TESE* microdissection testicular sperm extraction, *PESA* percutaneous epididymal sperm aspiration, *PICSI* physiological intracytoplasmic sperm injection, *RIF* repeated implantation failure, *TESE* testicular sperm extraction

to get a smaller concentration with no debris, which makes the injection process smoother and is less time consuming. Some laboratories use a short centrifugation of only 1–2 min after the density gradient step. This helps to minimize massive accumulation of sperm cells in the bottom of the tube, especially in cases of normozoospermia (Table 25.1).

25.7.1 Utility of Electronic Medical Records

Electronic medical records (EMRs), which are very common in IVF clinics, are a handy tool for embryologists to consider the previous seminal and IVF/ICSI history of the patient. The embryology laboratory sheet used on the day of egg retrieval may include a section including options such as "IVF–ICSI–IVF/ICSI" to choose from. In some laboratories, the embryologists/laboratory managers discuss the preferred type of insemination on the basis of the sample quality and the patient's preferences in their discussion with the couple after egg retrieval. Given recent media reports on neonatal outcomes in children conceived through ICSI, there may be concerns for patients about the types of insemination the laboratory chooses. So, it is appropriate to have a discussion with the couple regarding their preferences for the insemination after egg retrieval. The laboratory can explain the pros and cons of each type of insemination procedure. It is also a good idea to record a note in the male/female notes section of the EMR about the outcome of the discussion regarding the insemination type being used. During counseling sessions, embryologists obtain relevant information such as whether the woman has previously had a natural pregnancy or a pregnancy through IUI cycles, to make sure that conventional insemination will not yield failed fertilization.

The use of density gradient–based semen processing for separation of a fraction containing the most normal and mostly motile sperm has been the method of choice in most ART laboratories. This practice has become part of the SOPs of so many ART laboratories that other types of sperm preparation methods are no longer practiced in many laboratories. However, some other methods still have a place in the processing of particular types of semen samples.

The physical characteristics of certain types of semen samples may interfere with the processing technique that is used. Hyperviscous samples pose a problem if the density gradient method is used. Such samples and those with liquefaction problems may require alternative steps. Mechanical liquefaction using an 18-gauge needle used to be a common practice, but this can hamper the functional capacity of spermatozoa. One recent study compared DNA fragmentation in human sperm samples with reduced, physiological, and increased viscosity to evaluate whether the process used to reduce the viscosity (expulsion of semen through a needle and syringe) significantly altered sperm DNA fragmentation. There was no difference in the DNA fragmentation rates between samples with reduced, increased, and physiological viscosity; however, the physical process of expulsion of semen through a syringe and needle did increase sperm DNA fragmentation [40].

Samples that are not liquefied properly may be combined with the sperm preparation medium and mixed well, or can be added to α-chymotrypsin (which is available to andrology laboratories in ready-to-mix vials) to reduce the viscosity. This can be followed by the density gradient step. Sometimes a wash and swim-up method is the method of choice for hyperviscous samples, as density gradients can trap sperm between the gradients. Honea et al. found that limited proteolysis using α-chymotrypsin in the treatment of hyperviscosity was effective in an in vitro setting such as IVF or IUI [41, 42].

Samples with excessive numbers of nonreproductive cells (e.g., epithelial cells, round cells, etc.) can be diluted with buffered sperm-processing medium and fractionated into

25

multiple tubes for density gradient processing to get a better yield. In contrast to IUI sperm processing, the idea of this type of processing is to get a fraction of functionally good spermatozoa. Similarly, samples with many jelly particles can interfere with a good yield in density gradient processing. These samples should be diluted with buffered medium and kept for a few minutes so that the jelly particles settle down. The supernatant is then removed for DGC.

Unlike sperm function testing, which has been used only as a research tool for many decades because of its questionable relevance to ART, the sperm DNA fragmentation index (DFI) has made a successful entry into this field and has become an integral part of the infertility (male factor) workup. This is exemplified by the fact that the sperm DFI has been extensively correlated with embryo quality, pregnancy outcome, and miscarriage [43, 44]. Recently, many sperm selection techniques have been added to the armamentarium of ICSI. These include intracytoplasmic morphologically selected sperm injection (IMSI), physiological intracytoplasmic sperm injection (PICSI), magnetic activated cell sorting (MACS), microfluidic sperm sorting (MFSS), and microelectrophoretic sperm separation. Many prospective and retrospective studies have been done on the efficacy of these techniques and their outcomes. Adoption of some of these techniques seems a better option in ICSI because of the following realities: (1) ICSI for human treatment was introduced in the early 1990s as a technology before it became a science; (2) spermatozoa are selected randomly by a technician (with no component of natural selection); (3) the ART field is still searching for better treatment for male factor infertility; (4) the incidence rates of sperm DFI/sperm epigenome issues and "unexplained infertility" are increasing; and (5) there is still the problem of "what next" to offer in ART clinics when patients experience repeated failures.

MFSS devices have been tried at many clinics in recent times as an alternative to conventional processing techniques. A recent study [45] found significantly lower sperm DNA fragmentation rates with MFSS compared with centrifugation and the swim-up procedure. The microfluidic system can effectively separate raw semen samples into immobile and mobile groups without the need for centrifugation steps, at the same time avoiding damage to sperm, as single or multiple centrifugation steps damage spermatozoa via generation of ROS [46].

Similarly, MACS is a sperm preparation technique that isolates nonapoptotic spermatozoa on the basis of expression of phosphatidylserine in the membrane of apoptotic sperm. A systematic review and meta-analysis of prospective randomized trials by Gil et al. [33] showed that sperm selection using MACS resulted in statistically significant differences in pregnancy rates when compared with the DGC and swim-up techniques. Another study concluded that the MACs technique is a simple, noninvasive technique that can efficiently reduce DNA fragmentation in infertile patients with a varicocele prior to ART.

Human sperm that express hyaluronic acid receptors and bind to hyaluronic acid have a normal shape, minimal DNA fragmentation, and a low frequency of chromosomal aneuploidies. Use of hyaluronic acid–binding assays in ICSI cycles to improve clinical outcomes has been studied by many groups. In a recent systematic review and meta-analysis [47], use of a hyaluronic acid–binding sperm selection technique yielded no improvement in fertilization and pregnancy rates. Meta-analysis of all available studies showed improvements in embryo quality and the implantation rate, but when the analysis was restricted to prospective studies, it showed an improvement only in embryo quality. According to the authors, this analysis did not support routine use of hyaluronic acid–binding assays in all ICSI cycles. They concluded that further study is needed to identify patients who might benefit from this technique.

Majumdar et al. [48] examined whether injection of hyaluronic acid–bound sperm helps to improve outcomes in patients undergoing ICSI with unexplained infertility despite normal semen parameters. There were no differences in the fertilization rates, numbers of top-quality embryos, and clinical pregnancy rates between patients treated with ICSI and those treated with PICSI. However, a higher pregnancy loss rate (PLR) was observed in the ICSI group than in the PICSI group, although the difference was not statistically significant. In another study by Mokánszki et al. [49] the PLR was significantly lower with PICSI than with ICSI.

The diversity and the constant development of novel promising techniques to improve ICSI, in terms of spermatozoon quality, are certainly worth pursuing. Most of the techniques that have been discussed are still a long way from being established as routine practice in standard IVF laboratories. In most cases an experienced embryologist can achieve the same results. Although some of the techniques show great benefits, there is a need for large-scale, multicenter, randomized, controlled studies to quantify their importance before horizontal application can be suggested. Taking into consideration the a priori invasive nature of ICSI, when clinical application becomes a possibility, we need to proceed with caution and ensure that in the pursuit of innovation we are not sacrificing safety and the balance of the physiological and biological pathways of the spermatozoon's dynamic [50].

Finally, in cases of akinetozoospermia, the use of functional tests, such as a pentoxifylline test, a hypo-osmotic swelling (HOS) test, or, to a lesser extent, the laser touch technique, makes selection of viable spermatozoa easier.

Assessment of sperm morphology has been reconsidered since 2001, with the development of motile sperm organelle morphology examination (MSOME). This observation technique, which combines high-magnification microscopy and Nomarski interference contrast, makes it possible to select spermatozoa with as few vacuoles as possible before microinjection into the oocyte (via IMSI). More than 10 years after the development of the IMSI technique, the indications for IMSI and its ability to increase pregnancy and/or birth rates (in comparison with conventional ICSI) are still subject to debate. In an attempt to clarify this debate, Boitrelle et al. [51] performed a systematic literature review according to

the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines. Given the scarcity of head-to-head IMSI-versus-ICSI studies, the only confirmed indication for IMSI was recurrent implantation failure following ICSI. According to the authors, all other potential indications for IMSI require further investigation. In one study comparing the two sperm selection techniques, there were no differences in high-magnification morphology and hyaluronic acid binding in the selection of euploid spermatozoa with intact DNA [52].

Pharmacological sperm stimulation has been studied in surgically retrieved sperm samples and ICSI. Ebner et al. [53] evaluated whether the use of theophylline improves sperm motility and treatment outcomes in frozen–thawed testicular sperm extraction (TESE). All but one patient (98.5%) showed a significant improvement in testicular sperm motility when theophylline was employed as a motility enhancer. In addition, sperm selection by an embryologist during ICSI took significantly less time in cases where theophylline was used than in those where it was not used. The corresponding rates of fertilization (79.9% versus 63.3%), blastulation (63.9% versus 46.8%), and clinical pregnancy (53.9% versus 23.8%) were significantly increased with the use of theophylline.

The presence of a very high concentration of erythrocytes together with few sperm sometimes results in a much longer searching period and blockage of injection needles. Use of large-diameter ICSI needles is an option in these situations to pick up the sperm from red blood cell (RBC)–laden drops and place them in fresh polyvinylpyrrolidone (PVP) drops after a washing step in HEPES/MOPS drops. Once enough sperm are collected, the operator can change the needle and use regular ICSI pipettes for sperm immobilization and injection.

One option for testicular biopsy specimens is suspension in HEPES/MOPS–buffered medium [54]. This can then be centrifuged for 5 min at 300 × *g*. Treatment of the testicular sperm pellet with erythrocyte-lysing buffer is performed by resuspending the testicular sperm pellet in 2–4 mL of erythrocyte-lysing buffer (155 mM NH_4Cl, 10 mM $KHCO_3$, and 2 mM ethylenediaminetetraacetic acid (EDTA); pH 7.2) for 10 min at room temperature. Following this step, 5–10 mL of HEPES/MOPS–buffered medium supplemented with human serum albumin (HSA) is added to the suspension in the same tube and then centrifuged for 10 min at 500 × *g*. The resulting pellet is then resuspended with 1.5 mL of sperm wash medium. This resuspended pellet can be centrifuged again at 500 × *g* for 5 min. After centrifugation, the pellet is resuspended in 50 μL of sperm wash medium and used for ICSI.

The sperm membrane undergoes extensive surface remodeling as it matures in the epididymis. During this process, the sperm is encapsulated in an extensive glycocalyx layer, which provides the membrane with its characteristic negative electrostatic charge. In a recent study, Simon et al. [55] developed a method of microelectrophoresis to isolate sperm with a high negative membrane charge. The results suggested that selection of negatively charged spermatozoa (NCS) at a lower current may be an important biomarker to select healthy sperm for ART.

When sperm were picked according to their charge and analyzed directly, sperm DNA damage was lower in the NCS population (3.9% ± 1.5%) than in the control population (17.3% ± 3.2%) and the positively charged spermatozoa (PCS) population (27.8% ± 6.0%). The percentage of NCS was positively associated with the fertilization rate (r^2 = 0.469) and blastocyst development (r^2 = 0.308), and inversely associated with embryo arrest (r^2 = −0.253). The implantation rate and clinical pregnancy rate were higher in patients with a higher proportion of NCS.

25.8 Sperm-Processing Techniques

Sperm processing or preparation increases the potential for sperm fertility through different techniques performed in the laboratory to separate immotile spermatozoa, debris, and seminal plasma, and to select motile spermatozoa and male germ cells [14].

Sperm processing results in modifications of flagellar movement and head beating of the spermatozoa, facilitating their oocyte penetration. For this purpose, spermatozoa have to undergo the acrosome reaction, in which they release lysis enzymes enabling them to penetrate the zona pellucida. In this process, the sperm acrosomal membrane starts to merge with the external acrosomal membrane, leading to vesiculation and generation of pores through which enzymes are released.

Therefore, sperm processing is related to the facility of achieving sperm fertilization ability [56].

Before any ART, all samples should be processed by means of sperm processing or preparation techniques to select spermatozoa with the best motility and eliminate seminal plasma (with prostaglandins and motility inhibitors) and immotile spermatozoa, immature cells, and debris.

To determine the most optimal sperm preparation method for ART, different groups have studied diverse techniques for this purpose: the swim-up technique or migration method, swim-down, direct swim-up, DGC, sucrose, glass wool filtration, washing, and sperm concentration [57–59]. Today, an array of different methods is available, and the selection depends on the quality of the ejaculate. The ideal sperm-processing technique is one that is quick, easy, and cost effective; recovers a large number of motile sperm; does not cause sperm damage; removes immotile and dead sperm and other cells; eliminates toxic substances; and allows processing of larger volumes of ejaculate [14]. For these reasons, the swim-up and DGC techniques are the methods most often used in infertility laboratories because of their efficacy, simplicity, and good results in terms of pregnancies.

These techniques can be used together or separately. Several articles have concluded that use of them together is better [57, 60, 61]; however, other papers have reported the opposite [58, 62]. Despite differences in the percentage recovery of motile sperm with the different techniques, the

clinical outcomes, including fertilization and pregnancy rates, seem to be comparable [12, 63–65].

Going further, if we take into account which technique allows us to recover spermatozoa with the lowest rates of DNA fragmentation or apoptosis, although the differences between the swim-up, DGC, and DGC/swim-up methods were not significant [58, 61, 62, 66], the swim-up method was the best option for treatment of semen samples during IVF/ICSI, given its low cost and reduced time requirement [58]. Focusing on the sperm telomere length (STL), Zhao et al. [61] compared the effects of the DGC and swim-up procedures on STL, and the results showed that both methods could recover a sperm population with longer STL and better DNA integrity for ART. However, another group concluded that the choice of method depended on whether IVF/ICSI or IUI was to be performed, because they observed no functional differences between the spermatozoa selected by either method [66, 67].

Therefore, each laboratory employs the most suitable technique according to its needs.

25.8.1 Density Gradient Centrifugation

This technique is based on the ability of motile sperm to cross layers with different densities to reach the bottom of the tube, and seminal plasma, round cells, immature cells, debris, and nonprogressive spermatozoa are then discarded [68]. With this technique, the spermatozoa are separated on the basis of their density, as normal mature spermatozoa have slightly higher density than abnormal immature ones. Therefore, after centrifugation, each spermatozoon is placed at the gradient level that matches its density, and highly motile spermatozoa are at the bottom of the tube, forming a pellet [11]. This technique allows us to recover, in the best way, motile spermatozoa from oligozoospermic samples, asthenozoospermic samples, and samples with large numbers of cells and large amounts of debris [65, 69].

In fact, 20 years ago it was believed that DGC was the best technique for selecting sperm with normal morphology [70] and produced final spermatozoa pools with higher percentages of motility—and higher motility quality within all concentration ranges—than the swim-up technique [71].

The different steps in this procedure are:

1. Sliding a certain volume of culture medium impregnating the walls to the bottom of the tube, always starting with the highest-density layer.
2. Adding the same volume of gradient with a lower density than the previous one, placing it in the same way as in step one over the first bottom layer to avoid breaking the interface and avoid mixing the two layers. This volume and the sperm sample volume will depend on the sperm concentration and motility in the sample, from 0.5 mL to 1 mL.
3. Placing the same certain volume of semen into the tube, making it slide over the tube walls.
4. Centrifuging the tubes at 1500 revolutions per minute (rpm) for 10–20 min.
5. Recovering the pellets from all of the tubes and placing them in a new tube or removing all of the supernatants and placing all of the pellets together.
6. Washing this big pellet with a wash culture medium at 2200 rpm for 5–10 min, removing the supernatant, and resuspending the pellet with 0.5 mL of culture medium for ART.
7. Assessing the quality of the sample before it is used.

The density gradient may differ depending on the laboratory and the culture medium applied [70]. For example, if we use SpermGradient® (Cook Medical, Castletroy, Ireland), the layers will be 80% and 40%; if we use PureSperm®, the layers will be 80% and 40%; if we use ISolate®, the layers will be 50% and 90%; and if we use SpermGrad®, the layers will be 90% and 45%. Other culture media are PureSperm® 100% and SpermGrad 100%; in these cases the operator can prepare the layers with whatever density is desired.

Moreover, some laboratories have used three layers [72]. When Percoll® was used, it was concluded that the three-layer discontinuous density gradient should be adopted as the preferred method for preparation of spermatozoa for assisted reproduction. Nowadays, however, the trend is for two layers to be used.

25.8.2 Swim-Up Technique

This technique is based on the principle that only the sperm with the best motility are able to rise to the supernatant [73]. This technique is the oldest sperm preparation method and was originally described by Mahadevan and Baker [74]. This procedure is very easy to perform and allows recovery of a good number of progressive spermatozoa in normozoospermic samples. However, it presents several disadvantages, given that it decreases the percentage of normally chromatin-condensed spermatozoa, while pelleted spermatozoa are in close contact with other cells, debris, and leukocytes at the bottom of the tube, being exposed to high levels of ROS [14].

This method is divided into the following steps:

1. Washing the semen sample with wash culture medium in a ratio of 1:2 and centrifuging the sample at 2200 rpm for 10 min.
2. Decanting the supernatant.
3. Adding new medium over the pellet, making it slide slowly over the walls of the tube to avoid mixing. The added volume depends on the quality of the sample and the size of the pellet (from 0.5 mL to 1.5 mL).
4. Placing the tube inside an incubator at 37 °C, inclined at an angle of 45°, for 45 min (this time may vary depending on the quality of the sample). During this step, progressive spermatozoa will migrate from the pellet to the upper fraction of the new culture medium.
5. When the upper fraction changes its color, this is the best moment to extract the sample from the incubator.

6. Recovering 0.5 mL of the upper fraction containing progressive spermatozoa.
7. Assessing the quality of the sample before it is used.

25.9 Processing of Retrograde Ejaculate Samples

A particular type of sperm preparation is needed to deal with cases of retrograde ejaculation, where spermatozoa must be retrieved from urine in the bladder. This condition is responsible for about 0.3–2% of infertility cases; thus, it is relatively infrequently encountered in practice [75].

The normal process of ejaculation requires compound coordination between the different parts of the male reproductive tract, including the epididymis, vas deferens, prostate, seminal vesicles, bladder neck, and bulbourethral glands, at least [76].

The normal process of ejaculation delivers sperm rapidly through the vas deferens and into the urethra by means of the ejaculatory ducts, traveling via the bladder neck thanks to contraction of the periurethral muscles. Then the sympathetic nervous system performs closure of the bladder neck and seminal emission is initiated.

Any factor that interferes with this tightly coordinated process may lead to retrograde passage of semen into the bladder; among them are pharmacological, neurogenic, or anatomical causes, including the use of pharmacological alpha-adrenergic blockers or psychotropic medications, neurogenic spinal cord injuries, lumbar sympathectomy, retroperitoneal lymph node dissection (RPLND), aortoiliac vascular surgery, abdominoperineal resection, diabetic autonomic neuropathy, multiple sclerosis, myelodysplasia, cerebrovascular accident, the presence of congenital posterior urethral valves, utricular cysts and exstrophy, acquired transurethral bladder neck incision, and transurethral resection of the prostate.

The way to proceed with these kinds of samples is initially focused on avoiding the harmful effects of urine—particularly its low pH—on sperm viability. This involves converting the urine to a neutral pH and then removing the spermatozoa as soon as possible after retrograde ejaculation. Second, to avoid difficulty in obtaining and processing additional samples if needed, sperm-freezing protocols are then applied.

The clinical protocol in this case starts with the patient taking bicarbonate (1–2 tablespoons dissolved in water) the night before the sample collection and then again on the morning of the sample collection, when urination to empty the bladder is recommended, followed by ejaculation, and then the next urine available is taken to the laboratory as soon as possible. In the laboratory, after measurement of the pH to check for the effect of bicarbonate, washing with sperm preparation medium is recommended, followed by centrifugation and elimination of the supernatant containing the urine where the spermatozoa were present. The pellet is then resuspended in clean culture medium and a search for motile spermatozoa is conducted to determine the sperm quality after the process. Finally, the sample is frozen if motile spermatozoa are found. In almost every case of retrograde ejaculation, this process guarantees availability of motile spermatozoa to be employed in ART.

25.10 Processing of Cryopreserved Ejaculate Samples

Although there is no literature regarding preferences when dealing with cryopreserved sperm preparation, sperm density gradients are the preferred choice in our experience. This affirmation is based on the rationale of the process itself in comparison with the swim-up.

Swim-up techniques require high-speed centrifugation to obtain well-formed pellets. With frozen–thawed samples, the large number of dead cells (due to the cryopreservation process itself) and cellular debris, together with the cryoprotectant compounds, lead to a sticky pellet, with increased difficulties for sperm to move through the culture medium, yielding lower recovery rates than density gradients. In this sense we refer to recovery rates as the percentage of total motile cells recovered, in comparison with the total motile cells available after thawing. It is interesting to note that the percentage of motile cells after density gradients with frozen–thawed sperm is significantly lower than that obtained with the swim-up method, but provided the total number of motile sperm available remains sufficient, as per the minimum threshold criteria—and in this sense, the density gradient method is superior to the swim-up method—clinical pregnancy rates are comparable.

25.11 Processing of Frozen Donor Samples

Further to the recommendations given in the previous section, the only aspect that is specific to the condition of working with donor sperm concerns the total amount of the sample that is thawed. In this case, the post-thawing tests (done on test vials) conducted the day on which the donor ejaculate is frozen are crucial, since their results will determine the sperm volume to be thawed.

With our particular sperm-freezing protocols, we are able to fine-tune the volume of the sperm sample to be thawed. We freeze sperm samples in approximately 50-microliter pills, enabling the possibility of deciding the total amount of the sample to be thawed, given that the frozen sample is aliquoted into 50-microliter units. In cases where the donor sperm is frozen in straws, the number of straws to be thawed will also depend on the expected survival rates and the total number of motile cells needed after thawing, as per the particular protocol that applies at each center.

The decision will be taken to obtain approximately 15–20 million total motile cells after the thawing process.

This will make sure that after sperm preparation by density gradients, at least two million total motile cells are available to be either inseminated via IUI or prepared for classical IVF or ICSI.

25.12 Troubleshooting in Sperm Processing

Sperm preparation by the swim-up and density gradient methods are well-established protocols, technically requiring little expertise and practical abilities.

Few negative or adverse circumstances are likely to arise in classical sperm preparation protocols. However, there is a possibility that the sample will have to be rejected if the sample traceability has been lost, the sample identification is misleading, the container is broken, or the sample is spilled.

Precautions should be taken especially at centers where batching of IVF is done, which is very common in developing countries. The quality of sperm preparation media imported from foreign countries may be compromised as a result of delays in transit and customs clearance. It is best to do a sperm survival study on each new lot of sperm-processing medium once it arrives at the clinic and before using it for any IVF batches.

25.13 Quality Control in Sperm Processing

The only quality control that can be exerted in sperm-processing protocols concerns the recovery rates. The typical mean recovery rates may remain around 15%. This means that out of the total number of motile cells in the ejaculate or after thawing, only 15% will be available after sperm preparation. Nevertheless, these thresholds must be established at each center so it can decide, on the basis of its own information and experience, what the mean recovery rates are and also what the acceptable fluctuations are. Then systems must be put in place to periodically (or, if possible, systematically, by means of real-time visualization systems) check for these means in sufficiently large series. In the event that a significant decrease is found, close supervision of protocol adherence by all staff is recommended.

Review Questions

1. What is the aim of sperm processing?
2. Why is it necessary to prepare sperm samples before using them in assisted reproductive technology?
3. Can sperm preparation be considered a diagnostic tool to select the most convenient assisted reproductive technology?
4. Which are the different parts of the ejaculate?
5. What are the reference values of the total motile sperm for each assisted reproductive technology?
6. Are consents and standard operating procedures important documentation in laboratories?
7. Are sperm-processing/selection methods the same in all types of samples or cases?
8. Is a post-thawing test recommended for frozen samples?

26

Learning Objectives

- PESA and TESA are simple and effective percutaneous surgical methods for retrieving epididymal and testicular spermatozoa, respectively, in men with obstructive azoospermia.
- MESA is an efficient microsurgical method to retrieve sperm from the epididymis of men with obstructive azoospermia. MESA has the advantage of achieving higher numbers of sperm aspirated than PESA, favouring cryopreservation and allowing multiple ICSI attempts without the need of repeat retrievals.
- TESE, preferentially using microsurgery (micro-TESE), is the preferred approach to retrieve sperm from men with non-obstructive azoospermia. Micro-TESE improves sperm extraction efficacy and efficiency, as higher sperm retrieval rates and lower tissue removal are achieved than conventional sperm retrieval methods. The latter facilitates laboratory sperm processing.
- The primary goal of PESA/MESA/TESA/TESE sperm processing is the recovery of a clean sample containing motile sperm. Since these specimens are more fragile—and often compromised in quality—compared to ejaculated counterparts, laboratory techniques should be carried out with great care to avoid jeopardizing sperm fertilizing potential. The whole process starts with the surgical collection of the best-quality specimen as possible. During laboratory steps, minimal iatrogenic cellular damage may be achieved by strict control of centrifugation force and duration, exposure to ultraviolet light and temperature variation, laboratory air quality conditions, as well as the use of high-quality reagents, materials, and equipment.
- PESA and MESA sperm processing can be performed either by mini-gradient centrifugation or simple washing using small volumes of culture media.
- TESA and TESE specimens are processed by mechanical mincing of seminiferous tubules, followed by enzymatic digestion if required.
- The use of immotile epididymal/testicular sperm for ICSI negatively impacts clinical outcomes. Methods for selecting viable immotile sperm for ICSI include the HOST, STFT, and motility stimulants.
- Cryopreservation is used to intentionally freeze retrieved sperm for future use or surplus specimens that would be discharged after ICSI. Novel methods have been introduced to freeze low sperm number and quality with promising results.

26.1 Introduction

The development of intracytoplasmic sperm injection (ICSI) was a breakthrough for men with severe male factor infertility [1]. Equally important was the application of ICSI to azoospermic men and the confirmation that spermatozoa taken from either the epididymis or testis were capable of normal fertilization and pregnancy [2, 3].

Azoospermia is clinically divided into obstructive and non-obstructive. Obstructive azoospermia (OA) is characterized by normal spermatogenesis in which either a mechanical blockage exists somewhere between the rete testis and ejaculatory duct or the epididymis and vas deferens are absent (total or partial agenesis). Acquired OA is due to vasectomy; failure of vasectomy reversal; post-infectious diseases; surgical procedures in the scrotal, inguinal, pelvic, or abdominal regions; and trauma. Congenital OA is due to congenital absence of the vas deferens (CAVD), ejaculatory duct or prostatic cysts, and Young's syndrome [4].

Unlike OA, non-obstructive azoospermia (NOA) comprises a spectrum of severe testicular disorders resulting from various causes that include endocrine and genetic abnormalities, post-infectious diseases, trauma, environmental toxins, exposure to gonadotoxins (radiation, chemotherapy), cryptorchidism, varicocele; however, the condition may also be idiopathic. Whereas it is relatively easy to harvest sperm in men with OA, NOA represents a challenge for sperm retrieval [4, 5].

Several methods have been developed to retrieve epididymal and testicular sperm from azoospermic men. Among them, percutaneous epididymal sperm aspiration (PESA) [6] and microsurgical epididymal sperm aspiration (MESA) [2] are the techniques used to retrieve sperm from the epididymis, whereas testicular sperm aspiration (TESA) and testicular sperm extraction (TESE) are the methods to harvest sperm from the testicle in OA [6, 7]. In contrast, open testicular sperm extraction (TESE) using single or multiple biopsies [8–10] and TESE with the aid of microsurgery (microdissection testicular sperm extraction, micro-TESE) are methods to harvest sperm from men with NOA [11–13].

Processing surgically retrieved spermatozoa differs from the commonly used methods for processing ejaculates. In the former, sperm processing should not only ease the selection of the best-quality spermatozoa for ICSI but also optimize their fertilizing ability, whenever possible. The laboratory has a crucial role in handling the often-compromised surgically retrieved samples, particularly in NOA and cryopreserved specimens. Lab personnel should receive the best-quality extracted sample as possible, with minimal or no contaminants such as red blood cells and harmful microorganisms. Furthermore, mastering the processing techniques minimizes iatrogenic cellular damage during sperm processing. Among the methods used to properly handle such specimens, controlling centrifugation force and duration, exposure to ultraviolet light and temperature variation, laboratory air quality conditions, dilution and washing steps, quality of reagents, culture media, and disposable materials are of utmost importance. Lastly, if possible, techniques to improve sperm fertilizing potential should be applied, including the use of stimulants and methods to select viable sperm for ICSI. The latter is particularly important when only immotile spermatozoa are available.

In this chapter, our goals are to provide a step-by-step laboratory description of the commonly used methods for PESA/MESA/TESA/TESE sperm processing. Also, we provide protocols for identifying viable immotile sperm for

ICSI. We included our published data about the use of testicular and epididymal sperm for ICSI in azoospermic men and, lastly, provided valuable tips for processing such extracted sperm.

26.2 Step-by-Step Protocol

26.2.1 Materials, Equipment, Reagents, and IVF Laboratory Setup

26.2.1.1 Operating Room

- Sterile surgical gloves and syringes (1 mL, 20 mL)
- 0.7 × 25 mm, 0.45 × 13 mm, 1.2 × 40 mm (TESA/PESA) disposable needles
- 2% lidocaine
- Heating block for test tubes
- Syringe holder (TESA; see Fig. 26.3)
- Surgical loupe (PESA and TESA)
- Operating microscope (micro-TESE and MESA)
- Microsurgery instruments (micro-TESE and MESA)

26.2.1.2 IVF Laboratory

- Petri dishes
- Disposable serological pipettes
- Pipettor 1–200 μL and sterile tips
- Pipetting device
- 6-mL sterile centrifuge polystyrene tubes with caps
- 0.7 × 25-mm needles and tuberculin syringes
- Marker pen
- ICSI micropipettes
- Laminar flow cabinet
- Warming plate
- Stereomicroscope
- Centrifuge
- Inverted microscope equipped with Hoffman modulation contrast and electro-hydraulic micromanipulators
- HEPES-buffered Human Tubal Fluid (HTF) and Human Serum Albumin (HSA)
- Mineral oil
- Polyvinylpyrrolidone (PVP) solution
- Colloidal density gradient
- Erythrocyte lysing buffer
- Collagenase
- Pentoxifylline solution

26.2.1.3 Laboratory Setup

Note: Sterile handling conditions under a laminar flow cabinet or clean room environment should be used during all laboratory steps.

- Prepare a 10-mL (for PESA) or 20-mL (TESA/TESE/MESA) HEPES-buffered protein-supplemented (5% HSA) sperm culture medium, and keep it at 37 °C.
- Transfer a 5-mL aliquot of sperm culture medium to a 6-mL polystyrene tube, and send it to the operating room (buffered sperm media is used to flush the syringe + needle before aspiration and to incubate epididymal aspirates or testicular specimens).
- Place two Petri dishes on a warm surface (37 °C) inside the workstation (for PESA only).
- Prepare 4-well dishes (e.g. Nunc) by adding 0.5-mL sperm medium aliquots to each well (TESE). Keep them onto a warm surface (37 °C) inside the workstation.
- Mount two tuberculin syringes connected with 13-gauge (to be used as tools for mincing and squeezing seminiferous tubules in TESA/TESE processing).

26.2.2 PESA and MESA Sperm Processing

26.2.2.1 Surgical Technique

Note: We perform PESA and MESA under local and intravenous anaesthesia [14, 15].

For PESA

- A 10-mL solution of 2% lidocaine is injected around the spermatic cord near the external inguinal ring upon patient unconsciousness is achieved. The epididymis is stabilized between the index finger, thumb, and forefinger, while the testis is held with the palm of the hand.
- A 23-gauge needle attached to a 1-mL tuberculin syringe is inserted into the epididymis through the scrotal skin. Loupe magnification is used to avoid injuring small vessels seen through the skin (Fig. 26.1).
- Negative pressure is created, and the tip of the needle is gently moved in and out within the epididymis until fluid enters the syringe. The amount of epididymal fluid obtained during aspiration is often minimal (~0.1 mL), except in cases of CAVD in which more fluid can be aspirated.
- The needle is withdrawn from the epididymis, and the aspirate is flushed into a 0.5-mL 37 °C sperm medium.
- The tube containing the epididymal aspirate is transferred to the IVF lab. PESA is repeated at a different site of the same epididymis (from cauda to caput) or the contralateral one until an adequate number of motile sperm are retrieved. If PESA fails to retrieve motile sperm for ICSI, TESA is performed at the same operative time (Fig. 26.1).

For MESA

Note: Operating microscope and microsurgery technique are used throughout the procedure, as previously described [14, 16] (Fig. 26.2).

- A 10-mL solution of 2% lidocaine is injected around the spermatic cord near the external inguinal ring upon patient unconsciousness is achieved. After anaesthetic blockade of the spermatic cord, the anterior scrotal skin is stretched, and the skin and tunica vaginalis are infiltrated with 2 mL of 2% lidocaine. A transverse 3-cm incision is made through the anaesthetized layers, and the testis is exteriorized.

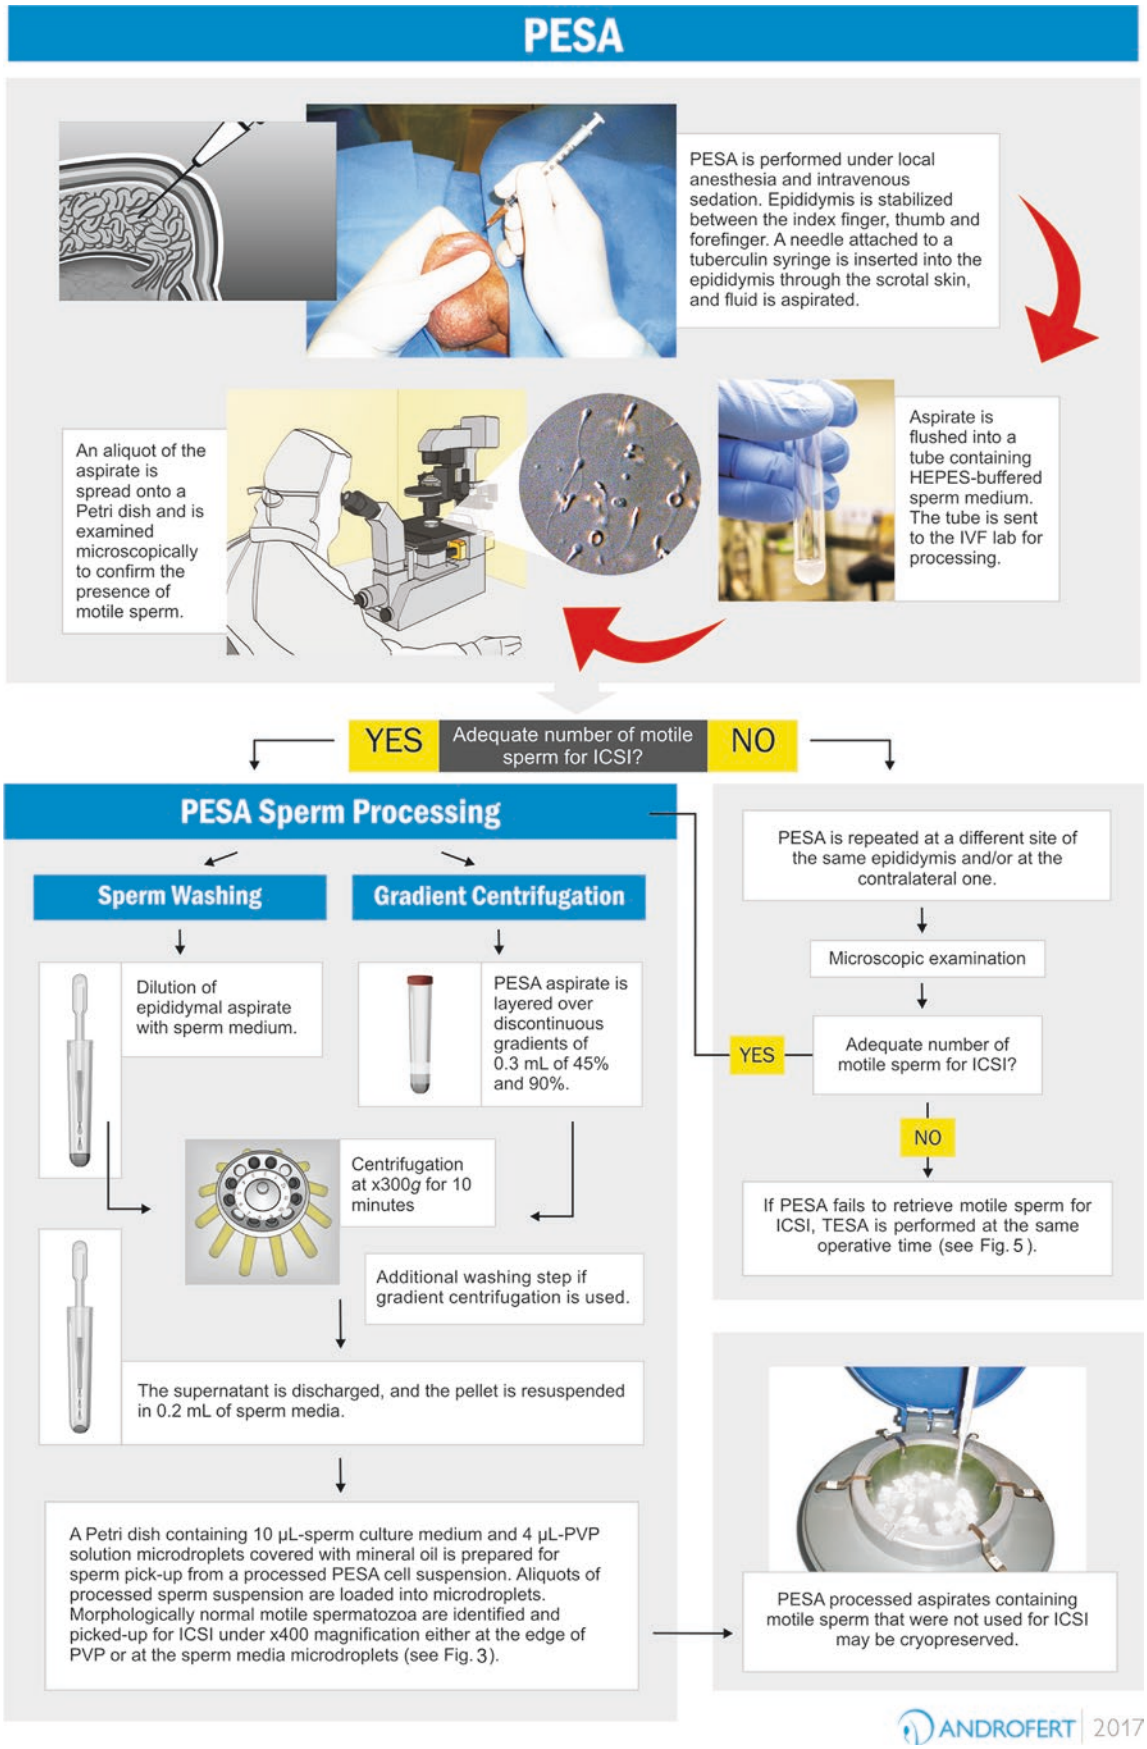

Fig. 26.1 PESA sperm processing. The flow chart illustrates the PESA steps from surgical procedure to processing of epididymal aspirates for ICSI or cryopreservation

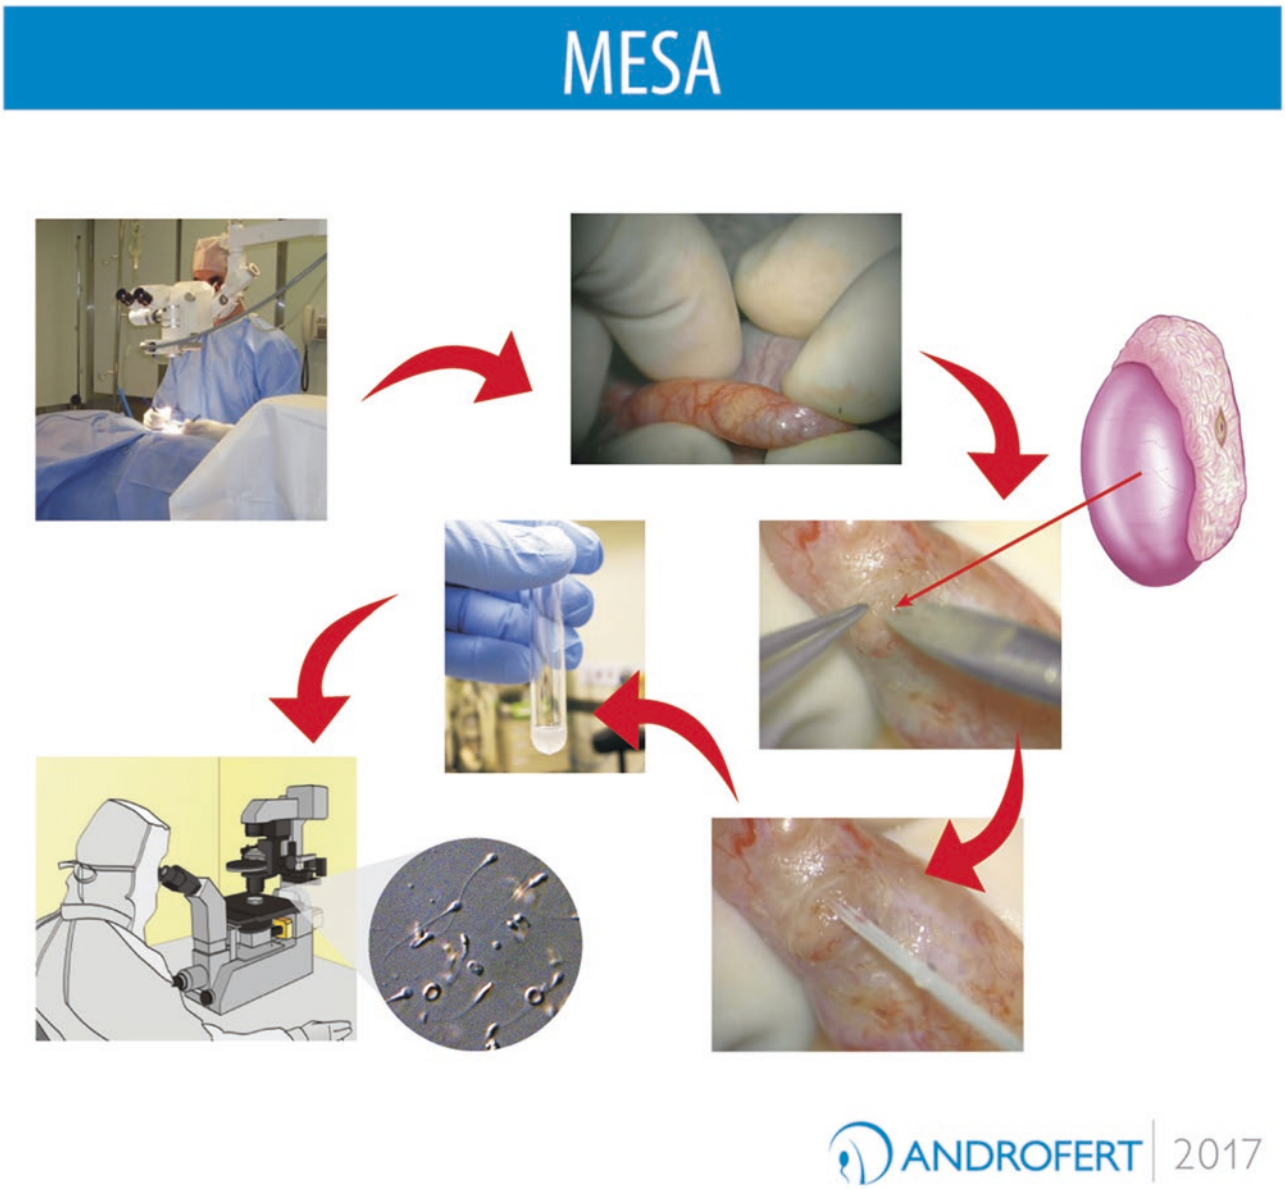

Fig. 26.2 Microsurgical epididymal sperm aspiration (MESA). After exposure of the testis and epididymis, a dilated epididymal tubule is dissected and opened. The fluid is aspirated, diluted with sperm medium, and sent to the laboratory for examination

- The epididymal tunica is incised, and an enlarged tubule is selected. An epididymal tubule is dissected and opened with sharp microsurgical scissors. The fluid that flows out of the tubule is aspirated with the aid of a silicone tube or a needle attached to a tuberculin syringe (Fig. 26.2).
- The aspirate is flushed into a tube containing warm sperm medium and transferred to the laboratory for examination. MESA can be repeated at a different site on the same epididymis (from the cauda to caput regions) or the contralateral epididymis until an adequate number of motile sperm are retrieved. If MESA fails to retrieve motile sperm, TESA or TESE can be performed as part of the same procedure. However, MESA often provides enough sperm for cryopreservation. A single MESA usually enables the retrieval of a large number of high-quality sperm that can be used for ICSI or intentionally cryopreserved for subsequent ICSI attempts.

26.2.2.2 Laboratory Handling of Epididymal Aspirates

- Identify aspirate-containing tube(s) according to the epididymis side and site of aspiration (caput, body, or tail). Homogenize the epididymal aspirate to avoid sperm agglutination (epididymal spermatozoa tend to agglutinate fast). Keep aspirate-containing tubes capped at 37 °C.

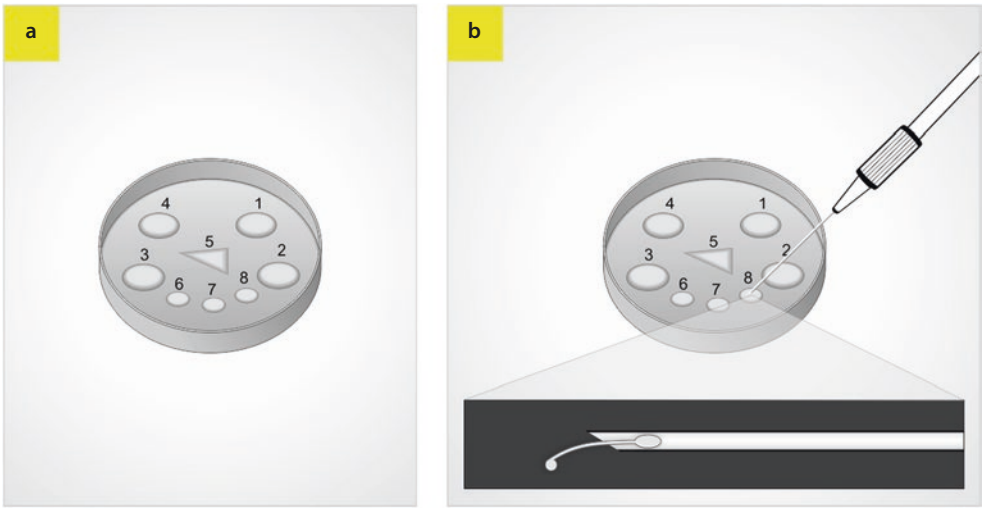

Fig. 26.3 Preparation of Petri dishes. A 50 × 09-mm Petri dish containing several microdroplets of culture medium under mineral oil is prepared for sperm pick-up from a processed epididymal or testicular cell suspension. Microdroplets are prepared as follows: four 10-μL sperm medium at dish periphery to load specimens (numbered 1–4), one 4-μL polyvinylpyrrolidone (PVP) at dish centre in a triangular shape to pick up selected sperm for ICSI (number 5), and two to three 10-μL sperm medium at dish centre below the PVP triangle for washing (numbered 6–8). Alternatively, one of the sperm medium-containing microdroplets (e.g. number 8) or the outer ones (1–4) is replaced with the hyposmotic or motility stimulant solutions, respectively **a**. The hyposmotic swelling test is illustrated **b**. The sperm tail is partially withdrawn from the injection micropipette into the HOS droplet. A swelling at the level of the tail tip may be seen under the inverted microscope with contrast at ×400 magnification

- Place a 10–20-μL specimen aliquot onto a Petri dish, and spread it using a micropipette tip. Examine the fluid under the inverted microscope to confirm the presence of motile sperm. Inform the surgeon promptly if an adequate number of motile sperm for ICSI are available. If more PESA specimens are taken, pool samples of similar quality together for processing or cryopreservation. If TESA specimens are obtained, process specimens according to the "TESA processing protocol" (Fig. 26.5).
- Identify aspirate-containing tube(s) according to the presence of motile sperm. Make a decision regarding the processing method to be used, i.e., simple washing or two-layer discontinuous mini-gradient centrifugation, based on a gross estimate of sperm count and motility. We use gradient centrifugation when the sperm number is high, particularly if contaminated with red blood cells, cellular debris, and immotile sperm. Otherwise, we use a simple washing.
- For density gradient centrifugation, layer an aliquot of the PESA aspirate up to 0.5-mL over 0.3-mL gradients of 45% and 90%, respectively, and centrifuge at ×300 g for 10 min. Resuspend the pellet in 1.5-mL fresh sperm medium and repeat centrifugation. Remove the supernatant carefully, leaving about 0.2 mL of the medium above the pellet. Resuspend the pellet and keep it at 37 °C until use or cryopreservation.
- For simple washing, dilute the epididymal aspirate with fresh sperm medium to a final volume of 1.5–2.0 mL. Centrifuge the mixture at ×300 g for 10 min, discharge the supernatant, and resuspend the pellet in 0.2-mL sperm medium. If the processed PESA specimen is still contaminated with an excessive number of red blood cells, make a new dilution with 2-mL erythrocyte lysing buffer and centrifuge the mixture (Appendix).
- Prepare a Petri dish containing a series of microdroplets under mineral oil for sperm pick-up from a processed epididymal cell suspension (Fig. 26.3).
- Load a 1-μL sperm suspension aliquot gently into the centre of the PVP droplet if the specimen contains motile sperm with progressive motility. Morphologically normal motile spermatozoa can be identified and picked up for ICSI with the injection micropipette at the edge of the PVP droplet. If progressive motility is low or absent and/or the specimen is contaminated with cellular debris, load a sperm suspension aliquot (1–4 μL) into each 10-μL outer microdroplet of HEPES-buffered culture medium to facilitate search and selection of motile sperm.
- Aspirate a small volume of PVP into the injection micropipette to improve control during sperm pick-up and to avoid blowing air bubbles during ejection of selected sperm into the PVP droplet.
- Pick up morphologically normal and motile and place them close to the edge of PVP. Make a final morphologic sperm assessment under ×800 magnification in the group of preselected spermatozoa for ICSI. Immobilize and inject the selected spermatozoa into the cytoplasm of metaphase II oocytes.

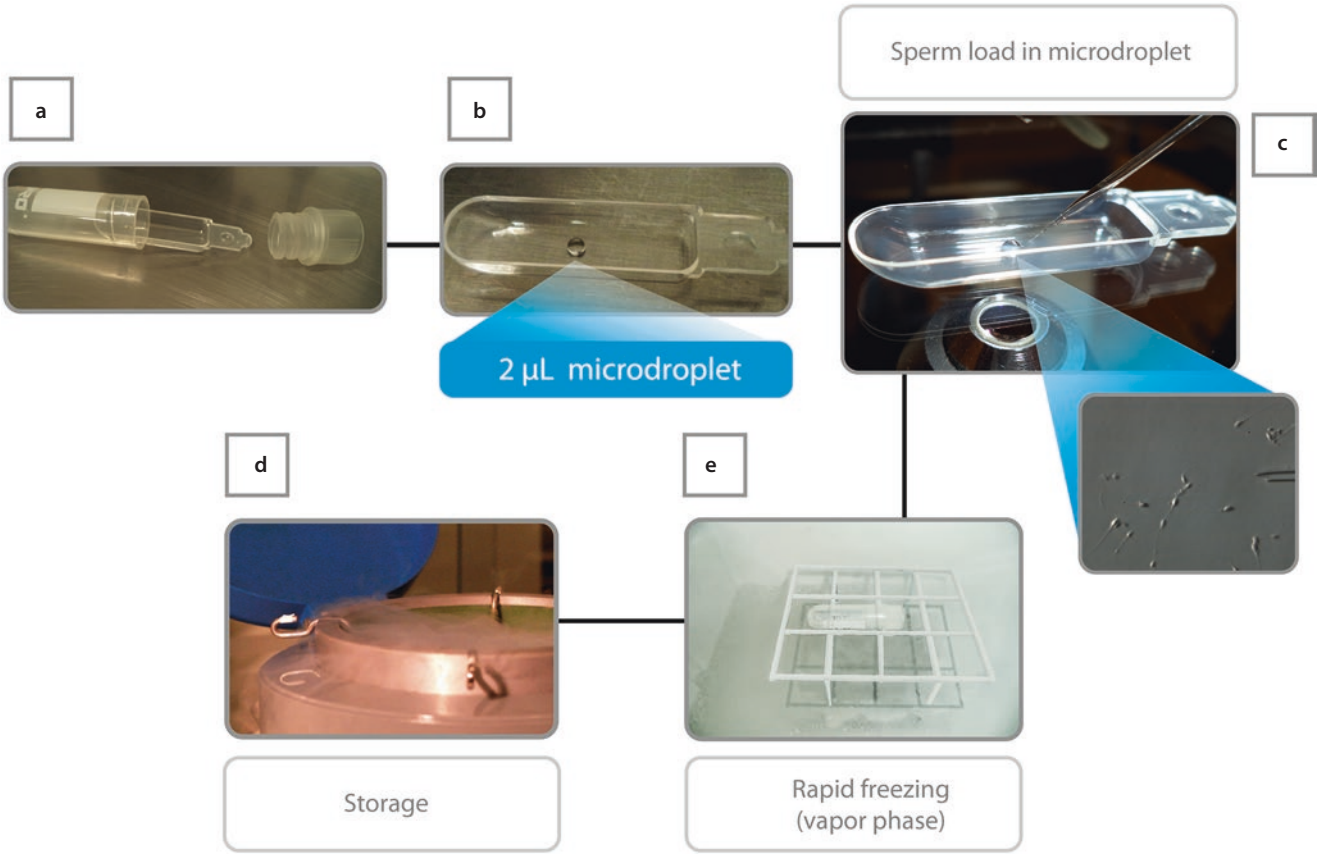

Fig. 26.4 The cell sleeper method for low count sperm freezing. The Cell Sleeper (Nipro, Japan) consists of an outer vial, an inner tray, and screw cap **a**. The inner tray is removed from the vial and placed in the lid of a large culture dish and a 2-µL droplet of cryopreservation solution is pipetted into the tray, in a central position **b**. Spermatozoa are aspirated and ejected into the droplet on the tray with the aid of a microinjection pipette **c**. Immediately thereafter, the tray is returned to the vial and the vial is closed with the screw cap. The vial is placed in a horizontal position 4–5 cm above the surface of liquid nitrogen **d**. After 2 min, the vial is submerged in LN2 and secured into a cryopreservation cane for storage **e**. (Reprint with permission from Springer, Esteves [20])

- Cryopreserve surplus PESA processed aspirates containing motile sperm not used for ICSI (or total specimen if intentional cryopreservation). We freeze PESA specimens using either (i) fast liquid nitrogen vapour method [17] or (ii) cell sleeper method [18, 19] or both. Cell sleepers are nonbiological closed devices in which a few spermatozoa can be frozen in microdroplets (Fig. 26.4). The method involves rapid freezing and has shown to be reliable for freezing surgically retrieved testicular sperm [18, 19].

26.2.3 TESA Sperm Processing

26.2.3.1 Surgical Technique

Note: We perform TESA under local and intravenous anaesthesia [14], as described elsewhere.

- After anaesthetic blockade of the spermatic cord, the epididymis is stabilized between the index finger, thumb, and forefinger while the anterior scrotal skin is stretched.
- A 13-gauge needle attached to a 20-mL syringe is connected to a syringe holder and is inserted through the stretched scrotal skin into the anteromedial or anterolateral portion of the superior testicular pole, at an oblique angle towards the medium and lower poles (Fig. 26.5). Loupe magnification is used to avoid small vessels seen through the skin.
- Negative pressure is created by pulling the syringe holder, whereas the needle is moved in and out within the testis in an oblique plane to disrupt the seminiferous tubules and sample different areas. When a small piece of testicular tissue is aspirated, the needle is gently withdrawn from the testis while the negative pressure is maintained. A pair of microsurgery forceps is used to grab the seminiferous tubules that exteriorize from the scrotal skin, thus aiding in the removal of the specimen (Fig. 26.5).
- The specimen is flushed into a tube containing 0.5–1.0-mL warm sperm medium and is transferred to the IVF lab. TESA can be performed at the contralateral testis at

26

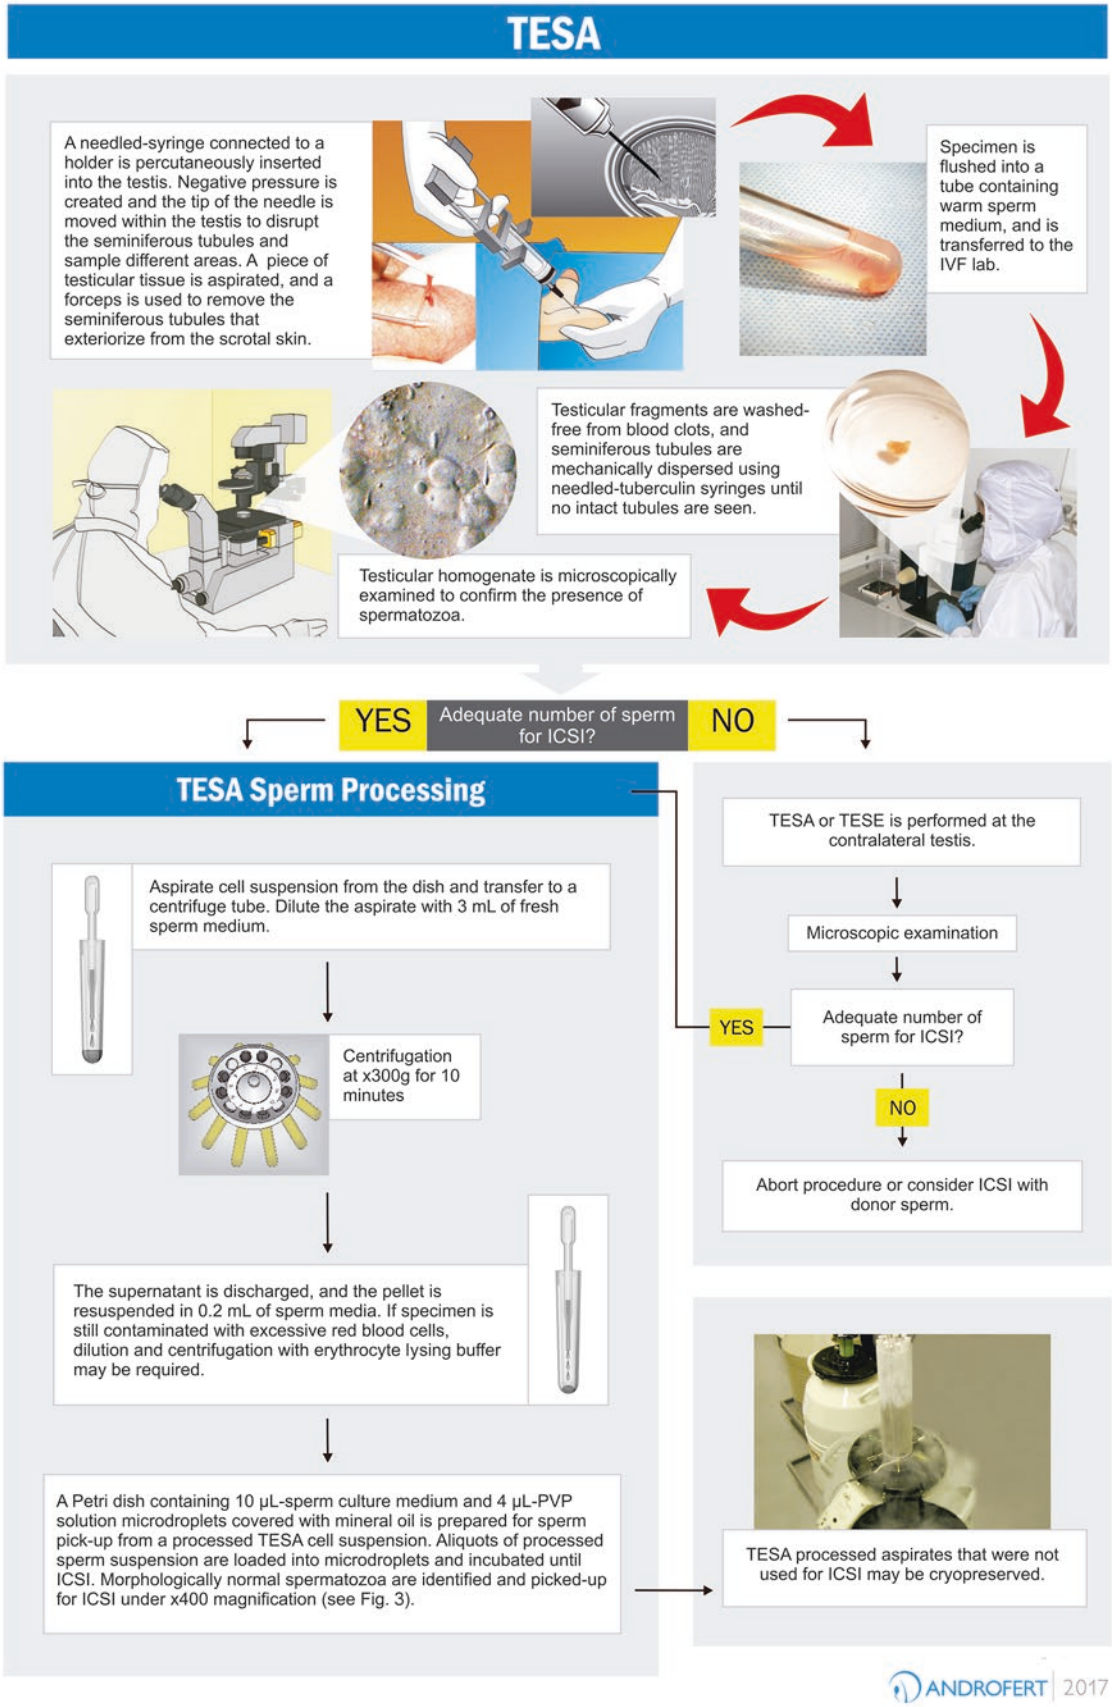

Fig. 26.5 TESA sperm processing. Flow chart illustrates TESA steps from the surgical procedure to the processing of testicular specimens for ICSI

the same operative time if an insufficient number of spermatozoa are retrieved for ICSI.

26.2.3.2 Laboratory Handling of Testicular Aspirates

- Discharge the TESA aspirate onto the Petri dish. Under the stereomicroscope, identify the seminiferous tubules and remove blood clots using the needled-tuberculin syringes.
- Transfer the seminiferous tubules to a Petri dish containing fresh sperm medium. Perform mechanical dispersion by mincing the tubules using both needled-tuberculin syringes (use one to hold tubules in place at the bottom of the dish and the other to squeeze and open them). Repeat this step until no intact tubules are seen.
- Examine the homogenate to confirm the presence of sperm using the inverted microscope at ×400 magnification. Inform the surgeon promptly if an adequate number of spermatozoa for ICSI are available. If other TESA specimens are taken, carry out the initial processing steps as described above.
- Aspirate and transfer the cell suspension to a sterile centrifuge tube. Dilute the aspirate with 3 mL of fresh sperm medium and wash it at ×300 g for 7 min. Discharge the supernatant and resuspend the pellet in 0.2 mL of sperm medium. If the processed TESA specimen is contaminated with an excessive number of red blood cells, dilute the specimen with erythrocyte lysing buffer and perform an additional centrifugation step (Appendix).
- Prepare Petri dishes as described in the "PESA protocol" for sperm pick-up (Fig. 26.3). Load 1–2-μL sperm suspension aliquot at each 10-μL outer microdroplet of HEPES-buffered culture medium to facilitate sperm search and pick-up.
- Pick up morphologically normal and motile and place them close to the edge of PVP. Make a final morphologic sperm assessment under ×800 magnification in the group of preselected spermatozoa for ICSI. Immobilize and inject the selected spermatozoa into the cytoplasm of metaphase II oocytes.
- Cryopreserve surplus TESA processed aspirates containing motile sperm not used for ICSI (or entire specimen if intentional cryopreservation). We freeze TESA specimens using either (i) fast liquid nitrogen vapour method [17] or (ii) cell sleeper method [18, 19] or both.

26.2.4 TESE Sperm Processing

26.2.4.1 Micro-TESE Surgical Technique

Note: We perform micro-TESE under local and intravenous anaesthesia [14], as described elsewhere. For micro-TESE, operating microscope and microsurgery technique are used throughout the procedure, as previously described [16] (Fig. 26.6).

- After anaesthetic blockade of the spermatic cord, the anterior scrotal skin is stretched, and the skin and tunica vaginalis are infiltrated with 2 mL of 2% lidocaine. A transverse 2-cm incision is made through the anaesthetized layers, and the testis is exteriorized.
- A single, large, mid-portion incision is made in an avascular area of the tunica albuginea under ×6–8 magnification, and the testicular parenchyma is widely exposed.
- Dissection of the testicular parenchyma is carried out at ×16–25 magnification searching for enlarged seminiferous tubules, which are more likely to contain germ cells and normal sperm production (Fig. 26.7). The superficial and deep testicular regions may be examined, if necessary, and microsurgery-guided testicular biopsies are performed by removing the enlarged tubules (Fig. 26.6). If enlarged tubules are not seen, then any tubule different than the remaining ones in size is excised [11]. If all tubules are identical in appearance, random micro-biopsies (at least three at each testicular pole) are performed.
- Each excised testicular tissue specimen is placed in a Petri dish containing sperm media. Specimens are washed grossly to remove blood clots and are sent to the IVF laboratory for processing.

26.2.4.2 Laboratory Handling of Testicular Specimens

- Under the stereomicroscope, remove blood clots using the needled-tuberculin syringes. Transfer fragments to another dish well containing fresh medium and wash again until no blood clots are seen.
- Perform mechanical dispersion by mincing the tubules using both needled-tuberculin syringes (Fig. 26.5). In our setup, a minimum of two laboratory technicians/embryologists work together to speed up the sperm searching process (one mincing the tubules under the stereomicroscope and the other searching for spermatozoa under the inverted microscope).
- Examine the homogenate to confirm the presence of sperm using the inverted microscope at ×400 magnification. The surgeon should be informed promptly if any sperm is found to allow him to decide on continuing micro-TESE in the same testis or moving to the contralateral side. If other TESE specimens are taken, carry out the initial processing steps as described above.
- Aspirate and transfer the cell suspension to a sterile centrifuge tube. Dilute the aspirate with 3 mL of fresh sperm medium and wash it at ×300 g for 7 min. Discharge the supernatant and resuspend the pellet in 0.2 mL of sperm medium. If the processed TESE specimen is contaminated with an excessive number of red blood cells, dilute the specimen with erythrocyte lysing buffer and perform an additional centrifugation step (Appendix).

26

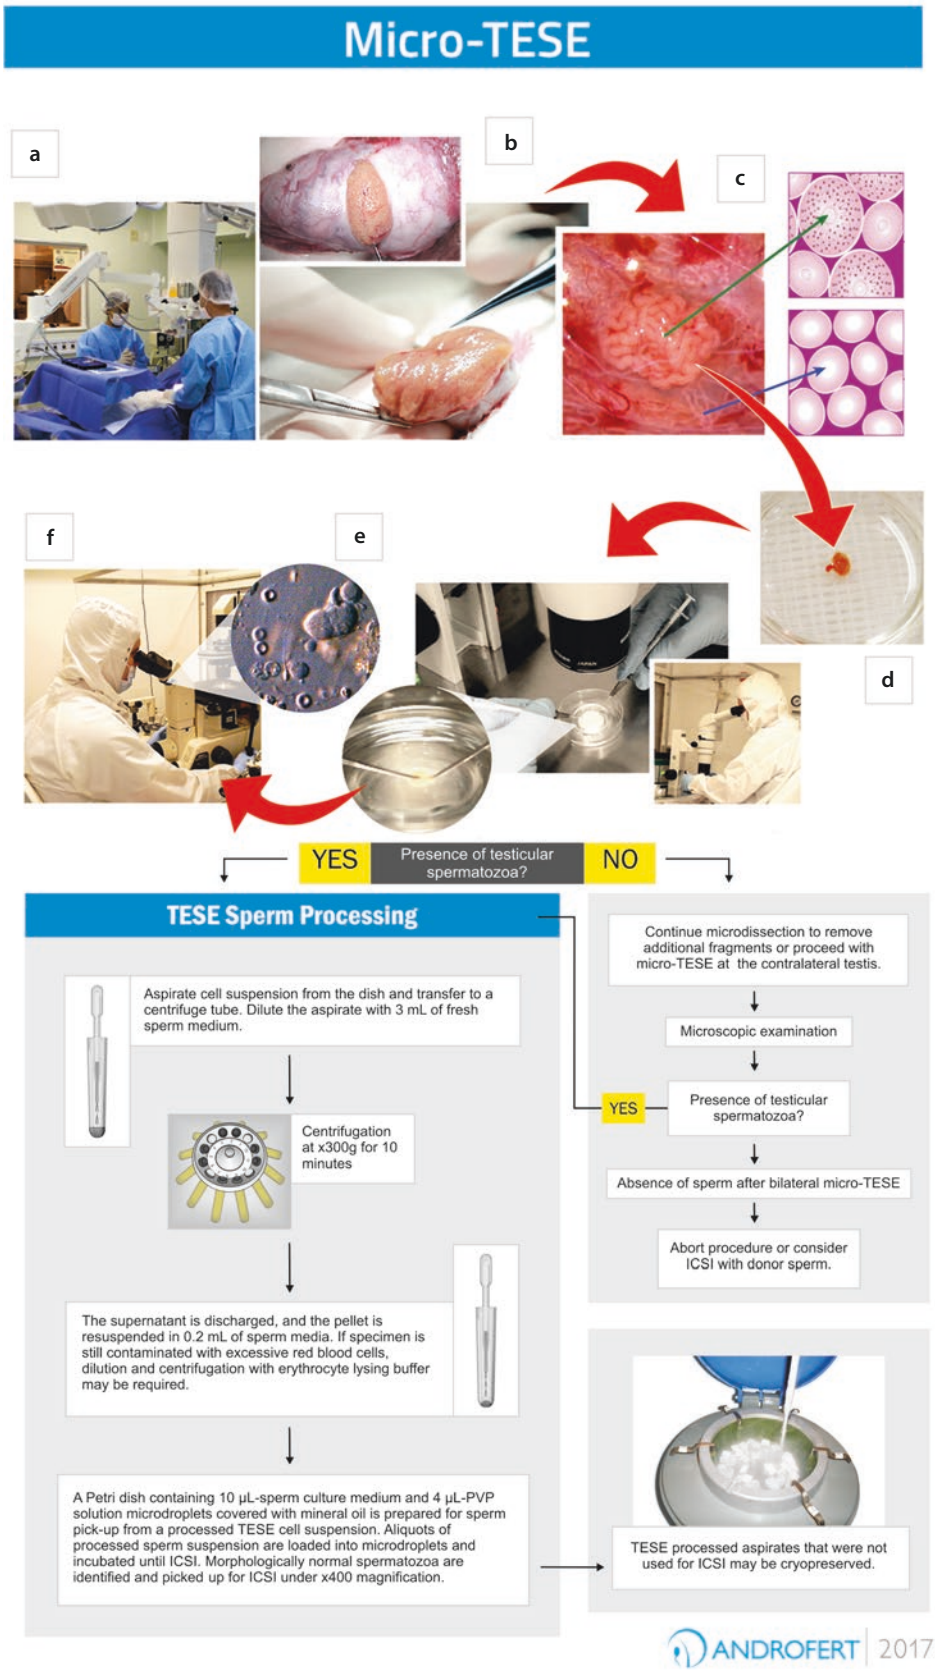

Fig. 26.6 TESE sperm processing. The flow chart illustrates the micro-TESE steps from the surgical procedure to processing of testicular specimens for ICSI. The rationale of micro-TESE is to identify focal areas of sperm production within the testes, based on the size and appearance of the seminiferous tubules, with the aid of the operating microscope **a**. A large incision is made in an avascular area of the tunica albuginea, and the testicular parenchyma is widely exposed **b**. The parenchyma is then dissected at ×16 to ×25 magnification to enable the search and isolation of seminiferous tubules exhibiting larger diameter in comparison with nonenlarged or collapsed counterparts **c**. These enlarged tubules are more likely to contain germ cells and eventually normal sperm production. Microsurgery-guided biopsies are performed by carefully removing such tubules, which are sent to the laboratory for examination **d**. The minimal tissue extracted facilitates laboratory processing and sperm search, thus increasing the process efficiency **e**. The initial laboratory step involves mechanical mincing of the seminiferous tubules and examination of specimens for sperm identification **f**. The use of optical magnification also reduces the chances of vascular injury by proper identification of testicular blood supply, thus reducing the chances of haematoma formation and testicular devascularization

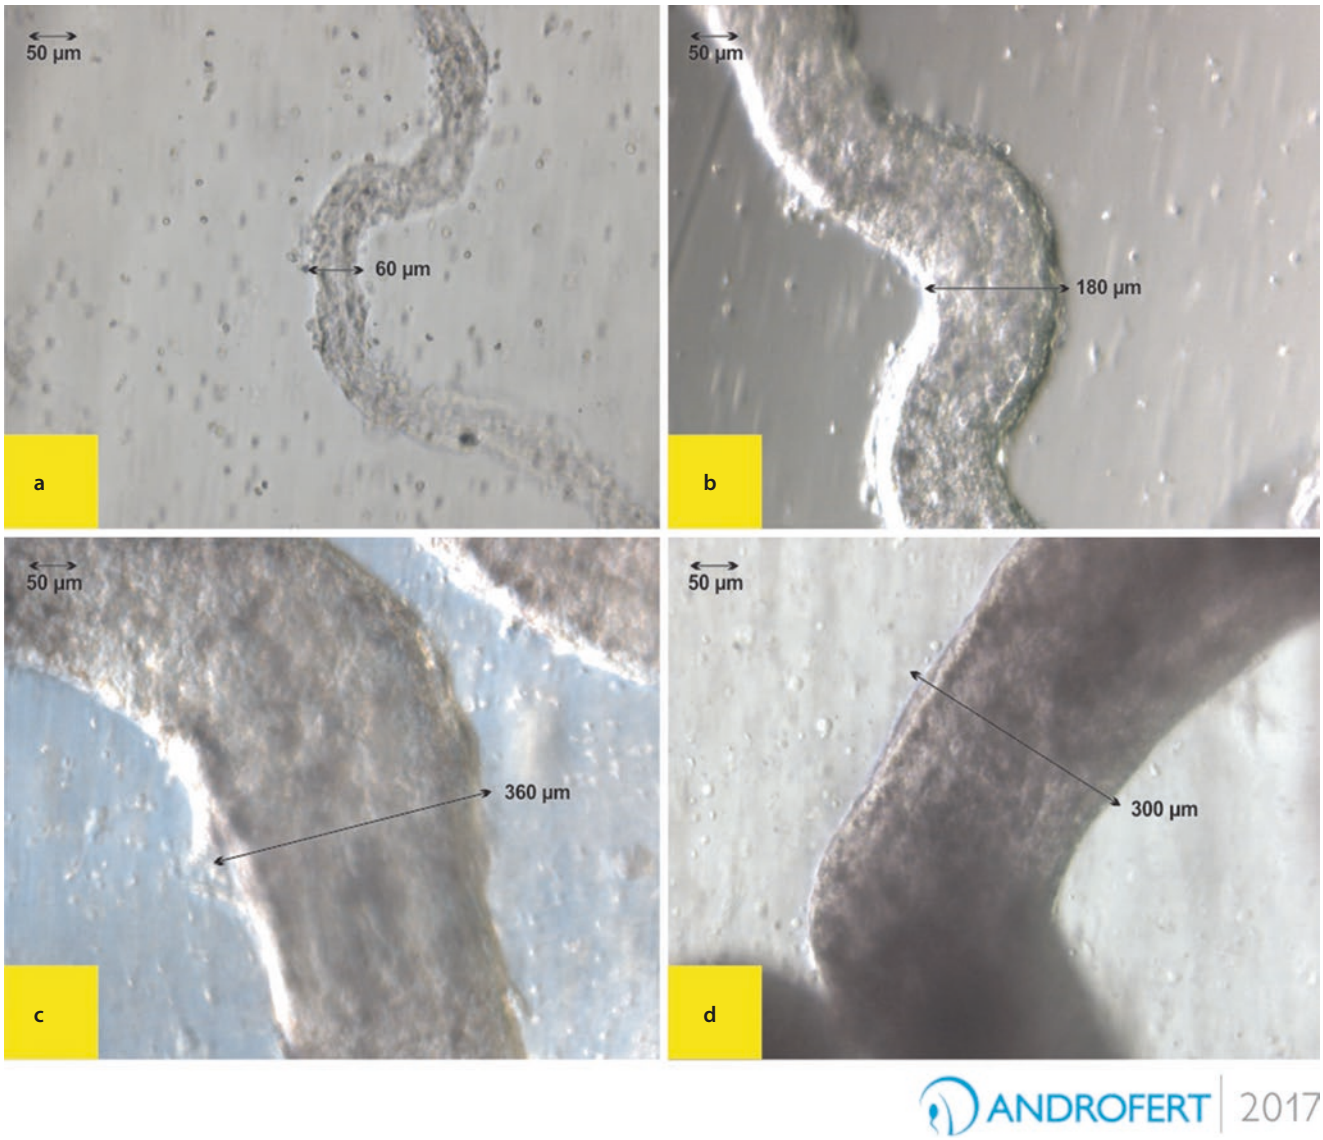

Fig. 26.7 Preprocessing microscopic appearance of fresh seminiferous tubules (Magnification: 100×, inverted optical microscope, Nikon Eclipse Diaphot 300 with phase contrast (Hoffman)). **a** and **b** Thin seminiferous tubules, as usually observed in the cases of Sertoli cell only; **c** and **d** seminiferous tubules of larger diameter than the previous ones **a** and **b**, compatible with the presence of germ cells and mature sperm

- Prepare Petri dishes as described in the "PESA protocol" for sperm pick-up (Fig. 26.3). Load 1–2-µL sperm suspension aliquot at each 10-µL outer microdroplet of HEPES-buffered culture medium to facilitate sperm search and pick-up.
- Pick up morphologically normal and motile and place them close to the edge of PVP. Make a final morphologic sperm assessment under ×800 magnification in the group of preselected spermatozoa for ICSI. Immobilize and inject the selected spermatozoa into the cytoplasm of metaphase II oocytes.
- Cryopreserve surplus TESE processed aspirates containing motile sperm not used for ICSI (or entire specimen if intentional cryopreservation). We freeze TESE specimens using the cell sleeper method (Fig. 26.4).
- Perform enzymatic digestion of testicular specimens with collagenase and repeat the search if no spermatozoa are found on both the initial and extended search (Appendix).

26.2.5 Laboratory Handling of Cryo-thawed Epididymal and Testicular Specimens

26.2.5.1 Cryopreservation by Fast Liquid Nitrogen Vapour Method

After thawing, removal of cryoprotectant is carried out by simple washing [21], as described in the "TESA sperm processing protocol".

26.2.5.2 Cryopreservation by "Cell Sleeper" Method

- Prepare a Petri dish as follows (warm stage off): four microdroplets containing each 10 μL of culture medium, two microdroplets containing 10 μL of culture medium and pentoxifylline [22] (final concentration 5 mM; see Appendix), one microdroplet containing 1 μL of culture medium, and one microdroplet containing 4.5 μL of PVP in a triangular shape (Fig. 26.3). Cover with mineral oil and warm the dish at 37 °C for 20 min.
- Prepare the micromanipulator using a micropipette with a large inner diameter (e.g. 5.5 μm) to facilitate capture of spermatozoa.
- Remove the cryovial from the liquid nitrogen cylinder and leave it capped at room temperature for 1 min.
- Open the cryovial and remove the inner tray. Using a micropipette, remove approximately 50–80% of the cell sleeper droplet volume and transfer it directly to one of the culture medium droplets of the Petri dish.
- Cover the cell sleeper platform with pre-warmed (37 °C) 300 μL of mineral oil.
- Place the cell sleeper tray onto the inverted microscope stage, lower the injection needle into the cryoprotectant drop where the sample is, and start to search for spermatozoa.
- Aspirate sperm into the injection needle, raise the needle, withdraw the tray, and insert the previously prepared Petri dish onto the inverted microscope.
- Leave the specimens in the culture medium droplets for at least 15 min to allow diffusion of cryoprotectant and cell hydration.
- Transfer the cells as follows: motile spermatozoa are transferred to PVP; immotile spermatozoa are transferred to the droplet containing pentoxifylline. Utilize a sperm selection method (see section below) if only immotile sperm is seen after pentoxifylline incubation.
- Perform sperm immobilization and microinjection as routinely done using motile or immotile sperm.

26.2.6 Methods for Selecting Viable Immotile Sperm for ICSI

Conventional seminal parameters have little or no influence in ICSI outcomes, except when only immotile spermatozoa are available [23, 24]. In such cases, fertilization rates are reduced. Different strategies may be used to differentiate live immotile spermatozoa from dead ones, thus aiding in the selection of viable gametes for ICSI, as described below.

26.2.6.1 Hyposmotic Swelling Test (HOST) [25–27]

- Using the microinjection pipette, pick up morphologically normal immotile spermatozoa from the sperm medium droplet and transfer to PVP.
- Aspirate a single spermatozoon head first into the pipette.
- Move the pipette into the HOS microdroplet (Fig. 26.3 and Appendix) and release only the sperm tail into the HOS solution. Keep it for 5–10 s and observe if a tail tip swelling occurs (sperm tail swelling is often minimal and is a marker of viability in fresh specimens, but may not be suitable for testing cryopreserved ones [27]).
- If tail swelling is seen, aspirate the cell back to the pipette and release it in a drop of fresh medium to allow osmotic re-equilibration (tail swelling often disappears in 5–20 s). If tail swelling is not seen, discharge spermatozoon into the HOS solution.
- Transfer the viable selected spermatozoon to the PVP drop. Repeat these steps until sufficient number of viable sperm is selected for ICSI.

26.2.6.2 Sperm Tail Flexibility Test (STFT) [28, 29]

- Using the microinjection pipette, pick up morphologically normal immotile spermatozoa from sperm microdroplet (Fig. 26.3) and transfer to the PVP solution.
- Align the spermatozoa near the PVP droplet edge.
- Touch sperm tail with the tip of the microinjection pipette, and force the tail to move up and down. Tail is considered flexible when it moves independently of the sperm head (sperm tail flexibility is considered a marker of sperm viability [28, 29]). If tail remains rigid upon touching and sperm head and tail move together as a unit, then spermatozoon is considered non-viable for ICSI.
- Repeat these steps until sufficient number of viable sperm is selected for ICSI.

26.2.6.3 Motility Stimulant Sperm Challenge (MSC) [30–32]

Note: Example given using a 5-mM Pentoxifylline (PF) solution [30] (Appendix).

- Load a 4-μL aliquot of fresh or cryopreserved PESA/MESA/TESA/TESE sperm suspension into the motility stimulant solution microdroplet and incubate for 20 min (Fig. 26.3).
- Examine the specimen microscopically to search for moving sperm. In cases of a positive MSC, a slight noticeable tail twitching is often seen (in rare occasions vigorous twisting may be observed).

- Pick up motile sperm using the microinjection pipette and transfer to a fresh microdroplet of sperm medium. Repeat this step 3–4 times to wash out any residual PF solution (PF was shown to be embryotoxic in animal studies [33], but is apparently safe if used only on sperm [32]).
- Keep selected spermatozoa in culture or place them into a PVP droplet for sperm selection and immobilization for ICSI.
- Repeat these steps until sufficient number of viable sperm is selected for ICSI.

26.3 Expert Commentary

PESA and TESA are effective surgical sperm retrieval methods for men with OA regardless of the cause of obstruction. However, strict criteria to diagnose OA are essential for obtaining a high success retrieval rate in the range of 90–100% [34, 35]. Using PESA, our approach is to perform the first aspiration at the epididymis corpus and proceed to the caput if necessary, since aspirates from the cauda are usually rich in poor-quality senescent spermatozoa, debris, and macrophages [15]. Based on our results, the cumulative sperm retrieval rate (SRR) by using PESA and PESA+TESA was 97.3% [36]. SRR did not differ among men with congenital bilateral absence of vas deferens (CBAVD; SRR = 100%) and vasectomy (SRR = 96.6%) and post-infection (SRR = 96.3%) groups (Table 26.1). In the study mentioned above involving 146 men with OA, the success of PESA was higher in the CBAVD group than in the vasectomy and post-infection groups (96.8% vs 69.5% and 76.4%, respectively, $p < 0.001$).

Most cases of PESA failures are not necessarily technical failures because immotile spermatozoa are found. However, epididymis fibrosis due to multiple PESA attempts or post-infection may render PESA ineffective to retrieve sperm. In such cases, PESA can be attempted at the contralateral epididymis or TESA can be applied successfully [35, 36]. We routinely perform sperm retrieval for OA (PESA/MESA/TESA) under local anaesthesia with intravenous sedation, either on the same day of oocyte retrieval or before if an intentional cryopreservation is planned [14, 37]. Patients are discharged 1 h later and can return to normal activities in the same day. Oral analgesics are prescribed, but pain complaint is minimal. The most common complication is fibrosis at the aspiration site. Other potential complications include haematoma, bleeding, and infection but are very rare [8]. Some authors advocate that MESA allows the collection of larger and cleaner quantities of sperm than PESA (reviewed by Miyaoka and Esteves) [35]. In our series of 146 men with OA, cumulative successful retrieval rate after PESA and TESA was 97.3% (Table 26.1), and an adequate number of motile sperm for cryopreservation were obtained in approximately 26.7% (39/146) of the cases. Although the

*Successful retrievals defined at obtaining motile sperm

†In a logistic regression model adjusting for male age, duration of infertility, and serum levels of FSH, LH, and testosterone, the overall comparison of SRR by PESA among groups continued to demonstrate statistical significant difference ($P = 0.021$), as well as the pairwise comparisons. No covariate adjustment was performed for analyses of cumulative SRR due to the very high success rates for this outcome

cryopreservation rate after PESA is lower than MESA, repeated aspirations can be carried out in men with OA at a lower cost and morbidity rate than MESA. However, MESA has the advantage of allowing the collection of a greater number of sperm that can be intentionally cryopreserved for future use, thus avoiding the need of repeat retrievals [38]. Moreover, MESA should be the preferred approach for men presenting with coagulopathies.

When gradient centrifugation is chosen for PESA sperm processing, we recommend that part of the sample is spared and processed by simple washing [39]. The reason is the unpredictability of gradient centrifugation to recover motile sperm in such cases. If recovery is suboptimal, we rely on the washed sample to select motile sperm for ICSI. Due to the relatively low sperm yields in PESA and TESA, it is important to use low volumes of media during sperm processing and wash the sample only once. Centrifugation force and time should be carefully controlled to avoid jeopardizing the often-compromised sperm motility.

In a study comparing SRR between OA and NOA, we found that the chances of obtaining sperm were markedly reduced among men with NOA compared with OA, even when micro-TESE was used as the method of sperm acquisition (Table 26.2) [40].

Table 26.2 Sperm retrieval rates (SRR) in azoospermic men with testicular failure and obstructive azoospermia

	Testicular failure	Obstructive azoospermia[a]	*p* value

As for NOA, our preference is to use *micro-TESE* as the sperm retrieval method [16]. Micro-TESE allows the identification of enlarged seminiferous tubules more likely to harbour sperm production. The minimal tissue extraction and preservation of intratesticular blood supply are important features of micro-TESE, thus reducing the risk of testicular devascularization (reviewed by Esteves [41]). Given the fact that micro-TESE is an invasive procedure, we used strict criteria for diagnosing NOA patients [14, 41, 42]. Our method includes semen analysis results, history and physical examinations, endocrine profiles, and genetic testing. Also, we confirm NOA by histological evaluation. The combination of these parameters was shown to be highly accurate to diagnose NOA.

Furthermore, the use of operating microscope during TESE limits the risk of vascular injury and optimizes the chances of finding sperm [10–12]. Although no absolute predictors for sperm retrieval are available in NOA cases, the probability of retrieving sperm varies according to the testicular histopathology results [12, 13, 43]. Proper identification of testicular vessels under the tunica albuginea is made prior to the placement of an incision into the testis. The microsurgical approach allows preservation of intratesticular blood supply, as well as identification of tubules more likely to harbour sperm production [16]. Therefore, efficacy of sperm retrieval is improved while the risks of large tissue removal are minimized. Excision of large biopsy samples in conventional TESE has been shown to impair testosterone production [44]. Tissue removal in micro-TESE is often 50- to 70-fold less than standard TESE [11], and the small amount of tissue extracted facilitates sperm processing. Selection of spermatozoa from a smaller population of contaminating testicular cells allows more ease and greater speed for sperm pick-up and injection process, as well as alleviates contamination and blockage of the injection needle with cells and debris. It is far less technically demanding and labour-intensive to extract spermatozoa from small-volume specimens than large pieces of testicular tissue that must be dissected, red blood cells lysed, and the rare spermatozoa searched for in a tedious fashion under an inverted microscope (Fig. 26.8). In fact, TESE sperm processing may be incredibly labour-intensive and the searching process may miss the rare spermatozoa within a sea of seminiferous tubules and other cells. TESE/micro-TESE can be scheduled either on the day of oocyte collection (or the day before) or as an elective pre-IVF procedure. In the former, processed specimens are incubated in a closed HEPES-buffered culture system (microdrops under mineral oil) at room temperature, inside a laminar flow cabinet or in a clean

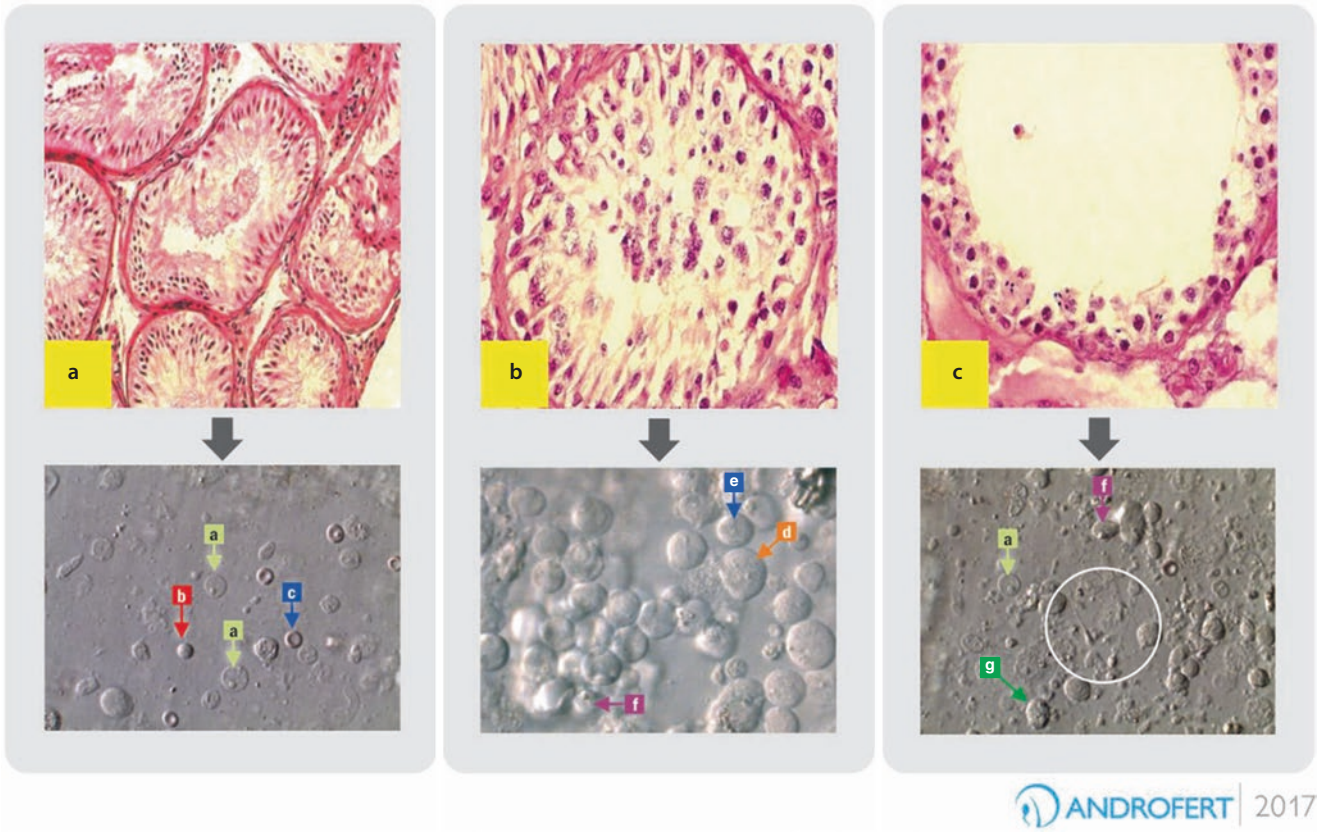

Fig. 26.8 Photomicrographs illustrating the association between testicular histology and cell pattern observed after testicular parenchyma processing. In the upper part, the three main histological patterns found in cases of non-obstructive azoospermia are shown: **a** Sertoli cell only (SCO); **b** maturation arrest (MA); **c** hypospermatogenesis (HYPO). At the bottom is the corresponding cell pattern usually found in each of these conditions as seen under the inverted microscopy. In SCO, only Sertoli cells (a), lymphocytes (b), and erythrocytes (c) are usually observed. In MA, the presence of a large number of germ cells is seen, and cell differentiation usually stops before sperm formation: (d) spermatogonia (e) primary spermatocytes, (f) round spermatids (observe the soft contour and prominent acrosome vesicle in the apical portion). It is important to highlight that isolated foci of active spermatogenesis with differentiation until spermatozoa can be found in SCO and MA. In HYPO, the presence of germ cells is reduced, but all the stages of spermatogenesis are present, including spermatozoa: (a) Sertoli cells, (g) secondary spermatocyte, (f) round spermatid and spermatozoon (highlighted). Magnification: 400×, inverted optical microscope, Nikon Eclipse Diaphot 300 with phase contrast (Hoffman) and haematoxylin/eosin stained for histological slides at 1000× magnification

room for a maximum of 48 h, to avoid bacterial contamination. In the latter, testicular sperm are frozen in special devices (cell sleepers) developed for cryopreservation of low sperm quantity [20]. Culture of specimens at 37 °C inside the incubator should be avoided since contamination with scrotum skin-derived bacteria is often seen [39]. From our data, optimal fertilization by ICSI using surgically retrieved sperm is obtained when the time frame from hCG administration to microinjection does not exceed 44 h [45]. Testicular tissue sperm processing, searching, and selection of viable spermatozoa for ICSI may take several hours in NOA cases. Our laboratory takes approximately 11.6 min to handle a single testicular spermatozoon from processing to microinjection in NOA, but only 5.5 min in OA. In other words, the average time required to perform ICSI in a standard NOA treatment cycle involving 8–12 metaphase II oocytes is approximately 2 h. Therefore, we usually perform micro-TESE the day before oocyte collection when a busy next-day IVF laboratory workload is anticipated. Additionally, we recommend that a minimum of two laboratory technicians work together during the initial processing steps (one mincing the tubules and the other searching for spermatozoa) to speed up the searching process and to allow a faster feedback to the surgeon who may decide to end the procedure if sperm is found or to continue dissecting the seminiferous tubules. Our laboratory performs the processing of testicular specimens by mincing and shredding the whole tissue. If spermatozoa are not found at initial search, a subsequent processing step involves enzymatic digestion using collagenase. The mechanical preparation has the advantage of being fast, requiring about 15–30 min, while enzymatic digestion is more time consuming, requiring at least 2 h [46]. Studies comparing the techniques are scarce, but the existing data were unable to confirm the superiority of one technique over the other for processing fresh and frozen testicular sperm for ICSI [46–49].

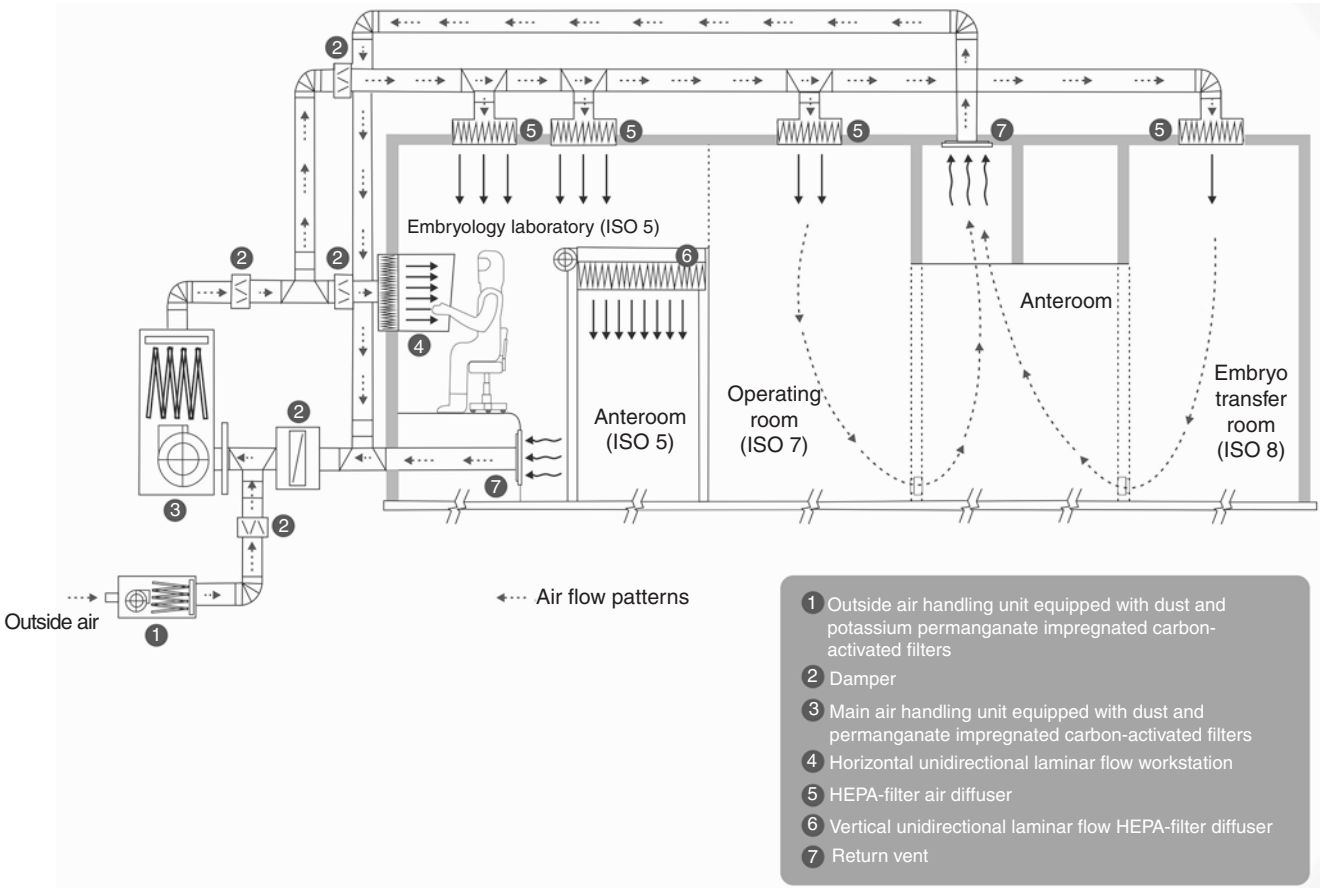

Fig. 26.9 Schematic representation of cleanroom IVF facilities, including airflow patterns and filtration units. The air handling ventilation unit room has a roof-top air-handling unit that draws outside air through coarse and charcoal prefilters before it enters into the main ventilation unit. A free-standing main ventilation unit pulls prefiltered outside air and cleanrooms' return air through coarse filters, past a 16-unit potassium permanganate impregnated pelletized coal-based activated carbon filters, and then through fine dust filters. Lastly, filtered air enters the cleanrooms through high-efficiency particulate air (HEPA) filter diffusers. Floor and ceiling-level vents in the cleanrooms' return air to the main ventilation unit, to be remixed with the existing air. Differential positive pressure is maintained between rooms. The embryology laboratory/anteroom is positive to the operating room, which is positive to both the embryo transfer room and the dressing room/hallways. (This is an Open Access article distributed under the terms of the Creative Commons Attribution Non-Commercial License, which permits unrestricted non-commercial use, distribution, and reproduction in any medium, provided the original work is properly cited))

At our centre, sperm retrieval, laboratory processing of PESA/MESA/TESA/TESE specimens, and micromanipulation are carried out in clean room laboratories with particulate and volatile organic compounds (VOC) removal (Fig. 26.9). A detailed description of our clean room facilities can be found elsewhere [51–53]. Evaluating results over a 9-year period, we demonstrated the benefit of operating under these optimum environmental conditions, which resulted in not only an increase in live births but also reduction in miscarriage rates.

In NOA, SRR varies according to testicular histopathology. Patients with maturation arrest (MA) had lower SRR compared with those with Sertoli cell only (SCO). Both categories had lower SRR compared with hypospermatogenesis (Table 26.3) [54]. On the contrary, efficiency of TESA for retrieving spermatozoa for ICSI in NOA is only 10–30% [55], except in the favourable cases of men with testicular histopathology showing hypospermatogenesis, to whom retrieval rates are approximately 80–100% [13]. Nonetheless, if a previous TESA attempt was successful for retrieving spermatozoa in a man with NOA, its positive predictive value for a successful second attempt is 70% [56].

Sperm cryopreservation is routinely used in association with sperm retrieval procedures at our centre. Lately, we prefer to retrieve and intentionally cryopreserve sperm for future use. This strategy offers the advantage of avoiding ovarian stimulation when no sperm is obtained from testicular specimens. If sperm is found and frozen, thawing can be done at any time, thus obviating the need to organize two operations (oocyte and sperm retrieval) on the same day. Also, cryopreservation is useful for surplus specimens that would be discharged after ICSI, in particular, if ICSI fails. Future ICSI attempts may be carried out without repeated surgical retrievals.

Table 26.3 Sperm retrieval rates (SRR), live birth, and obstetrical outcome of resulted offspring according to testicular histology results in patients with non-obstructive azoospermia

	Hypospermatogenesis	Maturation arrest	Sertoli cell-only	*p* value
Number of patients	84	67	205	–
Male age (years)	38.1 ± 9.7	36.4 ± 3.8	36.4 ± 7.2	0.50
SRR[a], *n* (%)	84 (100.0)	27 (40.3)	40 (19.5)	<0.001[b]
Live birth, *n* (%)	20 (23.8)	6 (22.2)	4 (10.0)	0.004[c]
Neonates born, *n*	31	11	6	–
Gestational age (weeks)	36.3 ± 3.2	35.9 ± 1.9	35.5 ± 3.9	0.18
Birth weight (g)	2987 ± 477	2629 ± 870	2583 ± 775	0.12

Data are means ± SD unless otherwise indicated
Kruskal-Wallis, Pearson chi-square test, and Fisher exact test were used for comparisons
[a]Defined at obtaining sperm
[b]$P < 0.001$ when adjusting for male age and serum levels of FSH, LH, and testosterone in a logistic regression model
[c]$p = 0.01$ when adjusting for co-variates including female and male age, male endocrine profile, duration of infertility, associated female infertility factor, and number of transferred embryos

In OA, motile sperm are usually available after thawing in such cases, and ICSI outcomes using motile fresh or frozen epididymal sperm seem not to differ [57]. On the contrary, motile post-thaw testicular sperm is not always available, and ICSI fertilization rates seem to be slightly lower when immotile testicular sperm are used than both motile frozen-thawed and fresh counterparts [58]. Notwithstanding, methods for selecting immotile viable sperm for ICSI are available. Still, HOST may not discriminate viable and non-viable frozen-thawed spermatozoa [27], and response to motility stimulants is unpredictable. Furthermore, STFT has not been validated in large series [28, 29]. The application of a single laser shot to the far end of the sperm tail has been shown to cause a curling of the tail only in viable sperm, similar to the reaction observed with the HOST, but this method has not been validated in cryothawed specimens [59].

Our first choice as regards handling immotile sperm for ICSI is to perform short-term incubation with culture media. Sperm culture media have the components to support normal metabolism of immotile mature retrieved spermatozoa that may become motile by incubation [60]. If no motile sperm are seen after 2–3 h of incubation, we use pentoxifylline as a motility stimulant. Lastly, we apply the STFT for discriminating viable and non-viable immotile sperm for ICSI after failed pentoxifylline stimulation.

We recently introduced a new method for freezing low sperm quantities, the cell sleeper method, as already described [18, 19]. Ready-to-use TEST-yolk buffer-free cryoprotectants is our preference when freezing sperm by the "cell sleeper" method, as it allows a clean and transparent microdroplet that aids in the process of finding spermatozoa after thawing.

As for the ICSI outcomes in azoospermic men with obstructive and non-obstructive azoospermia, our group has contributed a large amount of data to the literature [36, 40, 43, 54, 61–63]. In one study, the normal two-pronuclear zygote (2PN) and high-quality embryo rates were lower in patients with NOA (47.0% and 43.3%, respectively) than donor sperm (61.0% and 66.5%, $p < 0.001$) and OA (64.0% and 60.9%, $p < 0.001$) groups, respectively (Table 26.4). The mean number of transferred embryos was similar among the groups. Live birth rates were lower among men with NOA (19.9%) than in donor sperm (37.5%, $p = 0.003$) and OA (34.2%, $p < 0.001$) groups, whereas miscarriage rates did not differ among the groups.

Our data indicate that testicular spermatozoa of men with severely impaired spermatogenesis, like those with NOA, have decreased fertility potential. Such sperm may have a higher tendency to carry deficiencies related to the centrioles and genetic material, which ultimately affect the capability of the male gamete to activate the egg and trigger the formation and development of a healthy zygote and a viable embryo [63].

Lastly, we assessed obstetric and short-term neonatal outcomes of babies born after ICSI from azoospermic fathers and compared the results with our population of babies born from non-azoospermic men. In this study, 326 live births resulted from 1041 fresh embryo transfers (live birth rate of 31.3%). A total of 427 babies were delivered and assessed (Table 26.5). Overall, differences were not observed among groups for gestational age and birth weight

Table 26.4 ICSI outcome in azoospermic men with testicular failure, stratified by successful and failed sperm retrieval (donor sperm), and obstructive azoospermia

	Testicular failure	Donor sperm	Obstructive azoospermia[a]	*p* value
Number of cycles	151	40	146	
Female:				
Age	32.7 ± 5.4	31.4 ± 3.5	32.5 ± 5.8	0.32

[40] (This is an Open Access article distributed under the terms of the Creative Commons Attribution Non-Commercial License, which permits unrestricted non-commercial use, distribution, and reproduction in any medium, provided the original work is properly cited)

Data are means ± SD unless otherwise indicated; Kruskal-Wallis, Pearson chi-square test, and Fisher's exact test were used for comparisons; Donor sperm vs. OA not significant in all pairwise comparisons

*$p < 0.01$ when adjusting for co-variates including female and male age, male endocrine profile, duration of infertility, associated female infertility factor, and number of transferred embryos

[a]Previously reported (Esteves et al. [36])

[b]Testicular failure vs. donor sperm ($p = 0.003$; Wilcoxon Rank Sum Test) and OA ($p < 0.001$; Wilcoxon Rank Sum Test)

[c]Testicular failure vs. donor sperm and OA ($p < 0.001$; Wilcoxon Rank Sum Test)

[d]Testicular failure vs. donor sperm ($p = 0.008$; Fisher's exact test) and OA ($p = 0.002$; Pearson chi-square test)

[e]Testicular failure vs. donor ($p = 0.001$; Pearson chi-square test) and OA ($p = 0.003$; Fisher's exact test)

after controlling for parity. Likewise, the rates of preterm birth, low birth weight, and very low birth weight did not differ among the groups. The preterm birth rates were greatest for singletons in OA (17.9%) and for twins in both OA (47.1%) and NOA (44.5%) compared with the ejaculated group (9.7% and 27%, respectively), albeit differences were not significant. We noted a tendency ($p = 0.06$) towards lower gestational age for twins in the OA group (35.6 ± 2.8) than in NOA (36.2 ± 2.4) and ejaculated groups (37.0 ± 2.3), but the numbers were relatively small to reach statistical significance. The overall perinatal death and malformation rates were 2.8% and 1.6%, respectively, and again the results did not differ among groups. The frequency of babies of the male gender was higher in the OA group (56.4%) compared with the NOA (41.4%) and ejaculated (39.7%) groups ($p = 0.02$).

In another study, we evaluated the neonatal profile of babies delivered after ICSI using testicular sperm from men with NOA and OA. Gestational age, birth weight, and sex ratio of these children were comparable to those reported in a control group that used donor sperm for ICSI. The overall adverse neonatal outcome in the studied population was 4.1% (Table 26.6). Our data suggest that gestational age, birth weight, perinatal death, and malformation rates do not seem to be affected by azoospermia. Although our results on pregnancy and postnatal ICSI outcomes using non-ejaculated sperm are reassuring, the limited population analysed calls for continuous monitoring.

Table 26.5 Neonatal outcomes of children born following sperm injection in azoospermic and non-azoospermic infertile males

	Obstructive azoospermia	Non-obstructive azoospermia	Ejaculated sperm	*P* value
No. of live birth singletons	67	32	145

Birth defects were defined as structural, functional, or developmental abnormalities presented at birth or later, due to genetic or non-genetic factors acting before birth

*Perinatal death included stillbirths (birth of fetuses with no sign of life that occur after 20 weeks of gestation) and neonatal deaths (deaths within the first 28 days); one stillbirth occurred in each group

Table 26.6 Outcome of neonates born after ICSI in azoospermic men with testicular failure, stratified by successful and failed sperm retrieval (donor sperm), and obstructive azoospermia

	Testicular failure	Donor sperm	Obstructive azoospermia[a]	*p* value
Deliveries (%):				0.49[b]

[a]Previously reported (Esteves et al. [36])
[b]In a Poisson regression model for the number of babies born and adjusting for male and female age, duration of infertility, and serum levels of FSH, LH, and testosterone in addition to female factor infertility and number of transferred embryos, the overall comparison among the groups continued to demonstrate no statistically significant difference
[c]Includes stillbirth and neonatal deaths with frequency calculated as number of perinatal deaths/number of neonates born

Glossary

Azoospermia Absence of spermatozoa in the microscopic examination of the seminal fluid after centrifugation on at least two separate occasions.

Cryopreservation The freezing process for storage of gametes or gonadal tissue at ultra-low temperature.

ICSI *I*ntracytoplasmic *S*perm *I*njection: a procedure in which a single spermatozoon is injected into the oocyte cytoplasm.

MESA *M*icrosurgical *E*pididymal *S*perm *A*spiration: a microsurgical procedure used to aspirate spermatozoa directly from the epididymal tubules for use in an ICSI procedure.

Micro-TESE *Micro*dissection *Te*sticular *S*perm *E*xtraction: a microsurgical procedure used to dissect the seminiferous tubules within the testis in an attempt to identify areas of sperm production and extract spermatozoa for use in an ICSI procedure.

PESA *P*ercutaneous *E*pididymal *S*perm *A*spiration: a procedure in which a needle is inserted into the epididymis to retrieve spermatozoa for use in an ICSI procedure.

Sperm Processing Laboratory techniques used to remove contaminants (cellular debris, microorganisms, red blood cells, etc.) and to select the best-quality spermatozoa to be used in conjunction to assisted reproduction technology.

TESA *Te*sticular *S*perm *A*spiration: a procedure in which a needle is inserted into the testis in order to retrieve spermatozoa for use in an ICSI procedure.

TESE *Te*sticular *S*perm *E*xtraction: operative removal of testicular tissue in an attempt to collect sperm for use in an ICSI procedure.

Appendix

- *Erythrocyte Lysing Buffer Solution (ELBS):* 155 mM NH_4Cl + 10 mM $KHCO_3$ + 2 mM EDTA dissolved in sterile water. Adjust the pH to 7.2, if necessary. Upon finishing the first dilution and centrifugation step, resuspend the pellet with 2.0 mL of ELBS and keep the mixture at room temperature for 10 min. Then, centrifuge the sample at ×300 g for 5 min, discharge the supernatant, and resuspend the pellet in 0.2 mL of fresh HEPES-buffered protein-supplemented sperm medium [46].
- *Enzymatic Digestion:* Prepare 1.0 mL of HEPES-buffered Human Tubal Fluid (Modified HTF culture medium, cat.# 90126, Irvine Scientific, USA) supplemented with 5% of Human Serum Albumin (HSA, cat.# 9988, Irvine Scientific, USA) and 2.6 mg of collagenase type IV (Sigma C5138; activity: 378 Units/mg solid) [64, 65]. Upon finishing the first dilution and centrifugation step, resuspend the pellet with 1.0 mL of the enzymatic digestion solution and incubate at 37 °C for 1 h. Homogenize the suspension every 10–15 min during the incubation period to obtain better enzymatic digestion of the tissue. The digested tissue solution is centrifuged for 5 min at 300 g, and the pellet is resuspended in 100–200 μL of Modified HTF culture medium supplemented with 5% of HSA.
- *Hyposmotic Solution (HOS):* Prepare a 150-mOsm/kg HOS solution by dissolving 7.35-mg sodium citrate and 13.51-mg fructose in 1-mL sterile reagent water [27].

Alternatively, a 139-mOsm/kg HOS solution can be prepared by mixing 1-mL sperm medium to 1-mL sterile reagent water [25, 26].

- *Pentoxifylline Solution (PF)*: Prepare a 5-mM solution of PF by dissolving 1.391-mg pentoxifylline (Sigma cat.# P-1784) in 1 mL of HEPES-buffered culture medium [30].

Review Questions

1. What is the difference between PESA, MESA, TESA, TESE, and micro-TESE and when each method is indicated?
2. Which materials, equipment, reagents, and IVF laboratory setup are needed to perform PESA, MESA, TESA, TESE, and micro-TESE?
3. Which additional sperm processing techniques can be used during sperm search to improve the chances of finding sperm in specimens from non-obstructive azoospermic patients?
4. Which are the additional methods for selecting viable sperm for ICSI when only immotile spermatozoa are obtained after PESA/MESA/TESA/TESE/micro-TESE?
5. What are the advantages of using micro-TESE as the method of choice for harvesting sperm in men with non-obstructive azoospermia in preference over TESE or TESA?
6. What is the association between testicular histopathology results and wet tissue examination in retrieved testicular specimens?
7. Is sperm fertilizing potential similar in obstructive and non-obstructive azoospermia?
8. How to optimize sperm cryopreservation in cases in which only a few spermatozoa are recovered?

27.1 Introduction

Human immunodeficiency virus (HIV) is a retrovirus which is transmitted from one individual to another through blood, semen, vaginal fluid, pre-ejaculate (via unprotected intercourse, including oral or anal sex), and from mother to child (vertical transmission) during pregnancy and delivery, or via breast milk. Approximately 37 million people around the world are infected with HIV type 1 virus [1], and >80% of HIV-infected individuals are of childbearing age [2].

Over time, infection with this virus can cause acquired immunodeficiency syndrome (AIDS). AIDS is a condition in humans in which progressive failure of the immune system allows life-threatening opportunistic infections and cancers to thrive. This disease was defined in 1982 by the Centers for Disease Control and Prevention (CDC) in the USA. The current classification system is based on clinical, immunological, and diagnostic HIV features [3].

Without treatment, the survival time after infection with HIV is estimated to be 9–11 years; however, the emergence of highly active antiretroviral therapy (HAART) has prolonged the survival of HIV patients and has given rise to a new demand from SDC couples aiming at parenthood. Unfortunately, because of the risk of transmission of viral particles through semen, sexual intercourse in these requires use of protection, which eliminates the possibility of achieving pregnancy.

Thus, in the past, the only completely safe options available to fulfill these couples' desire for offspring were adoption or sperm donation. Nevertheless, many couples desire genetically related offspring.

When the male partner is HIV positive, it is essential to treat the infected semen with effective laboratory techniques that not only isolate the best motile spermatozoa but also remove HIV-infected cells from the semen. These males need special assisted reproduction technology (ART) protocols in order to father children without risking transmission of disease to their partners and offspring [4]. These protocols mainly involve treatment of the sperm sample and confirmation of viral absence before any use of the sample.

For HIV, there is a low transmissibility risk, established as 1–3 infections per thousand occurrences of sexual intercourse (or semen exposure) [4–6]. At this time, when the man is HIV positive and the woman is HIV negative, the options available for serodiscordant couples to have children involve a sperm-washing protocol, confirmation of absence of the virus in the washed sperm, and use of appropriate ART, such as intrauterine insemination (IUI) or in vitro fertilization (IVF)/intracytoplasmic sperm injection (ICSI) [6–8]. The employment of ICSI in these couples is an applicable alternative to diminish this risk when they undergo ART, because a single spermatozoon is injected directly into an oocyte, during which the pellucid zone of the oocyte is penetrated artificially.

Additionally, to prevent any accidental infection of the partner, offspring, and laboratory staff during ART, we need to employ the safest methods available. To this end, several strategies for treatment of SDC males have been developed in recent years to reduce the transmission risk as much as possible while maintaining reasonable and cost-effective pregnancy rates.

Our aim in this chapter is to present the reader with the available information regarding the safety, efficacy, and effectiveness of employing ART for processing of and insemination with sperm cells in SDC couples in which the male is infected with HIV.

27.2 Sperm Washing, Detection of HIV-1 RNA, and Proviral DNA Techniques

HIV belongs to the retrovirus family; they have the faculty to synthesize reverse transcriptase, convert the ribonucleic acid (RNA) form into deoxyribonucleic acid (DNA), and insert their genome, in this manner, into a host. This issue is very relevant to the detection methods employed [9], since we need to demonstrate the absence of HIV in a sperm sample by analyzing both DNA and messenger RNA (mRNA).

Sperm washing was first described in 1992 by Semprini et al. [10] for the purpose of separating motile sperm from the remaining seminal components, using astringent methods to obtain spermatozoa free of HIV DNA and RNA particles, thereby achieving elimination or minimization of the risk of transmission to the mother and baby when sperm cells are employed in ART. Afterward, different techniques had to be used to determine the absence of the virus in samples (Table 27.1) prior to their use.

Several years ago, when washed sperm samples were employed for IUI treatment, immunofluorescence methods to detect antigen p24 were used in the initial detection of HIV-1; at the present time, the routine detection methods for HIV-1 in sperm are based on amplification of well-defined sequences of the viral nucleic acids [10, 12].

These methods have been developed over time. The initially available methods had significant limitations, because their lower detection limit was 10,000 copies per milliliter. The second-generation techniques had a lower detection limit of 200–400 copies [3]. Another method (third-generation) evolved that included a sequence as a control system to demonstrate the efficiency of amplification for each tested sample, with sensitivity low as 50 viral copies [11], but it could not detect viral presence below this threshold.

The most commonly used method of detection is standard polymerase chain reaction (PCR), which consists of enzymatic amplification of specific sequences of the viral genetic material, but this technique also has a lower limit in the number of copies that can be detected (around 200 copies/mL of RNA), making it impossible to be 100% sure that the sample is free of the virus.

Table 27.1 Separation and human immunodeficiency virus (*HIV*) detection techniques used in sperm samples from HIV-positive patients

Study	Sperm washing	Swim-up	HIV semen detection method
Semprini et al. (1992) [10]	Double-density gradient (40–80%)	Yes	Indirect immunofluorescence
Lasheeb et al. (1997) [11]	Double-density gradient (40–80%)	Yes	NASBA nested PCR
Marina et al. (1998) [12]	Triple-density gradient (50–70–90%)	Yes	Amplicor PCR
Chrystie et al. (1998) [13]	Double-density gradient (50–90%)	Yes	NASBA
Hanabusa et al. (2000) [14]	Quadruple-density gradient (56–64–72–80%) in a double tube	Yes	Nested PCR
Sauer and Chang (2002) [15]	Double-density gradient (47–90%)	Yes	None
Politch et al. (2004) [16]	Double-density gradient (47–90%) in a double tube	No	RT-PCR
Garrido et al. (2005) [17]	Triple-density gradient (45–70–90%)	Yes	Nested PCR
Mencaglia et al. (2005) [5]	Triple-density gradient (45–70–90%)	Yes	None
Bujan et al. (2007) [18]	Triple-density gradient (50–70–90%)	Yes	HIV RNA PCR
Kato et al. (2006) [19]	Double-density gradient	Yes	Nested RT-PCR
Savasi et al. (2007) [7]	Double-density gradient (40–80%)	Yes	Real-time PCR
Molina et al. (2014) [20]	Double-density gradient (40–80%)	No	Real-time PCR
Zamora et al. (2016) [21]	Triple-density gradient (45–70–90%)	Yes	Real-time PCR

NASBA nucleic acid sequence–based amplification, *PCR* polymerase chain action, *RNA* ribonucleic acid, *RT* reverse transcription

Trying to improve the techniques available, our group developed a protocol to reduce the detection limit to a single RNA or DNA viral copy, using nested PCR (nPCR) or reverse transcription and nPCR for RNA [9]. With application of this method, it has been shown that many samples that were considered negative with other methods are in fact positive. Despite this, no reports of infection after use of different methods have been published.

27.3 Semen Analysis

All samples must be processed in a dedicated laboratory; it is necessary to employ highly trained and experienced staff, and to make use of an exclusive and isolated laboratory area, set apart from work with noninfectious samples, with use of a class II/B3 biosafety cabinet with a vertical laminar flow hood, a centrifuge with safety lids, an exclusive incubator, and a nitrogen tank used solely for storage of these potentially infectious samples.

Samples are collected by masturbation into a sterile polypropylene container after 3–5 days of ejaculatory abstinence. After liquefaction and homogenization, semen parameters are analyzed according to the World Health Organization [6, 22] criteria. The total sperm count and motility before and after the wash are recorded. Sperm morphology is not analyzed for safety reasons: it is not recommended to work with cutting elements when treating HCV-positive/HIV-positive samples, and, as these samples are always used for ICSI treatment, fresh sperm morphology is not needed.

27.4 Sperm-Washing Procedure

The sperm-washing procedure has emerged from a modification of classical sperm preparation methods. Although this procedure can differ in different clinics, the elimination of HIV from raw sperm commonly consists of double and consecutive processes to wash the semen sample by means of modified classical density gradient and swim-up techniques [10], both of which have a single aim: to isolate only motile sperm.

As mentioned earlier, these techniques are also used generally in sperm preparation for human reproduction to select the most suitable motile sperm for fertilization [23], but in this case we use them consecutively and with larger volumes of culture media to perform the procedure more strictly to remove the viral particles completely.

Most authors have applied the original protocol defined by Semprini et al. in 1992, but with small variations in the gradient concentrations [9, 12], double gradients [16], or omission of the swim-up technique [24].

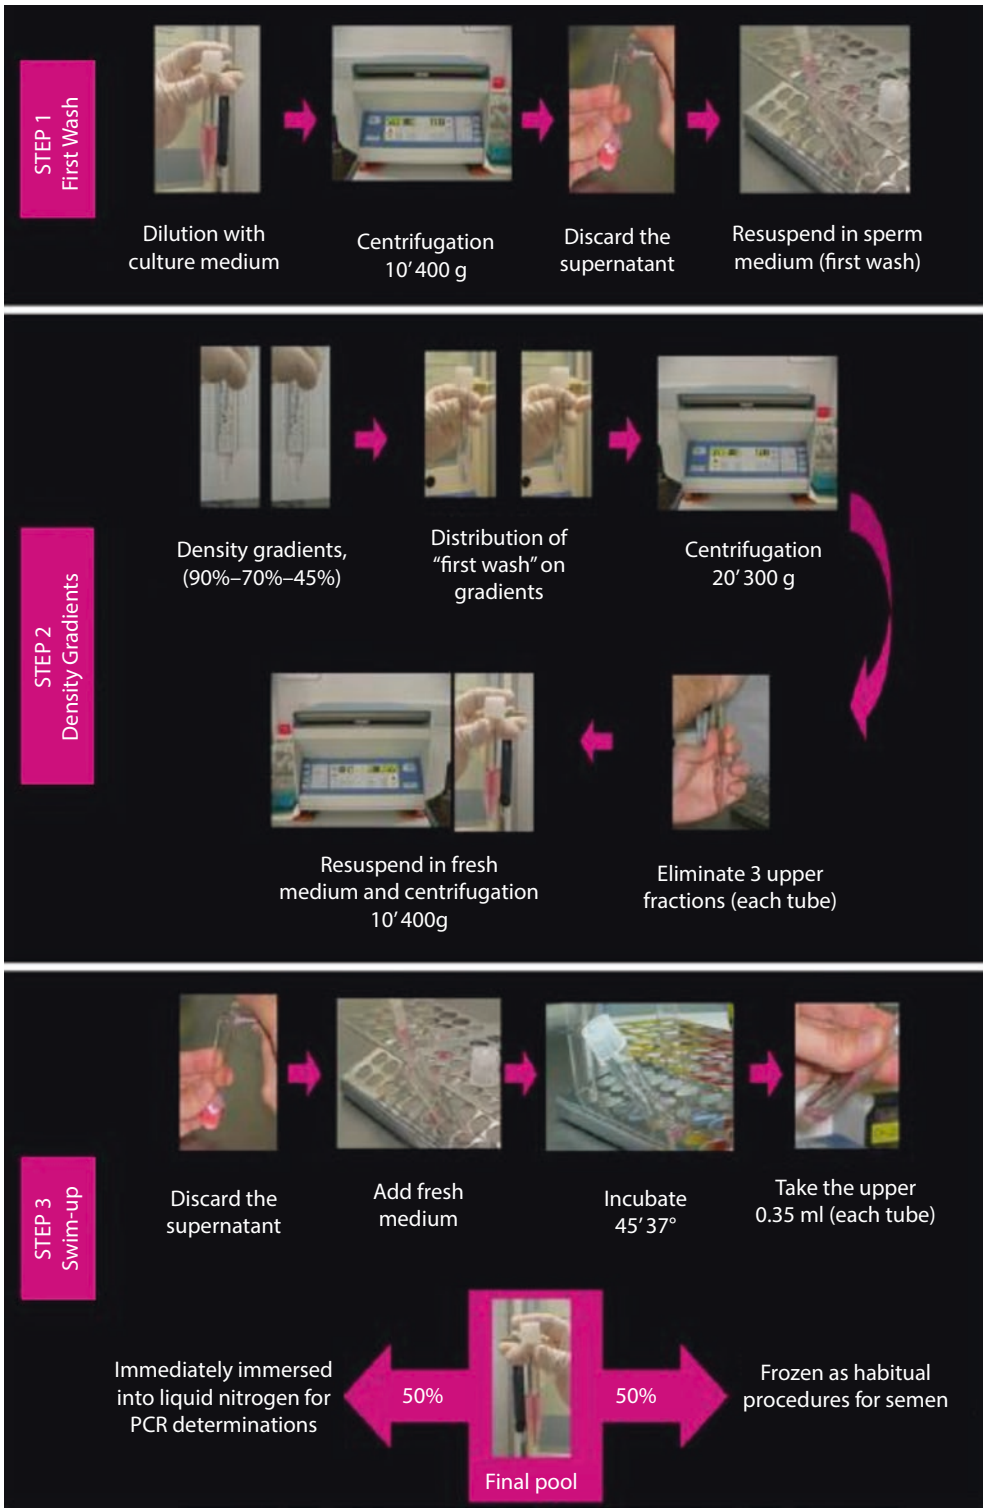

Fig. 27.1 The sperm wash procedure consists of three steps

The sperm-washing process consists of three steps (Fig. 27.1) [9].

Step 1. First wash: seminal plasma removal

- An initial dilution or first wash is performed in about a 1:1 proportion (vol:vol) with culture medium after liquefaction of the ejaculate.
- The sperm is then pelleted at 400 × *g* for 10 min, and the supernatant is discarded.
- The pellets are then resuspended in fresh culture medium (the "first wash").

Step 2. Density gradients: establishment of liquid layers of different densities

- Different conical tubes of triple-density gradients (Percoll®, PureSperm®, SpermFilter®, Ficoll®) with 1–1.2 mL in each layer (90%, 70%, and 45%) are prepared in order to separate different sperm cell fractions, and approximately 1 mL of the first wash is layered into each tube.
- Centrifugation is performed for 20 min at 300 × *g*; as a result, each component of the sperm begins to cross through the different layers until it reaches the layer where the solution density is equal to its own density.
- The upper fractions of the tubes are then eliminated.
- Each pellet is obtained and washed with 5 mL of fresh culture medium and then repelleted again at 400 × *g* for 10 min. The supernatants are discarded.

Step 3. Swim-up: selection of the best motile spermatozoa

- After the supernatant is discarded, a swim-up of 1 mL of fresh medium is done. After 45 min at a 45° angle in the incubator at 37 °C in a 5% CO_2 atmosphere, the upper 0.5 mL in each tube is extracted carefully and pooled in a new tube, meaning that the resulting washed sperm suspension is about 1 mL.
- After evaluation of the total count and motility, one half of the "pool" is immediately immersed in liquid nitrogen for PCR determination, and the other half is frozen with cryoprotectant medium, following the manufacturer's instructions, and stored until use in ART after a negative viral presence test [9].

Obviously, the process of strict sperm washing to eliminate as much of the virus as possible adversely affects the amount of available sperm for IUI or IVF, with recovery of only about 5% of the total number of spermatozoa available in the raw sample [3, 17]. However, our group has modified the usual sperm-washing protocols to be less strict in very poor samples and even in testicular biopsy samples [25, 26].

27.5 PCR Techniques for HIV Applied to Semen

Nucleic acids were extracted from washed spermatozoa using a NucliSens (Organon-Teknika, Barcelona, Spain), following the instructions of the manufacturer. Two extractions were run in parallel, one using a spermatozoa sample and the other using a spermatozoa sample with addition of HIV RNA obtained from HIV-infected plasma to detect the presence of transcription or amplification inhibitors after the nucleic acid extraction procedure. Both extracted samples were used for two HIV RNA transcriptions to detect genes from the *gag* and *pol* region, followed by nested DNA amplification [27]. The same samples were used to amplify HIV proviral DNA by nested amplification to detect both genes (*gag* and *pol*). The other extraction, run in parallel with added HIV RNA before nucleic acid extraction, was used as a positive control to detect the presence of inhibitors of the transcription or amplification. Besides use of negative controls to detect the presence of amplicons, contamination was carried out.

For HIV RNA transcription, the antisense external primers for annealing were used with nucleotides 1696–1676 and 3286–3265 for the *gag* and *pol* genes, respectively. Standardized conditions for transcription were followed, using 100 μM DTT, 1 mM of each dNTP, 0.2 μM antisense primer, 20 U of RNasin (Promega, Barcelona, Spain), and 5 U of AMV transcriptase (Promega) in a final volume of 20 μL. Nested DNA amplification used the external primers to anneal with nucleotides (from the ARV2/SF2 sequence) 1224–1243 and 1696–1676 and internal primers to anneal with nucleotides 1316–1335 and 1524–1504 for the *gag* region. External primers annealing with nucleotides 2623–2642 and 3286–3265 and internal primers annealing with nucleotides 2716–2741 and 3250–3227 for the *pol* region were used [28].

Standardized PCR conditions were followed, including 6 μL of reverse transcriptase (RT) or previous PCR product; 2.5 and 2 mM $MgCl_2$ for the *gag* and *pol* regions, respectively; 0.2 mM of each dNTP (Amersham Pharmacia, Madrid, Spain); 0.5 μM of each primer; and 2 U of Taq polymerase (Promega) in a 50-μL final volume. β-Actin gene amplification was performed to confirm the presence of DNA in the extraction from the spermatozoa suspension. The results were read after 2% agarose gel electrophoresis after ethidium bromide staining [27]. In all of the samples, a consistent result (either positive or negative) was obtained. The assay failure rate was zero.

The quantitative one-round PCR technique was performed according to the method specified by Roche Diagnostic Systems (Amplicor; Roche, Basel, Switzerland) and as described in the work by Marina et al. [12]. Briefly, RNA extraction was performed according to the Amplicor specimen preparation kit specifications (Roche, Barcelona, Spain).

To check for the HIV RNA load, reverse transcription and amplification using SK145 and SKCC1B were carried out (amplifying a limited region of the HIV-1 *gag* gene, which translates the viral proteins p18, p24, and p55). The PCR-amplified product was detected and quantified through hybridization with the use of a specific biotin-labeling probe. An enzyme-linked immunosorbent assay (ELISA) was used for subsequent detection.

The results obtained by Meseguer et al. [9] from the analysis for detection of the presence of viral molecules after the sperm washes demonstrated that approximately 7% of sperm washes still led to positive results afterward. In those cases, the sample was reanalyzed, and the results for the samples that tested positive by nested PCR were compared with those from the one-round PCR protocols, and the results were negative. The authors programmed another sperm wash after 2–3 weeks and never obtained a positive result after a second wash. The assay never failed to yield a diagnostic result.

This undoubtedly indicates that a negative sample in the protocols employing one-round PCR still had an undetectable viral presence [9]. Nevertheless, different institutions employ different methodologies, with highly variable efficiency and detection limits [29, 30].

Currently, we cannot predict the seminal washing results, but experience from different research groups seems to suggest that the rate of positive washes may be around 1–5% [17].

27.6 Use of Assisted Reproduction Techniques in Serodiscordant Couples

At the beginning of the AIDS epidemic, doctors refused to use ART in this population, because of the high morbidity and risk of infection (via horizontal and vertical transmission, or via transmission to medical personnel). However, the introduction of HAART has achieved a delay in the disease, extending the survival and improving the quality of life of people infected with HIV [23].

With this new therapy and its results, the ambition of patients to have children has increased, but, to avoid HIV transmission, these men cannot have unprotected intercourse with their partners. For that reason, doctors have recommended that patients consider sperm donation, adoption, or abandoning their hopes of fatherhood [31]. However, improvements in our knowledge of the disease and ART now allow these couples to have a family. For that, it is necessary to provide adequate reproductive counseling to achieve pregnancy [8].

To choose which treatment (IUI, IVF, or ICSI) should be used when the man is HIV positive and the woman is HIV negative, several aspects must be considered. IUI has been the alternative method used for a period of time, given the low degrees of difficulty and invasiveness [10, 12]. This method may be simpler and less expensive than others, but it presents some important inconveniencies, such as the need for a sperm wash result on the same day; if a positive result is found, the cycle will be canceled. Another problem is the small number of spermatozoa inseminated and the potential risk of viral transmission due to the exposure to thousands or even millions of "potentially infective" spermatozoa. Also, the whole sperm preparation must be inseminated within the same cycle. For these reasons the use of classical IVF or ICSI is recommended [32–34].

ICSI involves a smaller number of sperm cells than IUI (which requires millions of sperm) [15, 32, 33, 35, 36]. Despite the high cost of the ICSI process, the efficiency of this technique avoids the need for expensive repetitive virological semen testing and numerous cycles of ovarian stimulation. Another advantage over IUI relates to the increase in pregnancy rates per treatment cycle (more or less three times higher with ICSI; nearly 50% per cycle versus 17%), which should decrease the number of attempts needed to establish a successful pregnancy.

With ICSI, we are exposing the woman to a nearly infinitesimal risk: for each oocyte we employ just a single sperm obtained from a sample that has previously tested negative for HIV on PCR.

In another method, the semen samples are frozen, and the nPCR results can be confirmed as many times as needed, since the sample is not necessarily employed on the same day. Also, sperm washing can be performed before the cycle, thus not causing cancellation of any cycle because of a positive result. If the sperm-washing result is negative, it can be employed several times as needed, thus avoiding the need for (and expense of) new washes.

Additionally, in men with a priori lower semen quality that will not be sufficient for optimal IUI, ICSI is the only realistic treatment option because after the extensive procedure involved in sperm washing, and to avoid the possibility of a positive HIV result, the sperm recovery is very low (about 5% of the initial motile sperm).

Objectively, we must keep in mind that both techniques have been employed successfully to date to help serodiscordant people succeed in fulfilling their reproductive wishes safely [5, 10, 12, 37–40]; nevertheless, ICSI is the most preferred and safest method used so far [23], although it presents obvious disadvantages in comparison with IUI, such as the side effects associated with the procedure.

27.7 Sperm-Washing Results: Efficiency, Pregnancy, and Seroconversion Rates

Next, we analyze the results of a program for SDC couples in which the male was HIV positive, in terms of seroconversion (HIV transmission to HIV-uninfected women), vertical transmission (HIV transmission to newborns), and pregnancy rates when washed samples were employed.

In this study, our group [4] assessed couples comprising seronegative women and HIV-positive men (n = 18), HIV-positive men with HCV coinfection (n = 33), and infertile couples undergoing ART where the man was HCV positive (n = 40), providing a total number of 134 sperm samples to be washed. HIV infection was acquired by parenteral drug addiction in 25 of these cases (48.8%), plasma donation in 1 case (0.2%), sexual transmission in 11 cases (21.6%), blood transfusion in 6 cases (11.7%), and unknown in 8 cases (15.5%).

With regard to the female population, only those with demonstrated absence of HIV and HCV antibodies were accepted for inclusion in the study. They were also requested to practice sex with condoms.

Different gynecological findings were observed: 59 of the women were considered normal (64.8%), 15 of them were more than 36 years old (16.4%), 5 of them were low responders (5.5%), and 8 of them had endometriosis (8.6%). Depending on the patient characteristics, we treated these women with ICSI with their own oocytes or with oocytes obtained from healthy young donors. In the HIV-SDC couples, 11 procedures were performed with donated eggs, and seven procedures were performed with donated eggs in HCV-SDC couples.

In this work, we found a global pregnancy rate of approximately 45% per cycle [4], and almost 95% of the couples achieved pregnancy within four consecutive cycles.

Table 27.2 Global cycle results depending on the infection

	HIV infection (total)	HIV infection only	HIV + HCV infection	HCV infection
Follicular aspirations	73	27	46	51
Oocytes obtained	920	352	568	621
Metaphase II	742	293	449	514
Zygotes	511	211	300	305
Frozen embryos	169	78	91	68
Transferred embryos	154	59	95	116
Metaphase II/follicular aspiration	9.9 ± 2.3	10.9 ± 2.0	10.2 ± 2.0	10.5 ± 3.0
Fertilization rate/metaphase II, %	68.9 ± 6.3	72.0 ± 8.1*	66.8 ± 6.0	59.3 ± 5.3*
Embryos/follicular aspiration	4.3 ± 2.0	5.1 ± 1.8	4.0 ± 2.0	3.8 ± 0.7
Cleavage rate (embryos/metaphase II), %	57.3 ± 5.3	62.4 ± 5.6	53.4 ± 8.3	44.9 ± 10.2
Embryo transfers	64	23	41	42
Embryos/transfer	2.4	2.6	2.2	2.8
Positive pregnancy test	29	9	20	12
Negative pregnancy test	29	12	17	29
Biochemical pregnancy	5	1	4	1
Newborns	19	4	15	4
Pregnancy rate/cycle, %	46.0	40.1	48.7	40.1
Frozen embryo transfer	10	6	4	8
Frozen embryo positive pregnancy test	2	0	2	0
Frozen embryo negative pregnancy test	8	6	2	6
Frozen embryo pregnancy rate, %	20	0	50	0

Results are expressed as total number or as mean ± standard error of the mean
HCV hepatitis C virus, *HIV* human immunodeficiency virus
*$p < 0.05$

The results are shown in Table 27.2. Blood analyses after 3, 6, and 9 months confirmed no seroconversion in the women.

Recently, Barnes et al. [41] performed a systematic review and meta-analysis to study the efficacy and safety of ART in SDC couples, and found that sperm washing coupled with IUI, IVF, or ICSI was a safe method, with no cases of seroconversion reported.

Two years later, Zafer et al. [42] performed another systematic review and meta-analysis to evaluate the effect of sperm washing on HIV transmission among HIV-SDC couples. They, too, demonstrated that sperm washing was a safe and effective method to be used in positive HIV patients to achieve pregnancy. In their review they found no seroconversion among HIV-uninfected woman inseminated with washed semen, decreasing the risk of HIV transmission so far estimated, and they found no cases of vertical transmission. Moreover, clinical pregnancy was achieved by more than half of the couples included in the review.

Likewise, Zamora et al. [21] demonstrated that sperm washing using triple gradient sperm selection with extensive centrifugation and swim-up was a highly reliable technique for HIV removal, diminishing the frequency of postwash positive tests and maintaining pregnancy rates.

27.8 Influence of HIV-1 Infection on Semen Quality: Basic Sperm Analysis and the Embryo Point of View

As mentioned earlier, semen quality in seropositive men may be affected by different factors, including the HIV infection itself, the individual's overall health status, HAART therapy, or sperm washing [23]. Several studies [17, 43, 44] have focused on the assessment of seminal characteristics in HIV patients to analyze factors that make sperm washing fail and sperm quality in SDC males. Our group has evaluated male infection parameters, antiretroviral treatments received, and

Table 27.3 Receiver operating characteristic (*ROC*) curve analysis results for prediction of postwash polymerase chain reaction (*PCR*) results regarding infectious particles, according to semen parameters and human immunodeficiency virus (*HIV*) patient features ($n = 73$)

Parameter	Standard deviation of the value of area under the curve	Threshold	Sensitivity, %	Specificity, %	PPV, %	NPV, %

NPV negative predictive value, *PPV* positive predictive value, *TMP* total motile progressive sperm
[a]According to World Health Organization reference values [22]

sperm quality to identify positive-wash predictors [17]. This study included 73 healthy seronegative males (as a control population), who were partners of women who exclusively had tubal factor infertility, within the same period of time. The controls and HIV-positive males were matched for age (±2 years) and the number of days (±0.5) of sexual abstinence.

Between August 2001 and November 2003, a total of 125 males provided 136 samples to be washed. Their ages ranged between 21 and 54 years (median 37.1 years).

In the 70 HIV-infected males (45 (64.3%) of whom were also coinfected with HCV), the mode of infection was former addiction to parenteral drugs in 32 cases (45.7%), plasma donation in 2 cases (3.0%), heterosexual transmission in 15 cases (21.4%), and unknown in 14 cases (20.0%). The average duration of HIV disease was 9.6 years (range 1–20 years). According to the CDC classification of the disease, 12 cases (17.1%) were A1, 23 (32.8%) were A2, 5 (7.1%) were A3, 3 (4.3%) were B1, 7 (10%) were B2, 11 (15.7%) were B3, 2 (2.8%) were C2, and 6 (8.5%) were C3.

With regard to antiretroviral treatments, 21 of the patients (30%) were treatment free, while the remainder were receiving different treatment combinations: 2 were on a single therapy (2.8%), 4 on two therapies (5.7%), 36 on three therapies (51.4%), 6 on four therapies (8.5%), and 1 on six therapies (1.4%).

The average blood HIV load was 19,408 IU/mL (ranging from undetectable to 525,000 IU/mL), while 39 patients (55.7%) showed a negative viral blood load. The average peripheral blood CD4 cell count was 497.5 cells/μL, ranging from 26 to 1064 cells/μL.

The results of this work showed that there is no systematic way to predict a positive result after sperm washing, as demonstrated by the receiving operator characteristic (ROC) curve analysis of the different factors (Table 27.3). Moreover, we found no significant decrease in sperm quality in the HIV-positive group in comparison with the healthy controls, and the antiretroviral treatments received did not affect the sperm quality; with regard to this last issue, a similar finding was reported by Lopez-Ruz [45] in a recent prospective study. However, other authors have reported changes in semen analysis parameters (volume, total sperm count, and motility) [11, 43, 44].

Also, semen quality can be evaluated in different ways by studying sperm molecular factors related to male infertility [46, 47] or by studying the embryo quality obtained from these sperm samples in comparison with healthy controls [48]. This way of assessing semen quality has been used by Melo et al. [48] and by us. From our data, we concluded that the fertilization and cleavage rates were comparable between the groups. On days 2 and 3 of embryo development, very similar embryo features were found in the different groups. Additionally, there was no difference in the mean numbers of optimal embryos on day 3; however, when the embryos were cultured for up to 5–6 days, a significantly higher rate of embryo blockage was found in the SDC group than in the control group. However, the mean numbers of optimal blastocysts on day 6 were comparable in both groups. With regard to the numbers of cryopreserved and transferred embryos, and the implantation, pregnancy, multiple pregnancy, and miscarriage rates, no differences were found between the groups.

27.9 Is Sperm Washing Possible in Oligospermic or Azoospermic Samples?

For these sperm-washing protocols to be performed, the ejaculate must contain a minimum of two million motile sperm cells.

27.10 Patients with Severe Oligospermia

At our institution, approximately 2% of HIV- or HCV-seropositive men presenting for fertility treatment have severe oligospermia [4]. In these cases, execution of the exhaustive sperm-washing protocols described previously make it impossible to recover any sperm at the end of the procedure.

In males who present with lower sperm counts, we have considered the possibility of performing modified sperm washing, using serial dilutions of the sperm sample, and then confirming the absence of viral nucleic acids by use of PCR.

The first series was published in 2006; out of seven males with severe oligospermia undergoing modified sperm washes, none of the samples tested positive for HIV, and so they were able to be used in ART treatments [25]. This is, to our knowledge, the only published report of ART in oligospermic males with HIV.

27.11 Sperm-Washing Protocol for Oligozoospermic Males

This protocol is very similar to the main protocol but with small modifications.

Ejaculate obtained after sexual abstinence for 3–5 days should be allowed to liquefy for 10 min at 37 °C and then be diluted 1:1 (vol/vol) with culture medium. The mixture is then centrifuged for 10 min at 400 × *g*, and the supernatant is carefully discarded. This procedure has to be repeated twice, and the resulting cells are resuspended in a final volume of 0.5–1 mL.

One half of each sample must be submerged immediately in liquid nitrogen for PCR determination, and the other half must be frozen, as described elsewhere [9], and stored until it is used in ART once a negative viral presence has been confirmed.

27.12 Patients with Azoospermia

An extreme situation is presented by males with no sperm in their ejaculate. Two case reports are available in the literature, describing an epididymal search for motile sperm in azoospermic males presenting with obstructions in the genital tract. In these papers, only patients with epididymal sperm retrieval were presented [49, 50]. This technique could be inappropriate for some azoospermic males. For example, this method could not be applied if the obstruction is up in the genital tract, or in males presenting with nonobstructive azoospermia with no spermatozoa available in the epididymal reservoir.

Open testicular biopsies augment the chances of finding motile sperm cells in azoospermic patients, although the presence of blood and round cells could increase the risk of a viral presence after washing.

Our group has published three cases of open testicular biopsy in patients with azoospermia, which is also applicable to males presenting with nonobstructive azoospermia [26].

27.13 Sperm-Washing Protocol for Azoospermic Males

Samples were obtained from male patients by testicular sperm extraction (TESE) because of the absence of sperm in two consecutive sperm analyses obtained and analyzed between August 2007 and November 2008. All patients had a normal karyotype and no microdeletions on the Y chromosome.

TESE was performed as previously described [51]. Briefly, open testicular biopsies were carried out with a 2% mepivacaine spermatic cord block. After the scrotal skin and tunica vaginalis were opened, three small incisions were made through the tunica albuginea in different regions of each testicle, and small pieces of extruding testicular tissue were excised. Two fragments (one per testis) were placed in Bouin's solution and were sent for histopathological examination. The remaining fragments were taken to the adjacent laboratory for sperm retrieval. The testicular tissue was placed in 2 mL of culture medium and minced mechanically with sterile slides. The presence of sperm cells was checked under an inverted microscope at ×3400 magnification. If motile sperm were found, the samples were centrifuged for 10 min at 400 × *g*, the supernatants were then carefully discarded, and the samples were immediately frozen. This procedure was repeated twice, and the resulting cells were resuspended in a final volume of 0.5–1 mL.

When this initial microscopic evaluation did not show motile spermatozoa, the sperm suspension was transferred into a Falcon tube and centrifuged at 600 × *g* for 5 min. The pellet was resuspended in 0.5 mL of sperm medium and incubated at 37 °C in a 5% CO_2 atmosphere for 1 h. Then, the samples were checked again for the presence of motile sperm.

Continually, for freezing, an equal volume of cryoprotectant culture medium was added to the sperm pellet and the mixture was then homogenized and kept at room

temperature for 10 min. Sperm samples were frozen in small tablets on a dry ice surface for approximately 1 min and were then transferred to prelabeled cryotubes. One half of each sample was immediately submerged in liquid nitrogen for PCR determinations, and the other half was frozen, as previously described, and stored in separate liquid nitrogen tanks until it was used in ART once a negative viral presence had been confirmed.

For thawing, the pills were removed, transferred into 5-mL Falcon tubes, and placed in an incubator at 37 °C in a 5% CO_2 atmosphere. Then the samples were washed again with fresh medium and centrifuged at 600 × *g* for 5 min. The supernatant was discarded, and the samples were resuspended in variable amounts of medium. Thereafter, motile spermatozoa were checked again for ICSI.

After sperm washing, motile sperm were recovered to be frozen from all testicular biopsies, thus guaranteeing safe use of the spermatozoa found within the samples. Two pregnancies were achieved out of five follicular aspirations, with four fresh and two frozen–thawed embryo transfers, resulting in a healthy newborn and an ongoing pregnancy.

Although they were achieved in only a limited sequence of cases, our results confirm that TESE-ICSI treatments in azoospermic seropositive patients are possible, and that these males should not be rejected for ART if these techniques, together with sperm washing and PCR confirmation of viral absence, are available.

27.14 Conclusion

The laboratory is focused on two aspects: first, we need to eliminate any viral particles, since nested polymerase chain reaction (nPCR) is an extremely sensitive method, and any viral residue will be detected, thus yielding a positive result and forcing us to discard the sample; second, we must optimize the sperm-washing procedure to ensure that we retain as many motile sperm as possible, to permit as many intracytoplasmic sperm injection (ICSI) procedures as possible.

In conclusion, sperm washing seems to reduce the risk of transmission in serodiscordant couples in which the man is infected with human immunodeficiency virus (HIV), and it is an effective, safe, and reliable technique to remove viral particles. Thus, HIV-infected patients now have the possibility to become fathers, avoiding viral transmission to the mother and the future child. Moreover, the sperm parameters are not significantly different from those that the World Health Organization considers normal.

From all of this information, we can summarize that sperm washing, with use of nPCR as a confirmatory molecular biology technique, followed by ICSI, is the most suitable procedure to perform in serodiscordant couples in which the man is HIV infected, in order to create a family in a cost-effective and safe way.

An Emerging Medical Device: Electrophoretic Sperm Separation

Steven Fleming and Robert John Aitken

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_28

Learning Objectives

- Limitations of existing methods of sperm preparation
- Importance of sperm charge in defining gamete quality
- Understanding the basic design of an electrophoretic sperm isolation device
- Appreciation of the efficiency of this device in achieving the rapid efficient isolation of high-quality spermatozoa from the ejaculate

28

28.1 Overview

28.1.1 Principles of Electrophoresis

Electrophoresis is a term used to define particle dispersion within a liquid medium, the electrolyte, in response to a spatially uniform electric field. This electrokinetic phenomenon occurs as a result of the particles displaying a net positive or negative surface charge against which an external electric field can exert an electrostatic force. In fact, a surface charge may not even be necessary for electrokinesis, as it is theoretically possible that even neutral particles could migrate in response to an electric field by virtue of the molecular structure of water at their interface. This concept relates to the so-called double layer theory, whereby a diffuse layer of ions having the same but opposite charge to the particle surface screens them from the surrounding medium. Consequently, the electric field exerts an electrostatic force on the ions within the diffuse layer in the opposite direction to that exerted upon the particles, resulting in viscous stress, termed the electrophoretic retardation force. This hydrodynamic friction applied to the particles depends also upon the viscosity of the liquid medium in which they are dispersed, ultimately determining their electrophoretic mobility. Hence, it is necessary to carefully consider the molecular weight and charge of the particles relative to the conductivity and viscosity of the electrolyte to achieve the electrophoretic mobility required.

28.1.2 Electrophoretic Properties of Spermatozoa

Normal, mature spermatozoa carry a net negative charge that is imparted by the sperm glycocalyx, which is rich in sialic acid residues [1, 2]. One of these residues, called CD52, is a highly sialated glycosylphosphatidylinositol (GPI)-anchored protein that is acquired during epididymal transit and located on the sperm plasmalemma [3–5]. During spermatogenesis, there is a massive cell-cell transfer of GPI-anchored CD52 that occurs at the sperm surface, the magnitude of which may be dependent upon the negative charge associated with the sperm plasmalemma [6]. Therefore, the presence of a negative charge may reflect normal spermatogenesis, especially since CD52 expression appears to be significantly correlated with capacitation and normal sperm morphology [3]. Consequently, this differential negative charge imparted by the sperm plasmalemma has been exploited as a means for sperm separation using either simple electrostatic [7, 8] or sophisticated electrophoretic techniques [9–11].

28.1.3 Development of Electrophoretic Technology for Sperm Sorting

This technology developed as a result of a chance contact between Professor RJ Aitken from the University of Newcastle and the CEO of Gradipore, a Sydney-based life sciences company, Tim Wawn. One of the key technical competencies developed by Gradipore was a capacity to separate biomolecules on the basis of their size and charge, as embodied in the company's core separations technology platform, Gradiflow. In collaboration with Prof Aitken's research group in gamete biology at the University of Newcastle, Gradiflow technology was harnessed to create a prototype instrument designed for sperm separation, called the cell sorter 10 (CS10). The CS10 was based upon preparative isolation by membrane electrophoresis, a patented technique that is capable of purifying most macromolecules from complex biological samples. The principle of this mode of separation was developed from the hypothesis that the CS10 preferentially selects cells on the basis of charge differences between human spermatozoa due to the differential presence of sialated proteins on the sperm plasmalemma [9]. A subsidiary commercial entity originally, SpermGen, developed the CS10 to the point that it was used in clinical trials to test its efficacy in a clinical laboratory setting (Fig. 28.1). This prototype has subsequently been reengineered by the most recent incarnation of the original Gradipore company, Memphasys Ltd., into a more sophisticated prototype, code-named Felix, for clinical evaluation by the assisted reproductive technology industry.

The fundamental instrument applies an electric potential via platinum-coated titanium mesh electrodes to move

Fig. 28.1 The CS10 instrument

spermatozoa across a 5 µm polycarbonate separation membrane, the pore size of which allows the passage of morphologically normal spermatozoa while restricting larger cells within semen, such as immature germ cells and leukocytes (Figs. 28.2 and 28.3). Spermatozoa, which are negatively charged when suspended in a physiological buffer, are attracted toward the positive electrode, or anode. Consequently, spermatozoa not possessing a normal negative charge have less electrophoretic mobility and do not manage to pass through the separation membrane during the relatively short period (<5 min) of electrophoresis. The exploitation of this concept has been found to yield a high percentage of morphologically normal, motile spermatozoa with intact DNA following electrophoretic sperm separation [9].

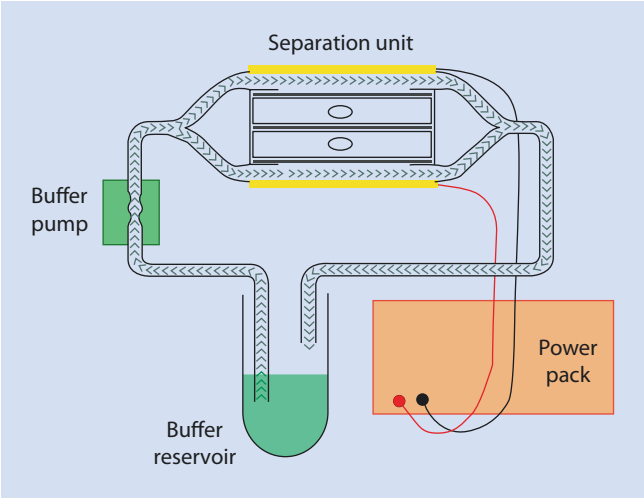

Fig. 28.2 Diagrammatic representation of the CS10 design

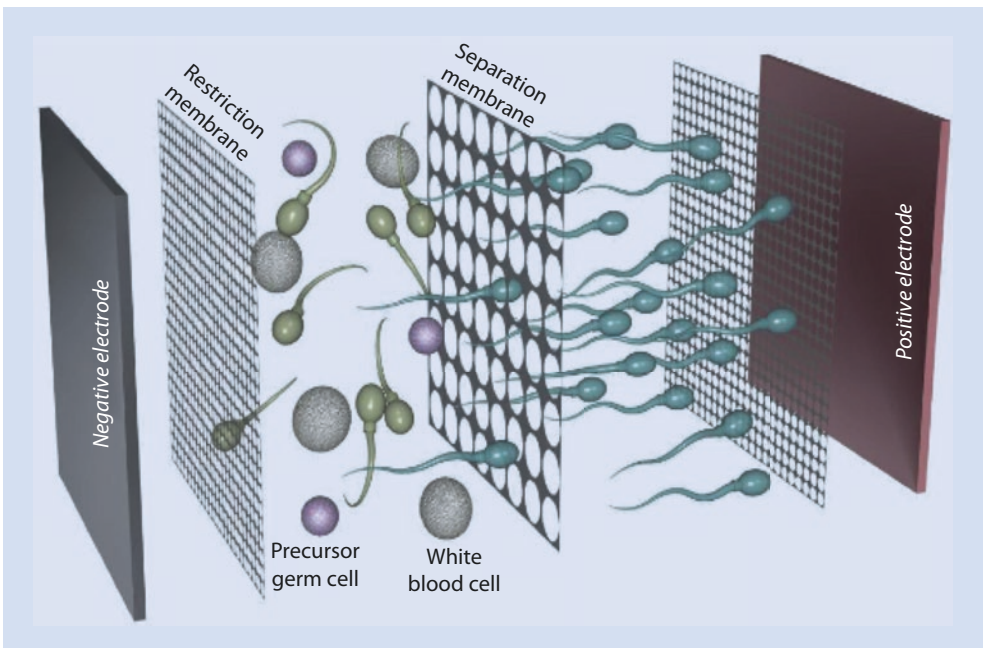
28.2 Equipment Setup and Separation Parameters

28.2.1 Separation Cartridges and Sample Handling

The separation cartridge is a self-assembled device that has an asymmetric design with an inoculation, or loading chamber volume of 2 ml, and a collection, or separation chamber volume of 400 µl (Fig. 28.4). Conveniently, 400 µl is also the estimated mean volume of the human uterine cavity and is, therefore, often the volume of sperm preparation inserted during intrauterine insemination (IUI) procedures. Consequently, the potential exists for electrophoretic sperm separation to be followed immediately by IUI of the entire volume of the sperm preparation retrieved, provided that the prostaglandins present within seminal plasma have been removed or reduced to clinically insignificant levels. However, for the purposes of in vitro fertilization (IVF) and intracytoplasmic sperm injection (ICSI), the spermatozoa could be used directly, provided that they are separated into an appropriate medium within the separation chamber. The component parts of the separation cartridge can be autoclaved to ensure sterility. A 5 µm polycarbonate membrane, with an active membrane area of 30 mm × 15 mm, separates the loading and separation chambers which are bounded by polyacrylamide restriction membranes with a pore size of 15 kDa that prevent cross-contamination between the semen sample and electrophoresis buffer while permitting free transit of electrolytes (Figs. 28.3 and 28.4).

The separation cartridge is inserted into the cartridge housing on top of the CS10 (Fig. 28.1), the housing being designed to ensure the cartridge can only be inserted in the correct orientation. Once the separation unit sealing mecha-

Fig. 28.3 Schematic diagram showing sperm electrophoretic mobility



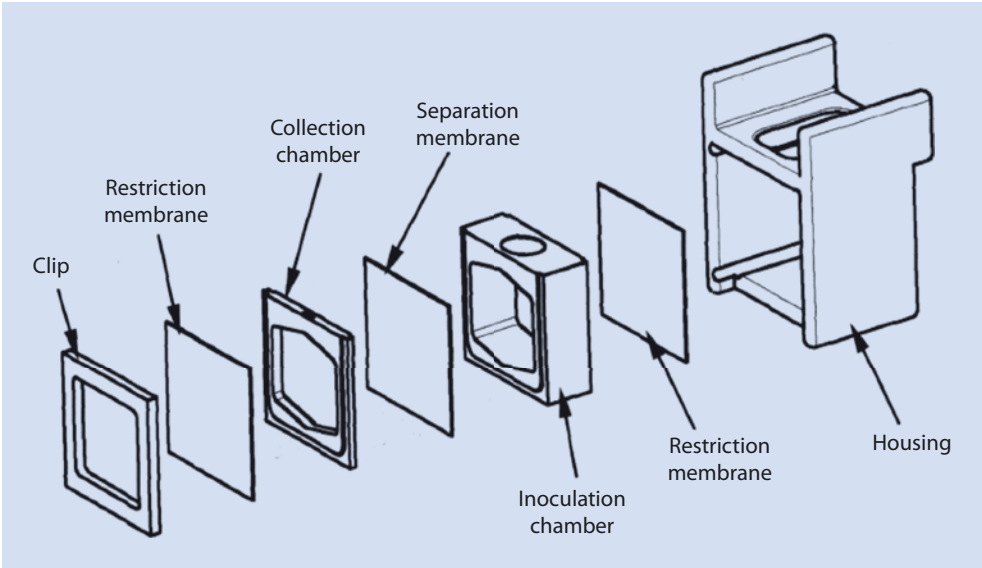


Fig. 28.4 Exploded diagram of the separation cartridge

nism is activated, the cartridge components are made watertight by the application of pressure. Semen samples are simply pipetted into the loading chamber of the cartridge using a sterile, nontoxic, disposable plastic pipette, left for 5 min to equilibrate, and then subjected to electrophoresis. Once separated, the sperm preparation is aspirated from the separation chamber of the cartridge using an elongated, sterile, nontoxic, disposable micropipette tip, as typically used in standard gel electrophoresis.

28.2.2 Electrophoresis Buffers and Temperature Settings

The electrophoresis buffer contains 10 mM HEPES, 30 mM NaCl, and 0.2 mM sucrose, having an osmolarity of 310 mOsm. kg^{-1} and a pH of 7.4, following adjustment using 2 M KOH. It is filter-sterilized prior to use with a 0.22 μm filter (Millipore Corp., Bedford, USA). In order to provide a physiological medium in which to maintain sperm viability, 400 μl of electrophoresis buffer is placed into the separation chamber prior to running a sperm separation. A sterile, disposable buffer reservoir is filled with 80 ml electrophoresis buffer and placed into the reservoir housing in front of the CS10 (Fig. 28.1). In order to prevent overheating during operation of the instrument, the buffer is maintained at 25 °C and is circulated around the instrument by means of a buffer pump (Fig. 28.2). In order to complete the electrical circuit, the buffer pump is run for at least 1 min prior to performing any sperm separations.

28.2.3 Current and Voltage Settings

The input power specifications of the CS10 are 115–240 V or 50–60 Hz. Electrophoresis is achieved via a constant current of 75 mA at a variable voltage of 18–21 V applied over a 5-min period. No electrical potential is applied until the separation run is initiated.

28.2.4 Cleaning of Equipment

At the conclusion of each sperm separation, any electrophoresis buffer remaining in the buffer reservoir is replaced with sterile, distilled water and the buffer pump is actuated to rinse the buffer lines. If no more separations are to be performed that day, the water is replaced with a 0.1 M NaOH cleaning solution, and the buffer pump is run for 30 s to circulate it through the lines of the CS10, and the cleaning solution is left in place overnight. The following morning, the cleaning solution is thoroughly rinsed out with a minimum of three washes of sterile, distilled water.

28.3 Method Validation

Initial validation of the CS10 system was performed using semen samples from normozoospermic sperm donors and a separation cartridge with a symmetrical design, the loading and separation chambers both having a capacity of 400 μl [9].

28.3.1 Sample Recovery and Purity

The mean sample concentration loaded into the system was $52 \pm 5.2 \times 10^6$ ml^{-1}. During an initial 5-min equilibration period, the starting concentration of spermatozoa in the separation chamber was $1.67 \pm 0.58 \times 10^6$ ml^{-1} (3.2% recovery), presumably as a consequence of the inherent motility of spermatozoa. Following just 30s of electrophoresis, the sperm concentration increased to $3.55 \pm 0.42 \times 10^6$ ml^{-1} (6.8% recovery), reaching a peak concentration of $22.31 \pm 5.85 \times 10^6$ ml^{-1} (42.9% recovery) after 15 min. The purity of the electrophoretically separated sperm preparations was extremely high, with contamination by round cells proving undetectable using phase-contrast microscopy [9].

28.3.2 Sperm Vitality and Motility

Sperm vitality, assessed using the eosin dye (0.05% eosin in phosphate-buffered saline) exclusion test, was 83 ± 1.5% in the original semen samples prior to electrophoresis. The percentage of viable spermatozoa in the electrophoretically separated sperm preparations was found to be consistent with that of the original samples and there was no significant change in vitality observed over the entire period (15 min) of electrophoresis [9].

Sperm motility, assessed using computer-assisted semen analysis (CASA), was 72 ± 2.1% in the original semen samples prior to electrophoresis. Similar to sperm vitality, percentage sperm motility was found to be consistent with that of the original samples and not significantly affected by the duration of electrophoresis, though a slight reduction was observed after 15 min [9]. Similarly, kinematic analysis by CASA demonstrated that the duration of electrophoresis had no significant effect upon the quality of sperm motility observed. Experiments in which field strength was progressively increased demonstrated that the sperm motility ultimately declines at higher power settings, particularly when the current was fixed and voltage was allowed to fluctuate [12]. The fact that motility is arrested under such circumstances and conditions where there is no evidence of oxidative stress or increased DNA damage suggests that exposure of human spermatozoa to an electric field might be an ideal means of achieving sperm immobilization in the context of applying ICSI therapy [12].

28.3.3 Sperm Morphology and DNA Integrity

The percentage of normal spermatozoa observed following staining by a modification of the Papanicolaou method [13] and assessed using the sperm deformity index (SDI) [14] was significantly increased ($p < 0.001$) by electrophoresis [9]. A higher percentage of morphologically normal spermatozoa within the separated sperm preparation was observed regardless of the duration of electrophoresis, with no significant variation between different time periods. Furthermore, SDI values for the separated spermatozoa were significantly below ($p < 0.001$) the threshold SDI value of 0.93 for all electrophoretic time points, indicating their normal fertilization potential [14].

DNA integrity, assessed using the terminal deoxynucleotidyl transferase-mediated deoxyuridinetriphosphate nick-end labeling (TUNEL) assay, was significantly reduced ($p < 0.05$) in the sperm preparation separated by electrophoresis [9]. This reduction was only observed at all time points up to 10 min of electrophoresis, beyond which there was no significant difference in the percentage of DNA-damaged spermatozoa.

28.3.4 Analysis of Genotype and Surface Carbohydrate Composition

Electrophoretic isolation of spermatozoa has also been found to generate sperm populations which contain approximately equal numbers of X- and Y-bearing spermatozoa after a 5-min period of separation [15]. Thus, the use of this electrophoretic sperm isolation system should have no significant impact on the gender of the progeny. In terms of the mechanisms underpinning the separation process, it is clear that the intrinsic motility of the spermatozoa is partially involved because the paralysis of sperm movement with benzoquinone does slightly reduce the number of spermatozoa isolated in this system, though not significantly [15]. However, if the surface sialic acid residues are removed from these immobilized cells with neuraminidase, then the number of spermatozoa isolated is significantly suppressed [15]. These observations confirm the overriding importance of surface sialic acid residues in carrying the negative charge that enables the electrophoretic separation process to occur.

28.4 Clinical Applications

The first successful clinical application of electrophoretic sperm separation was published as a case report following ICSI [10]. This provided proof of principle that electrophoresis could be used to prepare spermatozoa for use in assisted reproduction. However, since ICSI had been used to fertilize the oocytes in this instance, it was still unknown whether electrophoresis might compromise aspects of sperm function necessary for normal fertilization. This uncertainty was resolved following a prospective, split-sample, split-cohort controlled clinical trial, involving patients having both ICSI and IVF, with sperm prepared by either standard density gradient centrifugation (DGC) or by electrophoresis [11]. The design of this trial ensured that any differences in gamete quality between semen samples and cohorts of oocytes were controlled for. Approximately 400 oocytes were inseminated by either DGC or electrophoretically prepared spermatozoa, resulting in comparable rates of fertilization (63.6% vs 62.4%, respectively), cleavage (88.5% vs 99.0%, respectively), and embryo quality (26.1% vs 27.4% top grade embryos, respectively), regardless of whether ICSI or IVF was employed as the method of insemination [11]. Furthermore, six pregnancies resulted from the use of electrophoretically prepared spermatozoa, two of them from patients receiving ICSI and four from patients receiving IVF [11].

Previous work has demonstrated that spermatozoa can be efficiently isolated from a variety of sources [10]. Separation of frozen-thawed, cryostored semen ($39.6 \pm 11.1 \times 10^6$ ml^{-1}) resulted in 27% recovery of separated spermatozoa ($10.8 \pm 3.8 \times 10^6$ ml^{-1}) after just 5-min electrophoresis [10]. These sperm preparations were devoid of detectable contaminating cells, the separated spermatozoa displaying significantly greater viability ($p < 0.01$), motility ($p < 0.05$), and normal morphology ($p < 0.001$) than the cryostored semen [10]. Therefore, electrophoresis may prove an advantageous method for preparing cryostored semen, especially since it has recently been shown that such material is particularly

vulnerable to oxidative stress and subsequent DNA damage during processing by standard DGC [16].

A particularly promising potential application of electrophoretic sperm separation is the isolation of spermatozoa exhibiting low levels of sperm DNA damage from more complex mixtures of cells such as those found in surgically recovered aspirates and biopsies of the epididymis and testis. Testicular biopsy material, containing a range of mature and immature spermatozoa, has been shown to rapidly yield cells with greater residual motility, vitality, and normal morphology than those in the original biopsy following electrophoretic sperm preparation [10]. Importantly, the recovery of spermatozoa from the biopsy material was good (28.4 ± 7.1%).

28.5 Closing Remarks

Combined together, the basic scientific and clinical data suggest that electrophoretic sperm separation is particularly suitable for those patients requiring ICSI or IVF where the cause of infertility is due to poor sperm morphology and/or significantly damaged sperm DNA. Though electrophoresis has previously been demonstrated to be detrimental to sperm motility in a free-flow electrophoretic system [17], such impacts on sperm quality do not appear to be a problem with the system described above. The latter would therefore seem to offer some promise as a fast, efficient method for isolating spermatozoa exhibiting low levels of DNA damage for assisted conception applications ranging from IUI to ICSI [11].

Review Questions

1. What are the major approaches used to isolate spermatozoa in the context of assisted reproductive technology (ART)?
2. What are the basic principles underpinning the electrophoretic isolation of spermatozoa?
3. What are the key attributes of the sperm subpopulations isolated with this technique?
4. How has this device performed to date in a clinical setting?
5. Does it represent the future of sperm isolation in an ART context?

Learning Objectives

- Sperm selection strategies in assisted reproduction
- Apoptosis in human spermatozoa
- Basic principles of magnetic cell sorting
- Improvement of assisted reproduction outcome

29.1 Introduction

Magnetic separation has been successfully applied to many aspects of both biomedical and biological research and also in clinical areas like cellular therapies [1] for human autoimmune diseases, like rheumatoid arthritis [2], diabetes [3], multiple sclerosis [4], and systemic lupus erythematosus [5], and nucleic acid transfer as a transfection method [6] to optimize conditions for virus-mediated gene delivery (therapy) by magnetofection [7].

In the last decade, several studies have been carried out on the use of magnetic cell sorting in human reproduction, for decontamination of testicular cell suspensions in cancer patients [8] and for elimination of apoptotic spermatozoa from human semen samples [9–11].

Infertile men with poor sperm motility and morphology were found to have increased sperm DNA fragmentation compared with individuals with normal semen parameters [12]. Men with normal semen analysis may also have a high degree of sperm DNA fragmentation, which can be a major cause of unexplained infertility, and sperm DNA fragmentation may result from aberrant chromatin packaging during spermatogenesis [13], defective apoptosis before ejaculation [14], or excessive production of reactive oxygen species (ROS) in the ejaculate [15]. Exposures to environmental or industrial toxins [16], genetics [17], and lifestyle [18] are also known factors that may cause sperm DNA fragmentation and infertility.

Although the factors present in the paternal genome that may have an impact on poor reproductive outcome are still not well defined, there is accumulating evidence linking sperm nuclear DNA abnormalities to poor reproductive outcome and one of the most suspected organelles is the sperm nucleus. Studies reveal that severe teratozoospermia results in high preimplantation embryo aneuploidy [19, 20] and the interchromosomal effect is related to impaired semen parameters [21]. Studies have also shown that immature sperm have increased rates of lipid peroxidation and bear poor morphometric and morphological attributes, zona pellucida-binding properties, and fertility [22]. The ROS-induced lipid peroxidation is involved in the mechanisms by which spermatozoa are damaged in many cases of male infertility. Studies show a significant correlation between sperm morphology attributes and the expressed apoptotic markers like caspase-3 activation and mitochondrial membrane potential integrity [23].

The sperm nucleus, as the carrier of paternal DNA to the oocyte, remains as the greatest contributor to the potential success of reproductive outcome, where sperm nuclear DNA strand breaks, DNA repair mechanisms, apoptosis, and DNA remodeling processes are the main factors to be considered [24].

A number of novel sperm preparation and selection techniques have now been proposed that may assist in limiting the chance of selecting an abnormal spermatozoon prior to intracytoplasmic sperm injection (ICSI) [25]. In terms of preparing the whole sperm sample and enrichment of high-quality spermatozoa, a novel microfluidic system has been introduced [26]. The use of high-magnification microscopes to identify minor morphological defects of the living spermatozoa [27], selection of mature spermatozoa referring to the binding ability of human spermatozoa to hyaluronic acid [28], and a selection based on sperm membrane charge by a microelectrophoretic method [29] are also mentioned.

Programmed cell death in animals usually occurs by apoptosis. Cells dying by apoptosis undergo characteristic morphological changes. Most importantly, the surface of the cell becomes chemically altered, so that a neighboring cell or a macrophage rapidly engulfs them, before they can spill their contents [30].

An especially important change occurs in the plasma membrane of apoptotic cells. The negatively charged phospholipid phosphatidylserine (PS) is normally exclusively located in the inner leaflet of the lipid bilayer of the plasma membrane, but it flips to the outer leaflet in apoptotic cells by the activity of the enzyme scramblase, where it can serve as a marker of these cells. This process blocks the inflammation associated with phagocytosis. The PS on the surface of apoptotic cells can be visualized with a labeled form of Annexin V protein, which specifically binds to this phospholipid [30].

29.2 The Technique

The Annexin V-coated microbeads are used for the isolation of cells with exposed PS and removal of dead and apoptotic spermatozoa from seminal samples. Briefly, the PS-exposing spermatozoa are magnetically labeled by the protein Annexin V; then the magnetically labeled apoptotic and dead spermatozoa are retained on a magnetic activated cell sorting (MACS) column where the unlabeled non-apoptotic spermatozoa are in the flow-through. At the end, magnetically labeled, PS-exposing spermatozoa can be eluted from the column for various cellular tests (Miltenyi Biotec GmbH, Germany) [31].

The MACS technology is inexpensive and easy to perform. A brief step-by-step protocol is as follows:

- Perform all steps under a laminar air flow hood using aseptic techniques. Use only cell culture-tested disposable materials.
- Allow ejaculate to liquefy and evaluate the seminal parameters.
- Prepare 1 × Binding Buffer from 20 × Stock Solution (Miltenyi Biotec GmbH, Germany).

- Centrifuge sperm cells for 10 min at 300 × g. Remove supernatant and resuspend sperm pellet in 80 µl of 1 × Binding Buffer per 10^7 total sperm count.
- Add 20 µl of MACS Annexin V MicroBeads (Miltenyi Biotec GmbH, Germany) per 10^7 total sperm count, mix gently, and incubate for 15 min at 6°–12 °C, preferably in a temperature-controlled laboratory refrigerator.
- Wash sperm cells by adding 2 ml of 1 × Binding Buffer, centrifuge at 300 × g for 10 min, remove supernatant completely, and resuspend sperm pellet in 500 µl of 1 × Binding Buffer.
- For magnetic sperm separation, use a MS Column (Miltenyi Biotec GmbH, Germany). Place the column in the MACS separator (Miltenyi Biotec GmbH, Germany).
- Prepare column by washing with 500 µl volume of 1 × Binding Buffer.
- Apply sperm suspension in 500 µl amount of 1 × Binding Buffer onto the column. Let the cell suspension pass through drop by drop, and then rinse the column with 500 µl of 1 × Binding Buffer 4 times. Collect the sperm suspension and 2 ml Binding Buffer in the same test tube.
- Evaluate the post-separation sperm values.
- Either perform a density gradient centrifugation or a swim-up preparation on the sperm suspension according to sperm concentration and motility.
- Use the prepared motile sperm cells for intracytoplasmic sperm injection (Fig. 29.1).

29.3 Basic Studies

Several studies using MACS technique with human spermatozoa have been published over the years. Interests in these studies were mainly the molecular efficiency of the technique and improving the post-preparation sperm quality. One of the first studies on the yield of magnetic selection in human spermatozoa came in the mid 2000s. Researchers have evaluated the percentage of sperm recovery following the use of MACS as a sperm preparation technique, and they concluded that the integration of MACS with density gradient centrifugation (DGC) is an effective sperm preparation technique that does not lead to significant cell loss and separating a distinctive population of non-apoptotic spermatozoa with intact membranes might optimize the outcome of assisted reproduction [11]. Later on, the separation effect of MACS on capacitation and acrosome reaction was investigated in the non-apoptotic sperm fractions. Non-apoptotic human spermatozoa with intact plasma membranes were found to be characterized by a superior ability to capacitate and consequently by maximum potential to perform acrosome reaction after stimulation [32].

Studies have also shown that non-apoptotic sperm fractions selected by MACS technique have morphologically superior quality [23]; higher percentage of motility, viability, and apoptosis indices [33]; and routine sperm parameters [34].

At the end of the 1990s, separation of leucocytes from human seminal plasma was successfully performed by magnetic selection [35]. Later on, in the early 2000s, scientists focused on studying molecular analyses on human spermatozoa before and after MACS selection. It was shown that spermatozoa with deteriorated membrane and exposed PS are characterized by an increased lyso-phosphatidylcholine content that is likely generated by phospholipases [36] and also are characterized by an increase in activated caspases, which were found in infertile patients [9].

Reduction of apoptotic spermatozoa within the ejaculate by means of the MACS system results in a distinct reduction of spermatozoa with DNA fragmentation [37], enrichment of spermatozoa free of apoptosis [38], improvement of sperm viability, motility, and mitochondrial membrane integrity [39], elimination of aneuploidy [40], and enrichment of spermatozoa with good chromatin quality for both normozoospermic and also asthenoteratozoospermic seminal values [41].

The first report on the initiator and effector caspases of the main pathways of apoptosis in ejaculated human spermatozoa came in the early 2000s, and in that study, activated caspases were found especially in spermatozoa with disturbed membranes, where cryopreservation was used as a tool for increasing the number of spermatozoa showing an activation of caspases [42]. Further studies were performed on human sperm cryopreservation and the benefit of MACS on eliminating apoptotic sperm fractions from frozen-thawed semen samples. Studies revealed out that MACS separation before cryopreservation results in depletion of spermatozoa which are positive for activated caspases [10], depletion of low-quality spermatozoa from cryopreserved semen samples [43], and selection of a population of non-apoptotic spermatozoa which optimizes cryopreservation and thawing outcome [44].

29.4 Clinical Use

The integrity of the paternal genome is of paramount importance in the initiation and maintenance of a viable pregnancy in both natural and assisted reproduction. Studies have investigated the sperm's fertilizing potential using hamster oocyte penetration assay [45], and results suggested that non-apoptotic spermatozoa prepared by MACS display higher fertilization potential following ICSI, and this technique should be evaluated in a clinical setting for its impact on ICSI outcomes [46]. Studies also showed a reduced level of apoptotic markers, improved acrosome reaction scores [47], and superior morphological quality [48] after MACS preparation which may contribute to increased implantation and pregnancy rates.

The first assisted reproduction data and clinical pregnancies in the world with the use of MACS as a sperm preparation method in human assisted reproduction were presented in 2006 in a local meeting [49] as a preliminary study. MACS preparation did not yield any statistically significant improvement in terms of fertilization and embryo cleavage rates and embryo quality. This was related to the limited number of cases by the authors.

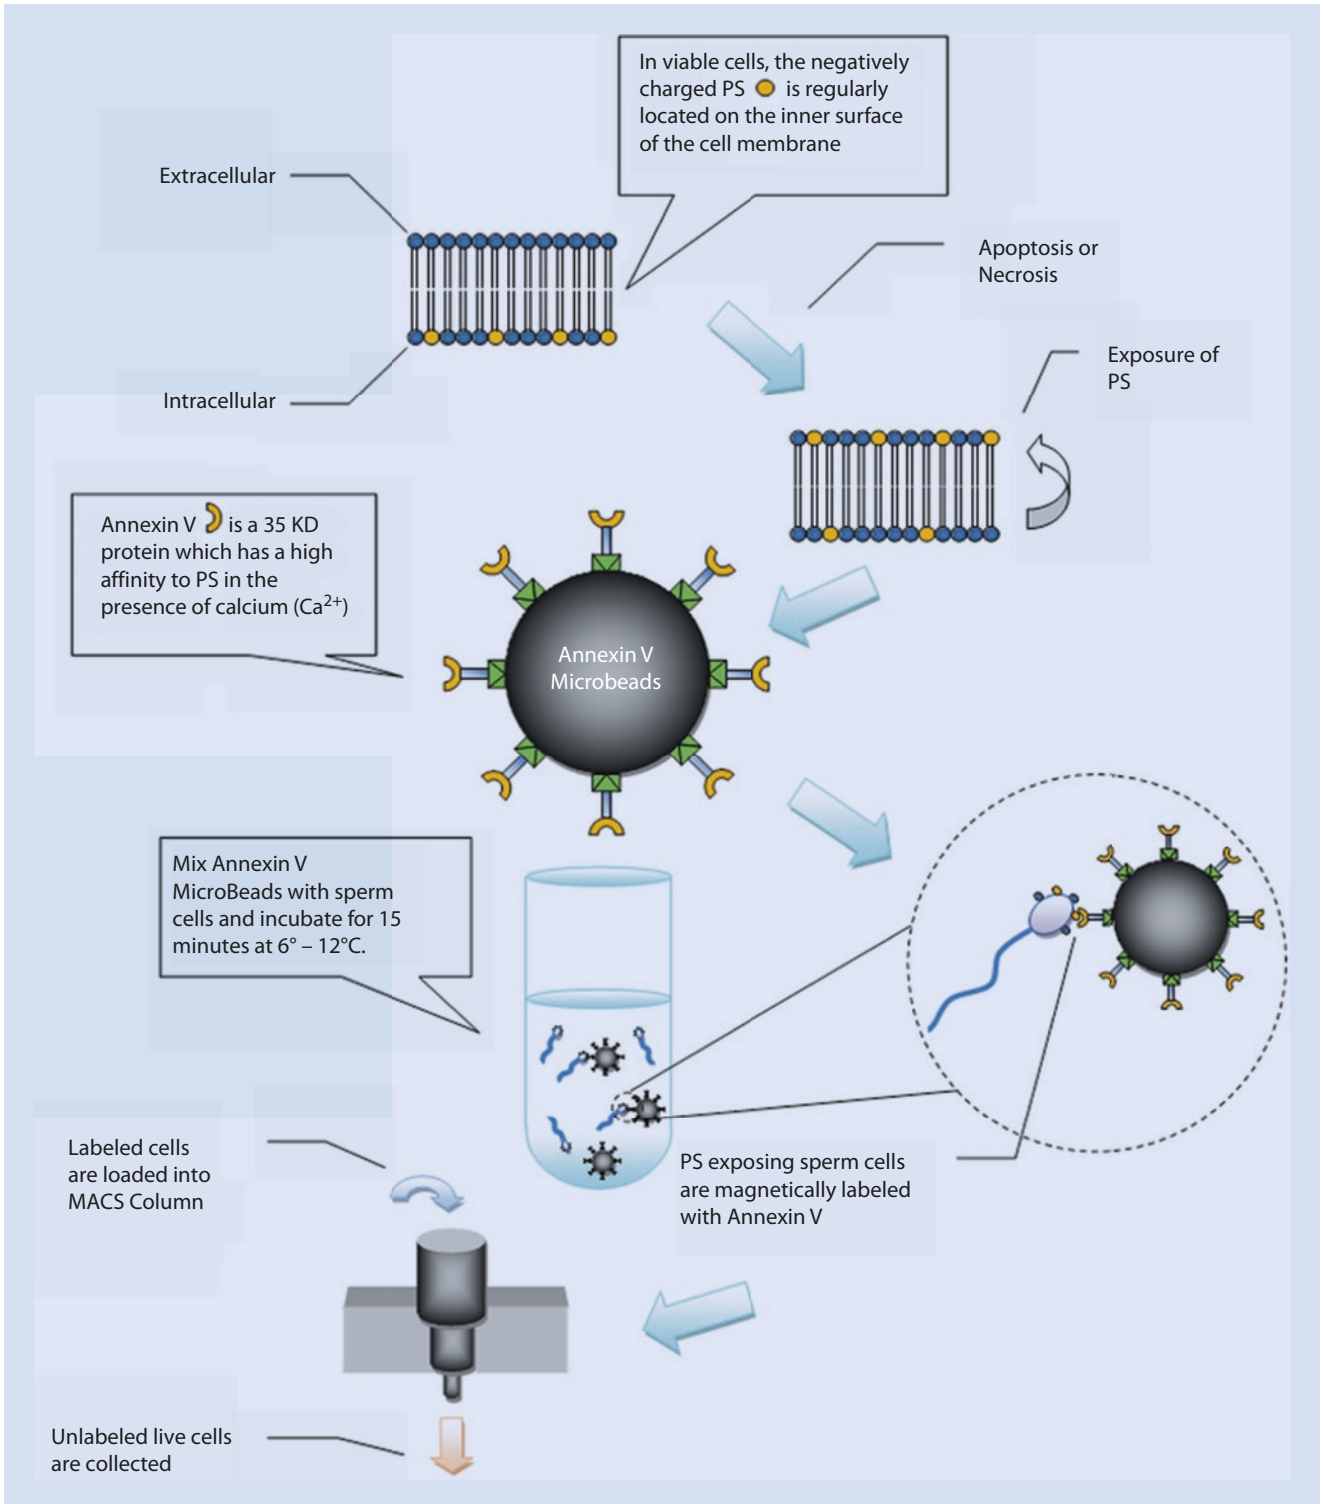

Fig. 29.1 The MACS technology is inexpensive and easy to perform. A brief step-by-step protocol is as follows

In 2008, a prospective study was published to assess the impact of MACS technique for selection of non-apoptotic spermatozoa on the outcome of ICSI [31]. The study compared the cleavage, fertilization, implantation, and pregnancy rates associated with two sperm preparation methods, MACS and DGC, in male factor cases. Although there were no significant differences between the two groups in terms of fertilization rates and embryo quality, there was a statistically significant improvement in the cleavage rate of the MACS group embryos. This difference resulted in a significantly

higher number of embryos on the embryo transfer day, by reducing the number of arrested embryos during in vitro culture [43]. Early embryo arrest is associated with possible deleterious factors [50–52] that can be introduced into the human oocyte by spermatozoa [53, 54] and impair the assisted reproduction outcome.

Another study reported 3 ongoing clinical pregnancies out of 10 cases by using MACS as a sperm preparation technique [55]. They also represented their first healthy baby born after MACS technique [56].

In 2013, healthy live births were reported after the use of MACS in cryopreserved spermatozoa [57]. A 4-year-old boy born after MACS-ICSI-TESA was examined for psychological and somatic scores and was found healthy in 2015 [58]. A unicentric, prospective, and randomized study was reported in 2015 on the outcome of MACS and hyaluronic acid binding, where MACS yielded higher clinical pregnancy rates [59]. But on the other hand, a Cochrane Review did not find any evidence on the effects of MACS on assisted reproduction outcome [60]. In order to address the safety issues, obstetric and perinatal outcome of babies born from sperm selected by MACS were examined and it was concluded that MACS technology did not increase or decrease adverse obstetric and perinatal outcomes [61].

A number of studies have shown that using spermatozoa prepared with MACS technique significantly improves the quality of post-preparation spermatozoa. These studies indicate that MACS enriches the sperm population by eliminating apoptotic, necrotic, chromosomally abnormal, and DNA-fragmented spermatozoa [38–40]. A systematic review was designed to evaluate the efficacy of MACS on assisted reproductive technology (ART) success rates and concluded that it appears to be safe and efficient to select spermatozoa [62]. On the other hand, a controlled and randomized trial implied that in an unselected male population, MACS did not have any beneficial effect on ART outcome both in terms of embryo quality and also pregnancy rates [63]. Unfortunately, there is no clear evidence that MACS technique has improved implantation and live birth rates in large clinical trials. Recently, a good manufacturing practices (GMP) product was introduced in the market which will be useful to put the MACS technique into clinical use in assisted reproduction.

Review Questions

1. What is the purpose of eliminating apoptotic spermatozoa prior to assisted reproduction?
2. Explain the depletion and enrichment techniques in magnetic cell sorting technologies.
3. What are the advantages of sperm selection in terms of improving assisted reproduction outcome?

Learning Objectives

Upon reading this chapter, the practitioner will be able to:

- Learn the indications for IUI.
- Learn the good medical practice-based workup of the infertile couple for IUI.
- Have an overview about the correct ovarian stimulation protocols for IUI.
- Know the correct techniques of sperm preparation for IUI.
- Physicians will learn the finer nuances of the correct technique of IUI.
- Learners will know how to overcome difficult IUIs and learn how to develop motor and cognitive skills for performing "ideal" IUIs.
- The goal is for practitioners to have an updated knowledge about the subject with recent advances in the field.

30.1 Introduction

Despite revolutionary advances in the field of assisted reproduction, such as in vitro fertilization (IVF), intracytoplasmic sperm injection (ICSI), and subzonal insemination (SUZI), intrauterine insemination (IUI) remains an inexpensive, non-invasive, and effective first-line therapy for selected patients with cervical factor, moderate male factor, unexplained infertility, immunological infertility, and infertility due to ejaculatory disorders and is now also proposed as a therapy for endometriosis, ovarian dysfunction, and even for tubal factor infertility. Though the technique of IUI has essentially remained the same, several advances in the type of stimulation protocols, gonadotropins, sperm preparation techniques, and ultrasound monitoring have led to promising success rates with IUI. IUI involves a pre-procedure evaluation including a thorough physical, clinical, and laboratory evaluation to determine the duration and etiology of infertility, semen quality, functional tubal status, and the follicular and uterine status. Controlled ovarian hyperstimulation with close monitoring of folliculogenesis and ovulation to avoid adverse complications, such as ovarian hyperstimulation syndrome (OHSS) and multiple pregnancies, may be used to obtain the adequate number of follicles. Following induction of ovulation with human chorionic gonadotropin (hCG), the processed semen sample is then inseminated in the uterine cavity. The objective in terms of preovulatory follicle number must be determined prior to stimulation in order to optimize the cycle outcome with a singleton birth [1]. IUI is the preferred conception-enhancing technique for women <35 years, functional tubes, short period of infertility, and moderate male infertility, particularly in technology-limited settings, and four to six IUI cycles may be performed before considering alternate therapy such as IVF [2, 3]. It is the method of choice vs. timed intercourse or natural cycle IUI [1]. The following sections will deal with the indications for IUI, technique, stimulation protocols, alternative insemination techniques, and prognostic factors that determine the outcome.

30.2 Indications for IUI

30.2.1 Cervical Factor Infertility

In couples with a cervical factor, diagnosed by a well-timed, non-progressive post-coital test with normal semen parameters [4], higher pregnancy rates (PRs) have been reported following IUI compared to expectant management (51% vs. 33%, respectively) [5] with acceptable pregnancy rates even without COH (9.7%) and without an increased risk for multiple pregnancy compared to COH (12.7%) [4]. Cumulative pregnancy rates of 19.7%, 36.8%, and 36.8% have been reported for a maximum of three IUI cycles in patients with a cervical factor without superovulation [6].

30.2.2 Male Factor Infertility

A male factor may be diagnosed if the semen analysis at an initial microscopic examination demonstrates low sperm count, motility, morphology, antisperm antibodies, or any combination of these or advanced testing indicates subnormal sperm function. While IUI is considered the best first-line treatment and most cost-effective procedure for moderate male factor subfertility [7], severe male factor infertility with a significant deterioration in sperm parameters or function may necessitate a direct referral to IVF or ICSI in that order, depending on the degree of severity [8]. Pregnancy rates of 12.8%, 29.3%, and 38.3% for a maximum of three cycles have been reported in couples with a male factor without superovulation [6], 7% per cycle following COH-IUI with clomiphene citrate (CC), and 12% per cycle with follicle-stimulating hormone (FSH) with multiple birth rates averaging 13% [9].

30.2.3 Unexplained Infertility

Despite the belief that IVF may be a more cost-effective primary treatment option compared to IUI in lieu of the low success rates with IUI and the subsequent requirement for IVF in the event of failure [10], the results of randomized controlled trials (RCTs) using live birth rates rather than pregnancy rates, and taking into account efficacy, complications, especially multiple pregnancy rates, patient compliance, and cost-efficiency, suggest that the initial treatment for idiopathic infertility should be IUI as opposed to IVF [11]. Although the pregnancy rate per cycle was higher in the IVF group than in the IUI groups [12.2% vs. 7.4% (spontaneous cycle) and 8.7% (COH-IUI), respectively; $p = 0.09$], the cumulative pregnancy rate for IVF was not significantly better than that for IUI. Moreover, the drop-out rates before a maximum of six attempts were higher in the IVF group compared to the IUI groups (42% vs. 15% and 16%, respectively; $p < 0.01$) [12].

30.2.4 Tubal Factor

Lower cumulative PRs have been reported in couples with isolated unilateral tubal occlusion compared to unexplained infertility after three cycles of COH-IUI (30.9% vs. 42.6%); cumulative PRs were lower in women with mid-distal or distal tubal occlusion compared to women with proximal tubal occlusion (19% vs. 38.2%) and significantly lower than in women with unexplained infertility (19% vs. 42.6%, respectively). Hence, though COH-IUI can be suggested as the initial treatment of choice in patients with unilateral proximal tubal occlusion, patients with mid-distal or distal tubal occlusion on hysterosalpingography (HSG) should be referred for laparoscopic assessment or IVF [13].

30.2.5 Endometriosis

An estrogen-dependent disorder, defined as the presence of endometrial tissue outside of the uterine cavity, endometriosis is a leading cause of infertility with a prevalence of 0.5–5% in fertile and 25–40% in infertile women [14]. Controlled ovarian hyperstimulation with IUI is recommended in early-stage and surgically corrected endometriosis when the pelvic anatomy is normal, while combined surgery with gonadotropin-releasing hormone (GnRH) analogue treatment has been proposed to be a first-line therapy followed by IVF as second-line therapy in advanced cases [15]. Comparable clinical PRs per cycle have been reported in women with minimal, mild endometriosis and unexplained infertility (21% vs. 18.9% vs. 20.5%) following COH-IUI with comparative cumulative live birth rates within four cycles of COH and IUI (70.2%, 68.2%, 66.5%, respectively); CPR/cycle with or without COH-IUI was lower in women with surgically untreated minimal to mild endometriosis than in women with unexplained infertility [16]. However, in patients with minimal or mild endometriosis with pathological uterotubal transport documented by hysterosalpingoscintigraphy (HSSG), IUI yields poor pregnancy rates despite normal semen parameters and patent fallopian tubes, necessitating recourse to IVF/ICSI [17]. Though IVF reduces time to pregnancy in early-stage disease compared to controls, it does not increase the chance of pregnancy after 3 years [18]. In patients with stage IV endometriosis and in women >38 years of age, significantly higher PR, fecundity, and cumulative fecundity have been reported following in vitro fertilization-embryo transfer (IVF-ET) compared to COH-IUI. Hence, IVF-ET should be the first-line approach in the management of infertility in such patients, and if COH-IUI is attempted, it should not exceed three to four cycles [19].

30.2.6 Contraindications

IUI may be contraindicated in women with sperm-immobilizing antibodies owing to antibodies secreted in the female reproductive tract that might impair sperm passage, inhibit fertilization, and prevent normal postfertilization processes [20]. Couples with severe male factor infertility, abnormal pelvic anatomy, not amenable to microsurgical repair; fallopian tube disease with an impaired ampullary mucosal architecture; advanced stage endometriosis (stages III and IV); or minimal/mild endometriosis (stages I and II) with documented failure in tubal transport may directly benefit from IVF/ICSI with or without surgical interventions. The total antral follicle number is reported to decrease with age ($P < 0.0001$). In women >35 years with antral follicle counts (AFCs) <5, the application of COH/IUI may not be indicated [21].

30.2.7 Workup Before IUI

Major causes of infertility include male factors, ovarian dysfunction, tubal disease, endometriosis, and uterine or cervical factors. A careful history and physical examination of each partner can reveal the underlying etiology and guide further management of infertility.

Investigations that must be carried out in the female partner include:

- Evaluation of folliculogenesis and documentation of ovulation by transvaginal sonography (TVS) or with a home urinary luteinizing hormone kit.
- Evaluation of the functional tubal status by HSG, confirmed by a laparo-hysteroscopy in case of an abnormality, which has diagnostic and therapeutic power and may guide future management.
- Further, a HSSG in patients with minimal or mild endometriosis may help document pathological uterotubal transport characteristic of the disease, necessitating IVF/ICSI despite normal semen parameters [17].
- A complete hormone evaluation including FSH, luteinizing hormone (LH), and thyroid hormone profile.
- Ovarian reserve testing of FSH and estradiol (E2) levels on day 3 of the menstrual cycle, the clomiphene citrate challenge test, or pelvic ultrasonography for AFC in women >35 years to determine treatment options and the likelihood of success [22].
- Testing for antisperm antibodies (ASAB) in the serum and cervical mucus.
- Infections such as chlamydial salpingitis, genital tract tuberculosis, and those caused by *Chlamydia trachomatis* and *Neisseria gonorrhoeae*.
- Testing for HIV/hepatitis.

30.2.8 Male Partner

- A thorough semen analysis. Abnormal seminograms of infertile men may be classified as azoospermia (no sperm in the ejaculate), oligozoospermia (sperm count <15 million/mL), cryptozoospermia (spermatozoa absent from fresh preparations but observed in a centrifuged pellet), teratozoospermia (normal sperm

morphology <4%), asthenozoospermia (progressive motility <32%), necrozoospermia (>58% dead sperm), or a combination of any of these conditions.
- Sperm function tests to evaluate sperm survival, viability, acrosome reaction, and sperm fertilizing ability.
- Testing for antisperm antibodies.
- Semen culture and sensitivity to evaluate infection.
- Testing for HIV/hepatitis.

30.3 Natural Cycles or Controlled Ovarian Hyperstimulation?

IUI may be performed with or without controlled ovarian hyperstimulation depending on the patient characteristics.

30.3.1 Natural Cycles

A majority of studies have reported better IUI outcomes in terms of the number of preovulatory follicles, clinical and ongoing pregnancy rates (OPRs), and live birth rates following ovulation induction (OI) compared with the natural cycle [23–28]. Significantly higher pregnancy rates have been reported following ovulation induction with CC/CC + gonadotropins/gonadotropins alone compared to natural cycles in husband (AIH) inseminations [26, 27] (Table 30.1), while no significant differences were observed between natural cycles and donor insemination (DI) cycles [27]. The overall pregnancy rates for AIH and DI cycles were 8.6% and 20.2%, respectively [27]. Pittrof et al. [23] reported a significantly higher number of preovulatory follicles (43.6%, 59.9%, 12.6%, $P < 0.0001$) and significantly higher pregnancy rates ($P = 0.038$) in CC/tamoxifen + gonadotropin-stimulated cycles compared to natural cycles [23]. However, Chen and Liu [26] concluded that though stimulated IUI is superior to natural cycle IUI in patients <35 years, natural cycle is preferable for patients ≥35 years. There were no significant differences in the abortion and delivery rates between the OI and the natural cycle insemination ($P > 0.05$) [26]. IUI in the spontaneous cycle carries fewer health risks than does IUI after mild hormonal stimulation and, therefore, should be the first-choice treatment [12].

30.3.2 Controlled Ovarian Hyperstimulation

Controlled ovarian hyperstimulation (COH) can be used in conjunction with IUI in couples with infertility factors not involving the fallopian tubes to increase the number of available oocytes at the site of fertilization [29, 30]. Ovarian stimulation is initiated after the selection of the dominant follicle, mostly on the fifth day of the cycle. Several drugs, including clomiphene citrate (CC), tamoxifen, aromatase inhibitors, and gonadotropins alone or in conjunction with GnRH agonist/antagonist, have been used for ovulation induction in various protocols that may be individually tailored according to the patient. These regimens and protocols and clinical evidence of their benefits are discussed in the following sections.

30.3.3 Clomiphene Citrate

Ovarian stimulation by clomiphene citrate (CC) and IUI remains the first-choice treatment for ovulatory dysfunction, unexplained infertility, endometriosis, or male subfertility [27] with pregnancy rates averaging 7% per cycle [8]. Clomiphene citrate, an antiestrogenic agent, is often administered for 5 days from day 3 to 7 of the menstrual cycle in doses of 50 mg once/twice a day. However, pelvic abnormalities, especially ovarian cysts, must be excluded prior to CC administration. Owing to the negative influence of CC on endometrial thickness, the medication should be reduced to 3 days in patients with retarded endometrial growth confirmed by ultrasonography [31]. Though no consensus exists about the drug of first choice to be used as hyperstimulation and there are no significant differences in clinical pregnancy (38% vs. 34.3%) and live birth rates (28.2% vs. 26.9%) between CC and recombinant FSH (rFSH), a randomized multicenter parallel trial concluded that being less expensive, CC seems to be the more cost-effective drug and, therefore, can be offered as drug of first choice [32].

30.3.4 Gonadotropins

Gonadotropins, such as FSH and human menopausal gonadotropin (hMG), alone or in conjunction with GnRH agonist/antagonist, are often used for ovulation induction. The dose and mode of administration of gonadotropins are adjusted according to the individual patient and may be varied depending on the response. The response of the patient to gonadotropins is monitored regularly by TVS. A meta-analysis of 43 trials involving 3957 women concluded that gonadotropins might be the most effective drugs when IUI is combined with ovarian hyperstimulation, yielding higher pregnancy rates compared to antiestrogens, comparable PRs with different types of gonadotropins, no improvement with GnRH agonist or antagonist but increased multiple pregnancy rates and OHSS rates with increased doses of gonadotropins, and significantly higher multiple pregnancy rates with the agonist. When gonadotropins are used for ovarian stimulation, low-dose protocols are advised since pregnancy rates do not differ from those obtained with high-dose regimens, whereas the chances to encounter negative effects from ovarian stimulation such as multiple pregnancies and OHSS are limited with low-dose gonadotropins. Further research is needed for each comparison made [33]. No significant differences have been reported among low-dose gonadotropin proto-

Table 30.1 Comparison in the clinical pregnancy rates following stimulation with various regimens and IUI

Study	Natural cycles	Stimulation regimens								*P* value
		CC	CC + gonadotropins		Tx + G	Aromatase inhibitors		Gonadotropins		
			hMG	rFSH		Letrozole	L + rFSH	hMG	rFSH	
Baysoy et al. [41]						18.4		15.7[a]		
Tehrani Nejad et al. [40]			14.3			32.8				<0.01
Gregoriou et al. [45]						8.9			14.0	
Barroso et al. [38]				20			23.8[b]			
Mitwally and Casper [43]							26.5		18.5	
Bedaiwy et al. [42]							15.77		18.07	
Mahani and Afnan [25]	2.0 (12.0)	4.0 (7.0)	7.0 (16.0)					9.0 (23.0)		
Pittrof et al. [23]	20.1		23.6		29.9					0.038
Chen and Liu [26]	11.35		19.61							<0.01
Custers et al. [27]	6.3	12.5	16.4					11.2		

CC was administered at a dose of 100 mg/day from day 3 to 7 of the menstrual cycle. Letrozole was administered at a dose of 5 mg/day from day 3 to 7 of the menstrual cycle unless otherwise specified. Gonadotropins were administered at a dose of 75 IU from day 6 to 7 of the menstrual cycle until hCG administration

Values in brackets represent CPR/patient

Tx + G tamoxifen + gonadotropins

[a]hMG was administered on day 3 at a dose of 75 IU for women <30 years old and 150 IU for women >30 years old

[b]Letrozole was administered at a dose of 2.5 mg/day from day 3 to 7 of the menstrual cycle

cols that differed in gonadotropin dosage (4/6/8/ampoules of 75 IU FSH) or the mode of administration in terms of cycle parameters, suggesting that an individualized and more intensive approach to ovarian stimulation is necessary for many women with unexplained infertility [34]. Lyophilized urinary hMG (HP-hMG) and rFSH are equally suitable in mild ovarian stimulation for IUI in patients with unexplained infertility. However, data derived from a larger study population are needed to determine whether higher amounts of two gonadotropins in this subgroup might produce any benefits or unfavorable effects [35].

With regard to the mode of administration, daily recombinant FSH (follitropin-beta) stimulation has been associated with higher CPRs (42% vs. 19%, respectively), higher total recombinant FSH dose (825 IU vs. 625 IU), and endometrial thickness (10.1 mm vs. 9.3 mm) compared to alternate-day FSH stimulation in women with anovulatory or unexplained infertility for over 12 months who had not responded to or not conceived with CC treatment though the duration of stimulation and the median number of follicles over 14 mm, AFC, and day 3 serum FSH were comparable between the groups. However, prospective randomized trials would be needed to determine whether this is indeed the case [36]. Mahani and Afnan [25] reported the highest CPRs/cycle and CPR/patient following IUI in patients stimulated with hMG compared with CC, CC + hMG, or natural cycle.

30.3.5 Combination Protocols

Clomiphene citrate may be used in conjunction with gonadotropins/dexamethasone for stimulation. Combination protocols are less costly and equally effective, with potentially fewer multiple births than with gonadotropins alone with fewer days of injections and fewer ampoules used. The advantages of a combination protocol in terms of pregnancy rates are depicted in Table 30.1. Although tamoxifen (40 mg/day from day 3 to 9) may not be a first-line treatment in patients with adequate endometrium, it may be a promising alternative for patients with a thin endometrium, yielding increased endometrial thickness ($P < 0.001$), CPR ($P = 0.015$), decreased early miscarriage rate ($P = 0.001$), and, thus, improved ongoing pregnancy rate ($P < 0.001$) compared to CC (100 mg/day for 5 days), despite a higher gonadotropin dose and stimulation duration and fewer follicles larger than 14 mm than clomiphene-treated patients [37].

30.3.6 Aromatase Inhibitors

Studies have reported a beneficial effect of the use of the aromatase inhibitor letrozole (2.5–5 mg/day from day 3 to 7 of the IUI cycle) alone/coadministered with gonadotropins compared to CC, CC + gonadotropins, or gonadotropins alone in terms of comparable if not higher CPR/cycle and take-home

baby rates. Significantly higher serum levels of LH, endometrial thickness, and progesterone at the time of hCG administration have been observed despite a significantly lower serum E2 level [37–39] with significantly lower costs, risks, and patient inconvenience in patients with unexplained infertility [37, 38, 40, 41], endometriosis, and combined indications [42] and lower FSH dose requirement and IUI cancelation rates in patients with ovulatory infertility [43] and older infertile women [39]. Letrozole may be more effective than clomiphene and tamoxifen in a combination protocol [44] and beneficial in patients who fail to respond to CC [45] (Table 30.1). The improved follicular response to aromatase inhibitors has been attributed to aromatase inhibition, a release in the estrogenic negative feedback, increased endogenous FSH secretion, and increased follicular sensitivity to FSH [43].

30.3.7 Additives

Abdel Razik's study evaluated the effects of nitric oxide donor's treatment on the pregnancy rate and uterine blood flow in patients with unexplained infertility undergoing clomiphene citrate stimulation and intrauterine insemination [46]. A total of 120 patients were randomly allocated to a control group who received 100 mg clomiphene citrate daily from day 5 to 9 of cycle plus placebo vaginal tablets, and a study group received clomiphene citrate plus isosorbide mononitrate 10-mg vaginal tablets. Vaginal ultrasound was done before treatment and every other day starting from day 12 of cycle to count mature follicles, and ovulation was triggered by IM injection of 10,000 IU hCG when one follicle measured ≥ 18 mm followed by intrauterine insemination after 36 h. The endometrial thickness, uterine arteries' resistance and pulsation indices, and endometrial vascular flow and vascular flow indices were measured before treatment and at the day of hCG injection. Results were analyzed after one cycle treatment using the mean ± SD, the student t test, and the Fisher Exact test. Significant result was considered at p values < 0.05. The study group had significant higher pregnancy rate/cycle and higher endometrial and lower uterine artery blood flow indices ($p < 0.05$) [46].

30.3.8 Stimulation Protocols

Various gonadotropin stimulation protocols have been employed depending on the patient characteristics. Stimulation may be initiated on the first day of a cycle (the short protocol) or in the cycle preceding the "proper" stimulation cycle (the long protocol).

30.3.9 The Short GnRH Analogue Protocol

GnRH analogue (0.1 mg Decapeptyl/triptorelin) is administered daily from the first day of a cycle until hCG administration, resulting in a gonadotropin flare-up effect. Gonadotropin administration (hMG/FSH) is initiated from the third day of the cycle in a step-up/step-down protocol, doses being adjusted individually according to patient requirements.

30.3.10 Step-Up Protocol

Generally, hMG is administered in a daily dose of 150 IU that may be stepped up to 225 IU when one or more follicles are ≥14 mm and the dose maintained until hCG administration. Low-dose step-up FSH treatment has been associated with a significant reduction in the incidence of OHSS compared to the conventional dose (8.3% vs. 27.1%, $P < 0.05$) and a significant decrease in the incidence of moderate OHSS requiring hospitalization (0% vs. 16.7%, $P < 0.01$) in patients with unexplained infertility despite comparable pregnancy rates. However, multiple pregnancies cannot be completely prevented with the low-dose protocol [47].

30.3.11 Step-Down Protocol

Gonadotropins (hMG) are administered in a daily dose of 225 IU that may be stepped down to 150 IU if an excessive reaction to stimulation is expected.

30.4 The Short GnRH Antagonist Protocol

30.4.1 Fixed Dose Protocol

Following the initiation of gonadotropins on day 3 of the menstrual cycle, antagonists, such as cetrorelix/ganirelix, are administered in a fixed dose (0.25–0.5 mg/day) when one or more follicles are ≥14 mm until hCG administration.

30.4.2 Flexible Dose Protocol

Following the initiation of gonadotropins on day 3 of the menstrual cycle, antagonists, cetrorelix/ganirelix, are administered in a flexible protocol (0.25 mg/day) when the leading follicles are 14 mm until hCG administration.

30.4.3 Low-Dose Protocol

Studies testing the effectiveness of GnRH antagonists in controlled ovarian stimulation (COS) for intrauterine insemination (IUI) have provided controversial results. A very recent study was undertaken to evaluate whether the use of a half of the conventional dose of the GnRH antagonist cetrorelix can be effective in increasing the successful rate of IUI cycles [48]. Patients started COS with human menopausal gonadotropin (hMG) on day 3 of the menstrual cycle. Cetrorelix was started when at least one follicle of ≥14 mm was detected in the ultrasound scan, according to the flexible multiple daily

dose protocol, and continued until the trigger day with recombinant hCG. Patients adopting GnRH antagonist at low dose had a pregnancy rate (21.7%) that was significantly higher ($p < 0.05$) in comparison to women receiving hMG only (8.7%). These results suggest that adding a reduced dose of GnRH antagonist to the COS for IUI cycles significantly improves the outcome of the procedure [48].

30.4.4 Scheduling IUI with GnRH Antagonists

In Spanish public hospital reproduction units, it is very problematic to perform programmed intrauterine insemination (IUI) on weekends, if indicated. Small previous pilot studies suggest that using a GnRH antagonist to avoid an LH weekend surge would allow to perform IUI on the following Monday, not impairing the expected pregnancy rate [49]. Between first January 2007 and 31st December 2015, 4.782 intrauterine inseminations were performed at Valladolid University Clinic, Spain, corresponding to 1.650 women. Of them, 911, corresponding to 695 women, should ideally have been performed during the weekend. If it happened that a member of the reproduction unit was on duty during that particular weekend, the standard protocol was not interrupted and the IUI performed as planned (control group, 685 IUIs). If the former was not the case, the weekend gap was bridged by administering 0.25-mg GnRH antagonist (GnRHa). Ovulation was induced by means of 250-μg recombinant HCG (rHCG) 36 h prior to IUI on the following Monday (study group, 226 IUIs). There were no differences in the clinical pregnancy rate (13.7% vs. 16.2%, $p = 0.371$) or in the ongoing pregnancy rate between groups (11.9% vs. 14.9%, $p = 0.271$). The multiple pregnancy rate was also comparable in both groups (14.7% vs. 18.5%, $p = 0.77$). Women with a planned IUI which cannot be performed at the ideal date can be offered postponement for 2 days with the support of GnRHa treatment, with results that are not inferior to those expected applying the regular protocol [49].

30.4.5 The Long GnRH Agonist Protocol

The long agonist protocol involves the subcutaneous (s.c.) administration of 0.1 mg Decapeptyl from the midluteal phase (the 21st day of the cycle preceding the proper stimulation cycle) and until hCG administration. Optimally, gonadotropin stimulation is initiated following pituitary downregulation, identified by estradiol (E2) levels <50 pg/mL and no ovarian follicle larger than 14 mm. However, stimulation may be started if there is a follicle >14 mm with E2 levels <50 pg/mL. Gonadotropins may be administered in a step-up or step-down protocol [32].

30.4.6 Ultra-long Agonist Protocol

The ultra-long agonist protocol (ULP) involves the subcutaneous (s.c.) administration of a single injection of 3.75 mg Decapeptyl followed by daily s.c. Decapeptyl (0.1 mg) administration 4 weeks later and until hCG administration. Gonadotropin stimulation is initiated once pituitary desensitization is achieved as assessed by serum E2 levels ≤100 MIU/mL. hCG, 10,000 IU, is administered when one or more leading follicles are ≥18 mm followed by IUI on evidence of follicular rupture on TVS or 34–36 h after hCG administration. A protocol of recombinant FSH (50 IU daily) and ganirelix (0.25 mg) fixed dose protocol is reported to represent an effective and safe regimen for ovulation induction, associated with a lower rate of mono-ovulation (53.3% vs. 78.8%, $P = 0.06$) and higher CPR per initiated cycle (34.4% vs. 5.9%, $P = 0.005$) compared to alternate-day FSH treatment in couples with unexplained infertility or moderate male subfertility [50]. However, the efficacy of the antagonist in preventing premature luteinization is disputed with some studies reporting in favor [51] and others against [52, 53].

Kutlu et al. assessed the relationship between the estrogen-progesterone alterations before and after ovulation trigger and treatment success in intrauterine insemination (IUI) cycles [54]. Two hundred fifty-one women with infertility underwent ovulation induction followed by IUI. For all subjects, estradiol and progesterone concentrations were evaluated on the trigger and IUI day. The results were analyzed to assess the relationship between hormone levels and positive pregnancy test. There were 34 women with a positive pregnancy test following controlled ovarian stimulation and IUI cycle. Estradiol and progesterone levels on the trigger day and the day of IUI were compared within groups with and without positive pregnancy tests. The comparison revealed significantly increased levels of progesterone after trigger in both groups; however, although there were estradiol level drops in both groups, the drop in the group with negative pregnancy tests was statistically significant. Significant drops in estradiol concentrations after ovulation trigger are associated with IUI cycle treatment failure [54].

30.4.7 Expectant Management

Some randomized trials report that COH-IUI and unstimulated IUI do not offer substantial benefit in couples with unexplained subfertility in terms of CPRs, OPRs, or live birth rates compared with expectant management, and expectant management for a period of 6 months therefore appears justified in these couples [55, 56].

30.5 Semen Parameters and Processing

30.5.1 Semen Parameters to Consider

Semen parameters that must be considered in an IUI program include the semen processing time, processed total motile sperm count, rapid progressive motility after processing, sperm morphology before and after processing, inseminating motile sperm count (IMSC), IUI insemination time, and 24-h sperm survival.

Delaying semen processing from 30 min up to 1 h and/or delaying IUI from 90 min up to 2 h after collection compromises the pregnancy outcome in gonadotropin-IUI cycles [57]. A universal threshold level above which IUI can be performed with acceptable pregnancy rates has not been determined yet [7]. However, IUI success may be impaired in couples with processed total motile sperm (PTMS) count <ten million [58], sperm survival <70% [59], <5% normal spermatozoa, inseminating motile count (IMC) <1 × 106 [7], and prewash IUI-semen pregnancy score (IUI-SPS) <150 [60], necessitating alternative therapy. The PTMS count has been independently associated with fertility after IUI ($P = 0.0014$) [58]. PTMS count ≥10 × 106; their 24-h sperm survival threshold of ≥70% [59]; normal morphology before sperm separation ≥15.5% [odds ratio (OR) = 2.2 ($P = 0.02$)]; rapid, progressive motility ≥25.5% after sperm separation ($P = 0.029$); and curvilinear velocity (VCL) after sperm separation ≥102.65 μm/s ($P = 0.002$) independently predict pregnancy outcome in patients with male factor infertility [61]. These variables would be helpful in counseling patients for future management [61].

There are many studies showing that more days of sexual abstinence increased sperm concentration; however, the direct influence between the days of abstinence and pregnancy rates has not been evaluated. The usual recommendation is 3–4 days prior to intrauterine insemination; this is based on the interval that maximizes the number of motile sperm in the ejaculate. There are some reports with better success rate when abstinence is less than 3 days. Kably-Ambe et al. evaluated the pregnancy rate post-intrauterine insemination according to days of sexual abstinence prior to obtaining semen sample [62]. They published a retrospective, observational, and transversal study in patients attending the Mexican Center for Fertility (CEPAM) for intrauterine insemination. For analysis, patients were grouped by age group, success rate, and days of sexual abstinence. A total of 3123 couples were included, and increased success rate for intrauterine insemination was obtained with less than 7 days of sexual abstinence. The rate of sperm retrieval is inversely proportional to the days of abstinence. A better pregnancy rate in intrauterine insemination was achieved with less than 7 days of sexual abstinence, and sperm retrieval rate was also recorded with fewer days of abstinence [62].

The parameters measured in the standard semen analysis may be insufficient for exact differentiation between fertile and infertile men. Therefore, Boyraz et al. assumed that the high rate of apoptotic sperm in ejaculate may play a role on the etiology of unexplained infertility [63]. Couples with unexplained infertility treated by ovulation induction and intrauterine insemination were consecutively enrolled ($n = 94$). To determine the proapoptotic sperm rate, the ejaculate from patients was stained with annexin V. Thirteen of the 94 couples (13.8%) conceived after intrauterine insemination. The annexin V-positive sperm rate was found to be 20.0% in the whole group. In women failing to conceive, the annexin V-positive sperm rate was 20.8% compared to 15.7% in patients who achieved pregnancy [63]. Although there is a trend toward higher preapoptotic sperm rate in couples failing to get pregnant with insemination, the difference did not reach statistical significance [63].

30.5.2 Semen Preparation Techniques

The rationale behind semen preparation techniques for assisted reproduction is the separation of motile morphologically normal spermatozoa from leucocytes, bacteria, and dead spermatozoa that produce oxygen radicals that negatively influence the ability of sperm to fertilize the egg [64]. There are several sperm separation techniques, and these are based on different principles like migration, filtration, or density gradient centrifugation (DGC). However, the kind of technique employed entirely depends on the quality of the semen ejaculate (i.e., count, motility, morphology, sperm survival, vitality) at an initial evaluation, prior to processing the sample. An ideal preparation technique would be rapid and inexpensive, would isolate all the motile sperms without damaging their fertilizing capacity, and would ensure that the adequate number of motile, functionally normal spermatozoa is present at the site of fertilization following IUI.

The double DGC with different media (IxaPrep, Nycodenz, Sil-Select, PureSperm, or Isolate) and the swim-up technique are the standard techniques in use and have been detailed in other chapters in the book. The swim-up technique (with or without centrifugation) depends entirely on the initial sperm count and percentage of progressive motility. Though swim-up yields a high number of progressively motile sperm and effectively separates sperm from bacteria and cell debris, it is of limited use in cases of low sperm count. DGC involves the use of different density gradients to separate cells by the density during centrifugation. It may be used to obtain a high yield of motile spermatozoa from poor-quality samples with borderline to moderate oligozoospermia/asthenozoospermia. Discretion at this point is very essential. It must be remembered that while a single sperm defect, i.e., a poor count, may be rescued with DGC, a combination of defects will yield poor postprocess results. The glass wool filtration technique may also be used for a high yield of motile spermatozoa. Owing to concerns that centrifugation increases reactive oxygen species (ROS) formation in semen and that high levels of ROS are associated with sperm membrane injury through spontaneous lipid peroxidation, which may alter sperm function, ejaculates with ROS production should not be centrifuged. The time of centrifugation is more important than the g-force for inducing ROS formation in semen, and a shorter centrifugation period in the preparation of sperm for assisted reproductive techniques may be beneficial [28].

Swim-down, refrigeration/heparin techniques, and filtration methods, such as the SpermPrep method and membrane-based electrophoretic filtration system [Cell Sorter-10 (CS-10)], are some of the other techniques that have been in use. The SpermPrep method is a Sephadex preparation with a different bead size that offers quicker, improved semen

manipulation for patients with oligozoospermia and/or asthenozoospermia [65], while the Cell Sorter-10 (CS-10) preferentially isolates spermatozoa with very low levels of DNA damage. Non-centrifugation methods include a novel Zech device that is a dual-chamber capillary dish that obviates the potential harmful effects of centrifugation on sperm.

30.5.3 Advanced Sperm Preparation Methods

The advanced methods for semen preparation include molecular sperm selection strategies such as hyaluronic acid-mediated sperm selection, annexin V magnetic-activated cell separation (MACS) that utilizes colloidal superparamagnetic microbeads (approximately 50 nm in diameter) conjugated with annexin V to separate apoptotic and non-apoptotic spermatozoa, and annexin V molecular glass wool filtration [66].

30.5.4 Density Gradient Centrifugation Versus Swim-Up/Sperm Wash

DGC techniques, utilizing PureSperm, yield significantly higher median total motile sperm counts (TMSC) (32.2 × 106 vs. 17.6 × 106), higher recovery rates of mature motile sperm (69.2% vs. 50.0%), longevity at 4 h (83.0% vs. 55.0%), and postthaw recovery and better preserve semen quality in fresh and cryopreserved semen compared to swim-up [67]. They yield higher pregnancy rates compared to sperm wash (14.3% vs. 11.6%, respectively; 18% vs. 4%, respectively, for samples with <22 million motile sperm in the inseminate) [68] and significant sperm enrichment compared to isolate (50% and 90%) [sperm recovery rates (30.0% vs. 19.7%, respectively)] [67]. Swim-up yields a significantly higher mean percentage of viable sperm but significantly lower recovery rates of total motile, progressively motile, and viable sperm compared with DGC despite similar low rates of apoptotic sperm [69]. Hence, while samples with an acceptable number of motile sperm can be processed efficiently by wash only, poor-quality semen samples should be processed using DGC. The percentage of sperm in the original semen sample with a velocity of ≥80 μm/s for the wash method influences the pregnancy outcome [68]. However, a meta-analysis of five parallel RCTs failed to demonstrate a significant benefit of one technique over the other and concluded insufficient evidence to recommend any specific preparation technique. Further, large high-quality randomized trials are warranted [70].

The combination of DGC and MACS is reported to be superior to all other sperm preparation methods, providing motile, viable, and nonapoptotic spermatozoa [64], improved cryosurvival rates [71], significant improvement in induced acrosome reaction test (IART) ($P < 0.001$) [72] with an improved ability to fertilize eggs using the hamster oocyte penetration assay [66], and significantly reduced levels of apoptotic markers versus DGC alone ($P < 0.001$) [72]. Because of a wide variety of ejaculate qualities, which influence the functions of spermatozoa to a great extent, the efficacy of different preparation methods will vary; hence, the technique to be used must be individually tailored.

30.6 IUI in Practice: Description of the Procedure

30.6.1 Timing of Insemination

IUI may be timed 34–36 h after the administration of 10,000 IU hCG intramuscularly, which may be timed following evidence of one or more follicles ≥18 mm during ultrasound monitoring of folliculogenesis and an endometrial thickness >7 mm (with triple-line development). Alternatively, IUI may be timed following sonographic evidence of follicular rupture and free fluid in the pouch of Douglas, or following biochemical evidence of an LH surge. A meta-analysis of seven controlled trials (2623 patients), examining the effectiveness of hCG administration before IUI on CPRs in comparison with LH detection, failed to demonstrate a consistent, clinically important benefit of hCG-induced ovulation compared with LH monitoring of spontaneous ovulation for IUI timing [73]. Despite comparable pregnancy rates between hCG-induced ovulation and LH surge-timed IUI (an increase in LH level ≥ 200% over a mean of preceding 2 days), a significantly longer time to IUI, significantly higher cancelation rates (31% vs. 11%) attributed mainly to failure to detect an LH surge [74], and favorable outcomes limited only to CC-induced cycles [75] have been reported, suggesting that the decision to use hCG for IUI timing should be influenced by factors other than pregnancy rates [74]. Postponing IUI until the observation of follicle rupture at transvaginal ultrasonography may yield a higher pregnancy rate (23.5% vs. 8.8%, respectively; $p < 0.001$) in couples with unexplained infertility and male factor subfertility [76].

With regard to the ovulation-inducing agent, a subcutaneous injection of a relatively low dose of GnRHa [triptorelin (Decapeptyl), 0.1 mg] can be as effective as hCG (10,000 IU) after follicular maturation in producing pregnancy in COH-IUI treatment cycles in patients presenting with amenorrhea, oligomenorrhea, or unexplained infertility with comparative conception rates (15.3% vs. 26.5%), abortion rates (18.2% vs. 33.3%), and term pregnancy rates (13.6% vs. 19.0%), respectively [77].

Giugliano et al.'s aim was to assess the impact of the ultrasonographic detection of follicular rupture on the intrauterine insemination success [78]. A total of 313 women undergoing ovarian stimulation for intrauterine insemination were enrolled. Transvaginal ultrasonography was performed to check whether the dominant follicle had ruptured, and according to that the patients were divided into two groups. The ultrasound detection of follicular rupture was observed in 156 patients (54%). The independent variables favoring follicular rupture were age (t: 7.646, $p < 0.0005$),

FSH value (t: −5.637, $p < 0.0005$), duration of infertility (t: −4.265, $p < 0.0005$), and menstrual cycle length (t: −4.927, $p < 0.0005$). Moreover, the logistic regression analysis demonstrated that the predictive variables for follicular rupture were FSH value (OR 1.7, CI 95% 1.3–2.3, $p < 0.0005$), duration of infertility (OR 2.6, CI 95% 1.6–4.2, $p < 0.0005$), and menstrual cycle length (OR 2.4, CI 95% 1.7–3.4, $p < 0.0005$). Pregnancy occurred in 23 patients of the group A (14.7%) and in 22 patients of the group B (16.5%) without a significant difference ($p = 0.6$). The logistic regression analysis confirmed that neither the evidence of follicular rupture nor any other variables influenced the pregnancy rate [78].

Liang et al. investigated the influence of the time interval from the end of semen processing to artificial intrauterine insemination with husband's sperm (AIH-IUI) on the rate of clinical pregnancy [79]. This study involved 191 AIH-IUI cycles with the same ovulation induction protocol. After Percoll density gradient centrifugation, they divided the sperm into four groups based on the incubation time: 0–19, 20–39, 40–59, and 60–80 min and again into another four groups according to the total progressively motile sperm count (TPMC): (0–9), (10–20), (21–30), and > 30 × 10(6). They analyzed the correlation of the clinical pregnancy rate with the time interval from the end of sperm processing to AIH-IUI and with other influencing factors, such as maternal age, infertility duration, and semen quality. The rate of clinical pregnancy was significantly higher in the 20–39-min group (18.3%) than in the 0–19-, 40–59-, and 60–80-min groups (12.7%, 11.4%, and 9.1%) (all $P < 0.05$). The (10–20) × 10(6) group achieved a remarkably higher pregnancy rate (16.7%) than the (0–9), (21–30), and > 30 × 10(6) groups (0%, 11.4%, and 8.3%) (all $P < 0.05$). Logistic multivariate analysis showed that the rate of clinical pregnancy was decreased with the increased age of women (OR 0.89, 95% CI 0.83–0.94) but significantly elevated in the 20–39-min group (OR 2.11, 95% CI 1.34–3.13) and in (10–20) × 10(6) group (OR 2.06, 95% CI 1.32–3.46). The time interval from the end of sperm processing to AIH-IUI is a significant factor influencing the rate of clinical pregnancy of AIH-IUI [79].

Çok et al. reported on the comparison of the effect of preserving prepared sperm samples at room temperature or at 37 °C before intrauterine insemination (IUI) on clinical pregnancy rate [80]. Clinical pregnancy rates were similar in IUI cycles in which prepared sperm samples were preserved at 37 °C and at room temperature (9.3% vs. 8.9%). Clinical pregnancy rates in IUI cycles with two follicles were higher than IUI cycles with one follicle (10.8% vs. 7.6%) ($p = 0.002$). Further statistical analysis after splitting data according to the number of the follicles revealed that there was no statistical difference between clinical pregnancy rates after IUI cycles in which the prepared sperm samples were preserved at 37 °C or at room temperature in both one-follicle (7.6% vs. 7.6%) and two-follicle cycles (11.5% vs. 10.1%). Preserving prepared sperm samples at room temperature had no negative effect on clinical pregnancy rates when compared with preserving prepared sperm samples at 37 °C during IUI cycles [80].

30.6.2 Insemination Procedure

IUI is performed with the patient in the dorsal lithotomy position on an empty bladder. The Cusco speculum is inserted, the cervical os is identified, and the cervix is cleaned with a swab of sterile saline. The os may be held in place with a vulsellum, if necessary. Meanwhile, in the laboratory, an atraumatic Wallace ET catheter is loaded with 0.5 mL of processed sperm. The catheter is inserted into the uterine cavity without touching the fundus, and the sperm suspension is gradually released. The patient is advised to rest in the same position for 15–20 min prior to discharge. Immobilization for 15 min after insemination yields significantly higher OPR per couple (27% vs. 18%) and live birth rates (27% vs. 17%) compared to the control group [81].

30.6.3 Ultrasound-Guided IUI Versus Blind IUI

Polat et al. performed a study to determine the effects of ultrasound (US) guidance during intrauterine insemination (IUI) on pregnancy rate [82]. The prospective study enrolled 130 couples who were scheduled to undergo IUI. The couples were randomized according to a computer-generated list into two groups: (1) the ultrasound-guided IUI group included 64 couples ($n = 64$) treated for 99 cycles and (2) the blind IUI group included 66 couples ($n = 66$) treated for 104 cycles. All women underwent controlled ovarian stimulation before IUI. The study's main measurements were pregnancy rate per cycle and pregnancy rate per woman. The pregnancy rates were similar in both the ultrasound-guided (USG) (16.2%, 16/99) and non-ultrasound-guided (NUSG) (12.5%, 13/104) groups ($p = 0.386$). The present results suggest a routine ultrasound guidance during IUI is not essential as it does not increase pregnancy rates but it can be used in such cases to overwhelm some sort of difficulties [82].

30.6.4 Luteal Phase Support

Following IUI, luteal phase support may be achieved with transvaginal administration of micronized progesterone (200 mg/day) or vaginal progesterone gel (Crinone 8% gel) for 2 weeks. A clinical pregnancy may be documented following sonographic evidence of a gestational sac with heartbeat at 6 weeks of amenorrhea and an ongoing pregnancy by >12 weeks of amenorrhea. Luteal phase support with vaginal progesterone gel (Crinone 8% gel) significantly affects the success of ovarian stimulation and IUI cycles in patients with unexplained infertility, yielding significantly higher CPR/cycle and CPR/patient (21.1% and 39.4%, respectively) compared to patients who received no luteal phase support (12.7% and 23.8%, respectively) [83]. Alternatively, intranasal administration of a GnRH agonist (buserelin) could be effective in providing luteal support with good pregnancy rates (28%) [84].

30.7 Post-procedure Care

Patients can pursue their routine activity following IUI but must take care to avoid excess physical exertion. Signs of spotting or bleeding must be reported immediately.

30.7.1 Single Versus Double Insemination

Studies have reported significantly better pregnancy outcomes following double insemination (12 and 34 h after hCG administration) versus single insemination (34–36 h after hCG administration) in couples with ovulatory dysfunction, endometriosis, male factor, unexplained infertility, tubal factor infertility, and combined diagnoses, particularly within gonadotropin protocols and ovulatory dysfunction and male factor diagnostic categories, and despite a significantly lower female age in the single IUI group [85] and slightly higher cost of double IUI [86]. However, a recent meta-analysis of six RCTs, involving 829 women, failed to demonstrate a clear benefit of double IUI versus single IUI in the overall CPR in couples with unexplained infertility [87]. Despite the 36th h being the preferred timing for IUI, no statistical difference regarding pregnancy rates has been reported between single 24th-h and double 12th- and 36th-h inseminations in patients with unexplained infertility, male factor, and ovulatory dysfunction following COH with gonadotropin + IUI, suggesting that the 24th-h IUI might be preferred in demanding situations [88].

30.7.2 IUI Versus Timed Intercourse (TI)

Despite evidence of a significant benefit of IUI over TI in two large meta-analyses in terms of the probability of conception, both in natural cycles and in COH cycles, with COH (gonadotropins)-IUI offering the best chance of conception in couples with male subfertility [29] and ovulatory infertility [89], a recent meta-analysis [90] failed to demonstrate a significant clinical benefit in terms of pregnancy rates between stimulated and natural cycle IUI, natural cycle TI/IUI, and stimulated IUI/TI. It concluded insufficient data to perform a statistical analysis or to recommend or advise against IUI with or without COH above TI, or vice versa, or to document adverse outcomes such as OHSS, multiple pregnancy, miscarriage rate, and ectopic pregnancy [90]. Timed intercourse following IUI with a low number of motile sperm is an alternative treatment that appears to be a practical, simple, and an inexpensive addition that significantly increases the pregnancy rates over IUI alone (27.7% vs. 10.5%, $P = 0.023$) in infertile couples with a normal sperminogram [91].

30.7.3 Number of Cycles

There is general agreement in the literature that four to six IUI cycles may be performed with acceptable pregnancy rates before resorting to alternative therapy [68, 92] though studies have reported acceptable OPR in high-order IUI cycles up to nine [27]. More than four cycles of CC-IUI can compensate for low pregnancy rates due to age, semen quality, or follicle number in patients with ovulation dysfunction. Significantly lower mean PRs have been reported in patients ≥43 years with poor semen quality, single preovulatory follicles, and diagnoses other than ovulatory dysfunction compared to those after four (CPRs 46% for ovulatory dysfunction; 38% for cervical factor, male factor, and unexplained infertility; 34% for endometriosis; and 26% for tubal factor infertility) or six (CPRs 65% for ovulation dysfunction, 35% for endometriosis, and unchanged for other diagnoses) cycles [92]. Morshedi et al. [68] reported 88% of pregnancies in the first three cycles of IUI and 95.5% within the first four cycles with an overall CPR/cycle of 13.0% and CPR/patient of 28.3% with a miscarriage rate of 34.0% [68]. Aboulghar et al. [93] reported significantly higher cycle fecundity in the first three trials of COH-IUI than in cycles four to six (16.4% vs. 5.6%, $P < 0.001$, $n = 594$, 1112 cycles), suggesting that COH-IUI for the treatment of unexplained infertility should be limited to a maximum of three trials and patients should be offered IVF or ICSI if they fail to conceive after three trials of COH and IUI [93]. Moreover, Qublan et al. [94] reported an increased incidence and recurrence rate of luteinized unruptured follicle (LUF) among patients with pre-existing LUF undergoing multiple IUI cycles. The incidence of LUF was 56.5% in the second cycle of IUI treatment with a recurrence rate of 78.6% and 58.9% among patients who underwent three consecutive IUI cycles with a recurrence rate of 90%. In these patients, other options of infertility treatment might be justified [94]. The use of clomiphene citrate for unexplained fertility for more than 12 cycles of IUI has been associated with a threefold increase in risk of ovarian cancer [95].

30.7.4 Intentional Endometrial Injury and Intrauterine Insemination

Intentional endometrial injury is currently being proposed as a technique to improve the probability of pregnancy in women undergoing assisted reproductive technologies (ARTs) such as in vitro fertilization (IVF). Endometrial injury is often performed by pipelle biopsy or a similar technique and is a common, simple, gynecological procedure that has an established safety profile. However, it is also known to be associated with a moderate degree of discomfort/pain and requires an additional pelvic examination. The effectiveness of this procedure outside of ART, in women or couples attempting to conceive via sexual intercourse or with low complexity fertility treatments such as intrauterine insemination (IUI) and ovulation induction (OI), remains unclear.

Lensen et al. set up a study to evaluate the effectiveness and safety of intentional endometrial injury in subfertile women and couples attempting to conceive through sexual intercourse or intrauterine insemination (IUI) [96]. They searched the Cochrane Gynaecology and Fertility Group

Specialised Register, Cochrane Central Register of Controlled Trials (CENTRAL), MEDLINE, Embase, PsycINFO, CINAHL, LILACS, DARE, ISI Web of Knowledge, and ► ClinicalTrials.gov, as well as reference lists of relevant reviews and included studies. They performed the searches from inception to 31 October 2015. They included randomized controlled trials (RCTs) that evaluated any kind of intentional endometrial injury in women planning to undergo IUI or attempting to conceive spontaneously (with or without OI) compared to no intervention, a mock intervention, or intentional endometrial injury performed at a different time or to a higher/lower degree. Two review authors independently selected trials, extracted data, and assessed trial quality using GRADE methodology. The primary outcomes were live birth/ongoing pregnancy and pain experienced during the procedure. Secondary outcomes were clinical pregnancy, miscarriage, ectopic pregnancy, multiple pregnancy, and bleeding secondary to the procedure. We combined data to calculate pooled risk ratios (RRs) and 95% confidence intervals (CIs). Statistical heterogeneity was assessed using the I^2 statistic. Nine trials, which included a total of 1512 women, met the inclusion criteria of this Cochrane review. Most of these studies included women with unexplained infertility. In seven studies, the women were undergoing IUI and in two studies, the women were trying to conceive through sexual intercourse. Eight trials compared intentional endometrial injury with no injury/placebo procedure; of these, two trials also compared intentional endometrial injury in the cycle prior to IUI with intentional endometrial injury in the IUI cycle. One trial compared higher vs. lower degree of intentional endometrial injury. The study is uncertain whether endometrial injury improves live birth/ongoing pregnancy as the quality of the evidence has been assessed as very low (risk ratio (RR) 2.22, 95% confidence interval (CI) 1.56 to 3.15; six RCTs, 950 participants; I^2 statistic = 0%, very low quality evidence). When they restricted the analysis to only studies at low risk of bias, the effect was imprecise and the evidence remained of very low quality (RR 2.64, 95% CI 1.03 to 6.82; one RCT, 105 participants; very low quality evidence). Endometrial injury may improve clinical pregnancy rates; however, the evidence is of low quality (RR 1.98, 95% CI 1.51 to 2.58; eight RCTs, 1180 participants; I^2 statistic = 0%, low quality evidence). The average pain experienced by participants undergoing endometrial injury was 6/10 on a 0–10 visual analogue scale (VAS) (standard deviation = 1.5). However, only one study reported this outcome. When the analysis compared hysteroscopy with endometrial injury to hysteroscopy alone, there was no evidence of a difference in ongoing pregnancy rate (RR 1.29, 95% CI 0.71 to 2.35; one RCT, 332 participants; low quality evidence) or clinical pregnancy rate (RR 1.15, 95% CI 0.66 to 2.01; one RCT, 332 participants, low quality evidence). This study did not report the primary outcome of pain during the procedure. When endometrial injury was performed in the cycle prior to IUI compared to the same cycle as the IUI, there was no evidence of a difference in ongoing pregnancy rate (RR 0.65, 95% CI 0.37 to 1.16; one RCT, 176 participants; very low quality evidence) or clinical pregnancy rate (RR 0.82, 95% CI 0.50 to 1.36; two RCTs, 276 participants; very low quality evidence). Neither of these studies reported the primary outcome of pain during the procedure. In all three comparisons, there was no evidence of an effect on miscarriage, ectopic pregnancy, or multiple pregnancy. No studies reported bleeding secondary to the procedure. It is uncertain whether endometrial injury improves the probability of pregnancy and live birth/ongoing pregnancy in women undergoing IUI or attempting to conceive via sexual intercourse [96]. Further well-conducted RCTs that recruit large numbers of participants and minimize internal bias are required to confirm or refute these findings.

30.8 Intrauterine Versus Other Forms of Artificial Insemination

30.8.1 Intracervical Insemination

Sperm may be deposited in or around the endocervical canal (cervical insemination—CI) or in the uterine cavity itself (IUI). IUI has been considered potentially more effective than CI as the sperm bypass the cervical mucus and are deposited closer to the fallopian tubes. The cost and risks of IUI, on the other hand, may be higher because of the need for sperm preparation, the introduction of foreign material into the uterus [97], and the consequent risk of infection and anaphylaxis [98]. Significantly improved pregnancy rates and live birth rates without a statistically significant evidence of an effect on multiple pregnancies or miscarriages have been reported following six cycles of stimulated IUI with CC/gonadotropins using cryopreserved sperm in comparison to cervical insemination [97].

30.8.2 Slow Release Intrauterine Insemination

A modified application technique of intrauterine insemination (IUI) is slow release insemination (SRI), first described by Muharib et al. [99], who postulated higher pregnancy rates with a slow release of spermatozoa for 3 h. To investigate this approach, two randomized controlled, crossover pilot studies were performed from 2004 to 2006 in Israel and Germany to compare SRI with the standard bolus IUI. Marschalek et al. aimed to present the results and perform a meta-analysis on available data for SRI [100]. Univariate comparisons of pregnancy rates were performed using one-tailed Z-tests for method superiority. For meta-analysis, a fixed-effect Mantel-Haenszel weighted average of relative risk was performed. Fifty treatment cycles (IUI, $n = 25$; SRI, $n = 25$) were performed in Germany, achieving four pregnancies (IUI, 4%; SRI, 12%; $p > 0.05$). Thirty-nine treatment cycles (IUI, $n = 19$; SRI, $n = 20$) were performed in Israel, achieving six pregnancies (IUI, 10.5%; SRI, 20%;

$p > 0.05$). Meta-analysis of all eligible studies for SRI ($n = 3$) revealed a combined relative risk for pregnancy after SRI of 2.64 (95% CI 1.04–6.74; $p = 0.02$). In conclusion, these results lend support to the hypothesis that the pregnancy rate might be improved by SRI compared to the standard bolus technique [100].

30.8.3 Fallopian Tube Sperm Perfusion

Fallopian tube sperm perfusion (FSP) is based on the pressure injection of 4 mL of sperm suspension with the attempt of sealing of the cervix to prevent semen reflux [34] and ensures the presence of higher sperm densities in the fallopian tubes at the time of ovulation than does standard IUI [101]. The IUI technique, on the other hand, is based on intrauterine injection of 0.5 mL of sperm suspension without flushing the tubes [30]. Despite previous reports of the advantages of FSP in terms of higher CPR and OPR/patient and reduced cost and complications in couples with unexplained infertility compared to IUI [102, 103], a recent meta-analysis of eight randomized controlled studies involving 595 couples with nontubal subfertility including a subgroup analysis in couples with unexplained subfertility reported no clear benefit for FSP over IUI [101]. In couples with long-standing infertility, intraperitoneal insemination (IPI), FSP, and IUI have similar efficacy in the achievement of a clinical pregnancy [104].

Intrauterine tuboperitoneal insemination (IUTPI) with 10 mL of inseminate has been proposed as a useful technique in the treatment of unexplained infertility, mild or moderate male infertility, and mild or moderate endometriosis compared to FSP (CPR/cycle 29.4% vs. 17.6%), and three attempts of IUTPI may be beneficial before moving on to more invasive and expensive methods of assisted reproduction [105].

30.9 Risks and Complications of IUI

30.9.1 Early Complications: Risks of the Procedure

Though complications after IUI are rare, studies have reported slight cervical contact bleeding and mild abdominal discomfort and/or cramps [106]. Vaginal administration of misoprostol at the time of IUI is associated with a significant increase in vaginal bleeding and abdominal cramping rates and does not seem to enhance the outcome [107]. Spontaneous abortions, blighted ovum, and ectopic pregnancies have been reported in 7.8%, 2.6%, and 1.3% of the pregnancies, respectively, in COH-IUI cycles [108]. Infectious complications associated with IUI are frequently cited, though rarely reported. According to Sacks and Simon [109], most reported cases of infection fail to show evidence for the actual presence of infection, and the prevalence is unaltered by the administration of prophylactic antibiotics or washing the semen sample with antibiotics. *Escherichia coli* septicemia has been reported subsequent to IUI [110]. *Chlamydia trachomatis* infection, acquired as an intrauterine infection, as well as during transit through the birth channel, may result in a number of adverse pregnancy outcomes, including ectopic pregnancy, early and late abortion, intrauterine infections of the fetus, stillbirth, prematurity, premature rupture of the membranes (PROM), and postpartum endometritis [110].

30.9.2 Late Complications

Although IUI itself is less invasive and expensive than other techniques of assisted reproduction, the adverse effects of COH, such as OHSS and multiple pregnancies, are a concern [22, 24, 90]. Miscarriage rates ranging from 11.8% [6] to 34.0% [4] have been reported following COH-IUI.

30.9.3 Multiple Births

Multiple pregnancy rates following IUI are significantly influenced by age and etiology of the patient. Multiple pregnancy rates of 6.0% in unexplained and male subfertility [33], 13.2% in anovulatory infertility [111], and 23.5% in couples with exclusive female factors, such as anovulation, cervical factors, or unexplained infertility and a maximum of three IUI cycles, have been reported [112]. Multifollicular growth is associated with increased pregnancy rates following COH-IUI. Surpassing the recruitment of two follicles would lead to a dramatic increase in the risk of OHSS and multiple pregnancies without a substantial gain in overall pregnancy rate [113, 114]. According to van Rumste et al. [113], one stimulated follicle should be the goal if safety is the primary concern, whereas two follicles may be accepted after careful patient counseling. They reported an absolute pregnancy rate of 8.4% for monofollicular growth and 15% for multifollicular growth. Compared with monofollicular growth, pregnancy rates increased by 5% and 8%, while the risk of multiple pregnancies increased by 6%, 14%, and 10% when stimulating two, three, and four follicles. The absolute rate of multiple pregnancies was 0.3% after monofollicular growth and 2.8% after multifollicular growth [113]. In patients <35 years old, the incidence of multiple pregnancies, particularly ≥3 implantations, tripled when ≥6 follicles were ≥ 12 mm in CC, hMG, and CC + hMG cycles and when E2 levels were > 1000 pg mL in hMG and CC + hMG cycles. In patients ≥35 years, pregnancy rates in hMG and CC + hMG cycles doubled when six or more follicles were ≥ 12 mm or E2 levels were > 1000 pg mL, whereas three or more implantations were not significantly increased [114].

Treatment strategies to reduce the incidence of multiple pregnancies in ovulation induction programs can be targeted to reduce multiple follicular development and subsequent ovulation by a more aggressive cancelation policy, follicle reduction by fine needle aspiration, conversion to IVF, or

dealing with the problem of multiple gestation after it has occurred (i.e., multifetal pregnancy reduction) [115]. Specifically, tailoring the rate of multifollicular development according to the duration and type of infertility (etiology, primary or secondary, female age) would prove to be a safer approach for achieving pregnancy as well as avoiding adverse effects such as the risk of OHSS and multiple pregnancies [116]. Withholding hCG or IUI in CC, hMG, and CC + hMG cycles when six or more follicles are ≥12 mm may reduce triplet and higher-order implantations by 67% without significantly reducing pregnancy rates for patients under 35 years of age [101]. According to Ragni et al. [117], in COH-IUI cycles, daily administration of 50 IU recombinant FSH with the use of GnRH antagonists and a policy of strict cancelation (if three or more follicles ≥16 mm and/or five or more follicles ≥11 mm) based on echographic criteria are associated with a satisfactory pregnancy rate per initiated cycle and a low risk of high-order multiple pregnancies. The CPR per initiated cycle was 9.2% with a 9.5% and 0% incidence of twins and high-order multiple pregnancies, respectively [117].

30.10 Success Rates with IUI

30.10.1 Factors Affecting Outcome

Overall CPRs/cycle ranging from 9.2% to 22% have been reported in the literature following stimulated IUI [4, 6, 7, 89, 109] with live birth rates of 10% for CC-stimulated and 8.7% for rFSH-stimulated cycles [37]. Guven et al. [118] reported a PR of 7.9% in the primary infertility group and 21.4% in the secondary infertility group. However, these results are largely determined by the patient selection criteria, the sperm and follicular characteristics, and the stimulation protocol in the various studies.

Characterization of prognostic factors for pregnancy is essential, particularly those for women at risk of multiple pregnancies after IUI [119].

30.10.2 Favorable Predictors of IUI Outcome

The following factors have been reported as significant predictors of the pregnancy outcome following IUI:

- Patient's age ≤ 35 years, irrespective of the method of sperm preparation used [68]. A higher birth rate (25.8%) has been reported in women <35 years undergoing COH-IUI compared to women ≥35 years (14.0%) when four or more follicles were greater than or equal to 12 mm [120].
- Infertility etiology. Pregnancy rates/cycle may vary among women with different etiologies, being highest in anovulatory infertility (19.2%) and lowest in endometriosis-based infertility (11.9%). The cumulative pregnancy rates varied greatly by diagnosis from 16% for patients with male factor infertility to 60% for patients with ovulatory disorder [121]. Cervical factor yields a favorable outcome [122].
- Sperm parameters.

Total motile sperm count (TMSC) before sperm preparation ($P > 0.05$) [118].

Sperm motility. Patients with original sperm motility ≥30% had a higher cumulative pregnancy rate (74%) than patients with motility <30% ($P < 0.005$) with a four-times increase in PR with an increase in motility of ≥30% [123].

Progressive motility [112].

Normal sperm morphology [118, 119]. Significantly higher PRs have been reported with samples with normal sperm morphology of >4% (according to Kruger's criteria) compared to ≤4% (22.2% vs. 6.7%, respectively; $p = 0.003$) [118].

Processed total motile sperm (PTMS) count ≥10 × 106 and 24-h survival of ≥70% can predict the IUI outcome with 94% sensitivity and 86% specificity [2]. An average TMSC of ten million may be a useful threshold value for decisions about treating a couple with IUI or IVF [124].

- Mild controlled ovarian hyperstimulation [120, 122, 125]. A significantly higher incidence of follicles (81% vs. 53%; $P < 0.05$) as well as cycles (63% vs. 49%; $P < 0.05$) with uniformly high-grade vascularity has been observed by transvaginal power Doppler ultrasonography on the day of insemination (32–36 h post-hCG administration) in COH-IUI cycles compared with unstimulated or clomiphene-induced donor cycles [125].
- Follicular dynamics.

Increase in the number of preovulatory follicles (1–4) at the time of hCG administration [2, 112, 122, 126].

Increase in AFC and, hence, increase in the dominant follicle number and E2 level on the day of hCG administration [7].

Serum E2 levels. Birth rate increased from 3.6% when E2 was <500 pg/mL to 19.6% when E2 was ≥2500 pg/mL [122].

High-grade follicular vascularity. Higher pregnancy and lower early pregnancy loss rates have been observed in cycles with uniformly high-grade follicular vascularity, possibly attributed to COH, compared with other vascularity grades [125]. However, a recent study by Ragni et al. [127] reported that follicular vascularity (follicles with a mean diameter ≥ 16 mm) does not predict the chance of pregnancy in women undergoing mild COH and IUI [127].

- Endometrial thickness [112].
- Shorter duration of infertility [112].
- Cervical mucus aspiration before IUI [66].

The etiology of infertility and the stimulation protocol used may have a significant effect on the pregnancy outcome. Pregnancy rates of 36%, 25.0%, and 30% have been reported following stimulation with sequential CC and hMG and three follicles in patients with anovulatory infertility, male infertility, and combined infertility, respectively, 21.1% fol-

lowing CC stimulation in endometriosis-based infertility, and 24.3% with an IMC >30 × 106. Ovarian stimulation in unexplained infertility resulted in PRs of 24.2% and 19.8% with three follicles and an IMC >30 × 106, respectively [111].

30.10.3 Factors Predicting a Poor Prognosis

A significant negative correlation of the following factors with the IUI pregnancy outcome has been reported:

- Increasing maternal age ≥ 35 [120–122]. A 0.0% cumulative probability of ongoing pregnancy following three cycles of IUI in women ≥40 years has been reported compared to women <40 years (28.2%) irrespective of the infertility history, use of ovarian stimulation, or baseline semen parameters, suggesting that the treatment of male and/or cervical factor by IUI is ineffective for women ≥40 years [128]. Treatment with CC is ineffective, and delivery rates following COH with gonadotropins and IUI are <5%. Therefore, it is recommended that after a short trial of gonadotropins and IUI, women aged 40–41 years should be quickly referred to IVF. At an older age, IVF is the primary treatment option [129].
- Decreased basal AFC. In women >35 years with AFCs <5, the application of COH-IUI may not be indicated [21]. Low basal AFC is associated with lower clinical pregnancy and live birth rates in unexplained subfertile couples treated with COH-IUI [130].
- Male factor infertility with initial sperm motility <30% ($P < 0.002$), initial sperm count <5 × 106 per mL ($P < 0.01$) [127], and normal sperm morphology <14% [125].
- Postwash TMSC ≤20 million/mL [121].
- Endometriosis and tubal factor-associated infertility [119–122].
- Uterine anomalies [122].
- Increasing number of cycles with more than four treatment cycles [120, 122].
- Longer duration of subfertility [122].
- Low midluteal progesterone (P4) level ≤ 25 nmol/L [131].

A recent study by Merviel et al. [132] concluded that the couple with the best chance of pregnancy following COH (gonadotropin)-IUI can be described as a woman <30 years with cervical or anovulatory infertility and a man with a TMS ≥five million spermatozoa. The "ideal" stimulation cycle enables the recruitment of two follicles measuring >16 mm with an E2 concentration > 500 pg/mL on the day of hCG administration. The best results are obtained when IUI is performed using a soft catheter [132]. Though male and female factors contribute to pregnancy outcome, the clinician can influence prognosis by increasing the number of follicles, especially in severe male factor cases [119].

30.10.4 Intrauterine Insemination and Major Congenital Malformations

Multiple pregnancies are a recognized adverse effect of assisted reproductive technologies; nevertheless, there is no consensus on the incremental risk associated with the ovarian stimulation (OS) used alone and intrauterine insemination (IUI). The relationship between OS and IUI and the risk of major congenital malformations (MCM) is unclear. Chaabane et al. set up a study [133] to summarize the literature and evaluate the risk of multiple pregnancy and MCM associated with OS used alone and IUI used with or without OS compared to natural conception (spontaneously conceived infants without any type of fertility treatments). They carried out a systematic review to identify published papers between 1966 and 2014 in MEDLINE, Embase, and the Cochrane Central Register of Controlled Trials. They included observational studies and randomized clinical trials related to the risk of multiple pregnancies and MCM conceived following OS alone or IUI compared to natural conception (spontaneously conceived infants without any fertility treatments). There were 63 studies included in this review. The systematic review suggests that the use of any OS alone was associated with an increased risk of multiple pregnancy compared to natural conception (pooled RR 8.80, 95% CI 5.09–15.20; $p = 0.000$; 9 studies). Similar increases in the risk of multiple pregnancies were observed following clomiphene citrate used without assisted reproductive technologies. Compared to natural conception, the use of IUI with or without OS was associated with an increased risk of multiple pregnancy (pooled RR 9.73, 95% CI 7.52–12.60; p = 0.000; 6 studies). Compared to natural conception, the use of any OS alone was associated with an increased risk of any MCM (pooled RR 1.18, 95% CI 1.03–1.36; 11 studies), major musculoskeletal malformations (pooled RR 1.48, 95% CI 1.21–1.81; 7 studies), and malformations of the nervous system (pooled RR 1.73, 95% CI 1.15–2.61; 6 studies). Compared to natural conception, the use of IUI was associated with an increased risk of any MCM (pooled RR 1.23, 95% CI 1.10–1.37; 10 studies), major urogenital malformations (pooled RR 1.52, 95% CI 1.04–2.22; 7 studies), and musculoskeletal malformations (pooled RR 1.54, 95% CI 1.20–1.98; 7 studies). The increased risk of multiple pregnancy and certain types of MCM associated with the use of less invasive fertility treatments, such as OS and IUI, found in this review, highlights the importance of the practice framing [133].

Heterogeneity in OS protocols, the combination with other fertility agents, the limited number of studies, and the methodological quality differences reduce our ability to draw conclusions on specific treatment. More observational studies, assessing the risk of multiple pregnancy or MCM, as a primary outcome, using standardized methodologies, in larger and better clinically defined populations are needed.

30.10.5 Interesting Case Reports

Bakas et al. [134] reported a rare case of maternal hyperthyroidism after intrauterine insemination due to hypertrophic action of hCG. A 36-year-old woman after successful intrauterine insemination and triplet pregnancy developed hyperthyroidism with resistance to medical treatment. All signs of hyperthyroidism resolved and the results of thyroid function tests returned to normal without any medication after embryo meiosis. De novo maternal hyperthyroidism may develop during pregnancy as a result of pathological stimulation of the thyroid gland from the high levels of hCG hormone that can be seen in multiple pregnancies. The risk of hyperthyroidism is related to the number of fetuses. Reversibility of symptomatology can be seen after fetal reduction of multiple pregnancies [134].

The management of pregnancy in young women with essential thrombocythemia is complex and may present a difficult problem. An adverse pregnancy outcome due to thrombosis or bleeding is a common complication. In addition, little is known about fertility in these women prior to the disease. Leković et al. published the first case of a young woman with primary infertility and essential thrombocythemia who had uneventfully delivered a healthy boy in the 40th week of pregnancy [135]. Her platelet count was normalized during treatment with interferon-alfa. The patient failed to become pregnant in the natural way and after three attempts of programmed intercourse. She conceived only following intrauterine insemination. During pregnancy, the patient was carefully monitored by a hematologist and gynecologist. Intrauterine insemination with minimal hormonal stimulation due to the risk of thrombosis could be recommended as the safest treatment option of infertility in women with essential thrombocythemia [135].

30.10.6 Recent Advances

The transcriptome of spermatozoa used in homologous IUI reveals profound differences between expression profiles of sperm samples that impregnate successfully and those that do not. These differences might improve the predictive power of sperm evaluation to estimate IUI success by complementing the basic sperm analysis [136]. Three-dimensional (3D) and 3D power Doppler (PD) when used with 2D ultrasound and color Doppler for pre-hCG follicular assessment improve pregnancy rates in IUI cycles by enabling an assessment of the follicular volume, perifollicular resistance index, and perifollicular vascularity index, all of which may influence the conception rates [137].

Swierkowski-Blanchard conducted an observational pilot study to determine the impact of the frequency and intensity of uterine contractions (UCs) at the time of IUI on subsequent fertility [138]. One hundred volunteer women scheduled for IUI between April 2011 and July 2013, in whom UCs were assessed during the ultrasound before IUI were included. A two-dimensional sagittal uterus elastography was recorded for 5 min. The elasticity index, defined as the mean ratio of elastographic measurements between the subendometrial area (of interest) and the endometrial area (control), was computed. UC frequency, endometrial thickness and volume, and subendometrial vascularization were also measured. These parameters, along with characteristics of the IUI cycle, were entered into a logistic regression model for predicting ongoing pregnancy. The elasticity index was significantly higher (2.4 ± 1.3 vs. 1.5 ± 0.7, i.e., with stiffer myometrium), and the endometrium was significantly less echogenic in future pregnant women. Factors closely reaching significance were age, previous fertility, day 3 hormonal assessments, number of inseminated spermatozoa, endometrial thickness, and UC count. In multivariate analysis, low UC frequency (<2.8/min; odds ratio [OR] = 0.039), high elasticity index (>1.7; OR = 63.26), high endometrial thickness on the ovulation triggering day (>8 mm; OR = 28.21), and low patient age (<32 years; OR = 0.001) were predictive of pregnancy after IUI. A low frequency and high intensity of UCs at the day of IUI appears associated with a higher pregnancy rate. Elastography provides a promising innovative tool for IUI monitoring [138].

Uterine contractibility is considered a powerful prognostic factor in predicting the embryo transfer outcome. Moreover, uterine contractions are known to be stimulated by prostaglandins which are produced by cyclooxygenase from arachidonic acid. As such, suppressing the inflammatory response and contractions using anti-inflammatory and relaxant agents is expected to result in increased success rate of embryo transfer and artificial insemination. Zarei et al. investigated the effect of piroxicam administration on the success rate in intrauterine insemination (IU) cycles in patients presenting with unexplained infertility [139]. This randomized, placebo-controlled clinical trial included 260 women with unexplained infertility undergoing IUI cycles. Patients were randomly assigned to receive either piroxicam 10 mg/day on days 4–6 after IUI or placebo (control group). The main outcome measures were number of IUI cycles, pregnancy, abortion, and multiple pregnancy rates. The pregnancy rate was found to be 25 (19.2%) and 16 (12.3%) in piroxicam and control groups, respectively ($p = 0.039$). Five patients (3.8%) in piroxicam group experienced twin pregnancy, whereas only three patients (2.3%) in control group had twin pregnancy ($p = 0.361$). The pregnancy rate per cycle was also significantly higher in those who received piroxicam as compared to controls (11.16 vs. 6.66; $p = 0.021$). Administration of piroxicam after IUI is associated with decreased number of cycles, as well as increased pregnancy rate and pregnancy rate per cycle in IUI cycles. However, piroxicam did not have any effect on abortion, multiple pregnancy, and ongoing pregnancy rates [139].

30.11 Conclusions

IUI is a simple, cost-effective, noninvasive first-line therapy for cervical factor, anovulatory infertility, moderate male factor, unexplained infertility, and immunological infertility with CPRs ranging from 10% to 20%. Optimal pregnancy rates following COH with a low-dose gonadotropin protocol and IUI may be obtained in couples with a short duration of infertility where the woman's age is ≤35 years with a PTMS count ≥10 × 106 and a 24-h survival of ≥70%, normal sperm morphology >4% (according to Kruger's criteria), 2–3 follicles ≥16 mm with uniformly high-grade vascularity and E2 levels >500 pg/mL on the day of hCG administration, adequate endometrium with a trilaminar pattern during insemination, and appropriately timed insemination using a soft atraumatic catheter. Strict patient selection criteria and individualized stimulation protocols tailored according to the age and etiology of the patient with a strict cycle cancelation policy will help to reduce the associated complications, such as multiple pregnancies and OHSS, while maximizing the overall pregnancy outcome. Three to six IUI cycles may be offered before considering alternate therapy. However, patients with advanced maternal age, severe male factor infertility, tubal pathology, or severe endometriosis will benefit from a direct referral to IVF/ICSI. Couples should be fully informed about the risks of IUI and COH as well as alternative treatment options. Larger randomized prospective controlled trials, investigating the important outcomes including live births, multiple pregnancies, miscarriage rates, and risk of ovarian hyperstimulation following IUI, are warranted.

Review Questions

1. How do you select a patient for IUI?
2. How will you work up the patient couple for IUI?
3. What will be the stimulation protocol you would select for your patient in an IUI cycle?
4. What is the correct technique of sperm preparation for IUI?
5. Would you prefer a blind IUI or an ultrasound-guided IUI?
6. Are there any known complications of IUI?
7. Are there any recent advances in the practice of intrauterine insemination?

Conventional IVF Insemination

Michael L. Reed

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_31

Learning Objectives

- Identify key environmental elements for developing a sperm capacitation protocol.
- Develop an understanding of the decision process regarding determining appropriate numbers of sperm for oocyte insemination.
- Identify key events from semen collection to sperm processing for insemination of cumulus-oocyte complexes.
- Identify a time line of events from oocyte retrieval to oocyte processing for insemination.
- Develop a knowledge base, including the historical perspective, for identification of physiological failure points for quality assurance and troubleshooting.

31

31.1 Introduction

In vitro fertilization (IVF) began by using what we call today conventional or traditional insemination techniques. In its most simplistic form, isolated cumulus-enclosed oocytes (in vitro matured or in vivo matured) are co-incubated with a number of motile spermatozoa (isolated from semen) for defined or less well-defined time periods. After co-incubation, oocytes are examined for proof that sperm penetrated the zona pellucida and oolemma: fertilization events that culminate in (1) formation of pronuclei that may be visualized in the oocyte cytoplasm or (2) cellular division if oocytes are evaluated after presumed pronuclear syngamy and dissolution.

On the surface, this approach appears to be very simple and not very challenging from a technical standpoint; in fact, achieving success with human in vitro fertilization is less challenging than working with a number of other mammalian species. Be that as it may, successful fertilization cannot occur in vitro without significant oocyte- and sperm-related events. Oocyte maturation involves resumption of meiosis (nuclear maturation) and completion of cytoplasmic activities, including production, accumulation, and activation of cytoplasmic components that allow nuclear maturation and support post-fertilization events (cytoplasmic maturation). Sperm maturation involves physiological changes that must occur during transit from the testicular environment to being housed within the epididymis prior to ejaculatory expulsion, which lead to fertilizing competence (capacitation) when the sperm approaches and binds to the oocyte zona pellucida.

31.2 Historical Perspectives

The first half of the twentieth century was explosive for reproductive physiology; endocrinology, ovarian physiology, and oocyte maturation and activation experiments were prominent; the fear that science would promote and forward a human-derived evolution was also common. Embryo transfer – movement of developing embryos, retrieved from a mated donor animal and then placed into the uterus or oviduct of a recipient animal – had been in practice since the late 1800s and further fueled concerns for humanity in this post-industrialized world.

In fact, the very real science that inspired the first chapter in *Brave New World* [1] allowed the public to experience a startling look into the basic principles of IVF and the possibilities for genetic manipulation (see [2]). But despite the many years of work dedicated to unraveling IVF, a basic understanding of the structural/functional changes that accompany sperm capacitation was lagging, and successful IVF in any mammalian species eluded researchers for decades, or was not substantially well-documented (see [2, 3]), including the many IVF attempts using human oocytes and sperm.

Regarding the practice of classical embryo transfer in humans, several publications, as early as in the 1980s and continuing into the early 1990s, described the attempts and successful utilization of embryo transfer with human oocyte donors – recovering uterine-stage embryos non-surgically (uterine lavage) from an oocyte donor that had been inseminated with the sperm from the husband of the embryo recipient. Despite the successes, this approach was eventually discontinued in favor of IVF [4]. Also interesting are the several photographs of human uterine-stage embryos presented in these multiple publications; embryos were photographed following lavage, but they were not studied to any extent prior to embryo transfer – notice that morphological features are very different from what we see in the laboratory today.

As one example of the early attempts with human in vitro fertilization, a large number of experiments were described, spanning a 6-year period. Rock and Menkin [5] described what is purported to the earliest account of successful fertilization in vitro following the observation of cleaving ova after insemination; 3 of 138 ova that had been exposed to sperm were cleaved. The time of evaluation was approximately 41–47 h post-insemination, but notably without evaluation for pronuclear formation events. Ejaculate sperm were washed in Locke's solution and then placed with oocytes at room temperature for 1 h (co-incubation also occurred in Locke's solution). There were no details regarding the sperm washing procedure, duration of sperm incubation in Locke's solution post-wash, or insemination concentration. Oocytes used in the Rock experiments were apparently retrieved from ovarian follicles during surgery, rinsed in Locke's solution, and matured in patient serum for 22 or 27 h prior to insemination. It is possible that serum components were carried over during co-incubation. Also consider the medium formulation used in these experiments: Locke's solution, per deciliter H_2O: 0.9 g NaCl, 0.042 g KCl, 0.024 g $CaCl_2$, 0.05 g $NaHCO_3$, 0.02 g $MgCl_2$, and 0.05 g dextrose. There will be more on the topic of capacitation media later.

Two landmark publications by independent researchers, Collin Russell Austin and Min Chueh Chang, cited the discovery that fertilization in vivo is preceded by a requisite exposure of sperm to the reproductive tract for several hours [6, 7]; capacitation, the term coined by Austin, refers to the many physiological and structural changes that sperm must

undergo to achieve the ability to undergo the acrosome reaction and fertilize an oocyte. Of interest, John Rock had been encouraged to apply the findings of Austin and Chang to his research, to repeat his experiments with in vivo capacitated sperm. However, Rock had already discontinued his work along these lines (see [2]), and there were no further attempts with IVF.

The discovery that sperm were required to undergo capacitation in vivo prior to fertilization led to the first successful IVF series; rabbit oocytes were exposed to sperm retrieved from the uteri of mated females. But fertilization of oocytes in vitro, with sperm not exposed to the reproductive tract but capacitated entirely in vitro, was not achieved until Yanagimachi and Chang [8, 9] were able to substantially document successful IVF in hamsters using epididymal sperm capacitated in vitro, where sperm were required several hours of incubation in vitro before any sperm-oocyte penetration events were noted.

The first well-documented, successful fertilization of human oocytes in vitro, using in vitro capacitated sperm, was reported in 1969 [10, 11]. The events specifically related to laboratory techniques leading up to this accomplishment were described in a detailed narrative by Barry Bavister [12]. Most notably, these successes were preceded by the significant foundation work set down by Dr. Bavister while he was a graduate student, studying golden hamster sperm capacitation.

31.3 A Conversation with Dr. Barry D. Bavister

I have had the pleasure of speaking with Dr. Bavister on several occasions regarding his work with sperm capacitation and IVF in the hamster model that led to the first successful human IVF – from these discussions and from his publications, I was able to build an image of the events, principal players, and emotions surrounding the successful fertilization as it played out, though I understand that it is difficult to convey the enthusiasm, the uncertainties, and the emotions in writing. I also posed specific questions to him about the timing of the events, the conditions for sperm capacitation, and the decision to use 1×10^6 million/ml sperm for the co-incubation.

In 1968, Barry Bavister was a graduate student working on hamster IVF; he focused on sperm requirements and refining the hamster IVF technique that had proven successful for Yanagimachi and Chang [8, 9]. He was approached by Dr. Edwards and given the opportunity to apply his experiences and advances with the hamster model (see below) to the problem of human in vitro fertilization. In context, Dr. Edwards had been working on oocyte maturation (including human oocytes) for several years [13, 14], but as with other researches documented, successful fertilization was lacking. The basic approach taken by Dr. Edwards then was to re-examine human IVF by building upon the success that Dr. Bavister had achieved with hamster IVF, using the modified culture medium that had proven successful for hamster sperm capacitation and gamete co-incubation.

To obtain sperm, a hamster epididymis is punctured while it is submerged in culture medium; the dense exudate passes into the culture medium; numbers of sperm (live and dead) released from each preparation can be extremely variable. Hamster IVF results were also variable, leading Dr. Bavister to question co-incubation conditions; one aspect, culture medium pH, was evaluated via qualitative observation (phenol red was added to the medium for comparisons against color controls). Dr. Bavister noticed that pH varied between the different sperm preparations, and when motile (viable) sperm numbers were higher after co-incubation, fertilization rates were lower, and when motile sperm numbers were lower (dead and nonmotile), fertilization rates were higher. The link between viable sperm concentration and pH was realized, where pH was altered according to numbers of viable sperm, or more specifically, by the concomitant concentration of metabolic acids produced by the sperm. Patterns of fertilization – monospermic, dispermic, and polyspermic penetration – were also correlated to medium pH (see [12] for more details). And fortunately, the acrosome reaction in the hamster could be visualized without staining; Dr. Bavister noted that the proportion of acrosome-reacted sperm increased as pH became more alkaline. In subsequent trials, controlling for both medium pH (adjusting bicarbonate and CO_2 to target pH of 7.6) and viable sperm concentration yielded the highest fertilization rates with minimized polyspermic fertilization. Dr. Bavister discovered and then followed up on key elements leading to successful and consistent sperm capacitation in vitro.

The gamete co-incubation system chosen for the human IVF trials was Tyrode-B [Tyrode's medium modified to 32.6 mM bicarbonate, 2.5 mg/ml bovine albumin, 0.1 mM pyruvate; 5% CO_2/air at 37 °C to maintain an alkaline pH (pH 7.6)]; a sperm concentration of 1×10^6 million sperm per ml, based on experiences with hamster sperm concentration and pH, was chosen. Human sperm were washed from the ejaculate and capacitated for 6–7 h prior to being co-incubated with in vitro matured oocytes; and each trial, by necessity, utilized only a few human oocytes, as starting materials – surgically retrieved ovarian tissue – were scarce. After multiple attempts, evidence of fertilization was finally observed, culminating in two remarkable publications [10, 11]. Human sperm capacitation times in vitro had not yet been fully defined despite progress made by Dr. Bavister; but based on the work of Chang [7], Austin [6], and Yanagimachi and Chang [8, 9], the in vitro incubation of human sperm for 6–7 h was thought to be acceptable, to achieve capacitation for the human IVF trials. The first successful fertilization events occurred with in vitro matured oocytes: (1) of the 56 oocytes held in vitro, 34 underwent nuclear maturation, and (2) of the 34 oocytes inseminated in this trial, many displayed evidence of zona binding/penetration, while only 2 were confirmed with 2 pronuclei. But, the birth of the first IVF baby is not achieved until much later, and only after IVF with oocytes that had been matured in vivo and recovered

surgically [15]. Compare Locke's solution (discussed earlier) to the Tyrode-B medium formulations and sperm incubation conditions, but also consider how this narrative relates to the present-day knowledge base regarding human sperm capacitation conditions: medium pH, sperm pHi, elevated bicarbonate, albumin, temperature, and time.

31.4 The General Process of IVF: Conventional Insemination

Retrieval of oocytes has moved, for the most part, to recovery of in vivo matured follicular oocytes via ultrasound-guided needle aspiration. The earliest successful pregnancy [11] utilized a surgical approach to obtain in vivo matured oocytes, as pregnancies, despite fertilization in vitro, had not been obtained using in vitro matured oocytes, an early demonstration of the functional difference between oocytes that develop and mature in vivo, compared to in vitro (see [16]). Ovarian stimulation by injection of gonadotropin preparations is the most common treatment prior to oocyte recovery, though minimal stimulation and natural cycle follicle aspiration cycles are also offered. As the purpose of this chapter is to review conventional IVF, ovarian stimulation protocols and oocyte aspiration procedures will be left to others for review; it is sufficient at this point to note that human ovaries are not poly-ovulatory in nature; rather it is more common that a single follicle matures for ovulation.

Follicle aspiration is usually preceded by an injection of a chorionic gonadotropin preparation with LH activity and/or injection of LH or GnRH; 34–36 h later (prior to ovulation), oocytes are recovered by insertion of the aspiration needle through the vaginal wall and into the ovarian follicular structure(s). Follicles are drained by application of vacuum pressure, and aspirates are then handed off to the laboratory for evaluation. At this stage, the cumulus cells surrounding the oocyte are visibly "watery," or "clear" with individual or clumps of cumulus cells suspended in an expanded hyaluronic mucin matrix. These complexes (cumulus-oocyte complex (COC)) are rinsed to remove blood and minimize carry-over of follicular fluid – which contains a number of serum exudates, which may or may not include anesthetic agents [17], toxins [18], or microorganisms [19–22]. The COCs are then placed into culture medium for several hours until co-incubation with sperm. The cumulus cell hyaluronate complex surrounding the aspirated oocyte may be quite large in relation to the size of the oocyte, and there may be small blood clots, degenerated cells, or follicular granulosa cell sheets attached; excess cumulus may be trimmed prior to insemination. And while cumulus may be removed prior to conventional insemination [23], as much as is done with sperm injection cycles, fertilization may not occur as efficiently as with insemination of intact COCs; cumulus cells and the surrounding hyaluronate matrix play a role in sperm preparation for fertilization and may be involved with sperm chemotaxis, via cumulus cell secretion of progesterone [24, 25].

Ejaculate sperm are processed out of the semen sample by one of the several techniques [26]. Two of the more common methods are density gradient separation and swim-up. The motile population of sperm is "enriched" by these preparations, via reduction of the majority of motile, less motile, and nonmotile sperm and non-sperm cells. The enriched population of motile sperm is suspended in capacitation medium and incubated for several hours prior to co-incubation with COCs.

A protocol for co-incubation of sperm and oocytes is usually formatted to define a specific number of motile sperm per oocyte per volume of medium, e.g., 50,000 sperm per oocyte/ml. Protocols differ from laboratory to laboratory, where sperm concentrations may range from 20,000 to 1×10^6 motile sperm/oocyte/ml. Extremes in sperm concentration will depend more so on the co-incubation vessel – well dish, micro- or macro-drops of medium under oil, test tubes, or other vessels – as the choice of vessel can dictate proximity of sperm to the COC. For example, a cell-well dish with 1 ml medium and one oocyte would require more sperm per volume than a 100 ul drop, under oil, that contains one oocyte; specifically, sperm in the micro-drop under oil are physically confined in closer proximity to the oocyte, and random encounters between sperm and oocyte investments are more likely. In any case, co-incubation may be allowed to continue for several hours to overnight – but evaluation for fertilization typically begins 16–18 h, or a similar interval from the time co-incubation was initiated. Pronuclear formation may be optimal within this time-frame, though earlier and later pronuclear formation is not uncommon. Ova are separated after evaluation, e.g., degenerated, immature, unfertilized, mono-pronuclear, bi-pronuclear, and tri-pronuclear and greater pronuclear, and may also be sorted based on morphology. Culture proceeds per laboratory protocol, with evaluation of development at defined intervals, prior to transfer, cryopreservation, or manipulation for genetic testing.

When patients refuse to use sperm injection despite having limited numbers of motile sperm in the ejaculate, it may be possible to bank sperm via cryopreservation of numerous ejaculates, or in cases where a few ejaculates would be sufficient, a multiple ejaculate collection protocol may be employed [27]. Insemination of COCs may also be approached, in cases with limited numbers of motile sperm, by insemination of COCs across a defined time interval, for example, using 1/3 of the capacitated sperm at each of three 1 h intervals; COCs may have to be combined into several or a single large macro-drop or test tube for this approach to work (Reed, unpublished data).

31.5 The Oocyte

Oocyte sourcing is, of course, ovarian – but the intermediate step(s) toward insemination include in vivo maturation, in vitro maturation, and use of cryopreserved oocytes. The use of sperm injection is recommended following cryopreservation of oocytes – ultrastructural changes impact

sperm/zona/oolemma dynamics with conventional insemination, so that topic will not be addressed [28–30]. In vitro maturation (IVM) has been practiced now for several years; the processes and protocols for IVM, in brief, typically rely on ovarian stimulation protocols with or without a priming treatment (chorionic gonadotropin, or LH/GnRH) prior to aspiration. A key difference is that ovarian follicles are aspirated at a much smaller mean diameter, germinal vesicle stage, and pre-cumulus expansion, followed by a period of in vitro culture (24–48 h) for nuclear and cytoplasmic maturation prior to insemination. These oocytes may respond equally, regarding post-insemination developmental and pregnancy potential, but there are differences in cytoplasmic maturation that may influence the outcomes (see [31, 32]). Insemination of IVM oocytes occurs in the same manner as oocytes retrieved just prior to ovulation: conventional insemination or sperm injection [33].

Conventional insemination protocols may differ on timing of insemination, according to the perception of oocyte maturity. Cumulus-oocyte complexes can be scored according to the expansion of both outer cumulus and the specialized inner cortical, zona-proximal granulosa cells (corona radiata). Immature, mature, and post-mature are used to describe COCs in some cases. Insemination times may be delayed for COCs that appear to be immature, though most protocols call for insemination of all COCs at the same relative time. Density of the cumulus and coronal cells may prohibit a true visualization of the oocyte cytoplasm and also make it difficult to visualize polar body structure(s).

There are two techniques, anecdotal but not practiced in my laboratory, used to displace the cumulus and mucin matrix, which results in a flattening of the COC to allow visualization:

1. Placement of a COC in a very small amount of medium, onto the bottom of a sterile Petri dish; the dish is slapped down onto the microscope stage, spreading the cumulus and mucin matrix out around the oocyte – this technique can allow for visualization of cytoplasm and polar body structure(s).
2. Drawing the COC into a small-diameter glass Pasteur pipette, essentially elongating the COC so that the oocyte can be viewed through the wall of the pipette.

The information gained by these two techniques may be overshadowed by the potential to compromise the oocyte via mechanical, pH, and temperature stressors. Qualitative evaluation of cumulus expansion may be useful (but should not be considered to be a reliable predictor of nuclear maturation) and is used by some laboratorians to assign insemination times. The laboratory generally has to rely on receipt of oocytes "as is," with regard to maturation and quality. Evaluation of oocytes at the time of fertilization evaluation will be covered in another section. Further, oocyte quality is not something that can be easily and positively modified by the laboratory before insemination; as such, ovarian stimulation protocols will not be addressed, but for further reading, see Beall et al. [34], von Wolff et al. [35], and Jungheim et al. [36].

31.6 Oocyte Nuclear and Cytoplasmic Maturation

The final stages of oocyte growth include acquisition of competency to maturation. The oocyte is released from stasis following limitation of cumulus cell-to-cell contact and release of cumulus cell contact with the oocyte membrane; the specialized cells close to the oocyte communicate directly with the oocyte via projections that extend through the zona and into the oocyte. Compartmentalization – and isolation via gap junctions – of the oocyte via these specialized cells allows for participation in and control of oocyte growth and maturation. Prior to ovulation exposure to luteinizing hormone (LH), or in the event of mechanical aspiration (in most IVF cases), an exposure to LH, chorionic gonadotropin (hCG), and/or LH after gonadotropin-releasing hormone (GnRH) administration accelerates the communication breakdown between the cumulus cells and the oocyte.

The simplified explanation is that the cumulus-oocyte communication breakdown is receptor-mediated, at the level of the cumulus cell – and withdrawal of the coronal cell projections from the oocyte membrane leads to a decrease in transport of inhibitory molecules from the cumulus to the oocyte. This leads to release from meiotic stasis, meiosis resumes, and one-half of the oocyte chromosome complement should be released or extruded from the oocyte in the form of the first polar body; essentially this process can be viewed as an unequal cytoplasmic division, where the oocyte proper contains a 2 N complement and the polar body contains a 2 N complement resulting in a metaphase II oocyte. Nuclear maturation does not imply that cytoplasmic maturation has occurred, but rather cytoplasmic maturation has proceeded to a set point where nuclear maturation is possible. Removing an oocyte from the follicular environment (and follicular fluid) may trigger spontaneous nuclear maturation (see [37, 38]), without cytoplasmic maturation.

Unlike polar body extrusion, acquisition of cytoplasmic maturation and future developmental competence is not a tangible event [39]. During growth and final stages of maturation, the oocyte builds a reservoir of maternal mRNA transcripts, cytoplasmic growth factors, and enzymes for processing the sperm (decondensation, remodeling, and pronuclear formation) and for pre- and post-syngamy events including cellular division. Essentially, the oocyte and early cleavage-stage embryo operate off of maternal controls up to the point of comprehensive genomic activation. Failure to achieve cytoplasmic, or molecular maturation as it has also been called, can lead to fertilization and post-fertilization event failures regardless of the method used for insemination of the oocyte [40].

31.7 The Sperm

There are two sources for sperm that do not require surgical intervention: antegrade and retrograde ejaculate. There are three primary sources for sperm that do require surgical intervention: seminal vesicle, epididymal, and testicular.

A less-often used source for sperm is recovery from the vas deferens at time of vasectomy or vasectomy reversal. As testicular sperm are immature and fewer in number compared to ejaculate sperm, sperm injection is the method of choice for assisted fertilization – this source will not be discussed in detail here; however, sperm may be harvested from tubules "fresh" at the time of retrieval, and/or they may be cryopreserved for future use. Seminal vesicle sperm aspiration can be successful in patients with ejaculatory obstruction, but despite recovery of very good numbers of sperm, the quality of the sperm retrieved from these structures may be compromised by the physiology of the seminal vesicle environment and of course the backlog of sperm due to ejaculatory blockage; sperm aspirated from seminal vesicles are characterized by very low motility and increased sperm DNA fragmentation (Reed, unpublished), making these sperm candidates for sperm injection procedures rather than conventional insemination [41–44].

31.7.1 Epididymal Sperm

The epididymis is situated outside of the testicular environment, with four associated segments: caput, corpus, cauda, and the proximal vas deferens. Epididymal aspiration is accomplished by percutaneous or microsurgical aspiration (see [45]). A complete review of the biology of the epididymis is beyond the scope of this chapter; however, it should be recognized that in the context of sperm fertilizing ability, particularly in reference to conventional insemination, transit of sperm through the epididymis is critical to final maturation of sperm – the ability to achieve progressive motility and sperm membrane modifications that allow sperm to undergo capacitation and the acrosome reaction – these are hallmark events critical for in vivo and conventional in vitro fertilization. It is also important to keep in mind that the epididymal environment may be modified following vasectomy reversal or other injuries/pathologies. For reviews on epididymal anatomy and functions, see Cooper [46–48], Cornwall [49], and Hinton [50].

In many species, epididymal sperm can be used for conventional in vitro fertilization (see Brackett [51]), and it is reasonable to consider that human epididymal sperm may also be used for conventional insemination; however, early successes became historical footnotes after widespread application of sperm injection techniques to human IVF.

In 1988, Silber et al. [52] retrieved epididymal sperm from two patients with congenital absence of the vas deferens; sperm were recovered from the proximal epididymis in both cases and used for conventional IVF preceding ZIFT. Aspirated sperm were diluted in modified Tyrode's with serum albumin; motile sperm were separated using a swim-up technique. Sperm were capacitated for 1 h in the modified Tyrode's and then aliquoted to tubes containing oocytes (5–7 per culture tube; Menezo's B2 with heat-inactivated fetal cord serum). Couple 1 yielded 28 oocytes, and all oocytes were exposed to sperm; 16 of 28 oocytes were fertilized. Couple 2 yielded 24 oocytes, and all oocytes were exposed to sperm; 6 of 24 oocytes were fertilized. One clinical and one biochemical pregnancy resulted. Also, Hirsh et al. [53] found that motility of the epididymal sperm was highest if taken from the caput, in 89% of patients, but overall despite differences in sperm motility by region, the mean fertilization rate following conventional insemination was only 11.2% and an overall 8.7% implantation rate per embryo.

One of the largest studies published describing outcomes after conventional insemination with epididymal sperm also included a smaller cohort of patients that underwent sperm injection using epididymal sperm [54]. From the publication, it is apparent that the two treatments were independent, that is, sibling oocytes were not divided within patient to explore conventional vs. sperm injection outcomes. Details regarding capacitation or other sperm incubation conditions were not presented; however, in this case, the data clearly demonstrated that the outcomes, both fertilization and gestational, were superior following sperm injection with epididymal sperm. Of 1427 oocytes undergoing conventional insemination, 98 embryos were generated, with an ongoing pregnancy rate of 4.5%, compared to sperm injection with 197 oocytes yielding 80 embryos and an ongoing pregnancy rate of 30%.

31.7.2 Ejaculate Sperm

Ejaculate sperm are recovered from semen using one of the many techniques (see Henkel [26]), where the goal is to concentrate or isolate motile sperm from the population of sperm and non-sperm cells in the ejaculate. Discontinuous gradient and swim-up are two of the most common methods used, but like many techniques, efficiency of motile sperm recovery varies from specimen to specimen. Sperm cell separation appears to be a simple process, on the surface, but extreme care must be taken during the procedures, to maintain aseptic technique and to prevent carry-over of contaminants from the semen that might inhibit sperm capacitation [55].

In some cases, it may be advisable to collect more than one specimen [27] for processing or to cryopreserved sperm ahead of the oocyte retrieval day as physiological and psychological pressure may make semen collection on the day of oocyte retrieval difficult.

31.8 Sperm Capacitation

Human ejaculate sperm are usually simple to capacitate, but details regarding incubation environment are still important to maximize the number of sperm that can undergo capacitation: (1) pH, (2) bicarbonate, (3) protein, (4) calcium, (5) temperature, and (6) time. Capacitation is a term used to describe a complex series of events that must occur before the sperm cell acquires the ability to fertilize an oocyte. As capacitation proceeds, the sperm gain the ability to hyperactivate; and these are the sperm that have the greater potential for undergoing the acrosome reaction [56].

While it seems simple on the surface, sperm biochemistry is a complex area of andrology: sperm membrane modification and hyperpolarization, intracellular ion shifts, protein tyrosine phosphorylation, and reactive oxygen species. I would point the reader to a more comprehensive series of papers for study [57–64].

An example of a simple sperm capacitation protocol would be to separate sperm (density gradient or swim-up) and concentrate the motile sperm by centrifugation. Resuspend the sperm at a concentration of 10 m/ml motile sperm in HTF with 10 mg/ml albumin at pH 7.5, and incubate at 37 °C for 4 h. At the time designated for oocyte insemination, aliquot an appropriate number of motile sperm into equilibrated medium (the same used for the oocytes), and place sperm with the COCs.

Most commercial media today are manufactured to achieve a given pH range at a given concentration of CO_2. Look closely at the manufacturer Certificate of Analysis; if there are any doubts, consult the manufacturer. The current thinking for embryo culture conditions is to maintain a lower pH relative to ideal pH for capacitation of human sperm, for example, embryo culture is targeted at pH of 7.2 in some laboratories and 7.3 in others [65]. Acrosome function, like motility following capacitation is pH dependent, and internal pH can be modified according to extracellular pH; but importantly, pHi should increase as capacitation proceeds. Under progesterone-challenge conditions, sperm acrosome responsiveness was improved as external pH increased [66]. Sperm ion channel regulation then is critical; and the only externally visible metric is modification of motility characteristics that change with in vivo and in vitro environmental pH [67–69]. These ion channels are also responsible for intracellular rise in calcium [70, 71]. Monitoring pH is, with regard to sperm cells, an important concept to remember as capacitation may not be efficient, or it may not occur at all for some patients, resulting in lower than expected fertilization rates. An anecdotal lesson from my own laboratory: on receipt of a "new-generation" culture medium many years ago, fertilization rates fell consistently to less than 10% across several patients. This same medium was used for both sperm capacitation and embryo culture, and medium pH was targeted to 7.18; changing to a different medium for sperm capacitation, targeted to pH 7.5, immediately solved the problem. Other laboratories expressed similar experiences.

Bicarbonate is critical for capacitation, both in vivo and in vitro [72–74]; and while culture media formulations vary [75], the concentration of bicarbonate in commercial culture media is sufficient for capacitation to occur, these concentrations being similar to if slightly lower than found in vivo. And of course, bicarbonate is a key player in maintenance of pH. A note of caution regarding bicarbonate: it is acceptable to incubate sperm destined for sperm injection in modified media, e.g., Brand-X with HEPES, or MOPS, or HEPES and MOPS, but these media are designed for use "in air," and not with incubator concentrations of CO_2. Most of these media have approximately a fivefold lower concentration of bicarbonate; the only modified medium that should be considered for sperm capacitation should have adequate bicarbonate as well, e.g., 25 mM bicarbonate, in addition to the Good's buffers [76, 77].

The type of protein supplementation is important for sperm function [74]; albumin is recognized as important for sperm membrane modifications and energy store regulation. Would inadvertent use of a medium, not supplemented with a protein source, affect capacitation efficiency? One study [78] trialed a sperm capacitation medium, SMART1®, which, "based on Earle's salts solution, contains glucose, amino acids, synthetic and plant molecules and is devoid of any animal compound." Initial capacitation trials and acrosome reaction challenges demonstrated reduced sperm movement (kinematics) characteristics, but similar acrosome reaction profiles. IVF using sibling oocytes demonstrated a significant increase in oocyte fertilization after using SMART1® for both capacitation and sperm-oocyte co-incubation, compared to the medium with albumin: 65% vs. 55%, respectively. There were no significant differences in the quality of embryos or transfer outcomes. A companion paper [79] compared SMART2®, a culture medium "devoid of any human or animal compound" for culture following sperm injection; no differences between treatments were found for embryo morphology, but pregnancy outcomes could not be compared. And last, comparing post-gradient motility characteristics between two media with albumin to protein-free (PF) medium (containing methylcellulose), it was noted that differences observed between treatments, e.g., lower percentage progressive motility and reduced sperm survival in PF medium, might be attributed to sperm sticking to the analysis chamber surface in PF medium; there was an increased sperm yield with PF medium, and there were no differences for washed sperm morphology or 24 h survival. No attempts were made to test the functionality of the sperm, e.g., binding or fertilization [80].

Use of albumin and albumin/globulin supplementation is most common, while use of heat-inactivated patient or fetal cord serum has essentially been abandoned. Media are typically available supplemented with 4, 5, or 10 mg/ml albumin and are acceptable to incubate sperm. Note also that one protein supplement, in particular, Synthetic Serum Substitute (Irvine Scientific, Irvine, CA), is formulated using saline as a base, rather than a bicarbonate base medium; therefore, pH will be slightly more acidic due to dilution of the bicarbonate when adding this supplement to protein-free medium. Also, a protein supplement and culture medium formulation interaction may exist, potentially reducing capacitation efficiency; medium selection must be evaluated independently [81], though this effect might be due to contamination of a protein supplement by a stabilizer common in some commercial preparations [82] and would require further study. Proteins, e.g., albumin particularly, not only participate in sperm membrane modifications during capacitation, but they also provide modest oncotic pressure, and they participate in surface particle charges, preventing sperm, ova, and embryos from sticking directly

to glass and plastic pipettes and surfaces. Other molecules, e.g., PVA and methylcellulose, may substitute for some of these nonphysiological functions.

Limiting temperature excursions should be a standard practice in any IVF laboratory for all aspects of the process: oocyte retrieval and identification of COCs, rinsing, and incubation (pre-, co-incubation, post-fertilization). Incubator and surface temperatures must be defined and rigorously monitored.

The temperature for sperm capacitation should not exceed the temperature limits set for embryo culture. Cooler temperatures, e.g., room temperature, may be sufficient, but maximizing sperm function for reliable and consistent results should be the goal; room temperature may also be different between laboratories. Time is one area of argument; how long must sperm be incubated to achieve optimal capacitation? The early success achieved by Barry Bavister in animal and human IVF demonstrated that time was also important; sperm were incubated for 6–7 h at 37 °C prior to insemination. But remember that sperm do not immediately bind to and penetrate the oocyte vestments; exposing sperm to oocytes does not stop capacitation; rather it occurs across a continuum, where different subpopulations will achieve capacitation at different times, including the time of oocyte-sperm co-incubation. The time set aside for sperm capacitation prior to co-incubation may be more important for the "short co-incubation" protocols that minimize sperm-oocyte co-incubation, e.g., where the protocol calls for rinsing oocytes after 1 or 2 h.

Consider maintaining a separate culture incubator for sperm capacitation; simple media, e.g., one of the HTF versions, with at least 4 mg/ml albumin and 25 mM bicarbonate, maintained to target pH 7.5 provide a consistent environment for incubating sperm. This is also a good technique to troubleshoot changes in overall fertilization rates. Remember that incubation of very large numbers of motile sperm per volume of medium will effectively reduce pH over time and may result in inhibition of sperm capacitation; see the notes from my discussions with Barry Bavister as an example. This is a simple experiment that can be done in any laboratory; begin with equilibrated medium that has a phenol red indicator; resuspend motile sperm to large-step concentrations, e.g., 1, 10, and 100 m/ml, by adding more sperm or reducing the volume of medium. Incubate for several hours, and then compare the color of each tube to each other.

31.9 Modification or Enhancement of Sperm Function Prior to Insemination

Sperm may be treated with various factors, hormones, and buffers in an attempt to improve sperm function prior to insemination (see [83]). Modifiers of motility (and therefore capacitation and acrosome reaction), for example, include exposure to heat-inactivated patient follicular fluid; progesterone; cAMP modifiers such as caffeine, pentoxifylline, or theophylline [84]; and growth factors such as platelet-activating factor. Extenders formulated originally for nonhuman animal sperm may also be useful; egg-yolk zwitterion buffers can maintain sperm function for at least 24 h and may help preserve sperm membrane integrity.

31.10 Oocyte-Sperm Co-incubation: The Devices

Culture tubes, well dishes, and micro- or macro-drops of medium under oil all have been used for conventional insemination of oocytes. Each device has both good and bad characteristics that should be considered, in particular, when trying to troubleshoot fertilization failure patterns, increased polyspermic fertilization rates, and so on. Selecting one device over another should include a review of the ease of use, e.g., placement of oocytes prior to insemination and recovery of ova for evaluation after co-incubation, and sperm behavior in the device.

Well dishes are typically large volume (usually 0.25–1.0 ml wells) with sloped or straight walls, though in recent years, there are a number of newer dishes with small-volume wells. Larger volumes used for co-incubation require larger numbers of motile sperm. For example, a center well dish with 1.0 ml medium containing one COC could be inseminated with 10^6 motile sperm; a case with ten oocytes would require ten separate dishes and 10×10^6 motile sperm under this configuration. More than one COC may be placed together for insemination. The dishes may be used with or without an oil overlay, but as with any culture dish used without oil, proper humidity must be maintained to minimize osmotic elevation due to evaporation of medium. Sperm will migrate outward to all regions of the well, and if deep enough, sperm will migrate upward as well. The COC and the oocyte after co-incubation can be visualized more easily, though straight-wall wells may be harder to use as ova may have moved to the edges against the wall where the visual image is less well-defined. Round and sloped wells are more easy to use.

Culture tubes, e.g., 4.0 ml round-bottom polystyrene culture tubes, are also common for co-incubation (and embryo culture in some labs) and may be used with or without oil. For example, 1.5 ml medium with a single (or more) COC may be inseminated with a lower number of motile sperm compared to a large-well dish; the physical shape of the culture tube, despite the volume, will maintain a greater concentration of sperm at the lower limits of the tube, though migration upward will still occur. Placing oocytes into culture tubes is relatively simple, but retrieving them after co-incubation requires either pipetting or pouring out; both techniques risk loss of the oocyte(s), and repeated rinsing may be needed to dislodge the ova. Pipette tips should be fire-polished to minimize scratching or etching of the plastic during the placement or retrieval of the ova.

Micro- and macro-drops under oil are efficient devices or containers for co-incubation; multiple drops per dish make management easier and effectively reduce the number of motile sperm required for co-incubation due to the physical limitations of the drop. For example, if the protocol calls for 10^5 motile sperm/oocyte/ml and the volume of the drop is 100 ul, then 10,000 motile sperm per oocyte per drop are required. The drop is shaped like a half-dome, contained by the oil overlay. COCs are easily placed, and ova are easily recovered after co-incubation as the entire drop can be visualized at one time.

There are a number of devices and dishes to consider for fertilization and embryo culture; please see [85, 86]. And regarding the topic of oil overlay, consider that one benefit of an oil overlay, aside from osmotic control, is that the oil behaves as a buffer between the medium and the outer environment. Case in point: a QA evaluation of sudden depression of fertilization rates determined that co-incubation of COCs and sperm in culture tubes without oil overlay exposed the culture medium directly to poor-quality air in the laboratory [87].

31.11 Insemination Concentration, Timing, and Duration of Gamete Co-incubation

Many of the protocols for conventional insemination, with regard to sperm concentration, need to be evaluated according to the device/dish used for insemination; millions of sperm/ml/oocyte is a common nomenclature. There are few publications directly and experimentally addressing insemination concentration.

One early publication [88] evaluated sperm concentration and fertilization outcomes (normospermic and polyspermic); insemination was carried out in organ well dishes (0.9 ml medium), and the authors describe each oocyte as a unit of study. Insemination concentrations were 500,000, 100,000, 50,000, 25,000, and 10,000 motile sperm/ml. Fertilization rates (%) and total oocytes inseminated for each of these treatments were 60.0% of 65 oocytes, 60.9% of 146 oocytes, 75.5% of 351 oocytes, 80.8% of 26 oocytes, and 28.6% of 7 oocytes. The incidence of polyspermic fertilization decreased as sperm numbers decreased. The authors described optimal numbers of sperm for insemination, based on normospermic and polyspermic fertilization outcomes, under these culture conditions, to be between 25,000 and 50,000 motile sperm/ml.

Increasing the numbers of motile sperm/ml may be useful in some patients [88, 89], for example, where previous fertilization failure had occurred, or in men with reduced sperm morphology or other sperm pathologies that may affect sperm function [90]. There is the requirement for increased numbers of sperm for insemination in vitro compared to what is presumed to be happening in vivo; laboratories cannot compete with in vivo physiology in regard to processing and selection of sperm cells. And this may also be explained, in part, by the fact that in vitro, only a small percentage of sperm can actually capacitate, undergo the acrosome reaction, and bind to and penetrate the oocyte vestments [91, 92]. Anecdotally, before the widespread use of sperm injection, low to no fertilization was more common, loosely estimated at 20% or so of all conventional insemination cycles. Certainly morphology and other sperm-related issues played a greater role in this. As sperm injection gained acceptance, sibling oocyte studies demonstrated the efficacy of sperm injection vs. conventional fertilization, most notably for surgically retrieved sperm [54], and in patients who do not have "male factor" infertility, study results vary, showing improved, no, or slight benefits of one approach over the other (see [93–95]).

Timing of insemination is discussed in relation to oocyte retrieval or more appropriately in relation to the administration of hCG to simulate the LH surge. Pre-ovulatory oocytes are harvested, incubated in vitro, and then placed with motile sperm for co-incubation. One of the earliest studies [96] demonstrated that fertilization rates (and % cleaved embryos) improved if insemination was delayed relative to the time of oocyte retrieval. The study spanned 0–0.5 h post-retrieval, then 4–4.5 h post-retrieval, 5–5.5 h post-retrieval, and 6–6.5 h retrieval. Essentially, this study demonstrated that pre-ovulatory oocytes required time to finalize "ovulating" in vitro. The intervals studied, essentially 4–6 h post-retrieval for insemination, are still in use. However, the interval is not absolute, as sperm and oocyte interactions continue, as do capacitation and oocyte maturation; Jacobs et al. [97] found no significant differences, regarding fertilization and post-fertilization development for conventional fertilization (1–7 h post-retrieval) or sperm injection (0.5–8 h post-retrieval) across a large number of cycles. From a quality assurance standpoint, standardizing sperm capacitation times and insemination times is a good practice; assignment of duties and timing of events can help during troubleshooting and help manage a busy schedule.

Management of semen specimens on the day of oocyte retrieval may be assisted by having all semen specimens required for cases that day to be collected early in the day. Semen specimens may be extended, 1:1 v/v with Refrigeration Medium TYB (Irvine Scientific, Irvine, CA), cooled, and held until processing; use of this buffer also allows specimens to be collected and extended on the day prior to the oocyte retrieval [27].

Duration of sperm-oocyte co-incubation varies: short co-incubation to the more generic "overnight" incubation. Sperm and oocytes are placed together at some point during the day of retrieval and then allowed to incubate until fertilization determination. Consider that sperm and cumulus cells produce metabolic waste products; sperm in particular, due to the higher numbers required for consistent fertilization, can as discussed earlier modify medium pH. Short exposure protocols, e.g., as little as 1 h co-incubation, have been successful in some settings [98], demonstrating that sperm penetration of the cumulus/hyaluronate matrix and functional sperm/zona receptor binding can occur quickly. Comparing a 6–16 h co-incubation period, Xiong et al. [99]

found that all outcome parameters were not significantly different, with the exception of a significantly reduced polyspermic fertilization rate with the shorter co-incubation period. Note that in this study, a relatively large sperm concentration was used: 10,000–15,000 sperm in a 50 ul drop of medium.

Evaluation for fertilization, e.g., pronuclear formation, varies also from lab to lab, from evaluation at 14–18 h post-insemination as one example to a time specified as, generically, "early the next morning." Dedicated laboratorians arrive very early in the morning for adherence to strict time lines, and this may be more important if you are using a pronuclear grading system [100] or using some other mechanism to determine early predictive potential [101]. But for all practical purposes, evaluation for pronuclear formation can be done at slightly later intervals, though data regarding embryonic potential may be lost, as demonstrated by time-lapse monitoring of pronuclear dynamics [102].

31.12 Recovery and Stripping of Oocytes for Fertilization Determination

COCs that have been exposed to sperm cells undergo a gross morphological change; enzymatic activity from release of sperm acrosomal contents causes a digestion of the hyaluronate matrix suspending cumulus cells around the oocyte. A collapse of these cells and a condensation of coronal cells immediately surrounding the oocyte can make visualization of the cytoplasm difficult. Complete or partial removal of cells from around the oocyte using a mechanical technique is required in most cases, and for new embryologists, this can be one of the most frustrating techniques to master; losing an oocyte or breaking an oocyte will happen eventually. And depending on the device/dish used for co-incubation, oocytes may have to be moved to another device for fertilization determination, e.g., oocytes inseminated in round-bottom culture tubes must be pipetted or otherwise recovered from the tube(s) and placed into a dish with medium prior to further processing. Using a dissection microscope, the oocyte must be freed from cumulus and coronal cells. The two most common approaches are (1) use of small bore pipettes, circa 130–140 um to gently aspirate the oocyte from the cells, or (2) use of small gauge needles, e.g., 27.5 or 30 g, to tease and push the oocyte from the collapsed cells. A combination of these two techniques is also common. Pulled glass pipettes with sharp edges at the tip are still used in some labs, though bore diameter is critical; too small and the oocyte may rupture; too large and the cells may not be sufficiently removed for visualization. Commercial small bore pipette tips come in a variety of sizes and are convenient, but it is still important to visually verify the diameter of the pipette tip before use; mistakes in manufacturing are not common, but possible. Other methods, for example, pulling the oocyte gently into the bevel of a 27.5 g needle, are more difficult, but each embryologist will need to master at least one technique.

31.13 Evaluation of Fertilization

In basic terms, the goal of the fertilization determination is to verify presence (and number) or absence of pronuclei and, in the absence of evidence of fertilization, to determine oocyte nuclear maturation status and evaluate sperm/zona binding. The biology of sperm decondensation, remodeling, and pronuclear formation is complex and will not be considered in detail (see [103–106]). Also, the events marking oocyte activation at fertilization, stemming from sperm fusion or sperm injection, will be yielded to the reader; the complexities of cytoplasmic events, translation of cytoplasmic mRNA stores, and microstructural changes can be found in detail elsewhere (e.g., see [107]).

Pronuclear formation following fertilization is not expected to be in perfect synchrony, as oocyte maturity and sperm penetration timing varies, particularly with conventional insemination compared to sperm injection cycles that are more predictable in regard to oocyte nuclear maturation status and sperm injection timing [108–110]. The majority of ova that will display pronuclei can be evaluated between 16 and 18 h post-insemination; however, early cleavage can be observed in some ova, as early as 20 h post-insemination particularly following sperm injection.

Fertilization status, specifically in relation to pronuclear observation, includes monospermic (1 sperm) and polypronuclear (polyspermic and polygynic). Monospermic fertilization (normospermic; one sperm) is evidenced, classically, by the presence of two to three polar bodies and two pronuclear structures in the cytoplasm. Maternal and paternal centriole structures provide the foundation for pronuclear formation; as such fertilization and oocyte activation dynamics can point toward the difference, for example, between polyspermic and polygynic morphology. Male and female pronuclei, unlike in the mouse, are more similar in size, and pronuclear proximity to the polar bodies is not sufficiently predictive to allow for absolute determination of male vs. female pronuclei, but identification of pronuclear status in the human is essential [111]; correction of polyspermy has been attempted, but due to the morphological similarities between male and female pronuclei, this should remain an experimental exercise [112].

Also, exceptions to oocyte quality metrics should be monitored as an oocyte cohort, though not homogeneous, may give clues to cycle stimulation or within-patient issues. An excellent resource for photomicrographs of post-fertilization cytoplasmic structures, including pronuclei, is Papale et al. [113]. In cases where it appears that polypronuclei are present in the cytoplasm, the presence of nucleoli should be verified, as a vacuole may mimic a pronucleus in size and position relative to other nuclear structures. Early IVF studies may not have included pronuclear evaluations; rather cleavage of the ova was determined to be sufficient evidence for fertilization.

Polyspermic fertilization is common following IVF (but usually below 10% of all oocytes inseminated), and as demonstrated by Wolf et al. [88], the incidence can be directly correlated to sperm insemination concentration. There can be within-patient oocyte characteristics where a majority of the cohort are found to be polyspermic, but typically, and unless the oocytes are immature [114], the blocks to polyspermy are relatively robust. This mechanism may be overwhelmed by multiple sperm penetrations prior to membrane depolarization, or when membrane depolarization events occur slower than normal, or if cytoplasmic maturation has failed to install appropriate cortical granule populations (see [115, 116]).

Establish a baseline for poly-pronuclear fertilization; patient-to-patient and within patient variation exist, but without metrics, systemic problems with fertilization rates, including poly-pronuclear fertilization, may go unnoticed. Polyspermic and polygynic fertilization, taken together as poly-pronuclear fertilization, occur to varying proportions, and tracking these events, regardless of method of insemination, is important; egg source and fertilization method can both alter these proportions [117]. Of 7664 oocytes retrieved, 6631 oocytes were inseminated by sperm injection or conventional fertilization (20,000 sperm per 200 ul drop, up to 3 oocytes per drop). For sperm injection cycles, 0.7, 0.1, and 0.7% of oocytes were poly-pronuclear (anonymous, donor, and patient oocyte cycles, respectively), and for conventional insemination cycles, 2.2, 2.5, and 4.7% of oocytes were poly-pronuclear (anonymous, donor, and patient oocyte cycles, respectively). In another large study [118], second polar body retention – polygynic fertilization following sperm injection specifically – was estimated at 2.5% of fertilized oocytes. Data were translated to conventional fertilization cycles, where 8.1% displayed 3-pronuclei; a "true" polyspermic fertilization rate of 5.6% was calculated, essentially a twofold greater incidence of polyspermy compared to polygyny.

31.14 Post-fertilization Events

The goal of conventional fertilization is to maximize the number of monospermic fertilized ova while minimizing poly-pronuclear fertilization, without the use of micromanipulation. Post-fertilization cleavage and continued development fall under embryo culture and have been discussed in detail in many other publications (for many examples, see [119–124]).

For this chapter, it is sufficient to state that there are likely as many approaches to embryo culture and determination of viability as there are embryologists: static, dynamic, and simple media, complex media, sequential and single media, interrupted and continuous culture, and, most recently, time-lapse incubation. But detailed records should be maintained to allow for backtracking embryo developmental failures to early pre- and post-fertilization events.

31.15 When Things Go Wrong

31.15.1 Fertilization Failure

With conventional fertilization, there are fewer data points available in regard to oocyte maturation at the time of sperm-oocyte co-incubation. The cumulus cells usually mask any obvious cytoplasmic and nuclear configurations; however, detailed records of the oocyte nuclear status, at time of fertilization evaluation, will help establish a baseline for ovarian stimulation efficacy and patient variation. Each presumptive unfertilized ovum should be identified as mature (MII) or immature (MI, GV, GVBD), degenerated, broken, and so on. Data regarding oocyte maturation when using sperm injection can be used as an inference guideline for all IVF cycles. For example, nuclear maturation status (MII) for 61 anonymous donors, 20 known donors, and 288 patient oocyte sperm injection cycles yielded 85.8, 81.6, and 80.1% MII oocytes, respectively [117]. The caveat to using these data to troubleshoot fertilization failure is that for sperm injection cycles, the data are real time, while oocytes may continue to mature overnight during the co-incubation period.

Many aspects of fertilization failure can be attributed to the oocyte (for an excellent review of this topic, see [40]), the sperm, and/or a combination of the two [91, 92]. Sperm morphology, particularly in reference to acrosomal defects, a complete lack of the acrosome (globozoospermia), or other sperm pathologies, should be considered in cases of fertilization failure [90].

Sperm function tests, for example, sperm binding assays or sperm decondensation assays, might also prove useful for predicting fertilization potential [125–127] or used in follow-up to reduced or failed fertilization; but few laboratories provide real-time testing using the same sperm that was used for the insemination procedure.

Evaluation of cumulus cell dispersion, sperm motility alongside of the oocyte(s), and sperm binding to the zona are also useful. There should be evidence that sperm enzymatic release worked to break down the cumulus-hyaluronate matrix, and there should be visible evidence of sperm/zona binding with conventional insemination; even mechanical stripping of the coronal cells does not dislodge all sperm bound to the zona. If no sperm can be found bound to the zona and if delayed pronuclear formation and cleavage does not occur – and if the laboratory has the equipment – fluorescent observation may be useful as sperm may have penetrated the oocyte without activating the oocyte [105].

Rescue sperm injection may be attempted – and can be successful – provided there are sufficient safeguards in place: examination of sperm binding patterns, accurate assessment of polar body status, and observation for delayed pronuclear formation (e.g., see [128, 129]). Delayed pronuclear formation should also be considered to be a possible oocyte dysfunction, possibly related to decreased capacity by the oocyte to remodel and repair compromised sperm [130].

A note of caution regarding rescue sperm injection: sperm injection, while there is a condensed sperm cell already in the cytoplasm, may result in the activation of the oocyte and processing of both sperm; careful observation of resulting pronuclei patterns is important. Fertilization determinations are usually performed early in the work day, and as early pronuclear formation can be seen approximately 6 h following injection, it is reasonable to evaluate "rescued" oocytes on the same day as the rescue injection; reliance on cleavage alone could lead to an embryo with an abnormal chromosomal complement.

Evaluate the oocyte retrieval process: recovery and rinsing media, temperatures of surfaces and holding blocks, pipetting of the COCs, and incubation conditions (pH, bicarbonate-base medium, protein, temperature, time for dish/device pre-equilibration).

Evaluate the insemination process: was the sperm concentration dilution protocol followed, were sperm observed at the time of insemination for quantity and quality of motility, were sperm observed for motility at the time of fertilization evaluation, were cumulus cells sufficiently dispersed, and, importantly, was the protocol for sperm capacitation followed (pH, bicarbonate-base medium, protein, temperature, time)?

31.15.2 Contamination of Co-incubation Devices/Dishes/Drops

On occasion there are observations that the fertilization environment has become contaminated; bacterial and fungal contaminations are the most notable, and most often, this is discovered after the sperm-oocyte co-incubation period. Technique breakdown can contribute to this, but also consider that gamete sourcing is a contributor as well; follicular fluid and semen are not sterile body fluids. Most gamete and embryo culture media contain some form of broad-spectrum antibiotic, but at times, this is not enough to prohibit overgrowth of a contaminant. Particularly with conventional insemination, given the "sticky" nature of the COCs and the numbers of sperm used for insemination, the opportunities for contaminants to be carried through to co-incubation are greater than for sperm injection protocols where cumulus cells are stripped away, and a single sperm cell is selected. For discussions on this topic, see [19–22].

In the event of a contamination event, ova should be recovered as quickly as possible and rinsed through a series of dilutions designed to minimize carry-over. There are no strict protocols for rinsing human embryos or oocytes that have been exposed to pathogens that I am aware of; however, the International Embryo Transfer Society has developed a washing technique [131]. I am aware of two laboratories that have employed this technique successfully after a bacterial overgrowth in one case and a fungal overgrowth in the other. The technique is essentially a series of ten dilutions, moving ova in 20 ul of medium into 2 ml, repeating this process with a new dish of medium and a new pipette tip each time; smaller volumes can be used, but the protocol stresses the importance of maintaining the 1:100 dilution factor for each of the ten steps.

31.16 Summary

It is increasingly important for each laboratory to maintain at least one functional protocol for conventional insemination; not all programs have joined the movement toward performing sperm injection on all cycles, as is required for increased use of genetic testing of embryos. And in some laboratories, the desire to ease the burden of managing personnel and resources may lead all cycles utilizing sperm injection. Regulations and opinions (providers and patients, as to the safety of sperm injection) vary; but also consider the importance of maintaining conventional insemination techniques in the event that the sole micromanipulation system in the lab breaks down or the sperm injection specialist is indisposed. Understanding the details is critical to the process of quality management; things will go wrong, and finding a solution, as quick as possible, is the responsibility of all members of the laboratory staff. Last, historically, it is good for all of us to remember the origins of IVF, the critical moments where the industry as we know it today was formed.

Review Questions

1. List the in vivo physiological conditions regulating sperm capacitation that can be translated to the in vitro process.
2. List the visible physiological change(s) that occur during sperm capacitation.
3. List three physiological failure points for troubleshooting a cycle with completely failed fertilization.
4. Identify the physiological and nonphysiological functions performed by protein supplements.
5. Describe the differences between polyspermic and polygynic pronuclei and identifiers of each condition, and detail an approach to remedy each condition.

Learning Objective

- To provide an overview of the reason that commenced the development of intracytoplasmic sperm injection and the current indications and address the safety concerns regarding the procedure

32.1 Introduction

ICSI involves the insertion of a single spermatozoon into the oocyte, bypassing all the egg coat penetration and gamete fusion steps characteristic of natural fertilization. This was first achieved in sea urchin [49], in mouse [62], and later in hamster eggs [134]. This micromanipulation approach was also plagued by oocyte injury and lysis [73], with only about 30% of injected mouse eggs surviving the procedure [131]. Because the sperm-egg fusion step is bypassed in ICSI, male pronucleus development generally required oocyte activation in most species tested. This was achieved by the vigorous suction of ooplasm prior to sperm nucleus insertion [98] or by exposure to A23187 [50, 143].

The first ICSI offspring were obtained in the rabbit following the transfer of sperm-injected eggs into the oviduct of a pseudopregnant female [51], with a bovine live birth reported soon thereafter [44]. Although applied to human gametes some years earlier [59], the first human pregnancies from ICSI were established only in 1992 [85], and since then, hundreds of thousands of ICSI babies have been born [85, 92, 99]. ICSI has made conception and parenthood possible for couples with many forms of male factor infertility and at rates similar to those in patients treated by the standard IVF with apparently normal gametes [80, 88].

32.1.1 Indications

Despite agreement in some areas, no universal standards for patient selection have been defined. However, there is a general consensus that ICSI be adopted when an extremely poor sperm sample is noted or following fertilization failure using in vitro techniques. Thus, in addition to male factor infertility, ICSI may be utilized in non-male factor settings as well.

When initial sperm concentration in the ejaculate is $<5 \times 10^6$/ml, the likelihood of fertilization with standard IVF is significantly reduced [144], and therefore, such couples should be considered unsuitable for this procedure, particularly where <1% normal forms are observed. However, fertilization of mature oocytes may still fail to occur in the presence of normal sperm [15] because of a hardening of the zona pellucida [22], or when oocytes reveal ooplasmic inclusions [2, 136]. Abnormalities of the zona pellucida prevent sperm fusion with the oolemma [57] thus justifying sperm injection. In most instances, however, failure of fertilization is due to coexisting sperm abnormalities presenting ICSI as the only treatment option [89].

Early experience showed that isolated nuclei of testicular and epididymal hamster spermatozoa decondensed soon after injection into mature hamster oocytes and formed pronuclei in activated eggs [135]. Although in vitro fertilization of human oocytes was accomplished in men with epididymal spermatozoa recovered in cases of obstructive azoospermia [117, 129], only with the advent of ICSI was it possible to obtain consistent fertilization with them [88, 118, 132]. Testicular biopsy was employed to obtain sperm cells from men who had a scarred epididymis and therefore, no chance of retrieval through that route [19, 36, 114]. However, the therapeutic possibilities of ICSI go even further since immotile testicular spermatozoa and even spermatids have been successfully used [130].

Some men produce only round-headed spermatozoa which have no acrosome and can neither bind to nor penetrate zona-free hamster oocytes [58, 70]. However, ICSI has enabled even such acrosomeless spermatozoa to establish pregnancies [32, 47, 64, 127, 128]. Moreover, ICSI's dependability has broadened its initial use from a technique capable of overriding the dysfunctionality of spermatozoa to one that may partly compensate for problems with the egg. Indeed, ICSI has allowed successful fertilization when only a few and/or abnormal oocytes were available [67]. Stripping cumulus cells from the oocytes allows a direct assessment of maturation, thus offering a woman with a limited number of oocytes a much greater chance of successful fertilization. In fact, the availability of ICSI has been instrumental in some European countries that include Italy and Germany in circumventing restrictive legislation that limits the number of oocytes inseminated or embryos to be replaced [6, 68, 69].

ICSI has also made possible a more consistent fertilization of cryopreserved oocytes [100] – overcoming the problem that freezing can lead to a premature exocytosis of cortical granules, resulting in zona hardening and inhibition of natural sperm penetration [52, 107, 120, 136]. ICSI is also the preferred conception method during the application of preimplantation genetic diagnosis (PGD). It avoids DNA contamination from additional sperm adhering to the zona, and it enhances the number of fertilizable oocytes and so embryos available for screening [34].

ICSI also has an impact in the arena of HIV infection. Three quarters of individuals infected by HIV or HCV are in their reproductive years. Male-to-female transmission of HIV is estimated to be only 1 per 1000 acts of unprotected intercourse [25] and even fewer in HCV-infected patients [39]. Moreover, because of antiretroviral therapies, the course of HIV-1 infection has shifted from a lethal acquired immunodeficiency syndrome to a chronic manageable disease. Though many patients infected with HIV-1 show interests in beginning a family, most serodiscordant couples are concerned, nevertheless, with the possibility of both horizontal and vertical transmissions of the virus. In such cases, intrauterine insemination (IUI) with spermatozoa processed by double gradient centrifugation followed by the swim-up has been the preferred method of treating serodis-

cordant couples with an HIV-1-infected male partner [14]. However, the use of ICSI has been proposed by several groups because of its negligible semen exposure, thereby reducing the risk of viral transmission [74, 105]. Advantages of ICSI over IUI also include the considerably higher success rate [74], requiring fewer attempts to achieve pregnancy while reducing viral exposure [96]. Fortunately, so far, no seroconversions have been reported following ART treatments including IUIs [137].

Finally, because only a single spermatozoon is needed for each egg, ICSI has allowed treatment of men who are virtually azoospermic (also defined as cryptozoospermic) [7]. Such cases of spermatogenic arrest have necessarily involved the injection of immature spermatozoa or even spermatogonia [31, 36, 130, 133]. Nonetheless, where fertilization occurs in such cases, conception is accomplished with embryo implantation following a similar pattern, at least in our experience, to that seen in IVF.

32.2 Equipment

- Micromanipulation system (NAI-2P, Narishige International USA, Inc.)
  - Hydraulic microinjector (IM-6), modified with a metal syringe (SYR-15)
  - Injector (IM-9C), air-filled
  - BDH oil – for loading the injector (BDH Laboratory Supplies, Poole, Dorset, England)
- Inverted microscope with Nikon Polarized Optics CFI S Plan Fluor (20× and 40× objectives) and CFI Apo (2×, 4×, and 10× objectives) (TE2000U, Nikon USA, Melville, New York, USA)
- Vibration-free table (Newport Research Corporation, Irvine, California, USA)
- Custom-designed horseshoe-shaped heated stage (Easteach Laboratory, Maspeth, New York, USA)
- Microtools (Vitrolife, San Diego, California, USA)
  - Injection pipette (15415; 4–5.5 μ ID)
  - Injection pipette (15346; 5–7 μ ID)
  - Holding pipette (15305)
- Oocyte transfer and denudation pipettes (hand-pulled, flame-polished Pasteur pipettes)
- ICSI dish (BD Falcon 351006; Becton, Dickinson & Co., Franklin Lakes, New Jersey, USA)
  - Stereomicroscope (SZX12, Olympus America Inc., Center Valley, Pennsylvania, USA)
  - Distriman® Repetitive Pipette (F164001, Gilson, Inc., Middleton, Wisconsin, USA) – ICSI medium dispenser
  - AutoRep™E Electronic Repeating Pipette (AR-E1, Rainin Instrument LLC, Oakland, California, USA) – oil dispenser
  - Pipetman P20 (F123600, Gilson, Inc.) – PVP and sperm loading

32.2.1 Reagents

- ICSI Cumulase® (16125000, MediCult, Origio, Mt. Laurel, New Jersey, USA)
- Embryo culture medium (home-brew, modified Cornell medium based on G1™ and G2™ components) [37, 38]
- ICSI injection medium (G-MOPS™ [10129] supplemented with 6% G-MM™ [10038], Vitrolife, Inc., Englewood, Colorado, USA)
- Tissue culture oil (ART-4008, SAGE In-Vitro Fertilization, Inc. A CooperSurgical Company, Trumbull, Connecticut, USA)
- 7% PVP with HSA (90121, Irvine Scientific, Santa Ana, California, USA)

32.3 Sperm Preparation

32.3.1 Ejaculated Sample

Semen samples are collected by masturbation after at least 2–3 days of abstinence; they are then allowed to liquefy for about 20 min at 37 °C prior to analysis. Other methods of semen collection such as electroejaculation and retrograde ejaculation have been described elsewhere [88].

Semen concentration and motility are assessed in a Makler counting chamber (Sefi Medical Instruments, Haifa, Israel). As might be expected, morphologic quality of the sperm has a significant positive correlation with male infertility. This evaluation is performed using the strict criteria of Kruger et al. [56]. Evaluations are carried out by spreading 10 μl of semen or sperm suspension on prestained slides (Cell-Vu®, Pre-stained Morphology Slides [DRM-900], Fertility Technology, Marietta, Georgia, USA), which can provide rapid results. At least 200 spermatozoa/slide are categorized microscopically at 100× under oil immersion. Two counts are performed for both concentration and morphology. Semen quality is considered suboptimal when the sperm concentration is $<20 \times 10^6$/ml, the progressive motility is <40%, or the proportion of spermatozoa with normal morphology is <4% of the spermatozoa.

For selection of spermatozoa, the sample is washed by centrifugation at 600 g for 5 min in HTF medium supplemented with 0.4% HSA. Semen samples with $<5 \times 10^6$/ml spermatozoa or <20% motile spermatozoa are washed in a home-brew medium by a single centrifugation at 600 g for 5 min. The resuspended pellet is layered on a discontinuous density gradient (Isolate®, Irvine Scientific) on two (90% and 50%) or single (90%) layers and then centrifuged at 300 g for 20 min when samples have a sperm density of $<5 \times 10^6$/ml spermatozoa and <20% motile spermatozoa. The sperm-rich fraction is rinsed by adding 4 ml of culture medium and centrifuged at 500–1800 g for 5 min to remove silica gel particles. For spermatozoa with poor kinetic characteristics, the sperm

suspension is exposed to a 3 μM solution of pentoxifylline for 15 min and centrifuged one more time. The concentration of the assessed sperm suspension is adjusted to 1–1.5 × 10^6/ml, when necessary, by the addition of HTF medium, and subsequently incubated at 37 °C in 5% CO_2 in air.

32.3.2 Surgically Retrieved Spermatozoa

Azoospermia can be indicative of epididymal vas obstruction or absence (obstructive azoospermia) or a failure of spermatogenesis (non-obstructive azoospermia). Obstructive azoospermia is characterized by normal sperm production and is often caused by congenital bilateral absence of the vas deferens, often associated with a cystic fibrosis gene mutation(s). The treatment for these men is microsurgical epididymal sperm aspiration (MESA), or when the epididymal access is lacking, direct testicular sampling is undertaken. On the other hand, non-obstructive azoospermia is characterized by a varying degree of spermatogenetic failure and may be associated with certain chromosomal abnormalities [41, 101]. The only method to retrieve spermatozoa from this form of azoospermia is a direct extraction of spermatozoa from the testis.

32.3.3 MESA

The infertility of men due to irreparable obstructive azoospermia has been treated successfully by microsurgical epididymal sperm aspiration (MESA) [111, 112] or percutaneous testicular retrieval of spermatozoa [115]. In the MESA procedure, 1–5 μl of fluid is aspirated from the lumen of an individual epididymal tubule in the midportion of the obstructed epididymis with a 300–350 μm glass pipette. The epididymal fluid is diluted with 300 μl of culture medium. Additional proximal punctures of the epididymis are performed until enough spermatozoa are obtained. Because sperm concentration in the epididymal fluid often reaches over 1 × 10^6/μl, only microliter quantities generally suffice. Epididymal fluid is diluted in 500 μl culture medium and processed like ejaculated spermatozoa. After removal of the density gradient medium, a 1 μl aliquot of the final suspension at approximately 1 × 10^6/ml is placed in the injection dish [86, 88].

32.3.4 TESE

In the case of men with non-obstructive azoospermia, spermatozoa are retrieved directly from the testis. Typically, multiple biopsies are needed to find the rare spermatogenetic foci that are present within the testes of such men. Biopsies are performed under optical magnification to identify and preserve the sub-tunical testicular blood supply with biopsy incisions made in avascular regions [113].

Each biopsy specimen is first rinsed in culture medium to remove red blood cells, separated into individual tubules on sterile glass slides, and minced using fine scissors. The resulting suspension of seminiferous tubules is then sequentially passed through a 24 gauge angiocatheter to further disrupt the tubules. Individual testicular samples are distributed in 5.0 ml centrifuge tubes (Falcon, Becton Dickinson and Company, Lincoln Park, NJ, USA) containing an excess of culture medium. To assess for the presence of spermatozoa, a small amount (~5 μl) of suspension medium is carefully studied under a phase-contrast microscope at 200–400×. In preparation for ICSI, the shredded testicular tissue is removed and the suspension medium subsequently centrifuged at 500–1800 g for 5 min, with the pellet being subjected to a single-layer density gradient centrifugation. It has been possible to identify individual and enlarged seminiferous tubules that presumably are supporting spermatogenesis in contrast to the surrounding thin sclerotic tubules. Biopsy samples are placed into 200–300 μl aliquots of culture medium on a glass slide and examined under a phase-contrast microscope and repeated until the presence of spermatozoa is documented. The specimen is then placed directly into a 40 μl drop under oil where the tips of two 25 gauge needles on 1 ml syringes are used to shred the testicular tissue. Subsequently, the tissue is removed from the droplet, and 3 μl of the suspension is placed directly onto the injection dish.

32.3.5 Micro-TESE

In cases of non-obstructive azoospermia, the procedure for direct microscopic identification of functioning seminiferous tubules is referred to as microdissection TESE [110]. As with the standard multi-biopsy approach, optical magnification (6–8 power) is used to visualize blood vessels under the surface of the tunica vaginalis, allowing testis biopsy incisions to be made in avascular regions. Instead of planning for multiple incisions in the tunica albuginea, an attempt is made to open it widely by creating the incision on the testis' midportion. This optimizes exposure of the testicular parenchyma without disrupting its blood supply. Direct examination is carried out at 20–25× under the operating microscope, during which an attempt is made to identify individual seminiferous tubules that were larger than others in the testicular parenchyma. Small (2–10 mg) segments are excised sharply from tubules that are larger and more opaque (whiter). Each excised specimen is further cut into smaller pieces to promote the release of any spermatozoa, with the resulting suspension examined as in standard TESE. Although additional incisions in the same or contralateral testes can be made until spermatozoa are retrieved or when further biopsies would appear to compromise the blood supply of the testes. Once spermatozoa are found, the procedure is terminated and testis sutured.

When no spermatozoa are identified, testicular tissue is placed in 1 ml of pre-warmed medium supplemented with 5% HSA, 1.6 mM $CaCl_2$ (Sigma Chemical Co., St Louis, MO), 25 μg/ml DNase (Sigma Chemical Co.), and 1000 IU/ml

collagenase type IV (Sigma Chemical Co.) [102]. DNase is added to the incubation medium to prevent clotting of the resulting cell suspension due to the release of free DNA from apoptotic cells [17, 18]. Testicular tissue is exposed to collagenase and incubated at 37 °C for 1 h. The suspension is pipetted every 10–15 min to enhance enzymatic digestion. Large portions of tubular walls are removed with fine tweezers. The digested suspension is then centrifuged twice at 500 g for 5 min. The supernatant is removed and the pellet re-suspended in 500 µl of sperm cell medium.

32.4 Oocyte Collection

Superovulation is performed by administration of gonadotropins in association with agonist or antagonist protocol [27]. Human chorionic gonadotropin (hCG) is administered when criteria for oocyte maturity are met, and oocyte retrieval by vaginal ultrasound-guided puncture is performed 35 h later. Under the inverted microscope at 100×, the cumulus corona cell complexes are scored as mature, slightly immature, completely immature, or slightly overmature. Thereafter, the oocytes are incubated for more than 4 h. Immediately prior to micromanipulation, the cumulus corona cells are removed by exposure to HTF-HEPES-buffered medium containing 40 IU/ml of ICSI Cumulase®. The removal is necessary for observation of the oocyte and effective use of the holding and/or injecting pipette during micromanipulation. For final removal of the residual corona cells, the oocytes are repeatedly aspirated in and out of a hand-drawn Pasteur pipette with an inner diameter of ~200 µm. Each oocyte is then examined under the microscope to assess the maturation stage and its integrity, metaphase II (MII) being assessed according to the absence of the germinal vesicle and the presence of an extruded polar body. ICSI is performed only in oocytes that have reached this level of maturity.

32.5 Intracytoplasmic Sperm Injection

32.5.1 Loading Tools

The holding and injection pipettes are inserted into the respective micromanipulation tool holders mounted on an inverted microscope. The controllers are pneumatic for the holding pipette and oil-filled for the injection pipette. Using the coarse motorized controllers, the pipettes are positioned in the center of the microscopic field at 20×, and then the magnification is gradually increased while maintaining the tools in focus by adjusting the hydraulic controllers. Under the highest magnification (400×), correct pipette positioning is achieved only by the use of the hydraulic joysticks, and both pipettes should be able to course through the entire optical field. With regard to tool tip angles, the distal bent portions of both microtools should be slightly above parallel to avoid the elbows touching the bottom of the dish and interfering with the control. This also allows prompt immobilization and visual control of the spermatozoon inside the injection pipette. Once properly aligned, the pipettes are raised by means of the coarse motorized controllers to allow placement of the ICSI dish on the microscope stage.

32.5.2 ICSI Dish Preparation

Nine drops containing 8 µl of injection medium are placed in a petri dish, with one in the center radially surrounded by the other eight (Fig. 32.1). The drops should be as close together as possible to allow full visualization within the 20 mm opening on the heated stage. The drops should then be gently overlaid with culture oil to prevent evaporation. Using a red non-embryo toxic wax pencil, the 12 o'clock position is marked, a circle is drawn around the central drop, and the drops are sequentially numbered starting from the 12 o'clock position, moving counterclockwise. This allows easy navigation between droplets during ICSI. ICSI dishes are stored at 37 °C until use.

32.5.3 Loading Gametes into the ICSI Dish

Immediately prior to the injection under a stereomicroscope, the central drop is removed and replaced with 1 µl of sperm suspension diluted in 4 µl of 7% PVP. Using a hand-pulled Pasteur pipette, MII oocytes are aspirated from the culture dish, and a single oocyte is placed in each drop.

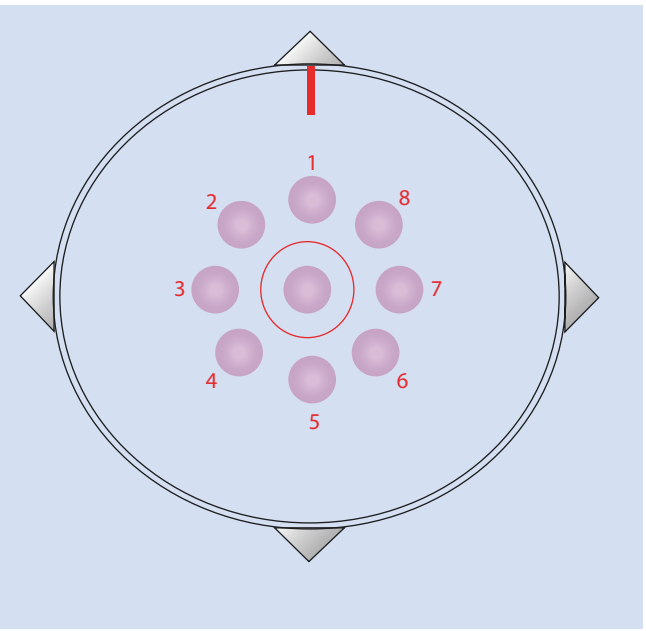

Fig. 32.1 The drawing depicts a petri dish containing the droplets of medium (8 µl) and sequentially numbered going counterclockwise. The center droplet is removed and replaced with PVP and sperm, while in each surrounding droplet, an individual oocyte will be placed

32.5.4 Sperm Immobilization

Position the spermatozoon at 90° with respect to the pipettes' tip, and gently lower the cylindrical tip to compress the principal piece of the tail, by rolling the posterior flagellum over the bottom of the petri dish (Fig. 32.2a–c). If initially unsuccessful, the procedure is repeated until the tail is clearly kinked, looped, or convoluted (Fig. 32.2d, 1–3). It is important to note, however, that a misshapen tail may adhere to the dish or to the inner surface of the pipette. The spermatozoon is aspirated tail first. The injection needle is lifted slightly via the two control knobs of the joystick to avoid damaging the needle spike. The microscope stage is then repositioned until the injection needle enters the oocyte drop. It is important to note that the difference in media consistency (PVP versus culture medium) may allow the sperm to move distally into the pipette and become loose.

32.5.5 Injection

To find the egg, the magnification is briefly lowered to 200×, and once the egg is centrally in the field, the magnification brought back to 400×. The oocyte is held in place by suction through the holding pipette, and, using both tools, the oocyte is rotated slowly to locate the polar body and the area of cortical rarefraction (or polar granularity) (Fig. 32.3a). When the equatorial plane of the oocyte is located, the depth of the holding pipette is adjusted to have its internal opening in the same plane. This allows for greater support of the holding pipette in a position opposite to the injection point. It is ideal to have the inferior pole of the oocyte touching the bottom of the dish, as it affords a better grip of the egg during the injection procedure. The injection pipette is lowered and focused with the outer right border of the oolemma on the equatorial plane at 3 o'clock. Bring the spermatozoon close to the beveled opening of the injection pipette, then bring the pipette to the zona, press against it to begin penetration, and thrust forward to the inner surface of the oolemma at 9 o'clock (Fig. 32.3b–d). At this point, a break in the membrane should occur at the approximate center of the egg (Fig. 32.3e). Such a break is indicated by a sudden quivering of the convexities of the oolemma (at the site of invagination) above and below the penetration point (Fig. 32.3f), as well as by the proximal flow of cytoplasmic organelles and the spermatozoon back into the pipette. The spermatozoon is then ejected with the cytoplas-

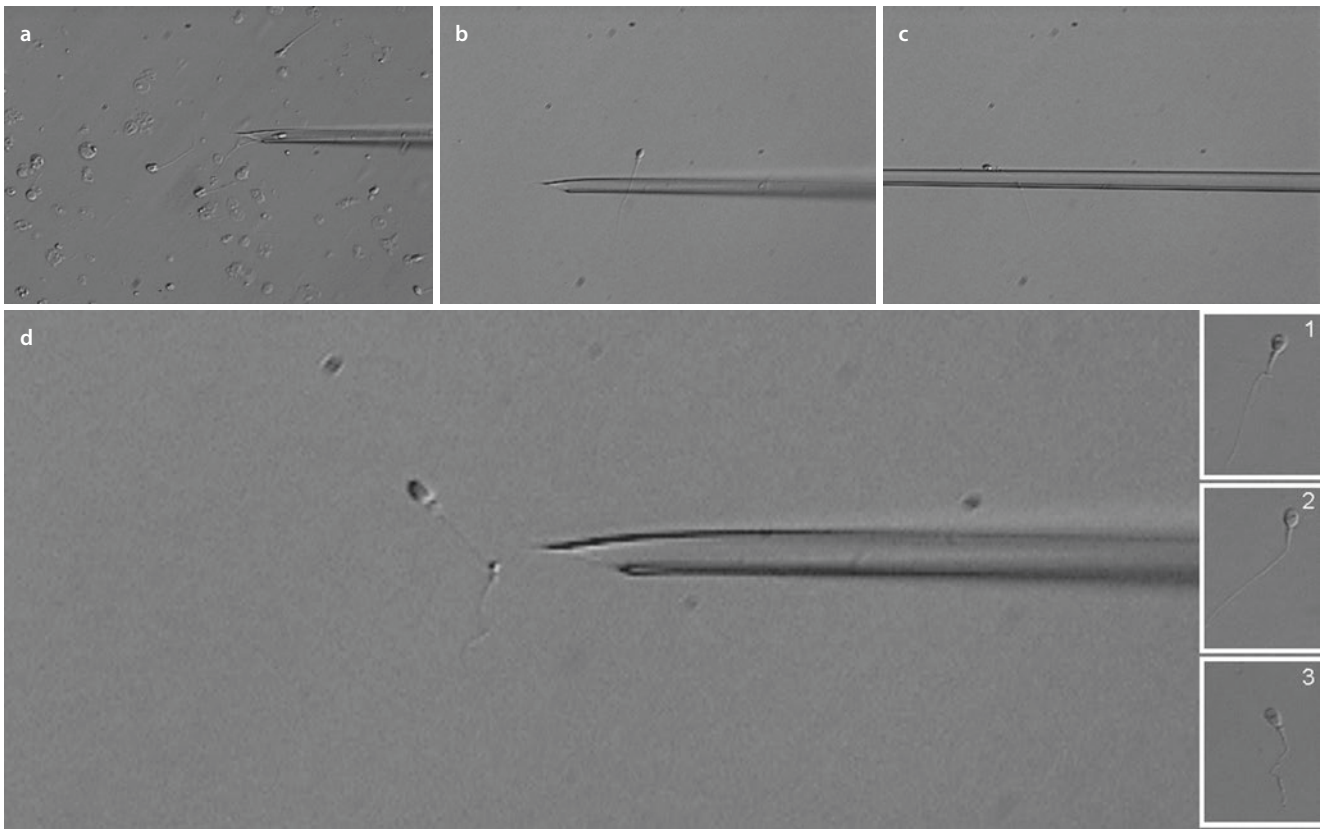

Fig. 32.2 Aggressive immobilization of a testicular spermatozoon prior to intracytoplasmic sperm injection. **a** A single spermatozoon displaying a satisfactory morphology is aspirated from a sperm droplet. Such droplets are made without PVP in cases where sperm count and motility are poor. **b** The chosen spermatozoon is then moved into the PVP droplet, where the injection pipette is gently lowered onto the sperm tail main piece, compressing it. Even though the spermatozoon is immotile, immobilization is still carried out to ensure the best chance of fertilization, since a damaged sperm membrane facilitates exposure of the nucleus to the ooplasm. **c** While maintaining downward pressure on the flagellum, the injection pipette is moved back and forth, effectively rolling the spermatozoon on the dish bottom. **d** Once immobilization is completed, the tail should be permanently distorted – either looped (1), kinked (2), or convoluted (3)

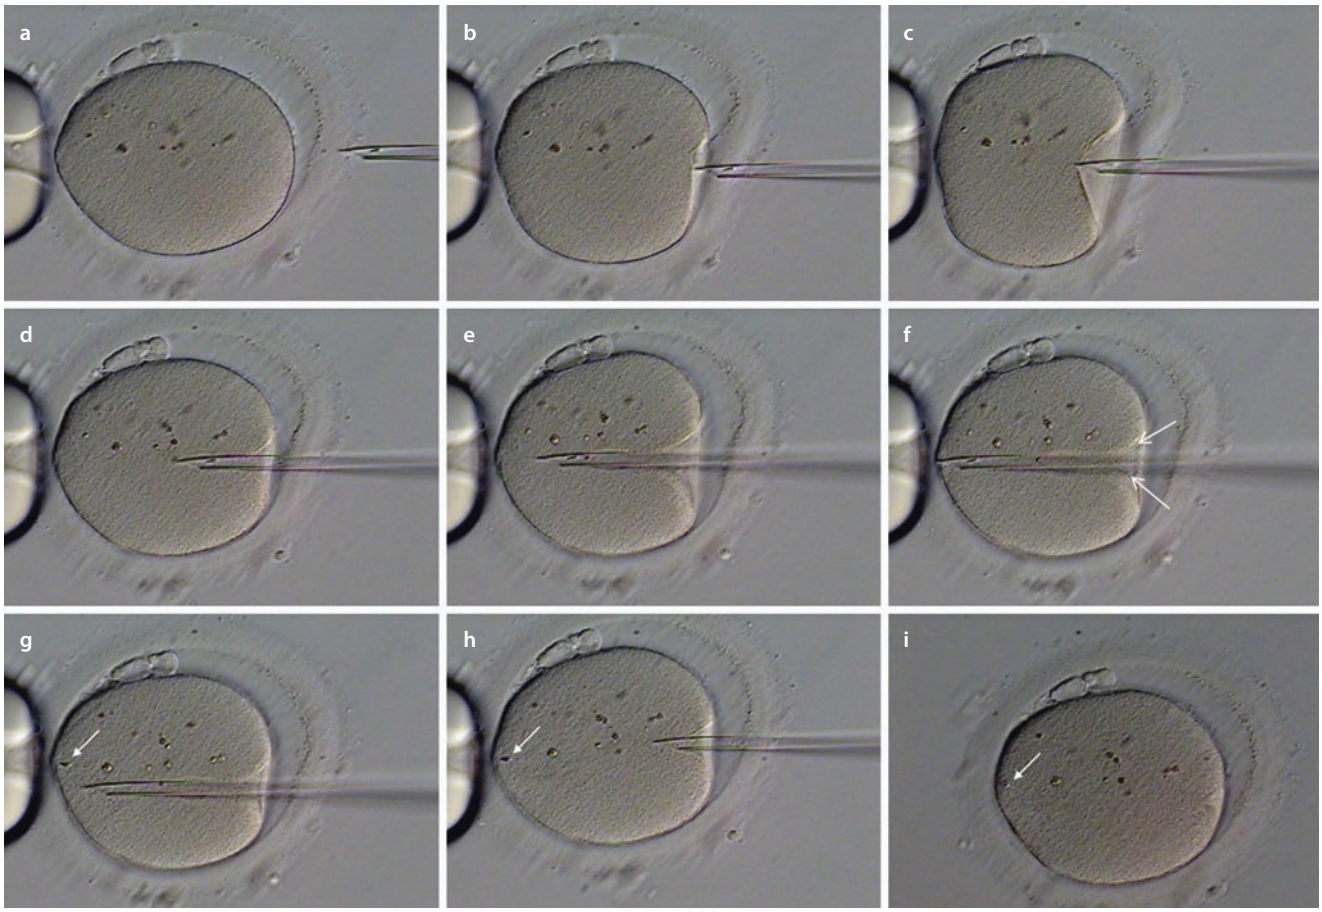

Fig. 32.3 Intracytoplasmic sperm injection of a human oocyte. **a** The oolemma at the 3 o'clock portion of the oocyte is brought into focus, as are the holding (left) and injection pipette (right) tips. Suction is applied on the holding pipette to stabilize the oocyte, and the spermatozoon is advanced to the tip of the injection pipette. **b** Advancement of the injection pipette through the zona at the oocyte's equatorial plane bypasses the zona and brings the pipette spike into contact with the oocyte membrane. **c–e** Its elasticity creates a funnel around the injection pipette as it moves deeper into the oocyte. **f** Once the oolemma is penetrated, there is a distinct quivering of the oocyte membrane, which then returns to its original position (arrows). **g** As the sperm is deposited in the ooplasm (arrow), a small amount of cytoplasm is aggressively aspirated and released to facilitate oocyte activation. **h** Removal of the injection pipette is accompanied by gentle aspiration from the center of the oocyte outward to facilitate resealing of the membrane by bringing the borders of the injection funnel into closer proximity. **i** An injected oocyte with sperm in the cytoplasm (arrow), displaying minimal evidence of tool penetration at its 9 o'clock edge

mic component (Fig. 32.3g). To optimize its interaction with the cytoplasm, the sperm should be ejected past the tip of the pipette to ensure a close intermingling with the ooplasmic lattices, which help maintain the sperm in place while withdrawing the pipette (Fig. 32.3h). To induce oocyte activation, additional ooplasm is aspirated back and forth with the injection pipette. It is paramount to avoid leaving behind residual medium with the spermatozoon as well as closing the breach of penetration. This is accomplished by generating a mild suction while removing the pipette. To do this, when the pipette is at the approximate center of the egg, some surplus medium is reaspirated so that the cytoplasmic structures can envelop the sperm, thereby reducing the size of the breach (Fig. 32.3i). This also expedites the closure of the terminal part of the funnel-shaped opening at 3 o'clock. Once the pipette is extracted, the edges of the entry point should maintain a funnel shape with the tip toward the center of the egg. If the border of the oolemma becomes everted, the cytoplasmic organelles can leak out, and the oocyte may lyse. The average time required to accomplish a single oocyte injection is about 30–40 s.

32.6 Embryo Development and Clinical Outcome

The popularity of ICSI to overcome almost all forms of male infertility has increased remarkably since its inception [93]. For example, the use of ICSI has increased from 36.4% in 1996 to 76.2% in 2012 in the USA [12]. Furthermore, the International Committee for Monitoring Assisted Reproductive Technologies reported that the global utilization of ICSI was 66% based on data from 2500 ART clinics in 58–61 countries between 2008 and 2010. However, large disparities were reported in ICSI utilization, i.e., 55% in Asia, 65% in Europe, and 100% in the Middle East [28].

There has also been a steady and progressive increase in ICSI utilization at our center starting at 32.2% in 1993 rising to 48.8% in 1995 and reaching 74% in the mid-2000s. In the last 23 years at Cornell, we have performed a total of 39,918 ART cycles with an average maternal age for IVF of 36.6 ± 4 years and for ICSI of 37.3 ± 5 years and mean paternal ages of 39.5 ± 7 years and 39.9 ± 8 years, respectively. Of those cycles, 33.2% (13,253) included the standard in vitro insemination of 138,815 oocytes with a fertilization rate of 63.6% and a clinical pregnancy rate of 41.5%, the remainder being ICSI cycles. IVF was generally performed in patients with normal semen, while ICSI has been used to treat couples with doubtful spermatozoa, a history of poor fertilization, and/or limited numbers of oocytes. Nonetheless, the two systems consistently generated similar results.

Of 18,863 couples treated by ICSI, the average number of oocytes retrieved was 10.56 per cycle (n = 349,560), of which 279,361 (80.0%) were at metaphase II and, therefore, subjected to ICSI. Of the oocytes injected, 94.93% (265,189/279,361) survived and 206,110 (73.78%) developed two pronuclei (PN). Of the oocytes that were abnormally fertilized, 7315 (2.62%) displayed 1 PN and 9709 (3.48%) 3 PN.

The types of mature spermatozoa included 26,397 ejaculated samples, 3684 cryopreserved, 89 obtained by electroejaculation, and 53 by bladder catheterization (Table 32.1). Among the collection/cryopreservation methods, fertilization rates ranged from 68.6% to 77.2%. The clinical pregnancy rate was comparable in all groups.

When more immature forms of spermatozoa were utilized, for example, those surgically retrieved, the fertilization rate of 58.6% was satisfactory but lower than that with ejaculated spermatozoa ($P < 0.0001$) (Table 32.2). While the clinical pregnancy rate was lower in the ejaculated group in comparison to the surgically retrieved spermatozoa, this difference may be attributed to the maternal age. The etiology of the *vas deferens or efferens* obstruction, congenital or acquired, had no effect on fertilization after ICSI giving an overall rate of 72.2% and a clinical pregnancy rate of 52.1%. However, after cryopreservation of epididymal spermatozoa, the clinical pregnancy was dramatically reduced from 60.9% to 47.6% ($P < 0.0001$).

In testicular extraction cases, with the compromised spermatogenesis typical of the non-obstructed azoospermic patient, the spermatozoa recovered generated a fertilization rate of 51.2% and a clinical pregnancy rate of 37.7%. When comparing fresh versus cryopreserved spermatozoa in testicular cycles, the clinical pregnancy rate was comparable between the two groups (40.5% versus 31.8%).

Of 33,111 ICSI cycles analyzed, 14,995 resulted in a positive ßhCG (51.9%), and in about 39.3% of all cycles, the presence of at least one fetal heartbeat was observed (Table 32.3). Among the positive ßhCG, 2619 (17.5%) were biochemical pregnancies, 855 (5.7%) were anembryonic, and 178 (1.2%) were ectopic. Among the 11,343 cycles with a fetal heart, 1320 spontaneously miscarried. This left an ongoing pregnancy rate of 30.3% per retrieval (10,023/33,111) and 34.7% per embryo replacement procedure (10,023/28,894).

When 30,796 ICSI cycles (after exclusion of the donor egg cycles) were plotted as a function of increasing maternal age, there was a progressive decrease in pregnancy ($P < 0.0001$) (Table 32.4) and consequently delivery rates ($P < 0.0001$). As predicted, there was a higher incidence of miscarriages, therapeutic abortions, and overall pregnancy losses as a function of the age of the female partner ($P < 0.0001$), pregnancy wastage being 2.4 times greater in women ≥40 years compared to those of <35 years.

A total of 9445 ICSI patients delivered 12,562 babies comprising 6241 males and 6143 females (with 178 unknown genders). A total of 3.3% (268) exhibited congenital abnormalities at birth, of which 130 were major and 138 were minor. IVF children (n = 4999) had a 3.1% overall malformation rate

Table 32.1 ICSI outcome according to semen source

Semen origin	Cycles	Fertilization (%)	Clinical pregnancies (%)
Fresh ejaculate	26,397	164,115/217,640 (75.4)	8950 (33.9)
Frozen ejaculate	3684	23,875/31,237 (76.4)	1132 (30.7)
Fresh electroejaculate	70	546/711 (76.8)	35 (50.0)
Frozen electroejaculate	19	140/204 (68.6)	6 (31.6)
Retrograde ejaculate	53	363/470 (77.2)	20 (37.7)

Table 32.2 Fertilization and pregnancy rates according to the origin of spermatozoa

No. of	Ejaculated	Surgically retrieved
Cycles	30,223	2888

(b) Clinical pregnancy (+FHB) (% on a)	4170 (51.6) (d)	3926 (41.2) (d)	2082 (22.7) (d)
(c) Delivery and ongoing pregnancy (% on a)	3901 (48.2) (e)	3498 (36.7) (e)	1570 (17.1) (e)

(d) (e) χ^2, 3 × 2, 2 *df*, effect of maternal age on pregnancy outcome, $P < 0.0001$

(90 major and 65 minor). Major malformations ranged from cardiac defects to multiorgan diseases including central nervous system anomalies, chromosomal abnormalities (gonosomal trisomies such as 47, XXX and 47, XXY and autosomal trisomies such as chromosomes 7, 18, 21), and urogenital disorders requiring surgery such as severe hypospadias and undescended testes. Examples of minor malformations were café au lait spots, urethral defects, and very mild form of clubfoot.

32.7 ICSI Failure

ICSI failure can occur on three different levels: a failure to obtain sperm for injection, failure of fertilization after injection, and a failure to establish a pregnancy after embryo transfer.

Failure to Obtain Sperm: In men with non-obstructive azoospermia, rarely it is impossible to retrieve any spermatozoa from the testis. On the other hand, as might be expected, sperm are recovered in virtually all attempts involving men with obstructive azoospermia.

Failure of Fertilization After ICSI: As noted above, fertilization failure occurs in about 2% of ICSI cycles, whether male infertility is present or not [8, 64]. The reasons for these few failures remain unclear but probably involve either poor sperm viability or an asynchronous oocyte maturation [33].

Some men carrying acrosomeless (also known as globozoospermic) spermatozoa cannot achieve syngamy even after ICSI [1, 64, 104]. However, successful fertilization, pregnancy, and offspring have resulted after treating the oocytes post-ICSI by either a chemical agent [47, 104, 140, 141] or an electrical pulse [72, 140]. Similarly, the chances of fertilization in these problematic cases may sometimes be enhanced by utilizing sperm-derived activating extracts or calcium-releasing compounds [77, 91]. Oocyte activation agents include calcium ionophore [50], electrostimulation [140], and strontium [141]. Such adjunct treatments help to activate the oocyte by increasing the Ca^{2+} permeability of the cell membrane, thereby allowing extracellular Ca^{2+} flow into the oocyte and also inducing Ca^{2+} release from the intracellular calcium stores. In one of the first series of assisted oocyte activations, in patients with previous fertilization failure [47], the authors first injected a spermatozoon together with $CaCl_2$ and, thereafter, a calcium ionophore – this dual exposure resulted in an overall fertilization of >70%. These approaches have been able to trigger oocyte activation and allow concurrent sperm nuclear decondensation and, therefore, zygote development. To further enhance oocyte activation and syngamy, spermatozoa may be exposed to an agent that facilitates sperm membrane permeabilization [42, 53].

The inability to activate an egg has been attributed to the absence of a specific sperm protein that has been investigated in many occasions [91, 95, 139]. More recently, however, one such factor – phospholipase C-ζ1 (PLCζ1) – has been identified in mice. Following its injection into mouse oocytes, PLCζ1 was capable of inducing calcium oscillations that were identical to those observed following fertilization by a sperm [106, 126]. As an interesting correlate, the PLCζ1 isoform was undetectable in sperm of men that experienced fertilization failure with ICSI [142]. Taken together, these findings open a new avenue in the diagnosis and potential treatment of couples whose ICSI cycles terminate abruptly with unexpectedly low or definitive absence of fertilization.

Failure to Conceive After ICSI Fertilization: It must be emphasized finally that the implications of one fertilization failure for subsequent ICSI attempts are not necessarily bleak. When couples with failed ICSI fertilization attempted further ICSI cycles, their success rates were similar to other couples undergoing repeat ICSI cycles [32, 47, 48, 76].

On the other hand, as with IVF, some couples fail to conceive despite repeated ICSI cycles where the causes range from centrosomal dysfunction to DNA abnormalities [35, 87, 91]. Two hundred couples who had 433 cycles of ICSI treatment without success subsequently had 23 (12%) live births with no further treatment within 4 years of the last ICSI cycle [84]. The only predictor of live birth after ICSI failure was a shorter time to pregnancy (the time between seeking infertility treatment and the actual achievement of a pregnancy), suggesting that unknown factors contributing to longer duration of infertility were barriers to success [65].

32.8 Safety

Notwithstanding the large number of babies born from the ICSI procedure worldwide, concerns still exist as to whether the use of suboptimal spermatozoa can result in genomic abnormalities in the progeny [66]. These qualms are not only limited to the inheritance of specific traits that bear on fertility but most importantly those related to the postnatal well-being of the offspring as reflected in growth [109] or cognitive development [13]. Therefore, follow-up of ART children is highly recommended and is being applied increasingly [11, 60, 82, 94]. Parent-administered questionnaire has been proposed as a way of doing this, since a routine office assessment is costly and time-consuming [78, 92, 121].

The specific concerns in regard to ICSI, whether real or theoretical [20, 23, 24, 30], involve the insemination method, the use of spermatozoa with genetic or structural defects, and the possible introduction of foreign genes. Even if there seems to be no evidence for a higher frequency of congenital abnormalities with ICSI compared to conventional IVF, more subtle effects might become evident in comparison to naturally conceived children. In fact, recent epidemiological studies of ART children report a twofold increase in infant malformations [46], a recurrent reduction in birth weight [108], certain rare syndromes related to imprinting errors [16, 26, 40, 45, 71, 83], and even a higher frequency of some cancers [75]. On the other hand, such observations do not prove that there is an increased risk of imprinting disorders and even less so childhood cancers in ICSI children [30]. A systematic survey aimed at clarifying imprinting issues suggests that only Beckwith-Wiedemann syndrome may have such a link [125].

A shorter gestational age and a lower birth weight have been noted in ART pregnancies irrespective of the conception method [108, 109]. The basis for this could lie in an unclear medical history [55], in the fact that a singleton may result from early in utero loss of a twin [21, 97], or where an ART delivery is performed at the slightest sign of fetal distress [116]. When our Cornell data were stratified according to maternal age, singleton ICSI children had the same mean gestational age and birth weight as those conceived naturally [92]. Similarly, in the study of Lin et al. [63], levels of neonatal distress, NICU admission, and congenital malformations were comparable in both groups. The most unsettling concerns in regard to the health of ART offspring relate to a reported twofold increase in major malformations [46]. However, this study failed to correct for maternal age and for other patient characteristics [122], for the presence of male factor [119], and even in its classification methods [124]. Our follow-up records, beginning in the mid-1990s, have revealed an incidence of malformations within the expected range for the general population of New York State [90]. In another series, ICSI versus naturally conceived singletons that were matched for maternal age displayed no difference in neonatal outcomes [63]; and this was clearly the case when the outcomes of neonates generated by different artificial conception procedure, ICSI versus IVF, were investigated [79].

In this connection, Bowen et al. [13] evaluated the medical and developmental state of 1-year-old children born after ICSI, IVF, or natural conception. They found that most 1-year-old ICSI children were healthy and developing normally, as measured by the Bayley Scales of Infant and Toddler Development. However, about 17% displayed learning difficulties compared to those conceived by IVF or naturally. It was a later report that dismissed this concern in 2-year-old ICSI toddlers [9] which inspired our follow-up study in 3-year-olds.

Because of the confounding role of multiple gestations, as part of a multicenter international investigation, we then decided to assess singleton births at 5 years of age. Although this revealed no differences in the full-scale IQ between ICSI and NC children, surprisingly NC parents displayed higher levels of distress and dysfunctional child interactions and had more difficult children compared to the ICSI group ($P < 0.05$) [99]. This study revealed also that ICSI children were indeed characterized by a lower birth weight ($P < 0.05$) and also by a higher proportion of major malformations ($P < 0.05$) than their NC counterparts. The higher proportion of affected children was concentrated in the Belgian center [10]. Another study comprising 1500 children from 5 European countries failed to show a higher incidence of major malformation in the ART group compared to NC children despite a clear difference in their parental age [11]. The same Brussels group confirmed a malformation level of 10.0% versus 3.4% in the same cohort of NC children once they reached 8 years of age [3]. These three additional malformations included an inguinal hernia and two nevus flammeus that required only minor surgical corrections. Interestingly, when the same ICSI progeny was reassessed for their physical and intellectual performances at 10 years of age, their state matched that of a natural conception group [61]. A prospective match-controlled study was performed to investigate the growth of children in the UK following IVF and ICSI up to 12 years of age. This study showed that height, weight, and head circumference did not differ between IVF and ICSI.

One must also note the emergence of studies evaluating the medical and reproductive health of young adults conceived via ICSI. A recent study compared 54 young men (18–22 years) conceived by ICSI because of male factor infertility to 57 naturally conceived peers and found that the mean levels of FSH, LH, testosterone, and inhibin B were comparable, even after controlling for age, BMI, and season [4]. Although young ICSI-conceived men were more likely to have inhibin B levels <10th percentile and FSH levels >90th percentile compared to naturally conceived peers, these results were not statistically significant [4]. A follow-up study by the same investigators showed that this group of 54 young men had lower median sperm concentration, total sperm count, and total motile sperm count than the naturally conceived peers [5]. However, the small sample size limits the generalization of these findings. The reproductive hormonal profiles of young ICSI-conceived women are currently awaited.

A limited number of studies have addressed the issue of cancer among children conceived by assisted reproduction. A report from the Netherlands identified five cases of retinoblastoma in IVF children – significantly more than expected [75]. A Swedish registry-based study identified five cases of Langerhans histiocytosis among 16,280 IVF infants in comparison to the 0.9 expected cases in the general population [54]. However, these two reports have not been verified by other investigations, and the overall risk of cancer and the individual incidence of all other recorded cancer were not greater than expected. In fact, since childhood cancers are rare, larger studies are required to reliably observe any increase in risk among ART children.

Questions have been posed also about the effect of the embryo culture medium on the health of ART children in general and whether this can induce imprinting disorders [29]. Imprinting disorders such as Angelman's syndrome (AS) [16, 83] and Beckwith-Wiedemann syndrome (BWS) [16, 81, 123] have been described in connection to assisted reproductive technologies. A survey of 1000 British families raising children afflicted with transient neonatal diabetes mellitus, Prader-Willi syndrome, AS, or BWS revealed that only the latter, where *H19*'s downregulation plays a pivotal role, appeared to maintain an association with the ARTs [125]. Both syndromes have been found to be largely due to epigenetic defects rather than a genetic mutation or uniparental disomy [43], thus suggesting that some aspect of the ARTs may be responsible.

In a recent study in mice, Wilson et al. [138] attempted to assess the role of standard IVF and ICSI on gene expression imbalances, and they compared these two procedures to natural mating. The authors concluded that IVF and ICSI were no different in regard to the issues of gene expression but had minor differences observed between the ART procedures and natural conception. Thus, the ART procedure itself does not induce the imprinting imbalances. Another group investigated the basic procedures common to IVF and ICSI such as embryo transfer and in vitro culture [103]. In vitro culture increases the loss of imprinting, but even basic techniques such as embryo transfer can also lead to misexpression of several imprinted genes during post-implantation development.

In summary, the most important factor that can lead to adverse outcomes in offspring conceived by IVF or ICSI is that of high order pregnancies. However, the introduction of single embryo transfer has reduced this considerably. Although perinatal outcomes such as prematurity, low birth weight, perinatal mortality, and increased incidence of malformations have been linked to the techniques of IVF and ICSI, the main culprit is related to infertility itself. Overall, no significant long-term neurodevelopmental differences have been found in connection with the ARTs, though the risks associated with childhood cancer and future fertility still require further research.

Acknowledgment We are grateful to the clinicians, scientists, embryologists, and nursing staff of The Ronald O. Perelman & Claudia Cohen Center for Reproductive Medicine. We are most grateful to Professor J. Michael Bedford, Derek Keating, and Alessandra Parrella for their critical reading of the manuscript, and Eugene Ermolovich for his photographic contribution. Queenie Neri was funded by the grant ULI RR024996 of the Clinical and Translational Science Center at Weill Cornell Medical College.

Review Questions

1. What is the least requirement for a selected spermatozoon to provide successful fertilization?
2. Does the presence of a polar body after cumulus removal absolutely indicate ooplasmic maturity?
3. What is the meaning and reason for a three-pronucleated zygote resulting from ICSI?
4. Does assisted fertilization have adverse implications on the health of the offspring?

Intracytoplasmic Morphologically Selected Sperm Injection

Pierre Vanderzwalmen, Romain Imbert, David Jareno Martinez, Astrid Stecher, Anne Vansteenbrugge, Sabine Vanderzwalmen, Barbara Wirleitner, and Maximillian Murtinger

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_33

Learning Objectives

At the end of this chapter, the readers will be conscious about and able to understand:

- The importance of spermatozoa morphology on fertility.
- Why it is imperative that critical morphological sperm selection criteria are applied before intracytoplasmic sperm injection (ICSI) to improve the chances of embryo development and successful pregnancy with healthy baby outcome.
- That with the introduction of Nomarski optics, subtle sperm head abnormalities such as vacuole-like structures (VLS) are observed.
- That almost 15 years after the first application of motile sperm organelle morphology examination (MSOME) and intracytoplasmic morphologically selected sperm injection (IMSI), selection of spermatozoa devoid of sperm head VLS has multiple benefits.
- That VLS are the morphological manifestation of nuclear dysfunction and represent a pathological situation during the sperm maturation process, which, in turn, may render spermatozoa more vulnerable to DNA damage. This is a strong and tangible argument to select sperm free of nuclear VLS seeing that abnormal chromatin remodeling during sperm maturation could be associated with alteration in the methylation pattern that could affect negatively the prevalence of major fetal malformations.
- Debates and skepticism still exist about the efficiency of IMSI, mainly due to a low number of controlled randomized studies published yet. IMSI is indeed important in women with advanced maternal age, possibly due to reduced correction and reparation capacity of spermatozoon defects in the presence of aging oocyte. In addition, IMSI may prevent absence of blastocyst in case of failure of embryo development to the blastocyst stage in case of previous IVF attempts.
- That the introduction of IMSI made embryologists aware that in times of ICSI, the selection of sperm has to be given proper attention.

In order not to consider IMSI as a frightening technique, practical and technical aspects of sperm selection need to be considered to facilitate the workflow while performing sperm selection before oocyte injection.

33.1 Importance of Spermatozoa Morphology on the Fertility: A Valuable Reason to Improve Its Selection

The introduction of the intracytoplasmic sperm injection (ICSI) 25 years ago permitted to overcome severe male infertility diagnosed by low sperm count and/or poor sperm motility and/or infertility due to morphology deficiency. Sperm morphology – the size and shape of spermatozoon – is one factor that is examined as part of a semen analysis to evaluate male infertility.

The assessment of sperm morphology by Kruger's strict criteria is routinely applied and highlights that sperm morphology analysis of the whole population of a semen sample [1] turns out to be the best predictor of a man's fertilizing potential [2].

A normal sperm has a smooth, oval-shaped head that is 5–6 micrometers long and 2.5–3.5 micrometers wide; a well-defined acrosome cap that covers 40–70% of the sperm head; no visible abnormality of the neck, midpiece, or tail; and no cytoplasmic droplets on the sperm head that are bigger than one half of the sperm head size.

But when we move from the diagnostic level toward patient treatment with intracytoplasmic sperm injection where we have to select only one spermatozoon for injection, the situation is completely different.

The importance of morphologically normal sperm selection is reinforced when facing the reproductive outcomes in terms of fertilization, embryo development, and pregnancy and abortion rates when the oocyte injections can only be done with abnormally shaped spermatozoa (i.e., sperm with elongated, tapered, or amorphous heads, broken necks, or cytoplasmic droplets) [3]. It becomes more and more accepted that abnormally shaped spermatozoa from patients diagnosed with terato- and asthenozoospermia have a significantly increased frequency of aneuploidy, a higher DNA fragmentation index (DFI), and increased rate of mitochondrial dysfunction [4]. With the implementation of restrictive law regulating the number of embryos to transfer, methods of gamete and embryo selection are of paramount importance.

If we keep in mind that ICSI bypasses the natural barriers of reproduction, and knowing the importance of the sperm morphology [3], several novel microscopic approaches, such as differential interference contrast (DIC) microscopy [5], digital holographic microscopy [6], and atomic force microscopy [7], are currently used or in development to assess the morphology of the spermatozoa. They allow a more detailed observation of the different parts of the sperm head (nucleus and acrosome), the midpiece, and the tail.

33.2 Morphological Observation of Living Spermatozoa in Real Time: The MSOME Approach

In order to counteract the problem of morphological evaluation on stained spermatozoa with complex and high-tech systems [6–8], Bartoov [5] introduced, more than 15 years ago, a new innovative noninvasive technique for a more precise morphological evaluation of motile spermatozoa in real time. With the use of Nomarski differential interference contrast (DIC) optics, the so-called motile sperm organelle morphology examination (abbreviated as MSOME) changed the perception of how a spermatozoon suitable for injection should appear. At magnifications ranging from 630x up to 12000x, a more in-depth evaluation of the quality of semen in real time provides substantial information about the normalcy of the head, the neck, and midpiece and in addi-

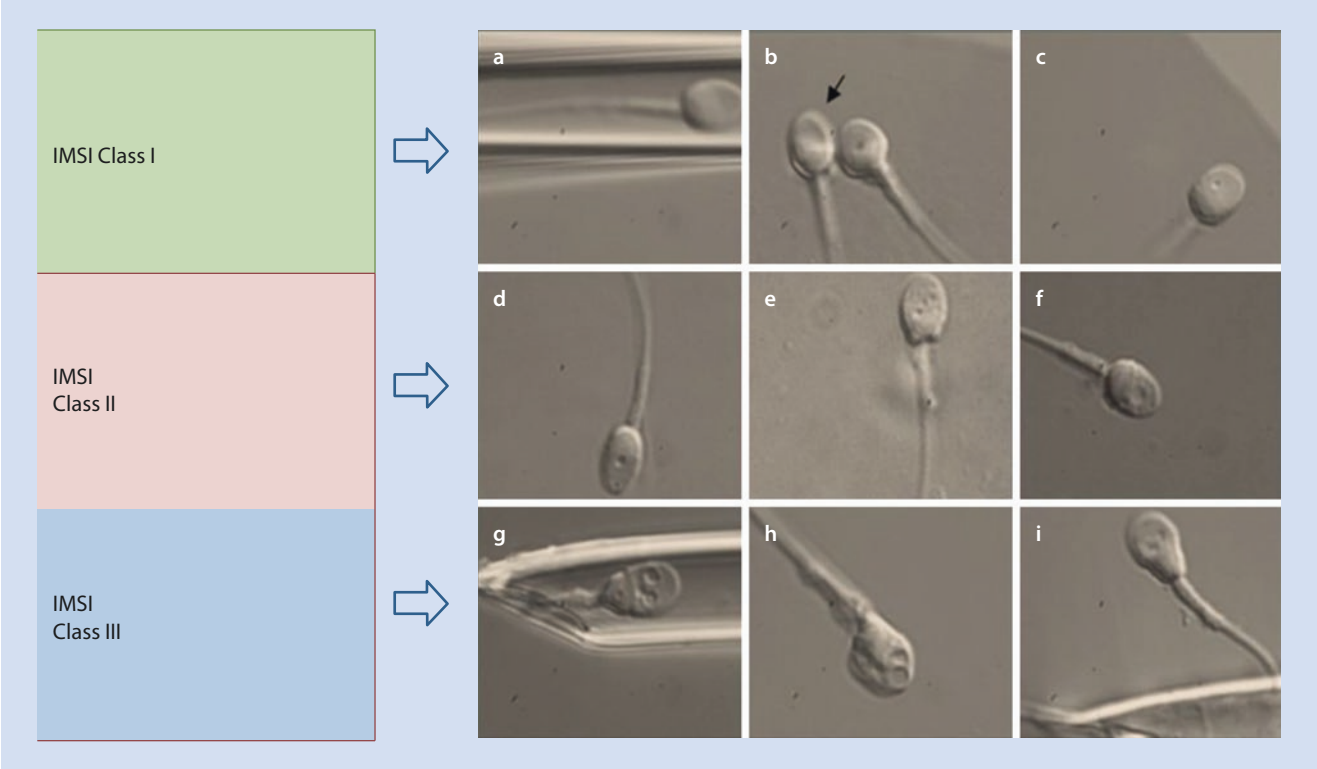

Fig. 33.1 Classification of spermatozoa selected at 6000x

tion allows the detection of subtle sperm head nuclear abnormalities. Morphological assessment at a magnification more than 1000x is obtained after increasing the magnification with a zoom and coupling the microscope with a high-definition digital video camera and a high-definition video monitor.

Bartoov et al. [5] defined the morphological normalcy on motile sperm nucleus according to the shape and chromatin content. The shape has to be smooth, symmetric, and oval with average length and width limits estimated to be 4.75 ± 0.28 μm and 3.28 ± 0.20 μm, respectively. The chromatin mass has to be homogeneous and contains no extrusions or invaginations with a maximum of one vacuole involving less than 4% of the nuclear area.

Regarding the acrosome and the post-acrosomal lamina, they were considered abnormal if absent, partial, or vesiculated. An abaxial neck, with the presence of disorders or cytoplasmic droplets, was considered abnormal, as well as the presence of broken, short, or double and coiled tail.

According to Bartoov [5], normal spermatozoa should not contain nuclear vacuole(s) exceeding more than 4% of the nuclear area. Saidi [9] and Perdrix [10] classified the relative area of the vacuole into three groups: less than 5.9–6.5%, between 6.5% and 13% or between 5.9% and 12.4%, and greater than 13% or 12.4%. For Franco [11], large nuclear vacuoles in spermatozoa were defined by the presence of vacuoles occupying ≥50% of the sperm nuclear area.

In order to estimate the impact of specific sperm defects on embryo development and further outcome in an accurate way, different groups established models of sperm classification according to the normalcy of the shape and the presence and size of vacuoles [12, 13]. Vanderzwalmen [12] classified the spermatozoa into three groups according to the presence and size of vacuoles: Grade I, normal shape and maximum of two small vacuoles; Grade II, normal shape and more than two small vacuoles or at least one large vacuole; and Grade III, abnormal head shapes with or without large vacuoles in conjunction with other abnormalities at the level of the base (Fig. 33.1). Cassuto [13] established a detailed classification scoring in three scales ranging between 6 and 0 points according to the normalcy of the head, the symmetry of the base, and the absence of vacuole.

33.3 Are Sperm Head Vacuoles Authentic Vacuoles?

The morphology of seminal spermatozoa is the end result of a highly complex process of cellular modifications occurring during spermiogenesis. In humans, it leads to widely heterogeneous morphological patterns, with many cellular abnormalities which may be associated with sperm dysfunction [14]. In the WHO classification, one of those defects observed on the head of the spermatozoon is called vacuole. After staining, what is called vacuoles appeared as a clear circle, varying in number, size, and content.

With the introduction of Nomarski optics, subtle sperm head abnormalities such as large or small vacuoles are better

observed. From biological definition, a vacuole present in a cell is a membrane-bound cavity filled with a substance. Boitrelle [7] investigated the structure of vacuoles using atomic force microscopy that permits a three-dimensional scanning of the entire surface of the head of the spermatozoa at high resolution. Boitrelle [7] observed that the sperm plasma membrane was intact but sunken nearby the vacuole and that the sperm head's thickness fell from 700 nm to 300 nm at the site of the large vacuole. They concluded that vacuole-like structures are nuclear depressions which correspond to a concavity in the plasma membrane rather than a hole. Large and small vacuoles were identified as an abnormal, "thumbprint"-like nuclear concavity covered by acrosomal and plasmic membranes.

Using other microscopic optics such as Nomarski differential interference contrast (DIC) optics, other terminologies such as craters [15], concavities [7], hollows [16], or lacunae [17] were assigned confirming that vacuoles appear more as depressions at the cell surface instead of a true vacuole structure that is by definition surrounded by a membrane. As a consequence, the terminology "vacuole" for these structures is misleading and should be better substituted by vacuole-like structure (VLS).

33.4 Pathological Character of Nuclear VLS: A Tangible Argument to Select Sperm Free of Nuclear Defect

33.4.1 Spermiogenesis and Protamine: Histone Transition

During a normal spermiogenesis process, round spermatids undergo four stages, a complex morphological change: successively, the Golgi phase, the cap phase, formation of tail, and the maturation stage. In addition to the visible morphological transformation, the chromatin is radically reorganized and undergoes an extreme condensation resulting in a shift from a nucleosome-based genome organization to the sperm-specific, highly compacted nucleoprotamine structure [18]. During this process, which is essential for the establishment and maintenance of a viable pregnancy, about 85% of human sperm histones are replaced by protamines, whereas only 15% of the DNA remains organized by histones or is attached to the nuclear matrix [19].

These unique cellular reconstruction processes that protect the paternal genome during the transit from the male to the oocyte prior to fertilization require spermatid-specific genes to execute their regulatory roles. It is estimated that 600–1.000 germ cell-specific genes participate in spermiogenesis, and specific genes such as Prm1, Prm2, Tnp1, Tnp2, and H1t2 are involved in chromosomal packaging [20].

Rousseaux et al. [21] and Montellier et al. [22] reported that testis-specific proteins are a new keystone in DNA compaction in humans and murines. One testis-specific protein partially responsible for the replacement of histones by protamines is called bromodomain (BRDT), which possesses two bromodomains capable of interactions with hyperacetylated histones [21]. The genome-wide incorporation of a new histone variant called testis-specific histone 2B (TH2B) might also play an important role in this histone to protamine transition as shown in murine models [22].

Prior to histone replacement by protamines, the nucleosomes are destabilized by hyperacetylation and by DNA methylation level [23]. Crucially, the distribution of the remaining 15% nucleosomes after the 85% nucleosomes to nucleoprotamine replacement is not random but concerns gene regions involved in the epigenetic control and the early embryonic development [19, 23–25]. Repackaging of the haploid genome before delivery in the oocyte is a crucial step. On the other hand, the ratio between the two protamine subtypes protamines 1 and 2, which should normally be close to 1, can have a significant negative impact on fertility when disturbed [26].

Taken together, these data support the idea that bad condensation of sperm DNA has a great impact on male fertility. All these potential epigenetic pattern disturbances may represent the basis of numerous human disorders.

33.4.2 The Hidden Face of VLS

33.4.2.1 VLS and Abnormal Chromatin Condensation

Since the implementation of MSOME to assess sperm morphology, we are more concerned about the presence of large and small VLS and consider them as potential defects [5, 27, 28]. One crucial question to investigate, if we want to implement MSOME in our ICSI procedure, is if VLS are the morphological manifestation of nuclear dysfunction. Assuming that they seem to appear during the last maturation step of round spermatids, do they originate from a natural process or, more likely, from pathological (stress) situations during spermiogenesis or even early in the first stage of the spermatogenesis? In other words, what hides behind spermatozoa mostly with large VLS?

The literature is controversial – while some studies reported that sperm vacuoles should be regarded as a normal feature of the sperm head [16, 29], others mentioned that it is related to male subfertility [30]. However, Tanaka et al. [29] highlighted that the size of the vacuoles is of importance and suggested that spermatozoa with large VLS should not be used for injection. DNA damage may be considered in three different forms: (i) fragmentation of the DNA in the form of single-stranded or double-stranded DNA strand breaks, (ii) nuclear protein defects that may interfere with histone to protamine conversion and subsequent DNA compaction, and (iii) chromatin structural abnormalities causing altered tertiary chromatin configuration [31].

A multitude of studies concluded that vacuoles reveal indirectly nuclear dysfunction in terms of lower mitochondrial potential [32], loss of DNA integrity, higher aneuploidy rate, and problems related to chromatin condensation.

A clear consensus showing a correlation between the presence of VLS and increased aneuploidy and DNA fragmentation

rates was not reported. According to the growing body of literature, a negative correlation between the incidence of vacuoles and abnormally condensed chromatin was observed in all conducted studies [4, 7, 16, 33–38]. In some studies, spermatozoa with or without LVS were selected by micromanipulation before being studied by different microscopy and immunocytochemistry techniques. All the conducted studies concluded first that vacuoles did not take their origin in the acrosome but that they are linked to areas of chromatin decondensation [7]. Moreover, the presence of crater structures most likely reflects molecular defects responsible for anomalies of sperm chromatin packaging and abnormal chromatin remodeling during sperm maturation [27, 28, 39]. Boitrelle et al. and Cassuto et al. [7, 34, 36] observed chromatin condensation at the site of the vacuoles and concluded that large vacuole appears to be a nuclear "thumbprint" linked to failure of chromatin condensation. Perdrix et al. [40] recently published their observations of the correlation between the presence of large nuclear vacuoles and chromosome architecture modifications, adding a new argument for the association between nuclear vacuole-like structure and chromatin disorganization.

We may assume that the integrity of the chromatin is related to the presence or absence of vacuoles in the head of spermatozoa and loss of chromatin compaction renders the DNA more vulnerable to reactive oxygen species (ROS) [41–43].

With the disorganization of the chromatin and the vacuoles in the sperm head, the spermatozoa and its DNA become more assailable to attacks by ROS [34, 45, 46]. Thereby, DNA fragmentation would depend on two steps: the occurrence of vacuoles in connection with insufficient chromatin condensation and the presence of ROS. This could explain why the correlation between the presence of vacuoles and the rate of DNA fragmentation is not observed unanimously seeing that ROS environment is not comparable from one semen sample to another [44, 45].

We may also postulate that when the oxidative stress during spermatogenesis and/or during sperm transport is below a critical level, the DNA and chromatin will not be affected. Above a critical level of ROS, genomic problems start to occur, thereby affecting the reproductive outcome.

33.4.2.2 Potential Consequences of Chromatin Disorganization

Prior to histone replacement by protamines, the nucleosomes are destabilized by hyperacetylation and by DNA methylation level [23]. Crucially, the distribution of the remaining 15% nucleosomes after the 85% nucleosomes to nucleoprotamine replacement is not random but concerns gene regions involved in the epigenetic control and the early embryonic development [19, 23–25]. Repackaging of the haploid genome before delivery in the oocyte is a crucial step.

The spermatozoon delivers a novel epigenetic signature to the egg, required in early embryogenesis that is crucial for normal embryo development [23], and the offspring [44] DNA methylation is a key regulator of transcription and is a major factor controlling imprinted gene expression during embryo development. By analyzing sperm DNA methylation and RNA transcripts in spermatozoa, a recent study showed the paternal contribution and the crucial role of sperm epigenome in embryonic development [46].

Epigenetic patterns are usually faithfully maintained during development. However, this maintenance sometimes fails, resulting in the disturbance of epigenetic processes, which represents the basis of numerous human disorders. Epigenetic modifications in mature spermatozoa play an important role, and, as a consequence, altered methylation profiles may increase the risk of fertilization failure, dysfunction of embryogenesis, preterm birth, low birth weight, congenital anomalies, autism, and perinatal mortality [47–49]. These altered methylation errors are subsequently transmitted to the embryo, conferring a potential risk of imprinting disorders to the offspring [50].

In men with impaired spermatogenesis, the sperm epigenetic landscape is frequently altered. DNA methylation errors and gene expression defects are more frequent in men with abnormal semen criteria than in normozoospermic sperm [51, 52]. Hypermethylation of sperm nuclear DNA could be associated with abnormal semen samples [53] and defective and apoptotic sperm [54]. Epigenetic defects, mainly hypermethylation of certain genes, can lead to altered spermiogenesis and produce poor sperm morphology or defective spermatozoa with a risk of adverse effects on embryo development and increasing risk of imprinting disorders with health implications for the next generation [55, 56].

The fundamental questions to solve are if VLS are related to alterations in the methylation pattern and if potential epigenetic mechanisms could be implied in chromatin condensation failures. In a recent manuscript, Cassuto et al. [57] detected different levels of DNA methylation after morphological sperm selection using the MSOME approach. Sperm DNA methylation level was significantly lower in the normal morphological group compared with the group of abnormal spermatozoa carrying VLS. The same authors previously observed a strong correlation between the presence of nuclear vacuoles and chromatin defects [34]. From these preliminary studies, we may assume that hypermethylation, the source of epigenetic defects, is related to sperm morphology and the presence of VLS.

33.5 MSOME in Combination with ICSI: Intracytoplasmic Morphologically Selected Sperm Injection (IMSI)

The MSOME approach in observing spermatozoa was considered as an additional tool to ICSI and took the name "intracytoplasmic morphologically selected sperm injection" (IMSI) [16, 19, 23–25, 27–58].

Based on previous results of Cassuto et al. [57], deselecting spermatozoon with VLS may effectively predict sperm DNA methylation profiles. IMSI will enable us to discard before injection spermatozoa with a higher risk of methylation aberration due to a predictably poor prognosis and ensure safer biological and clinical outcomes for ICSI.

33.6 Impact of VLS on Early Embryo Development, Pregnancy, and Birth Outcome

The importance of selecting normal spermatozoa becomes obvious when comparing the reproductive outcomes in terms of fertilization, embryo development, pregnancy-abortion rates, and birth outcome when oocyte injections are done with morphologically normal sperms and spermatozoa exhibiting different subcellular defects.

33.6.1 Vacuoles and Embryo Development

In several successive papers [59–63], it was shown that the occurrence of large nuclear vacuoles and/or abnormal shape reduces the percentage of good-quality embryos reaching the blastocyst stage after culture until day 5. Following the outcome of each embryo after injection of spermatozoa, they clearly demonstrated that the use of spermatozoa with no vacuoles or less than two small vacuoles can be associated with significantly higher blastocyst rates than injection with spermatozoa showing more than two small vacuoles or one large vacuole with or without abnormal shape. These studies support the previously issued hypothesis that the impact of male infertility may be at an early stage (early paternal effect) [64], when spermatozoa are not able to attain, penetrate, and/or activate the oocyte, or at a late stage (late paternal effect), when they could not support embryo development, implantation, and pregnancy to term. Late paternal effects are observed after paternal genome activation, and blastocyst development failure is one of their first manifestations [65, 66].

33.6.2 Vacuoles and Pregnancy: Miscarriage

A more specific analysis on the impact of sperm cells with normal nuclear shape but with large vacuoles was first carried out by Berkovitz [27] on two matched IMSI groups of 28 patients each, either with normal nuclear shape but with large vacuoles or with normal nuclear shape spermatozoa lacking vacuoles. No differences in the fertilization and early embryo development up to day 3 were reported. However, injection of spermatozoa with strictly normal nuclear shape but large vacuoles appeared to reduce significantly pregnancy outcomes (18% vs 50%) and seemed to be associated with early abortions (80% vs 7%). Other studies showed also that the selection of normal shape spermatozoa with a vacuole-free head was positively associated with pregnancy and lower abortion rates after day 3 embryo transfers in couples with previous and repeated implantation failures [12, 28, 58, 67–69] and in patients with an elevated degree of DNA-fragmented spermatozoa [28].

Knez [68] showed that there was no significant difference in the pregnancy rates after the IMSI and ICSI procedures and blastocyst transfer. However, after ICSI more pregnancies terminated by spontaneous abortion, whereas after IMSI there were no spontaneous abortions. One explanation could be that IMSI procedure permits to select spermatozoa without defect and, as a consequence, provides more "healthy" blastocysts without chromosomal abnormalities, possibly, in spite of highly comparable development and morphology to ICSI-derived blastocysts.

The link between sperm head vacuoles and impaired chromatin condensation and the occurrence of DNA fragmentation in the presence of ROS may explain why vacuoles can be related to impaired pregnancy outcomes [41, 42, 66, 69, 70].

33.6.3 Vacuoles, Health of Babies Born, and Incidence of Malformations

Up to now, there have not been sufficient numbers of published studies concerning the health of children born after ICSI to draw any firm conclusions about the long-term safety of this procedure. However, it is important to emphasize that animal data are absolutely unequivocal on this point and clearly indicate that DNA damage in the male germ line is potentially hazardous for the embryo and therefore for the resulting offspring [71]. According to a recently published paper, sperm nucleus morphological normalcy, assessed at high magnification, could decrease the prevalence of major fetal malformations in ICSI children [72].

33.7 Vacuole-Like Structure: Acrosomal or Nuclear Origin?

Baccetti et al. reported that nuclear and acrosomal invaginations are formed during spermiogenesis [73]. Based on the classification of Clermont et al. [74], the highest rates of vacuoles (93.8%) are observed when spermatids reach the Sc acrosomal phase [29].

It is obvious that small and large vacuoles are observed in the majority of ejaculated spermatozoa, and their frequency differs according to the severity of male infertility. It is often difficult to observe vacuole-free sperm cells in ejaculates from infertile men, in contrast to semen derived from proven fertile men. According to De Vos et al. [75], the prevalence of vacuoles in normally shaped spermatozoa seems to be low. According to Silva et al. [76] and De Almeida Ferreira Braga et al. [77], the frequency of large nuclear vacuoles was significantly higher in advanced paternal age compared to the younger age groups.

For Kacem et al. [78] and Montjean et al. [79], vacuoles are mostly of acrosomal origin. Vacuoles are mainly filled with acrosomal enzymes such as trypsin-like acrosin that may induce a harmful effect after oocyte injection [78]. As a consequence, they concluded that a large majority of normal, regularly shaped spermatozoa showing no vacuoles have already undergone their acrosome reaction and should be selected for injection. This could be true if vacuoles were a completely closed entity. But seeing that VLS

are considered as a depression and not as a closed structure, it is improbable that such hypothesis and mechanism reflect the reality.

Montjean et al. [79] tested the effect of inducers of the acrosome reaction. After incubation of sperm in either hyaluronic acid or follicular fluid for 90 min, they observed a highly significant decrease in the presence of vacuoles as a consequence of the acrosome reaction.

On the semen of two men suffering from globozoospermia, Gatimel et al. [80] confirmed, by transmission electron microscopy (TEM) and scanning electron microscopy (SEM), that vacuoles were present in the majority of spermatozoa at a rate comparable to that observed in fertile controls, even though the totality of spermatozoa lacked acrosomal structures. Neyer et al. [81] monitored the same population of spermatozoa in a sperm capture channel for 24 h and observed that the induction of the acrosome reaction using calcium ionophore A23587 did not lead to any modifications in preexisting vacuole appearance, disappearance, or formation.

We may conclude that there is a negative relation between the presence of vacuoles and the sperm capacity to undergo acrosome reaction. According to Boitrelle et al. [7, 36], the sperm membrane and the acrosome cap are intact at the site of these depressions. Likewise, Perdrix et al. [33] demonstrated an exclusive nuclear origin of these large head surface depressions using TEM supporting their severe impact on sperm quality.

Such studies reinforce the opportunity to identify and discard prior to injection low-quality spermatozoa carrying nuclear vacuoles, which have a higher risk of DNA hypermethylation [57].

33.8 Indications for IMSI

As we mentioned previously, there is a real benefit to selecting morphological spermatozoa free of vacuoles. But, for different reasons, there is undeniable evident skepticism about this method of spermatozoa selection. Different doubts and interrogations may justify the hesitations to apply IMSI.

After several years, the superiority of IMSI over ICSI is still a matter of debate, and even to date randomized and well-powered studies to confirm a benefit of IMSI are limited – and even depict conflicting results [82].

According to the literature, controversial conclusions have been drawn, especially in terms of fertilization, top-quality embryo rates, and pregnancy, after comparing IMSI and ICSI. Some studies have shown that IMSI improves reproductive outcomes in cases of male factor infertility and/or previous failed ICSI attempts in terms of implantation and clinical pregnancy rates as compared with conventional ICSI [28, 58, 59, 68, 83–87, 88, 89]. On the other hand, IMSI and conventional ICSI seemed to provide comparable laboratory and clinical results when an unselected infertile population was evaluated [75, 89] or when IMSI was applied as the first treatment option [90].

33.8.1 Full Benefit of IMSI Is Attained with Blastocyst Culture

One of the main benefits of IMSI is the higher rate of blastocysts obtained per cycle when morphologically good-quality spermatozoa are selected [13, 59, 61, 68]. Nowadays, with successful vitrification techniques, the full benefit of a better spermatozoa selection is highlighted, if we are able to produce one more blastocyst per cycle. In fact, more blastocysts provide higher chances for the patient to achieve pregnancy in successive vitrified-warmed embryo transfer cycle(s).

33.8.2 MSOME Selection in Globozoospermia to Circumvent Artificial Activation

Globozoospermia is a male factor infertility that affects men because several abnormalities of sperm remodeling during spermiogenesis will entail to formation defects or premature elimination of acrosomal structures. Fertilization capacity after ICSI is low mainly due to a lack of sperm-specific phospholipase C (PLCzeta) that is responsible for inducing Ca2+ oscillations essential for oocyte activation [91, 92].

At present, births have been reported after ICSI followed by artificial Ca2+ oscillation induction via the use of assisted oocyte activation protocols by exposing oocytes to ionophore [93–95].

Another approach proposed by Gatimel [80] and Kashir [96] is to apply MSOME to maximize the efficacy of ICSI/IMSI. Sermondade [97] selected spermatozoa that exhibited a small acrosome which was not visible using conventional sperm selection methodology. Gatimel identified those with some sparse oval forms revealing the presence of Golgi residues [80]. These authors showed that some globozoospermic spermatozoa possess an acrosomal bud that contains a total amount of PLCzeta that is not significantly different from fertile controls and which correlates to successful oocyte activation and fertilization without the need for artificial oocyte activation with exogenous chemical agents.

33.8.3 IMSI and Advanced Maternal Age

Injection of a morphologically normal spermatozoon overcomes the low oocyte quality in older women, resulting according to Setti [98] in improved embryo quality and in a ninefold increase in the clinical pregnancy rate. Our results (unpublished data) corroborate the data of Setti [98] that semen quality seems to be more important with advancing maternal age, a group of patients that are of big relevance in assisted reproductive technology (ART). The rate of single blastocyst transfer (SBT) with top-quality blastocysts in the younger women group (<38 years) was 56.9% when morphologically normal spermatozoa were selected and 54.2% with spermatozoa carrying large VLS. On the other hand, for

women aged ≥38 years, the rate of SBT was 31.0% with normal spermatozoa and 25.0% ($p < 0.01$) with spermatozoa carrying large VLS.

Regarding the birth rates (BR) per SBT, IVF success was impaired in the higher age groups after injection of sperm with VLS. In the younger group, BR of 45.1% and 54.2% were obtained, respectively, after injection of normal and VLS spermatozoa. In contrast, a significant decrease in the BR is observed, 31.0% (normal Sp.) versus 12.5% (Sp. with VLS), in the advanced maternal age group.

Blastocysts derived from fertilization of sperm with VLS and/or suboptimal morphology decreases chances for a live birth in women >38 years probably because of reduced correction and reparation capacity of the aging oocyte.

33.8.3.1 DNA Damage-Repairing Factors

If we assume that a majority of nuclear defects reflected in vacuoles may be correlated with DNA integrity, we may have an optimistic view in the sense that this damage brought into the zygote by the fertilizing spermatozoon may be effectively repaired by oocyte factors [99–101]. We may then postulate the possibility to obtain blastocysts that will further develop into a healthy baby even though the oocyte was injected with a spermatozoon carrying a large vacuole. This aspect is related to the tolerance of the oocytes toward DNA decays [99], especially if young and/or good-quality oocytes are capable of repairing and rescuing the DNA of poor-quality spermatozoa. As a consequence, even if the fertilizing spermatozoon carries DNA damage in its genome, the oocyte could repair this damage, and therefore, it would be of no consequence for embryo and fetal development.

However, we cannot determine whether the oocyte would be capable of repairing this damage. In fact, oocytes can repair sperm DNA damage; however, a threshold exists beyond which sperm DNA cannot be repaired. This mainly depends on the degree and the type of sperm DNA damage (single-stranded vs double-stranded damage) [102]. Also, oocytes whose DNA repair mechanisms are not functional (aging oocytes – in vitro culture conditions) or have been damaged by endogenous (e.g., free radicals) or exogenous (e.g., radiation and environmental toxicants) factors might not be able to repair this damage.

33.8.4 Limitation of IMSI: Semen with Only Morphologically Abnormal Spermatozoa with VLS

There is a great heterogeneity between all the semen samples. Thus, the frequency by which good spermatozoa can be selected varies greatly from one patient to the other. In some cases, only one part of the oocytes can be injected with morphologically normal spermatozoa. For other patients, as already noticed earlier by Berkovitz et al. [27, 83], in spite of having a more powerful selection method at hand, it is not always possible to find and select morphologically completely normal-appearing spermatozoa for injection, even after extensive search. In such situations, is IMSI helpful? We have observed, out of 1146 MSOME analyses, a low frequency (#14, 1.2%) of semen samples with 100% abnormal shape and VLS. After 14 IMSI cycles, four pregnancies were noticed, resulting in one birth (7.1%) in a woman of 33 years old.

33.9 IMSI in 2017: Still a Debate

Several reservations concerning the technical aspect, organization, and injury of the gametes were arguments against applying this method of spermatozoa selection.

Three critics about IMSI are frequently argued. First, some argue that exposing the spermatozoa for a longer period at 37°C increases the rate of VLS. The second one concerns the prolonged period of time for oocytes out of the incubator during spermatozoa selection. The third criticism is the point that the prolonged selection time of male gametes may be at the detriment of oocyte and promotes oocyte aging. In addition, other criticisms such as it is a time-consuming technique and requires a very sophisticated, complicated, and high-cost system are frequently evoked.

33.9.1 In Vitro Formation of Vacuoles: A Reality at 37°C

Peer et al. [103] concluded that after 2 h of incubation at 37°C in culture media, the incidence of spermatozoa with vacuolated nuclei was significantly higher, so that prolonged sperm manipulation for assisted reproduction therapy should be performed at 21°C rather than 37°C.

Neyer et al. [81] using the sperm-microcapture channels technique observed that neither incubation at 37°C nor induction of oxidative stress induces de novo formation of nuclear vacuoles. According to these observations, they concluded that nuclear vacuoles on the sperm head are already produced at earlier stages of sperm maturation and are not induced or modulated by routine laboratory procedures [104]. Schwarz et al. [105] concluded that sperm nuclear vacuolization is unaffected by temperature in motile sperm isolated by swim-up.

33.9.2 How to Facilitate the Workflow While Performing IMSI

33.9.2.1 First Approach

In order to reduce either the time for the oocytes out of the incubator or the selection time of spermatozoa to avoid oocyte aging, a practical and technical approach is implemented. Spermatozoa are first selected using the Nomarski DIC optics and then injected on the conventional Hoffman ICSI microscope [106].

With such a strategy:

1. The oocytes are not present in the IMSI dish during selection of the spermatozoa. After selection, the dish is incubated for 15–30 min in order to stabilize the temperature (T°) and/or the pH value (in case no HEPES buffer culture medium is used).
2. In case of severe teratozoospermia, taking into account that more time for sperm selection is needed, we plan the selection at least around the time of oocyte pick-up (OPU). With such a policy, oocyte injection can be performed 2–3 h after OPU (38–40 h post hCG administration) on the ICSI station, avoiding oocyte aging.
3. The IMSI microscope is not occupied for an excessive period, and finally the oocytes are removed from the incubator only for the injection step. In case of several IMSI, the IMSI station is only occupied for the selection process and not for the injection phase, causing a better organization of the laboratory work.

Under sterile conditions, several drops are deposited in a glass bottom dish (Fig. 33.2). Two dishes are prepared when more than two mature oocytes are available.

A small aliquot of washed sperm (1–10 µl according to the semen sample quality) is deposited into drop A (Fig. 33.2a) The motile spermatozoa swim into the long "snake shape" drop. The morphologically normal ones and the best second class are selected, at 1000x magnification, with an ICSI pipette. The selection starts first at the end of the drop (A1). The selected motile spermatozoa are transferred in the host-selected spermatozoa microdrop (C). Release carefully the spermatozoa in order to keep them motile until the time of ICSI. In case of severe asthenozoospermia, the sperm aliquot is deposited at least 1 h before starting selection in order to give time to the spermatozoa to swim out in the "snake drop."

After collecting spermatozoa (if possible, 1.5 times the number of oocytes to inject), the dish is removed from the IMSI station and placed on a 37°C heating stage for temperature recovery (~30 min).

After this period of incubation at 37°C, the oocytes are placed into the culture media (D), and ICSI is performed using a conventional Hoffman microscope at 400x magnification (Fig. 33.2b). Motile spermatozoa are aspirated from the preselected host drop (C) and immobilized in the PVP drop (B) before injection.

33.9.2.2 Second Approach

In a second approach, the selection and injection are performed exclusively on the Nomarski DIC microscope. As previously described (Fig. 33.2), a minimum of two dishes are prepared except that sperm host drops (C) are not prepared.

Selection and injection are realized:

1. When few IMSI cycles are planned, so that the IMSI microscope will not be occupied for a too long period.
2. When the purpose of the study is to follow the outcome of embryo development in relation to the type of injected spermatozoon (photo documentation of the injected spermatozoon).

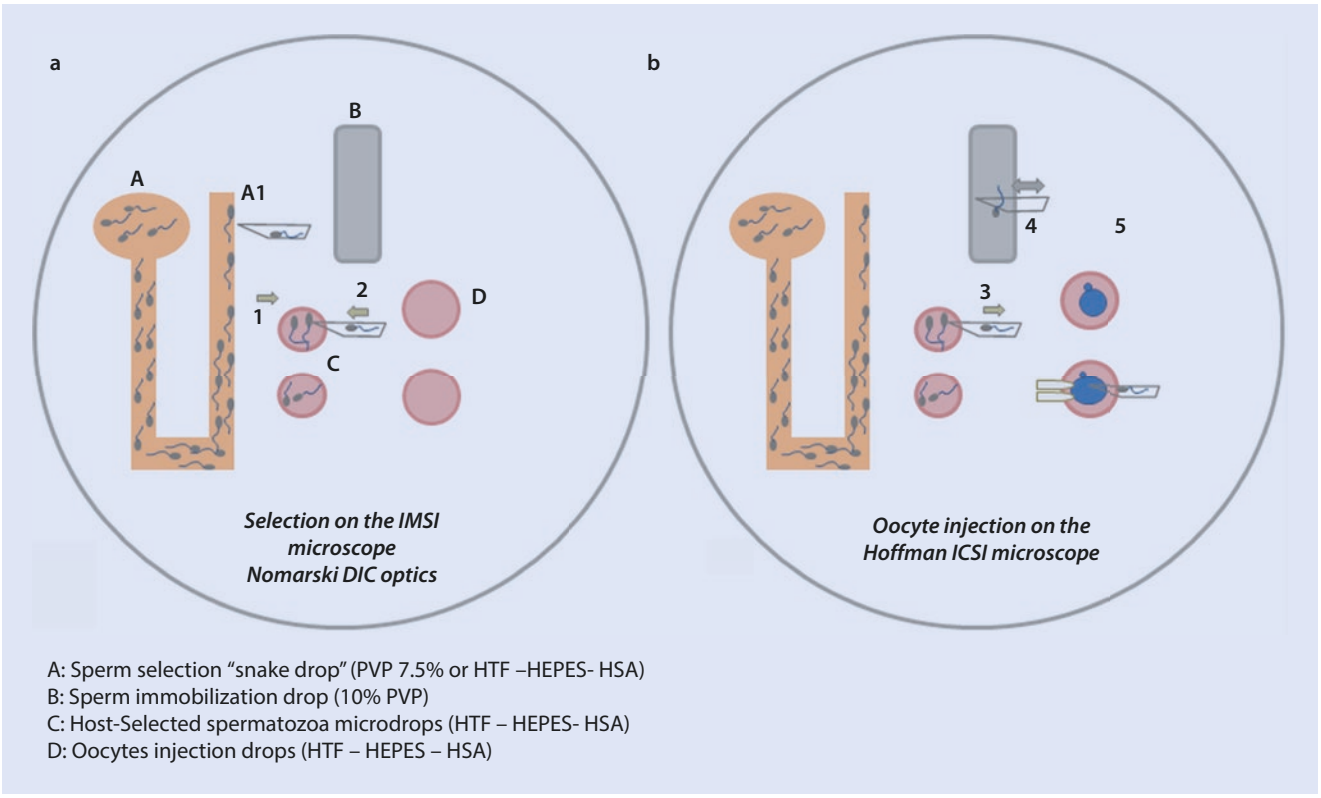

Fig. 33.2 Sperm selection with Nomarski DIC optics **a** and oocyte injection on the Hoffman ICSI microscope **b**

With such a strategy a maximum of two oocytes are deposited in drop D. But before applying this approach, the time spent to select one spermatozoa of class I or II has to be assessed. The primary intention is to choose normally shaped spermatozoa without any vacuoles (class I) for injection into the oocytes. Depending on the degree of impaired sperm morphology, the mean time required for selecting the best sperm ranged between 2 and more than 10 min.

When the time does not exceed 2–3 min per spermatozoon, then two oocytes are deposited in the drop. For a period ranging between 3 and 10 min, oocytes will be injected one at a time. In case the time exceeds 10 min, then the first approach is realized.

Moreover, when it is obvious after 10 min of sperm examination that it is not possible to select class I spermatozoa, the second-best spermatozoa with the least number of vacuoles and/or other abnormalities are selected for injection.

33.10 Conclusion

One of the most essential questions is not under which technical conditions the selection of spermatozoa should be recommended but rather if we have to consider selecting the best spermatozoa and, if possible, excluding those carrying defects such as vacuoles.

It is increasingly obvious that large vacuoles, which are concavities in the sperm head, reflect a pathological situation. VLS first appear during the spermiogenesis, rendering the nucleosome and DNA and connected molecules more vulnerable to intrinsic or extrinsic attacks by ROS. According to the level of ROS, DNA fragmentation may appear.

The literature reveals a clear significant correlation between sperm head morphology and DNA methylation profile. High-magnification visualization of sperms in real time provides the opportunity to identify and discard low-quality spermatozoa, which have a higher risk of DNA hypermethylation, prior to injection, ultimately improving ART outcomes by decreasing the risk of birth defects, major malformations, and epigenetic diseases either in the offspring or for the future generation through ICSI.

Considering the thesis of reduced reproductive outcome due to DNA damage in sperm and the notion that such DNA damages are displayed by the formation of VLS which are accurately evaluated at high magnification by MSOME, we may suggest that the more sophisticated selection of spermatozoa using the MSOME approach will most probably substitute the classical ICSI sperm selection method within the next years.

IMSI is for sure an indication for older patients. Semen quality seems to be more important with advancing maternal age. Blastocysts derived from fertilization of sperm with VLS and/or suboptimal morphology decreases chances for a live birth in women >38 years. This is most possibly due to reduced correction and reparation capacity of the aging oocyte. Thereby the application of IMSI leads to more blastocysts of higher quality, increasing the chances to transfer an embryo with a high implantation potential and to achieve the birth of a healthy baby.

Seeing that this simple, noninvasive technique still raises debates and skepticism about its efficiency, mainly due to a low number of controlled randomized studies published yet, one fundamental question is whether we should – with the knowledge that sperm VLS are related to abnormal chromatin packaging and possibly to DNA fragmentation – select spermatozoa with these defects for injection if we have only to change the optics. As far as we know, there is no reason for not selecting the morphologically best spermatozoa. Why therefore perform a spermocytogram as the first exam if there is no belief in morphological sperm selection?

Review Questions

1. You want to implement a low cost IMSI station:
   Which equipment is mandatory to observe precisely and easily spermatozoa with small or large vacuoles?
   High magnification system
   or
   Nomarski differential interference contrast (DIC) optics

2. Why should spermatozoa with large VLS be deselected for injection?

3. Why is repackaging of the haploid genome before delivery in the oocyte a crucial step?

4. In which situations is it better to apply IMSI?
   Previous attempt with no fertilization
   Previous attempt with fragmented embryo development
   Woman aged older than 38 years

5. You have to face the following situations: woman with 15 follicles and man with one million spermatozoa. How will you organize chronologically your work?
   Oocyte retrieval – sperm preparation – dish preparation – sperm selection and isolation of the best-looking spermatozoa – IMSI
   or
   Sperm preparation – dish preparation – sperm selection and isolation of the best-looking spermatozoa – oocyte retrieval – IMSI

Oocyte Activation Deficiency and Advances to Overcome

Marc Yeste, Celine Jones, Siti Nornadhirah Amdani, and Kevin Coward

Authors' contribution:
M.Y. wrote the chapter. C.J., S.N.A. and K.C. critically revised the chapter and approved the final version.

Z. P. Nagy et al. (eds.), *In Vitro Fertilization*, https://doi.org/10.1007/978-3-319-43011-9_34

Learning Objectives

- To learn what oocyte activation is and when it does occur
- To understand the mechanisms underlying oocyte activation and to emphasize the crucial role of a sperm-specific protein, PLCζ
- To comprehend the relationship between oocyte activation deficiency and human infertility
- To obtain a global picture of current ART that allows artificial activation of the oocyte

34.1 What Is Oocyte Activation?

Upon ovulation, oocytes have not yet completed the second meiotic division and remain arrested at metaphase II (M-II; see Tripathi et al. [1] for review) until the oocyte is fertilized by a spermatozoon [2, 3]. The process by which the oocyte resumes the second meiotic division is known as "oocyte activation" [4, 5]. During this process, a sperm cell triggers a series of calcium (Ca^{2+}) oscillations within the ooplasm which are involved in crucial events, such as the exocytosis of cortical granules, extrusion of the second polar body, regulation of gene expression, and the initiation of embryogenesis [4, 6, 7].

Although substantial progress has been made over the last decade, the precise mechanism by which the presence of a sperm within the ooplasm triggers the process of oocyte activation remains debatable, and the identity of the sperm factor responsible for this process has been the source of much scrutiny [8]. During the 1980s, three theories were proposed to explain this event (reviewed by Machaty [5]): (1) the "receptor" theory, which proposed that a sperm ligand interacted with a receptor situated on the oocyte plasma membrane and that the oocyte was activated upon this interaction [9]; (2) the "sperm factor" theory, which hypothesized that oocyte activation was triggered by a catalytic substance residing within the sperm head which entered the ooplasm following gamete fusion [10]; and (3) the "calcium bomb" theory, which proposed that sperm acted as a conduit to transport Ca^{2+} into the oocyte [11]. Of these, the "sperm factor" and "receptor" theories were the most credible. However, the "receptor" theory was readily dismissed when the first intracytoplasmic injection (ICSI) attempts demonstrated that oocyte activation was possible even when a potential ligand-receptor binding mechanism involving the gamete membranes was completely bypassed [12]. In support of the "sperm factor" theory, studies published in the 1990s demonstrated that Gq proteins were not associated with sperm-mediated oocyte activation [13] and that the microinjection of soluble sperm extracts into the oocyte cytoplasm successfully triggered Ca^{2+} oscillations [14, 15]. Progress during this vital era was fueled by developments in our ability to image changes in the Ca^{2+} content of oocytes in response to experimental test substances, a technique which was instrumental in demonstrating the ultimate suitability of the "sperm factor" theory [16], which remained as the only credible theory.

34.2 The Sperm-Borne Oocyte Activation Factor

34.2.1 The First Attempts

The identity of the sperm-borne oocyte activation factor (SOAF) has been the target of several researchers, and, from a historical point of view, different candidates have been suggested.

In 1996, Parrington et al. [14] found that glucosamine-6-phosphate deaminase (GNPDA), a protein referred to as "oscillin," triggered Ca^{2+} oscillations in hamster oocytes following fertilization. However, subsequent attempts to confirm these findings failed as neither the microinjection of recombinant oscillin nor its human and porcine homologues were able to trigger Ca^{2+} oscillations [17–19]. As a result, oscillin was quickly dismissed as the SOAF.

Following oscillin, five other putative sperm factors have been reported for vertebrates in the literature. It should, however, be emphasized that some of these candidate proteins were proposed from studies performed in nonmammalian species.

34.2.2 The Truncated Form of CD117 (TR-KIT)

One suggested candidate was the truncated form of CD117, the mast/stem cell growth factor receptor (SCFR) also known as c-kit tyrosine kinase receptor (TR-KIT). This protein resides in equatorial and postacrosomal sperm regions and was reported to release M-II arrest in mouse oocytes, induce cortical granule exocytosis, and be involved in the formation of pronuclei [20–22]. Although the mechanism of action for this protein is not yet fully understood, it has been suggested that CD117 interacts with FYN, a Src-like tyrosine kinase present in the oocyte cortex [158]. Following this interaction, it was postulated that CD117 would be cross-phosphorylated by FYN and that the CD117/FYN complex would interact with PLCγ1, an oocyte phospholipase [22, 23], which, in turn, would initiate the typical Ca^{2+} oscillation pattern. While clinical evidence points to other SOAF candidates, and the mechanism of action of CD117 is not fully understood, some studies have indicated that the presence of CD117 in human sperm is correlated with DNA integrity and that sperm from globozoospermic patients exhibit lower amounts of this protein relative to normal sperm from fertile men [24, 25].

34.2.3 Cytrate Synthase

Work conducted in amphibians by Harada et al. [26] led to the suggestion that cytrate synthase (CS) could represent a SOAF candidate. This 45 kDa protein is found in the connecting and intermediate pieces of the sperm from *Cynops pyrrhogaster* and is able to activate the eggs of this species. However, it was not possible to ascertain the precise role that

this protein plays, as other suggested SOAF candidates, such as mouse phospholipase C zeta (PLCζ), are also able to activate amphibian eggs. Moreover, no clinical data are available for this protein in human spermatozoa, and researchers thus directed their efforts toward other SOAF candidates.

34.2.4 Postacrosomal Sheath WW Domain-Binding Protein

One of the SOAF candidates that has attracted much attention recently is the postacrosomal sheath WW domain-binding protein (PAWP, also known as WBP2NL). This protein resides in the sperm perinuclear theca at the postacrosomal sheath level [27, 28], a region that has been suggested by different authors to be crucial for the activation of the oocyte [29–31].

With regard to how PAWP works, this protein presents a consensus PPXY sequence which binds WW group I protein domains, from which the name is derived. For this reason, the PPXY domain of PAWP has been postulated to interact with the WW group I protein domain from an oocyte PLCγ, which would be directly involved in the onset of Ca^{2+} oscillations [32]. Related to this, another PLC oocyte isoform (PLCβ1) has been reported to be involved in Ca^{2+} oscillations, as a reduction in the levels of PLCβ1 in mouse oocytes results in Ca^{2+} oscillations of lower amplitude.

The literature remains inconsistent with regard to the exact role of PAWP during oocyte activation (reviewed by Amdani et al. [8]). Indeed, different studies have indicated that the microinjection of recombinant PAWP, or protein extracts from the perinuclear theca (where PAWP resides), into the oocytes of *Xenopus*, pig, cattle, macaque, and humans allowed M-II oocytes to conclude meiosis II [27, 32, 33]. In addition, PAWP levels evaluated through immunofluorescence in bull and human sperm were related to their fertilizing ability when assessed following in vivo fertility trials and ICSI, respectively [34–36]. Yet, sperm from globozoospermic men present significantly lower levels of PAWP than those from fertile men [25].

In contrast, Nomikos et al. [37, 38] reported that PAWP failed to trigger Ca^{2+} oscillations when injected into mouse oocytes, and Satouh et al. [39] found that a knockout mouse model for PAWP was able to trigger normal Ca^{2+} oscillations and give rise to normal embryonic development. Therefore, at present, PAWP does not appear to represent a credible SOAF candidate as it does not trigger Ca^{2+} oscillations, but clinical data indicate that it could be involved, at least to some extent, in other events occurring at the beginning of embryogenesis.

34.2.5 Phospholipase Cζ (PLCζ)

Mounting evidence currently indicates that PLCζ (1-phosphatidylinositol 4,5-bisphosphate phosphodiesterase zeta-1) is the most credible SOAF candidate responsible for oocyte activation [40–44], as microinjection of either recombinant PLCζ or complementary RNA (cRNA) encoding for PLCζ triggers Ca^{2+} oscillations, causes cytoplasmic movements coincident with Ca^{2+} oscillations, and allows embryogenesis to begin [45–48]. As with any PLC, PLCζ hydrolyzes phosphatidylinositol 4,5-bisphosphate (PIP_2) into inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol (DAG; [49]). Inositol 1,4,5-trisphosphate then interacts with its receptor (IP_3R), residing on the endoplasmic reticulum (ER) membrane within the oocyte. This induces the release of Ca^{2+} from the ER into the cytosol and Ca^{2+} oscillations begin to occur. Diacylglycerol activates protein kinase C, which also depends (at least in the case of conventional isoforms) on the Ca^{2+} released from the ER [50, 51].

It is worth mentioning that PLCζ is a sperm-specific PLC isoform, which not only is the smallest PLC (70.4 kDa in human sperm) but does not function in the way that other PLCs do. Indeed, PLCζ is not located on the plasma membrane of oocytes and sperm and is not linked to G-protein-coupled receptors (GPCRs). In addition, PLCζ does not hydrolyze PIP_2 residing in the plasma membrane, but rather appears to target stores of PIP_2 residing in specific oocyte vesicles distributed across the ooplasm [52, 53].

Although the exact mechanism of action for this molecule remains unknown, several attempts have allowed us to shed light on this particular issue through the use of PLCζ chimeric forms. In terms of structure, PLCζ presents four EF hand domains (a helix-loop-helix domain typical of Ca^{2+}-binding proteins) and, a C2 domain, along with catalytic X and Y core domains (Fig. 34.1). In contrast to other PLCs, PLCζ does not possess a PH domain, which is the domain that normally targets the PIP_2 residing in the plasma membrane [55, 56]. EF1 and EF2 domains are involved in protein activity [57], while EF3 is a Ca^{2+}-sensitive domain [58]. The C2 domain interacts with phosphatidylinositol 3-phosphate and phosphatidylinositol 5-phosphate but not with PIP_2, which reduces PLCζ activ-

ity [57]. The X-Y linker region targets PIP_2 and confers maximal enzymatic activity [53, 59, 60].

Phospholipase Cζ has been identified in the sperm of humans and other mammals, such as monkeys, hamsters, pigs, and horses [40, 43, 61–64], and in nonmammalian species [65, 66]. With regard to its localization, PLCζ is mainly found in the equatorial and postacrosomal regions of ejaculated spermatozoa [67–69]. Immunogold and transmission electron microscopy have also provided definitive evidence that this protein resides in the perinuclear theca [41]. Following capacitation and the acrosome reaction, PLCζ is mainly localized to the postacrosomal sperm region [70].

As mentioned earlier, PLCζ is, at present, the strongest SOAF candidate. Most of this credibility comes from the analysis of clinical data, which points to a relationship between PLCζ and male infertility. In effect, proportions of sperm exhibiting PLCζ are significantly higher in fertile men than in infertile patients and are correlated with fertilization rates following ICSI [68, 71]. In addition, abnormal localization and mutations in PLCζ have been associated with oocyte activation deficiency (OAD) and total fertilization failure [48, 72–79]. Furthermore, the absence of PLCζ or deficient forms of PLCζ do not appear isolated in some cases but are concomitant with other anomalies. This is the case of globozoospermia, a rare and very adverse condition in which sperm are morphologically abnormal, exhibit high DNA fragmentation levels, and possess little or no PLCζ [25, 80–83].

In spite of all these observations, some researchers have challenged and raised concerns over the suitability of PLCζ as the principal SOAF. For example, Aarabi et al. [84] concluded that PLCζ was not present in the perinuclear theca, the sperm compartment in which the SOAF is supposed to reside [29–31], and observed PLCζ staining following the acrosome reaction and sperm-oocyte membrane fusion. Furthermore, these authors reported that rather than being present in spermatids at the end of spermiogenesis, PLCζ was secreted by principal epididymal cells [84]. In contrast to the work by Aarabi et al. [84], Escoffier et al. [41] did identify PLCζ in the perinuclear theca of human sperm, and Castillo et al. [85] observed PLCζ in the soluble chromatin fraction of the sperm head, which supports the idea that this protein arises during spermatogenesis. Given that the specificity of antibodies is always a matter of concern, as different antibodies may provide different results, more research is warranted to confirm the crucial role of PLCζ, despite the supportive evidence obtained thus far. Finally, a knockout mouse model for PLCζ has recently been produced through the CRISPR/Cas9 gene editing tool [86]. Interestingly, while sperm from these *Pcz1*$^{-/-}$ males were unable to trigger Ca^{2+} oscillations in mouse oocytes, which supports PLCζ as the most credible SOAF candidate, those males were subfertile rather than sterile, and oocyte fertilization, although in a less efficient manner (higher polyspermy), occurred in the absence of PLCζ [86]. For this reason, it is prudent to suggest that other proteins and/or alternative routes may be involved in oocyte activation.

34.3 The Sequence of Events During Oocyte Activation

After intercourse, sperm are deposited in the vagina and traverse the cervical mucus, which works as a selection barrier. Spermatozoa then move toward the fallopian tube [87]. It is not yet clear whether a sperm reservoir exists in the isthmus in humans, as proven for other mammals with an estrous cycle [88, 89]. In any case, what is clear is that sperm must become capacitated before being able to fertilize the oocyte and that this process also takes place within the fallopian tubes [90, 91]. Following capacitation, spermatozoa are able to trigger acrosome exocytosis [92].

While it has been widely reported that sperm trigger the acrosome reaction upon interaction with the proteins within the zona pellucida (ZP), recent data indicate that this event could take place earlier, in response to progesterone secreted by the cumulus cells [93–95]. The acrosome reaction allows the sperm to pass through the ZP. Following this, binding between the sperm and oocyte plasma membranes occurs, involving several proteins such as sperm proteins from the ADAM family, oocyte protein CD9, and other proteins which have yet to be identified [96–98]. It has been demonstrated that IZUMO1, a protein located in the equatorial sperm region, interacts with JUNO, its oocyte receptor, and that this binding is critically involved in membrane fusion [99–101].

After membrane fusion, the sperm is engulfed by the oocyte cytoplasm and PLCζ protein diffuses, via a yet unidentified mechanism which involves a PLC/phosphoinositide transduction pathway, across the ooplasm for approximately 10 min [102, 103]. PLCζ then targets PIP_2 molecules residing in oocyte vesicles distributed across the ooplasm rather than those present in the inner oolemma leaflet and initiates the first calcium wave within 30 min of gamete fusion [53, 104]. Given the specificity of PLCζ for PIP_2 residing in oocyte vesicles, Swann and Lai [104] raised the hypothesis that PLCζ is likely to interact with one or more than one oocyte-specific protein located on the membrane of these vesicles. This would explain why PLCζ hydrolyzes PIP_2 molecules of these vesicles and not those present in the oocyte plasma membrane (Fig. 34.2).

PLCζ hydrolyzes PIP_2 into IP_3 and DAG. Inositol trisphosphate is then released from the oocyte vesicle, diffuses across the ooplasm, and interacts with its receptor (IP_3R), a ligand-gated channel present in intracellular Ca^{2+} stores such as the endoplasmic reticulum, via two phosphate groups which bind to opposite sides of the IP_3-binding site (Fig. 34.2). This interaction triggers a conformational change which opens the channel, allows the Ca^{2+} to be released from the stores, and initiates the typical pattern of Ca^{2+} oscillations [106]. As a ubiquitous secondary messenger, Ca^{2+} intervenes in many events, regulates the activity of several proteins which are involved in the release of M-II arrest, and coordinates movements in the oocyte cytoplasm which take place

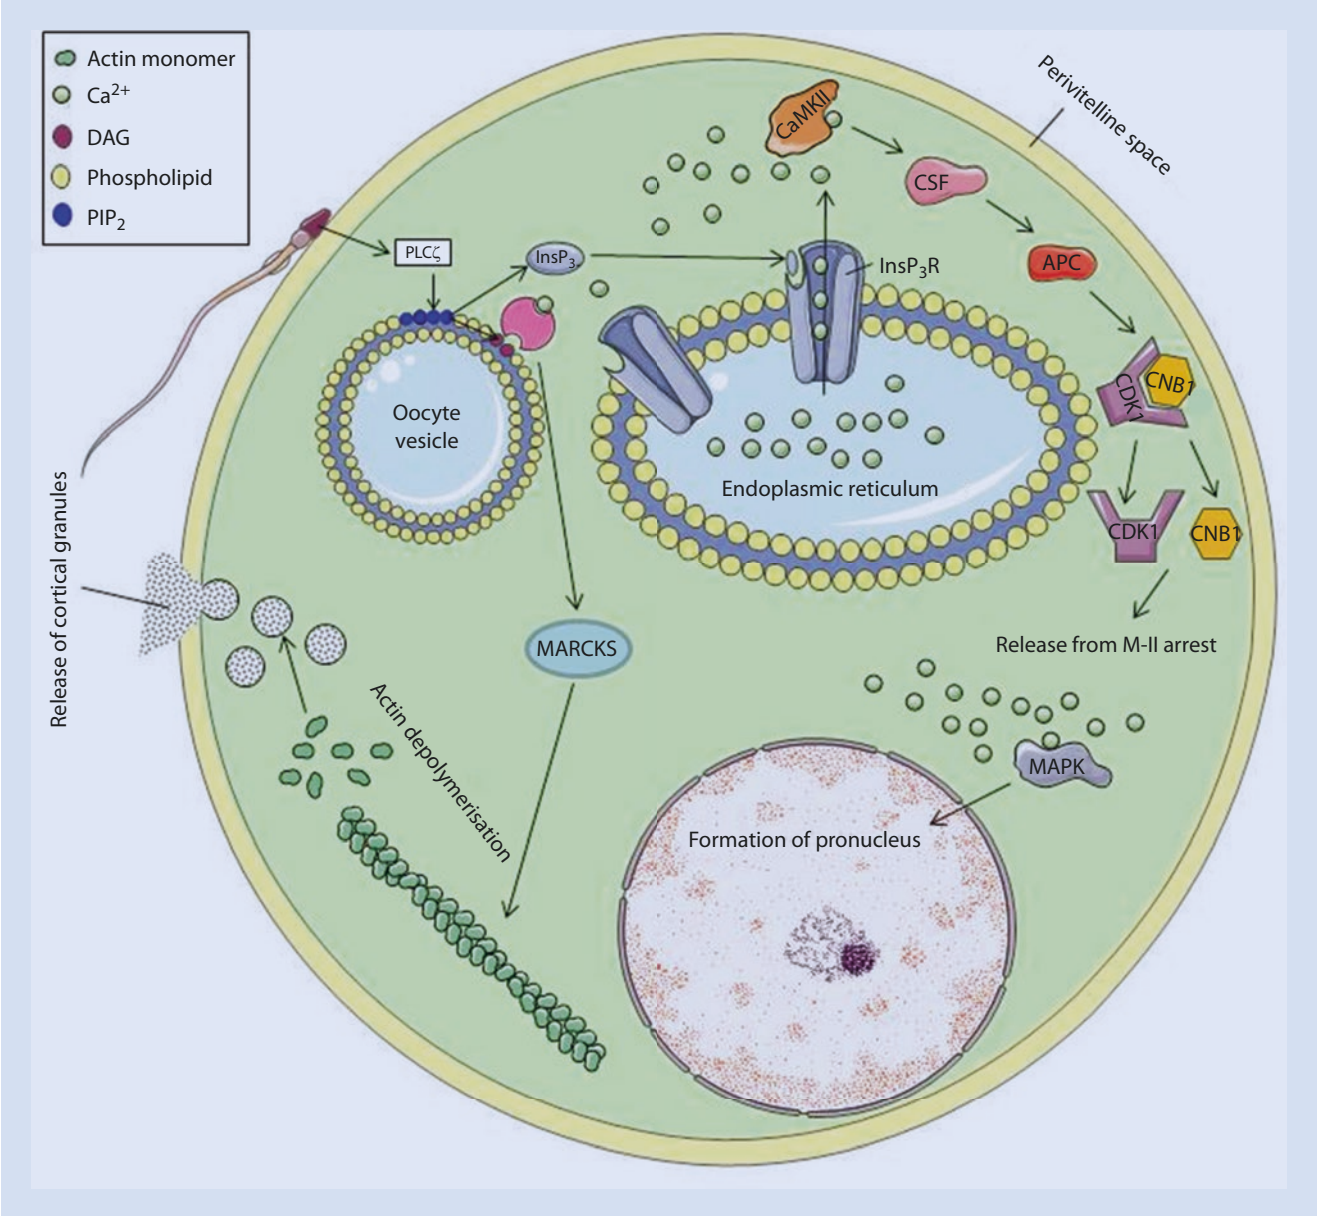

Fig. 34.2 Oocyte activation triggered by PLCζ, a sperm-specific protein factor. (Reproduced with permission from Yeste et al. [105])

shortly after fertilization [47, 107, 108]. Ca^{2+} binds calmodulin (CaM), a ubiquitous Ca^{2+} sensor protein, which activates calcium/calmodulin-dependent protein kinase II (CaMKII) [109–111] (Fig. 34.2). Subsequently, CaMKII phosphorylates F-box protein 43 (FBXO43), also known as early mitotic inhibitor 2 (EMI2), which is an anaphase-promoting complex inhibitor which maintains the levels of maturation-promoting factor (MPF) and thus M-II arrest. In brief, MPF is a heterodimer of cyclin-dependent kinase 1 (CDK1), previously known as cell division cycle 2 (CDC2), and cyclin B1 (CCNB1). FBXO43 inhibits the anaphase-promoting complex/cyclosome (APC/C) and blocks CCNB1 degradation [112–115]. The phosphorylation of FBXO43 by CaMKII leads to its degradation via ubiquitin-mediated proteolysis, in a process that involves Polo-like kinase 1 (PLK1), and results in MPF degeneration which allows the oocyte to be alleviated from M-II arrest. Upon completion of meiosis II, the pronuclei is formed in a process that is also reliant upon Ca^{2+} levels and involves the MAPK pathway [116] (Fig. 34.2).

In turn, Ca^{2+} oscillations and cytoplasm movements terminate as a consequence of a negative feedback regulation mechanism, as sustained levels of IP_3 lead to the downregulation of IP_3Rs [117–121]. Indeed, high cytoplasmic Ca^{2+} levels inhibit IP_3R via CaM/CaMKII, and since there is no Ca^{2+} release after IP_3R inhibition, Ca^{2+} levels in the cytoplasm are reduced, and a new Ca^{2+} oscillation may occur [122]. It is also worth mentioning that not only does IP_3R play a crucial role during oocyte activation events but also during oocyte maturation and early embryo development [123, 124].

It has been suggested that DAG remains attached to the oocyte vesicles, but this hypothesis has yet to be proven. Diacylglycerol should interact with protein kinase C (PKC), a Ser/Thr protein kinase, via its C1 domain. At least in the case of conventional PKC isoforms, PKC is also regulated by Ca^{2+} through the C2 domain [125]. An activated PKC phosphorylates multiple substrates, via C3 and C4 domains, in a manner which remains to be identified [126]. Among the known substrates, PKCα phosphorylates myristoylated alanine-rich C-kinase substrate (MARCKS) proteins, which are involved in the regulation of actin network and thus in the prevention of polyspermy [127–129]. PKCs are also converted into catalytic subunits (PKC-M), which subsequently distribute across the ooplasm and phosphorylate cytoskeleton proteins and other substrates [130, 131]. Finally, while it is yet to be proven whether any Ca^{2+} pump involved in producing Ca^{2+} oscillations in mammalian oocytes is phosphorylated by PKC, one should note that voltage-gated calcium (Cav2.2) channels in *Xenopus* oocytes are regulated via their phosphorylation by PKCs [132].

The distribution of PKC isoforms has been reported to be related with oocyte activation, as specific isoforms play precise roles during oocyte maturation and activation upon fertilization. Indeed, PKCδ and PKCθ are also involved in oocyte maturation, specifically in the meiotic resumption of germinal vesicle oocytes [133]. PKCα is uniformly distributed before fertilization and translocates to the oocyte cortex thereafter, showing kinetics similar to the Ca^{2+} oscillations induced by sperm [134]. In addition, PKCα is implied in the generation of the second polar body and the extrusion of cortical granules [127, 135]. Finally, it is worth mentioning that PKCβ1 is also involved in oocyte activation, as it is translocated from the cytosol to the oocyte plasma membrane following fertilization [136].

34.4 The Significance of Calcium (Ca^{2+}) Oscillation Patterns in the Oocyte and Their Role in Controlling the Molecular Mechanisms of Oocyte Activation

As previously described, oocyte activation events are mainly driven by Ca^{2+} oscillations, and an increase in Ca^{2+} levels within the ooplasm is critical in allowing M-II resumption. It is thus crucial to comprehend how relevant the proper management of Ca^{2+} homeostasis is for oocyte maturation and activation, as anomalies in this homeostatic mechanism may affect the oocyte's ability to be activated [105]. Ca^{2+} oscillations are evoked by the SOAF and exhibit complex temporal and spatial properties which begin shortly after fertilization and persist beyond the completion of meiosis II [43, 57, 107, 137, 138]. This indicates the existence of a very precise regulatory mechanism which controls how intracellular stores are filled, emptied, and refilled. Related to this, it is worth noting that the oocyte takes up extracellular Ca^{2+}, which is crucial for filling the intracellular stores which are then emptied by the action of the SOAF. If fertilization takes place in an extracellular environment devoid of Ca^{2+}, Ca^{2+} oscillations evoked by the SOAF terminate earlier [139].

The major factors responsible for Ca^{2+} homeostasis are proteins which constitute the store-operated Ca^{2+} channels (SOCE) which manage Ca^{2+} entry into intracellular stores [140, 141]. The main components of this system, which are gated channels activated when Ca^{2+} levels in the intracellular stores are depleted and allow Ca^{2+} influx from the extracellular space to the cytosol and endoplasmic reticulum, are stromal interaction molecule-1 (STIM1), Ca^{2+} release-activated Ca^{2+} channel protein 1 (ORAI1), sarco/endoplasmic reticulum Ca^{2+}ATPase (SERCA), and other unidentified membrane channels (Fig. 34.3) [140–143].

The particular role of these proteins has also been shown in mammalian oocytes [144], as STIM1 and ORAI1 are involved in Ca^{2+} influx to the oocyte and subsequent Ca^{2+}-filling of internal stores during oocyte maturation [145, 146]. STIM1 is a single-pass, type I transmembrane protein which acts as a sensor for Ca^{2+} levels within the ER and features an EF hand domain and a sterile alpha motif domain in the lumen of the ER [147–149]. The sensing ability of STIM1 is related to ORAI, a Ca^{2+} channel, which is activated by STIM1 and allows extracellular Ca^{2+} to enter [150–152]. The interaction of STIM1 with ORAI1 occurs via direct protein-protein interaction involving the ER (STIM1) and the plasma membrane (ORAI1; [146, 153, 154]). In addition to ORAI1, there are also plasma membrane Ca^{2+} ATPases (PMCAs) which pump Ca^{2+} from the cytosol into the extracellular milieu [155]. This helps to increase the cytosolic levels of Ca^{2+}, which are used to refill the ER, as detailed below.

In combination with STIM1, ORAI1, and PMCAs, sarco/endoplasmic reticulum Ca^{2+} ATPases (SERCAs), which reside in the membrane of the ER, are also implicated in Ca^{2+} homeostasis as they are responsible for the active transport of Ca^{2+} from the cytosol to the lumen of the ER [156, 157] (Fig. 34.3). The main role of these ATPases is to continuously fill the ER with Ca^{2+}. In effect, without the pumping activity of SERCAs, a second, new Ca^{2+} oscillation cannot be generated after emptying the lumen of the ER for the first time following the interaction of IP_3 with its receptor [141]. The most important SERCA isoform is SERCA2b which is organized into clusters when the oocytes reach the M-II stage and maintain this organization until the pronuclear stage is reached, which concurs with the duration and pattern of Ca^{2+} oscillations [139].

Yet, it should be mentioned that mitochondria are also important for modulation of Ca^{2+} signaling [156, 158]. It has been reported that oocytes with altered mitochondrial function and reduced ATP production show an abnormal Ca^{2+} oscillation pattern [159]. Furthermore, oocytes may enter an apoptotic mitochondria-mediated caspase pathway when there is excessive Ca^{2+} oscillatory activity [160]. Therefore, the involvement of mitochondria in the dynamics of Ca^{2+} homeostasis should also be contemplated when trying to understand the events underlying oocyte activation.

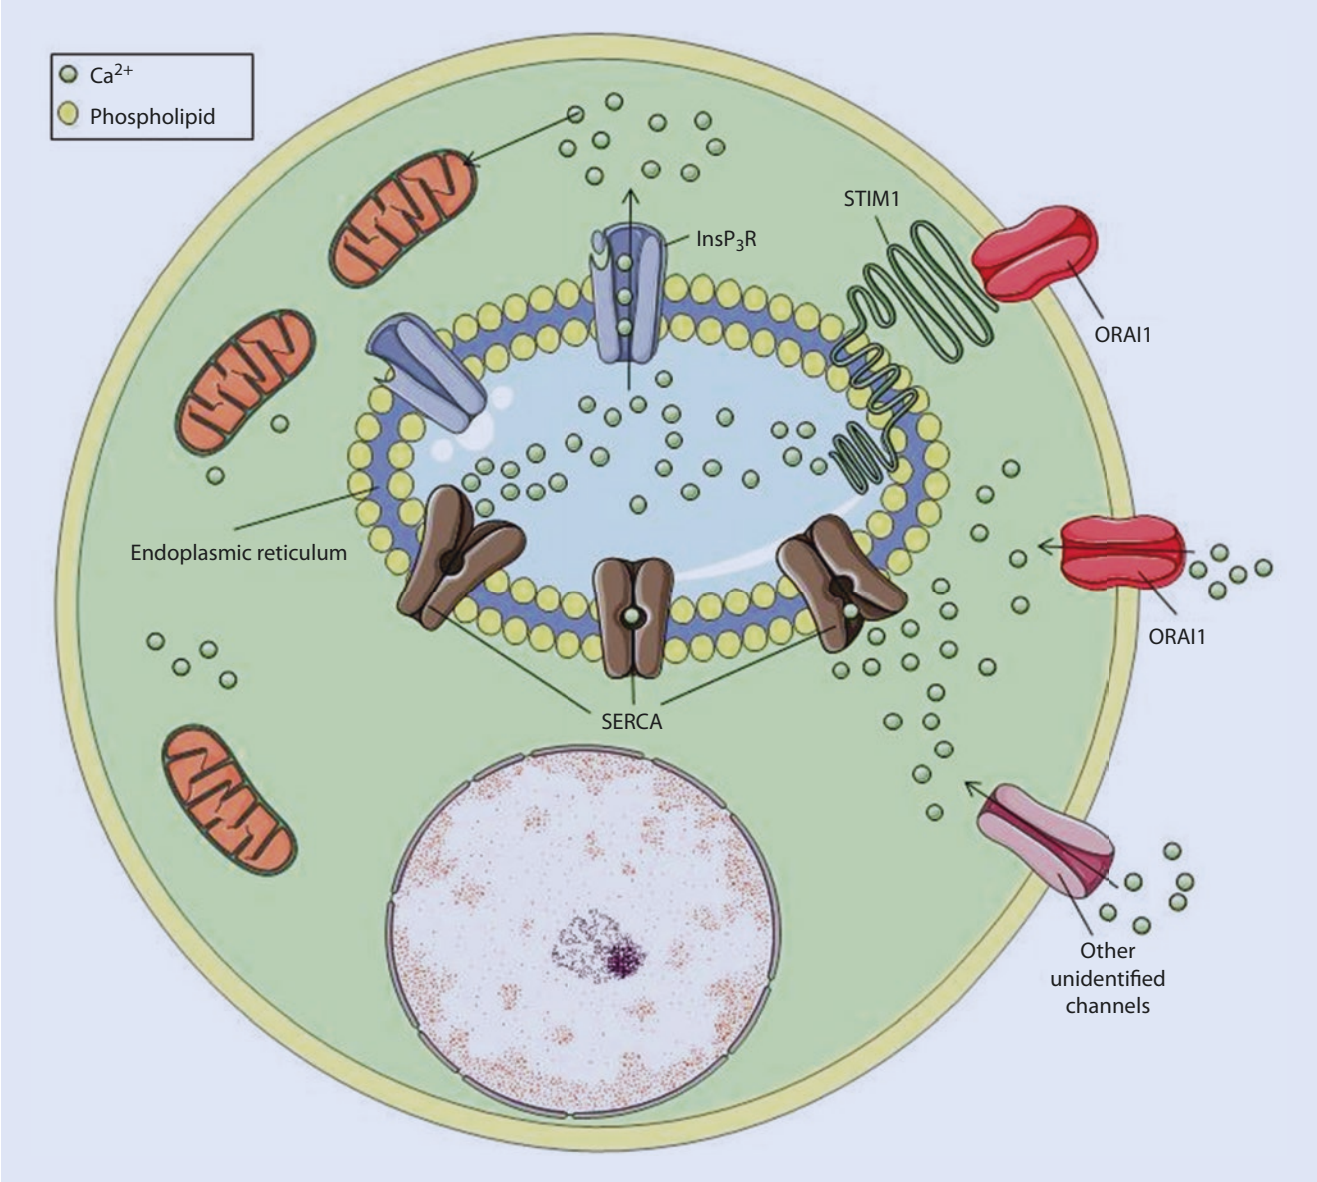

Fig. 34.3 Oocyte mechanisms involved in the regulation of Ca^{2+}. It is important to note the relevance of SOCE (SERCA, ORAI1) for Ca^{2+} homeostasis, as well as the role of mitochondria. (Reproduced with permission from Yeste et al. [105]). Abbreviations: SOCE, store-operated calcium entry; SERCA, sarco/endoplasmic reticulum calcium ATPase; ORAI1, calcium release-activated calcium channel protein 1

34.5 Oocyte Activation Deficiency in the Context of Human Infertility

Having outlined what oocyte activation is and the main events involved, we should now focus upon the impact of oocyte activation deficiency (OAD) on human infertility. Infertility is defined as the inability of a sexually active couple to achieve pregnancy after 1 year of unprotected vaginal intercourse [161]. With an incidence between 10% and 16% of couples [162–166], infertility is now considered as a disease by the World Health Organization [167].

Regarding the origins of infertility, a male factor is predominantly involved in between 20% and 30% of cases, a female factor is thought to underlie between 20% and 35% of cases, and both male and female factors are implicated in 25–40% of cases (reviewed by Yeste et al. [105]). In the remaining 10–25% of cases, the precise cause of infertility remains unexplained. The strategies to treat infertility depend upon the origin, but in some cases, assisted reproductive technology (ART), which includes in vitro fertilization (IVF), intracytoplasmic injection (ICSI), and embryo transfer, may be suitable to rectify at least some of these cases (reviewed in Yeste et al. [105]).

One specific cause of infertility is oocyte activation deficiency (OAD), in which the oocyte fails to activate following sperm-oocyte fusion. Intracytoplasmic sperm injection, whereby a single sperm is directly injected into the oocyte, is a suitable alternative to rescue fertility when IVF fails [12]. However, total fertilization failure can still occur in 1–5% of ICSI cycles (reviewed in Yeste et al. [105]). While the causes

that may underlie such failure are of a broad nature and can include a variety of technical factors (e.g., incorrect injection) and sperm (poor nuclear chromatin condensation) and oocyte (spindle) defects [168, 169], OAD is considered to be the principal cause of total fertilization failure and low fertilization rates following ICSI, accounting for 40% of such cases [170, 171].

Although, as previously stated, abnormalities and deficiencies in PLCζ may explain some cases of OAD, the causes of oocyte activation failure are not necessarily restricted to sperm defects but may also involve the oocyte, since oocyte quality plays a pivotal role in fertilization success (reviewed by Yeste et al. [105]). Indeed, as OAD and total fertilization failure may also occur when spermatozoa present normal PLCζ patterns [68, 172], sperm factors other than PLCζ and oocyte proteins involved in the critical downstream signaling events triggered by the SOAF could also underlie OAD, as suggested in previous investigations [173–176]. It has already been emphasized that oocyte quality, morphology, and age together with specific oocyte proteins may be responsible for OAD [177–181]. Therefore, further research on the potential contribution of the oocyte in OAD is much warranted [95, 105]. However, ethical issues and restrictions on the availability of healthy human oocytes donated for research make conducting studies with female gametes far more difficult than with sperm.

34

34.6 Artificial Oocyte Activation

Over recent years, artificial oocyte activation (AOA) has represented the only treatment option to rescue cases of total fertilization failure that are related to OAD. Artificial oocyte activation is defined as the use of any laboratory method which helps overcome OAD and thus facilitates oocyte release from M-II arrest [174]. This procedure is advised when fertilization rates are below 30% following conventional ICSI and allows the rescue of cycles in which severe male factor infertility and deficient oocyte maturation are involved [174, 175, 182–184]. In spite of this, AOA may not be a suitable strategy when the suspected factor underlying OAD is related to the oocyte [181]. It is also worth mentioning that the pattern of Ca^{2+} oscillations triggered by AOA differs greatly from that observed following normal fertilization, as a single Ca^{2+} transient rather than a series of physiological Ca^{2+} oscillations is usually observed [169] (Fig. 34.4). Finally, one should also note that the use of AOA is not only restricted to rescuing fertility, but this technology may also be utilized for nuclear transfer and parthenogenesis [186].

34.6.1 Methods to Activate the Oocyte Artificially

The suite of methods for activating the oocyte artificially are classified into three main groups: mechanical, electrical, and chemical [171, 187].

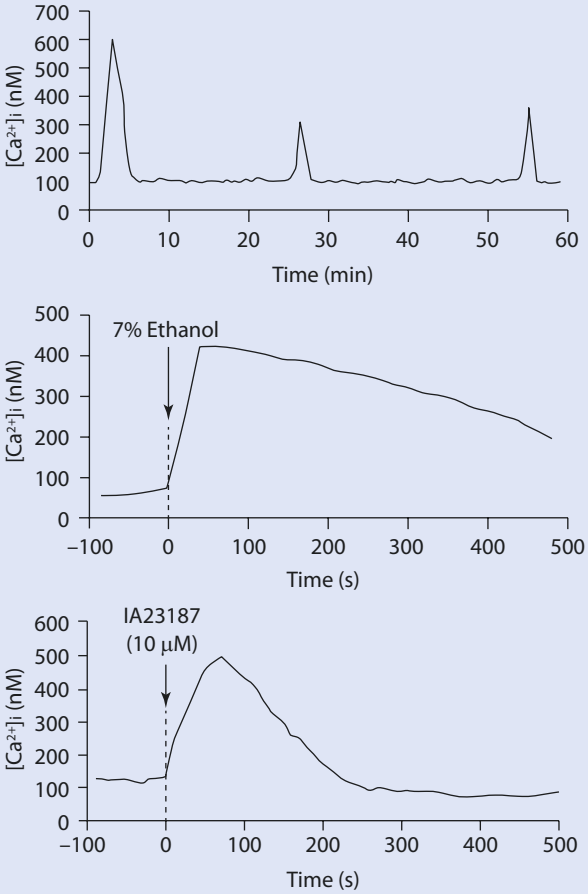

Fig. 34.4 Calcium oscillations in bovine oocytes after in vitro fertilization **a** and in response to artificial oocyte activators (**b**, ethanol; **c**, calcium ionophore A23187). Note that whereas the characteristic pattern of Ca^{2+} oscillations is present after IVF, a single Ca^{2+} spike is observed when chemical activators are used. (Reproduced with permission from Nakada and Mizuno [185])

Mechanical oocyte activation consists of vigorous aspiration of the oocyte peripheral cytoplasm and further deposition of such aspirated cytoplasm and the spermatozoon in the center of the oocyte during ICSI. This peripheral cytoplasm has mitochondria with high inner membrane potential and ATP content which, when deposited in the center of the oocyte, are thought to increase energy supply in the site of pronuclear formation and facilitate oocyte activation [188]. Another way to mechanically activate the oocyte is the disruption of its plasma membrane immediately before ICSI using a microneedle, as this allows maintaining Ca^{2+} influx [187]. However, these mechanical methods are not common in clinical practice, as they are difficult to standardize, are invasive, and entail a higher risk of damaging the oocyte [189].

Electrical oocyte activation stimulates oocytes electrically using electrodes and an electric chamber. In brief, oocytes are subjected to a single, pulsed-direct current waveform. This electric stimulus opens pores in the plasma membrane, allows Ca^{2+} influx from the surrounding medium, and ultimately increases the intracellular Ca^{2+} levels [169, 190].

Artificial oocyte activation via the use of chemicals is currently the most common clinical procedure, as success rates are higher than those obtained with either mechanical or electrical stimulation [191]. In the case of chemical stimulation, oocytes are, following ICSI, transferred to a medium which contains an AOA. It is worth mentioning that most agents cause a single, prolonged Ca^{2+} transient in the oocyte (Fig. 34.4), whereas others cause multiple oscillations.

Calcium ionophores, such as ionomycin and calcium ionophore A23187, and inhibitors of kinase activity and protein synthesis, such as 6-dimethylaminopurine and puromycin, cause a single Ca^{2+} transient [175, 192–198]. Specifically, calcium ionophores are lipid-soluble molecules, which bind to ions and work as ion carriers, thus allowing the transport of such ions across the plasma membrane, which is impermeable to them otherwise. Therefore, the exposition of oocytes to calcium ionophores increases permeability of the plasma membrane to Ca^{2+}, which allows extracellular Ca^{2+} to flow into the oocyte from the surrounding medium and increases intracellular Ca^{2+} levels in a single transient manner. This single Ca^{2+} transient triggers downstream events which are driven by Ca^{2+}/calmodulin and CaMKII [183]. Calmodulin kinase II may remain active, although to a lesser extent (50–80% kinase activity), when partially autonomous (Ca^{2+} independent) following dissociation from Ca^{2+}/calmodulin. This kinase activity lasts until phosphatases dephosphorylate CaMKII and override its autophosphorylation activity [199].

Chemical agents which cause multiple transients include strontium chloride, phorbol esters, thimerosal, and anhydrous alcohol [200–203]. Although strontium chloride is the most used and is effective in mice, its use in humans is still under debate [171, 204, 205]. In spite of this, it has been indicated that strontium chloride may be appropriate in those clinical cases in which calcium ionophore A23187 is proven to be ineffective [201]. While the mechanism by which strontium chloride induces Ca^{2+} oscillations is not fully understood, it appears to bind to and activates a Ca^{2+}-binding site on the IP_3R [206, 207]. On the other hand, it is worth indicating that the use of anhydrous alcohol as an agent for AOA has been shown to improve blastocyst development in vitrified GV and M-I oocytes following in vitro maturation [203].

There are only a limited number of studies comparing the effectiveness of these three AOA methods. Vanden Meerschaut et al. [208] evaluated embryo development, pregnancy, birth, and fertility of pups using a mouse model for globozoospermia (wobbler mouse) exhibiting oocyte activation deficiency. These authors reported that electrical activation and chemical activation with strontium chloride were more efficient in rescuing fertility and supporting embryo development than ionomycin. In spite of this, ionophores are the most used chemical agents in humans and show reasonable results [208]. Another study with parthenogenetic mouse and human embryos observed that blastocyst development at day 6 was higher following electrical stimulation than in response to chemical activation with either ionomycin or strontium chloride [186].

34.6.2 Artificial Oocyte Activation in Clinical Practice

Available data on the use of AOA agents are encouraging, but this is yet to be considered as an established treatment [171]. Unfortunately, a systematic review and meta-analysis which compared conventional ICSI with ICSI+AOA concluded that, in general, fertilization rates are higher following ICSI-AOA than following ICSI. Indeed, the studies reviewed were so different that no evidence on the efficacy or safety of ICSI-AOA could be concluded [209]. The specific concerns with regard to AOA safety will be discussed later in this chapter.

Ionomycin and calcium ionophore A23187 are the most common AOA agents used in clinical practice. The first case of AOA using calcium ionophore A23187 was reported in 1997 [210]. Fertilization rates of artificially activated oocytes with calcium ionophore A23187 range from 25% to 48%, and live birth rates are around 28% [211]; nonetheless, differences have been observed between studies. For example, Aydinuraz et al. [212] did not find a clear effect of AOA with calcium ionophore A23187 upon cleavage rates but did observe that the number of high-quality embryos was increased in the group of artificially activated oocytes.

Artificial oocyte activation with calcium ionophore A23187 has also been found to be efficient when using in vitro matured oocytes [213]. Yet, not only is this procedure effective with ejaculated sperm of good quality but also with ejaculated oligoasthenoteratozoospermic spermatozoa and even with testicle-extracted spermatozoa [214, 215]. Interestingly, AOA with calcium ionophore A23187 was found to rescue a case of male infertility associated with Kartagener syndrome [216]. The man suffering from this syndrome, which is related to primary cilia dyskinesis, presented severe oligoasthenoteratozoospermia with sperm unable to respond to theophylline, a motility activator. In this case report, treating oocytes with calcium ionophore A23187 was shown to allow fertilization and blastocyst formation and resulted in a successful pregnancy and the birth of two healthy twins. In contrast, conventional ICSI produced no fertilized oocytes [216].

Still related to calcium ionophore A23187, it is worth mentioning that a recent study has found that the combination of calcium ionophore A23187 with recombinant granulocyte-macrophage colony-stimulating factor (GM-CSF) had synergistic effects and increased cleavage rates, embryo development, and the number of euploid blastocysts [217].

34.6.3 Is AOA Safe for Child Health?

Artificial oocyte activation represents a relatively new therapeutic strategy which can rescue some cases of total fertilization failure. However, there are concerns with regard to

the safety of the procedures involved. Despite Ca^{2+} being a ubiquitous secondary messenger involved in several vital processes, artificial oocyte activators induce an increase in the intracellular Ca^{2+} levels which is not regulated by the endogenous molecular machinery inside the oocyte. In effect, artificial activators and artificially generated Ca^{2+} oscillations could impact upon gene expression and epigenetic regulation [183, 218, 219]. For this reason, it is of great concern that we still know so little about the specific downstream events which could be affected by unregulated changes in Ca^{2+} concentration in oocytes and early embryos; these concerns have fueled significant debate on the safety of this ART procedure [171, 187]. As a consequence, AOA is still considered as an experimental procedure and should only be applied under specific circumstances, when no alternative solution is possible [183].
